Contents

Preface	xxi
Scientific Committee	xxiii
Plenary Lectures	
1. Resilient Design and Operations of Chemical Process Systems <i>Jian Gong, Fengqi You</i>	1
2. Developing key PSE skills for the workforce of the future <i>Concepción (Conchita) Jiménez-González</i>	7
3. COSMO-RS: From Quantum Chemistry to Fluid Phase Thermodynamics <i>Andreas Klamt</i>	9
4. Multi-Parametric Optimization in Smart Manufacturing & Process Intensification <i>Efstathios Pistikopoulos</i>	11
Model Development and Simulation	
5. LCSOft as a Tool for LCA: New LCIA Methodologies and Interpretation <i>Tanathip Rattanatum, Rebecca Frauzem, Pomthong Malakul, Rafiqul Gani</i>	13
6. Modeling the Performance of Low Pressure Reverse Osmosis Membrane System for N-nitrosamine Rejection <i>Mudhar A. Al-Obaidi, Chakib Kara-Zaitri and Iqbal M. Mujtaba</i>	19
7. Model of a Formaldehyde Absorption System Based on Industrial Data <i>Catarina G. Braz, Henrique A. Matos, A. Mendes, J. Rocha, R. Alvim</i>	25
8. A multi-fluid approach to simulate separation of liquid-liquid systems in a gravity settler <i>Anurag Misra, Cyrille Bonamy, Luís M. de Souza, Lena Hohl, Markus Illner, Matthias Kraume, Jens-Uwe Repke and Dominique Thévenin</i>	31
9. Comparative Life Cycle Assessment of Ethylene from Wet Shale Gas and Biomass <i>Minbo Yang, Xueyu Tian, Fengqi You</i>	37

10. Model-based Design of Experiments Using a Flowsheet-Simulator
Norbert Asprion, Juliane Ritter, Roger Böttcher, Michael Bortz 43
11. Modeling of Non-Isothermal Adsorption Process in a Silica Gel Desiccant Packed Bed
Siripan Murathathunyaluk, Koranut Srichanvichit, Amata Anantpinijwatna, Prakob Kitchaiya 49
12. Modeling the Effect of Temperature on Microalgal Growth under Outdoor Conditions
Pooya Darvehei, Parisa A. Bahri, Navid R. Moheimani 55
13. Prediction of stability and thermal conductivity of nanofluids for thermal energy storage applications
B.H. Mahmoud, M. Fairweather, L.F. Mortimer, J. Peakall, H.P. Rice, D. Harbottle 61
14. Multiobjective optimization of eco-industrial parks: evaluation of environmental impacts at the watershed scale
Laura Garcia de Dios, Marianne Boix, Sabine Sauvage, Iréa Touche, Roxelane Cakir, Ludovic Montastruc, Jose Miguel Sanchez Perez 67
15. Coke Formation Model in Crude Oil Furnace for Maintenance Scheduling
Amata Anantpinijwatna 73
16. Microbubble coalescence during transport in vertical channel flows
K.S. Asiagbe, M. Fairweather, D.O. Njobuenwu, M. Colombo 79
17. Kinetic Modeling of Methanol Synthesis - Impact of Catalyst Deactivation
Carsten Seidel, Andreas Jörke, Bert Vollbrecht, Andreas Seidel-Morgenstern, Achim Kienle 85
18. Assessing the GHG emissions footprints of newly ultra-sour gas developments in the Middle East region for electricity production
Alberto Betancourt-Torcat, Mohammed Alkatheri, Ali Almansoori 91
19. Influence of cylinder-to-particle diameter ratio and filling speed on bed porosity of random packed beds of spheres
Johanna Fernengel, Jennie von Seckendorff and Olaf Hinrichsen 97

20.	Analyzing the link between G^E -model parameter regression and optimal process design <i>Mirko Skiborowski, Philipp Temmann, Chrstoph Brandenbusch</i>	103
21.	Kinetic Modeling of Precipitation Terpolymerization for Functional Microgels <i>Franca A. L. Janssen, Agnieszka Ksiazkiewicz, Michael Kather, Leif C. Kröger, Adel Mhamdi, Kai Leonhard, Andrij Pich, Alexander Mitsos</i>	109
22.	Towards predictive models for organic solvent nanofiltration <i>Rebecca Goebel, Tobias Glaser, Ilka Niederkleine and Mirko Skiborowski</i>	115
23.	COSMO-derived descriptors applied in ionic liquids physical property modelling using machine learning algorithms <i>Ismael Díaz, Manuel Rodríguez, María González-Miquel and Emilio J. González</i>	121
24.	A CFD investigation of the effect of particle sphericity on wellbore cleaning efficiency during oil and gas drilling <i>Emmanuel I. Epelle, Dimitrios I. Gerogiorgis</i>	127
25.	Process network modelling for the assessment of environmental impacts <i>Raul Calvo-Serrano, Gonzalo Guillén Gosálbez</i>	133
26.	Data-driven degradation model for batch processes: a case study on heat exchanger fouling <i>Ouyang Wu, Ala E.F. Bouaswaig, Stefan M. Schneider, Fernando Moreno Leira, Lars Imsland and Matthias Roth</i>	139
27.	Applying New Sustainability Metric in Different Natural Gas Liquid (NGL) Recovery Configurations to Extend Investment Decision and Incorporate Sustainability Analysis <i>Saad A. Al-Sobhi, Ahmed AlNouss</i>	145
28.	Identification of Mass Flow Dynamics in a Pretreatment Continuous Tubular Reactor <i>Ismael Jaramillo, Arturo Sanchez</i>	151
29.	Exploiting meta-modeling approach to investigate the effect of oil characteristics on the optimal operating conditions and biodiesel properties <i>P. Chhabra, L. Zhou, I. A. Karimi and M. Kraft</i>	157

30. Mixed-integer multiparametric Metamodeling: A machine learning tool applied to reactive scheduling
Gicela Lupera, Ahmed Shokry, Georgios M. Kopanos, Antonio Espuña 163
31. Resolved Numerical Analysis of Drying on a Vibrating Grate
Bernhard Peters, Mohammad Mohseni, Marc Demouling and Thorsten Kläs 169
32. Assessing the Performance of Industrial Ethanol Fermentation Unit Using Neural Networks
Rauber D. Pereira, Alberto C. Badino, Antonio J. G. Cruz 175
33. Thermal and hydraulic performance of pillow-plate heat exchangers
Olga Arsenyeva, Julian Tran, Eugeny Y. Kenig 181
34. Predicting Research and Motor Octane Numbers based on Near Infrared Spectroscopy: Models based on Partial Least Squares Regression and Artificial Neural Networks
Ana L. Leal, Jorge C. Ribeiro, Artur M. S. Silva, F. G. Martins 187
35. Modeling of an air quality monitoring network with high space-time resolution
Daniele Sofia, Aristide Giuliano, Filomena Gioiella, Diego Barletta, Massimo Poletto 193
36. Modelling of biomass residence time distribution and xylan depolymerization kinetics analysis in a Pilot-Scale Pretreatment Continuous Tubular Reactor
Felicia Rodríguez, Arturo Sánchez 199
37. Simulation and Analysis of Indian Residential Electricity Consumption Using Agent-Based Models
Sohini Dhar, Babji Srinivasan and Rajagopalan Srinivasan 205
38. Dull or bright you still get electric delight: A new approach to the design of all-weather panels
Sahar Hajizeinalibioki, Daniel Sebastia Saez, Oleksiy V. Klymenko, Harvey Arellano-Garcia 211
39. Direct Reduction of Iron-Ore in Fluidized Beds
M. Efe Kinaci, Thomas Lichtenegger and Simon Schneiderbauer 217

40. Experiments and Direct Computer Mapping Based Model for Photo-Fenton Process
Francesca Audino, Mónica Varga, Montserrat Pérez-Moya, Moisès Graells, Antonio Espuña and Béla Csukás 223
41. Surrogate-based modeling in flotation processes
Achref Rabhi, Abdellah Chkifa, Saad Benjelloun, Abderrazak Latifi 229
42. From Process Graph to Process Simulation with Proper Model Documentation
Arne Tobias Elve and Heinz A. Preisig 235
43. Graph-Based Modelling with Distributed Systems
Heinz A. Preisig and Arne Tobias Elve 241
44. Closure Development for Multi-Scale Fluidized Bed Reactor Models: A CLR Case Study
Stefan Radl, Federico Municchi, Schalk Cloete, Hendrik Cloete, Stefan Andersson, Joana Francisco Morgado, Thomas Gurker, Rosa Quinta-Ferreira, Christoph Kloss, Christoph Goniva, Shahriar Amini 247
45. Life Cycle Assessment of calcium carbonate loop CO₂ capture technology for brown coal power plant unit of the Czech Republic
Kristína Zakuciová, Vladimír Koči, Karel Ciahotný, Ana Carvalho, Jiří Štefanica, Jana Smutná 251
46. Computer-Aided Simulation of the Volumetric Efficiency of a 2 MW Gas Engine
Guillermo E. Valencia, Franklin E. Consuegra, Marisol Osorio 259
47. The Ordinary Kriging in Multivariate Dynamic Modelling and Multistep-Ahead Prediction
Ahmed Shokry, Antonio Espuña 265
48. Modelling and advanced dynamic optimization strategies for hydrological and water quality management in continental water bodies
A.G. Siniscalchi, L. Fritz, C. Garcia Prieto, V. Estrada, M. Hoffmeyer, R.J. Lara, M.S. Diaz 271
49. Recursive Model Estimation for the Plasma Parameters Quality Control
Junmo Koo, Damdae Park, Sangwon Ryu, Gon-Ho Kim, Youn-Woo Lee 279

50.	Model transformations and integration for process plant simulation, optimization and visualization <i>Manuel Rodriguez, Ismael Diaz</i>	285
51.	Property Prediction of Pharmaceuticals for Designing of Downstream Separation Processes <i>Getachew S. Molla, Lukasz Ruszczynski, Jens Abildskov, Gürkan Sin</i>	287
52.	Incorporating fouling model in plate heat exchanger modelling and design <i>Olexiy Demirskyy, Petro Kapustenko, Olga Arsenyeva, Olexandr Matsegora, Pavlo Arsenyev, Vladimir Tovazhnianskyi, Alisher Khusanov</i>	284
53.	Multi-scale modelling and simulation of Ca-looping cycle process for CO ₂ post-combustion capture <i>Carla I.C. Pinheiro, Rui Filipe, Miguel Abreu Torres, João M. Silva, Henrique A. Matos</i>	291
54.	Good modelling practice for process engineering: pitfalls and requirements to develop fit for purpose models <i>Ingmar Nopens</i>	293
Methods, Software and Tools		
55.	Efficient simulation of ion exchange chromatography with application to bioseparations <i>Marcus Fechtner, Malte Kaspereit and Achim Kienle</i>	295
56.	Virtual splitting of shared resource networks for price-based coordination with portfolio tariffs <i>Simon Wenzel, Lukas Samuel Maxeiner and Sebastian Engell</i>	301
57.	Ensuring $(n - 1)$ -reliability in the optimal design of distributed energy supply systems <i>Dinah Elena Hollermann, Dörthe Franzisca Hoffrogge, Maike Hennen and André Bardow</i>	307
58.	Integrating Real-time Operational Constraints in Planning of Water and Energy Supply <i>Negar Vakilifard, Parisa A. Bahri, Martin Anda, Goen Ho</i>	313
59.	Leveraging the Power of Big Data Analytics for Process Scheduling under Uncertainty using a Stochastic Robust Optimization Approach <i>Chao Ning, Fengqi You</i>	319

60. A hierarchical approach for solvent selection based on successive model refinement
Kai Fabian Kruber, Jan Scheffczyk, Kai Leonhard, André Bardow, Mirko Skiborowski 325
61. Optimal synthesis of mass exchange networks through a state-task-representation superstructure
Miguel Angel Velázquez-Guevara, Agustin Ramon Uribe-Ramirez, Fernando Israel Gómez-Castro, Juan Gabriel Segovia-Hernandez, Salvador Hernández, Jose Maria Ponce Ortega 331
62. Optimization of Cryogenic Carbon Capture and LNG process by Mathematical programming
Orakotch Padungwatanaroj, Kitipat Siemanond 337
63. A methodology of a hybrid hydrogen supply network (HHSN) under alternative energy resources (AERs) of hydrogen footprint constraint for sustainable energy production (SEP)
Soonho Hwangbo, ChangKyoo Yoo 343
64. Kinetic Modeling of Plastic Waste Pyrolysis in a Laboratory Scale Two stage Reactor
Zoltán Till, Tamás Varga, János Sója, Norbert Miskolczi, Tibor Chován 349
65. Experimentally Driven Guaranteed Parameter Estimation: a Way to Speed up Model-Based Design of Experiments Techniques
Arun Pankajakshan, Marco Quaglio, Federico Galvanin 355
66. Optimal Design of a Dividing Wall Column for The Separation of Aromatic Mixtures using the Response Surface Method
Pedro Barbosa de Oliveira Filho, Marcio Luis Ferreira Nascimento, Karen Valverde Pontes 361
67. Simulation/optimization of bio-hydrogenated diesel process with techno-economic analysis
Phooreerat Tawai, Kitipat Siemanond 367
68. A Bilevel Decomposition Method for the Simultaneous Synthesis of Utility Systems, Rankine Cycles and Heat Exchanger Networks
Cristina Elsidio, Emanuele Martelli, Ignacio E. Grossmann 373
69. Energy and exergy analysis for cryogenic process design/retrofit
Nattawat Threerachannarong, Kitipat Siemanond 379

70. Ammonia/Urea Production Process Simulation/Optimization with Techno-Economic Analysis
Jiranart Jeenchay, Kitipat Siemanond 385
71. Towards a Quantitative Food-Energy-Water Nexus Metric to Facilitate Decision Making in Process Systems: A Case Study on a Dairy Production Plant
Styliani Avraamidou, Aaron Milhorn, Owais Sarwar, Efstratios N. Pistikopoulos 391
72. Numerical Evaluation of Different Turbulence Models for Single-Phase Flow in the Outer Pillow-Plate Channel
Marco Vociante, Mark Piper, Alexander Zibart, Eugeny Y. Kenig 397
73. Improving Convergence Behavior of Nonlinear Equation Systems in Intensified Process Models by Decomposition Methods
Saskia Bublitz, Erik Esche, Jens-Uwe Repke 403
74. Optimizing Decolorization Efficiency of Methylene Blue by Photo-Fenton Process over Fe-Diatomite using Central Composite Design
Pongsert Sriprom, Varocha Champa, Prakob Kitchaiya, Pornsawan Assawasaengrat 409
75. An optimization method to estimate the SOFC market in waste water treatment
Sonja Sechi, Sara Giarola, Andrea Lanzini, Marta Gandiglio, Gbemi Oluleye, Massimo Santarelli, Adam Hawkes 415
76. Optimal Chemical Grouping and Sorbent Material Design by Data Analysis, Modeling and Dimensionality Reduction Techniques
Melis Onel, Burcu Beykal, Meichen Wang, Fabian A. Grimm, Lan Zhou, Fred A. Wright, Timothy D. Phillips, Ivan Rusyn, Efstratios N. Pistikopoulos 421
77. Solution of the Population Balance Equation by the Meshless Moving Particle Method (MMPM)
Menwer Attarakih, Hans-Jörg Bart 427
78. Multi-objective optimization of a CO₂-EOR process from the sustainability criteria
Juan Pablo Gutierrez, Eleonora Erdmann, Davide Manca 433

79. A software tool for optimizing intra-logistic activities
Dimitrios Poulimenos, Dimitrios Bechtsis, Dimitrios Vlachos, Eleftherios Iakovou 439
80. Electricity mix assessment of the EU member countries using DEA and EffMixF
Patricia Zurano-Cervelló, Carlos Pozo, Josep María Mateo-Sanz, Laureano Jiménez, Gonzalo Guillén-Gosálbez 445
81. CFD modelling of pulsed sieve plate liquid extraction columns using OOSPM as a reduced population balance model: hydrodynamics and mass transfer
Samer Alzyod, Menwer Attarakih, Hans-Jörg Bart 451
82. Systematic generation of insulation materials via DEA and Building modelling
A. Torres-Rivas, C. Pozo, A. Ewertowska, D. Boer and L. Jiménez-Esteller 457
83. Simulation-Based Optimization of Chemical Processes Using the Extended Cutting Plane Algorithm
Juan Javaloyes-Antón, Jan Kronqvist, José A. Caballero 463
84. Towards a Methodology for Reusable Ontology Engineering: Application to the Process Engineering Domain
Nikolaos Trokanas, Linsey Koo, Franjo Cecelja 471
85. Simultaneous Optimization for Integrated Cooling Water System with Chemical Processes
Fei Song, Nan Zhang, Robin Smith, Yujiao Zeng, Jie Li, Xin Xiao 477
86. Parameter Estimation of Biosurfactant Production from Agro-industrial Waste Using Genetic Algorithm
Ana Luiza Campos, Júlia Nogueira, Filipe A. Coelho, Brunno F. Santos 483
87. Comparison of reformulations of the Duran-Grossmann model for Work and Heat Exchange Network (WHEN) synthesis
Haoshui Yu, Matias Vikse, Truls Gundersen 489
88. Semantic Networking Facility for the Biorefining Community
Edlira Kalemi, Linsey Koo, Franjo Cecelja 495

89.	Economic and environmental benefits of waste-based energy closed-loop integration in process industries under uncertainty <i>Shabnam Morakabatchiankar, Kefah Hjaila, Fernando D. Mele, Moisés Graells, Antonio Espuña</i>	501
90.	Minimum Entropy Based PFR Analysis <i>David Rosa, Paulo Goes, João Manzi</i>	507
91.	Exergy Analysis of an Extractive Distillation Column for Reducing Energy Consumption in a Bioethanol Production Process <i>J. Cristóbal García-García, Danahe Marmolejo-Correa, J. Carlos Cárdenas-Guerra, Ricardo Morales-Rodríguez</i>	513
92.	A Relaxed Knapsack-Problem Based Decomposition Heuristic For Large-Scale Multistage Stochastic Programs <i>Zuo Zeng, Selen Cremaschi</i>	519
93.	A Time-series-based approach for robust design of multi-energy systems with energy storage <i>Paolo Gabrielli, Florian Fürer, Portia Murray, Kristina Orehounig, Jan Carmeliet, Matteo Gazzani, Marco Mazzotti</i>	525
94.	Ordinary Kriging: A Machine learning tool applied to mixed-integer multiparametric approach <i>Gicela Lupera, Ahmed Shokry, Sergio Medina-González, Eduardo Vyhmeister, Antonio Espuña</i>	537
95.	Assessment of technology portfolios with enhanced economic and environmental performance for the energy, water and food nexus <i>Rajesh Govindan, Tareq Al-Ansari, Anna Korre, Nilay Shah</i>	537
96.	Multi-objective Optimization for Plant Design via Tabu Search <i>Faiz Mandani, Kyle Camarda</i>	543
97.	Alternative mixed-integer reformulations of Generalized Disjunctive Programs <i>Miloš Bogataj, Zdravko Kravanja</i>	549
98.	LES of particle collision and agglomeration in vertical channel flows <i>T. Ogholaja, D.O. Njobuenwu, M. Fairweather</i>	555
99.	Improved modeling of membrane separation in integrated hybrid processes <i>Bettina Scharzec, Mirko Skiborowski</i>	561

100. Ontology engineering approach to support process of model integration <i>Linsey Koo, Edlira Kalemi, Nikolaos Trokanas, Franjo Cecelja</i>	563
101. Approximation Algorithms for Process Systems Engineering <i>Dimitrios Letsios, Georgia Kouyialis, Ruth Misener</i>	565
Process Synthesis, Process Design and Life Cycle Modelling	
102. Alternative processes for obtaining solar grade silicon <i>Cesar Ramírez-Márquez, Marta Vidal Otero, José Antonio Vázquez-Castillo, Mariano Martin, Juan Gabriel Segovia-Hernández</i>	567
103. An Engineering Tool to Screen and Integrate Biomass Valorization Paths in Multiple-Feedstock Biorefineries <i>Konstantinos A. Pyrgakis, Antonis C. Kokossis</i>	566
104. Processes Separation to Furfural, Design and Optimization Involving Economical, Environmental and Safety Criteria <i>G. Contreras-Zarazua, E. Sánchez-Ramírez, J.A. Vázquez-Castillo, C. Ramírez-Márquez, J.G. Segovia-Hernández</i>	579
105. Techno-economic assessment of a lignocellulosic biorefinery co-producing ethanol and xylitol or furfural <i>Aristide Giuliano, Diego Barletta, Isabella De Bari, Massimo Poletto</i>	585
106. Endpoint-oriented Life Cycle Optimization Models for Sustainable Design and Operations of shale Gas Supply Chains with Modular Manufacturing <i>Jiyao Gao, Fengqi You</i>	591
107. Surrogate-based Optimization Approach to Membrane Network Synthesis in Gas Separation <i>Jos E.A. Graciano, Rita M.B. Alves and Benoit Chachuat</i>	597
108. Balancing Costs, Safety and CO ₂ Emissions in the Design of Hydrogen Supply Chains <i>Anton Ochoa Bique, Leonardo K. K. Maia, Fabio La Mantia, Davide Manca, Edwin Zondervan</i>	603
109. Process Integration as an Effective Route Towards Sustainable Oil Refinery Development <i>Poland Jelihi, Timo Wassermann, Edwin Zondervan</i>	609

110. Experimental Study of a Biomass Downdraft Gasifier with Multi-tube Gas Outlets to Improve Synthesis Gases Quality
Ajaree Suwatthikul and Paisan Kittisupakorn 615
111. Design and Optimisation of Novel Cascade Refrigeration Cycles for LNG Production
Fernando Almeida-Trasvina, Robin Smith 621
112. Method of Removing water from Products of Dehydration Reaction of 3-hydroxypropionic acid in Acrylic acid Process
Jae-Hyeon Yang, Chul-Jin Lee 627
113. Multi-floor process plant layout using mixed-integer optimization
Jude O. Ejeh, Songsong Liu and Lazaros Papageorgiou 633
114. Feasibility study of using reactive distillation for the production of renewable aviation fuel
Maritza Lisette Soria-Ornelas, Claudia Gutiérrez-Antonio, Fernando Israel Gómez-Castro, Salvador Hernández 639
115. Extended Value Chain Synthesis towards the Design of Multi-Feedstock Algae Biorefineries
Melina Psycha, Maria Kapnisi, Antonis C. Kokossis 645
116. Selection of fractionation pathways and intermediates for mixed consumer products
Alberto Castiglioni, Jochem Jonkman, Renzo Akkerman, Albert van der Padt 651
117. Sustainable Optimal Strategic Planning for Shale Water Management
Alba Carrero-Parreño, Rubén Ruiz-Femenia, José A. Caballero, Juan A. Reyes-Labarta, Ignacio E. Grossmann 657
118. Compact and Multi-Stream Heat Exchanger Design
Somei Hayashi, Kitipat Siemanond 663
119. Optimal design of biogas supply chains
Grégoire Alain Chomette, Theodoros Damartzis, François Maréchal 669
120. Retrofit of mass exchange networks using a reduced superstructure synthesis approach
Adeniyi J. Isafiade 675

121. Optimization-Based Process Synthesis for Integrated Crystallizer-Wet Mill System for Improved Crystal Shape Control <i>Botond Szilagy, Zoltan K. Nagy</i>	681
122. Mathematical Modeling and Simulation in Natural Flavors and Fragrances Bioproduction Intensification <i>Ivan Červeňanský, Mário Mihal', Jozef Markoš</i>	687
123. Simulation and economic evaluation of NO _x removal in wet scrubbers of low-speed two-stroke vessels using H ₂ O ₂ as a replacement for conventional EGR <i>Yeongryeol Choi, Junghwan Kim</i>	693
124. Comparative Performance Analysis of Industrial Scale Catalytic Steam Reformer with Membrane Steam Reformer <i>Arun Senthil Sundaramoorthy, Arun Prem Anand Natarajan, Sundaramoorthy Sithanandam</i>	699
125. Towards the synthesis of modular process intensification systems with safety and operability considerations - application to heat exchanger network <i>Yuhe Tian, M. Sam Mannan, Zdravko Kravanja, Efstratios N. Pistikopoulos</i>	705
126. Design, Control and Economics of a Process for Isobutyl Acrylate Production <i>Mihai Daniel Moraru, Diana Adela Berinde, Costin Sorin Bildea</i>	711
127. Optimization based design of an industrial cluster for economic and environmental benefits <i>D. Varshney, P. Mandade, Yogendra Shastri</i>	717
128. Process Simulation and Optimization of 10-MW EFB Power Plant <i>Jaechan Han, Junghwan Kim</i>	723
129. Dimethyl Carbonate Production Process from Urea and Methanol <i>Daniel Vázquez, Juan Javaloyes-Antón, Juan D. Medrano-García, Rubén Ruiz-Femenia, José A. Caballero</i>	731
130. Design and Analysis of Edible Oil Processes Containing Lipids <i>Olivia A. Perederic, Sten Appel, Bent Sarup, John M. Woodley, Georgios M. Kontogeorgis, Rafiqul Gani</i>	737

131. Multi-objective optimization of sustainability criteria in the design of chemical plants <i>Federico Scotti, Nicola Fabricatore, Davide Manca</i>	743
132. Evaluating the effect of separation and reaction systems in industrial symbiosis <i>Ana Somoza-Tornos, Moisés Graells, Antonio Espuña</i>	749
133. A framework for optimised sustainable solvent mixture and separation process design <i>Eduardo Sánchez-Ramírez, Jaime D. Ponce-Rocha, Juan G. Segovia-Hernandez, Fernando I. Gómez-Castro, Ricardo Morales-Rodriguez</i>	755
134. Optimal Design and Operation of Hybrid Osmosis Processes for Simultaneous Production of Water and Power under Different Demand Conditions <i>Jyh-Cheng Jeng, Heng-Yi Chu</i>	761
135. Superstructure optimization (MINLP) within ProSimPlus Simulator <i>Qiao Zhao, Thibaut Neveux, Mounir Mecheri, Romain Privat, Philippe Guittard, Jean-Noël Jaubert</i>	767
136. Sustainable Supply Chain: Monetization of Environmental Impacts <i>Cátia da Silva, Ana Paula Barbosa-Póvoa, Ana Carvalho</i>	773
137. Design of Biotechnological Production of 2-Phenylethanol <i>Peter Vargai, Ivan Červeňanský, Mário Mihal', Jozef Markoš</i>	779
138. Process Innovation through bio-inspired design <i>Anne Marie Barthe-Delanoë, Stéphane Negny, Jean Marc Le Lann</i>	785
139. Heat pump assisted azeotropic DWC for enhanced biobutanol separation <i>Iulian Patraşcu, Costin Sorin Bildea, Anton A. Kiss</i>	791
140. Optimization based design of a resilient biomass to energy system <i>Ashish Soren, Yogendra Shastri</i>	797
141. Optimal on-grid hybrid power system for eco-industrial parks planning and influence of geographical position <i>Florent Mousqué, Marianne Boix, Stéphane Negny, Ludovic Montastruc, Louis Genty, Serge Domenech</i>	803

<i>Contents</i>	xix
142. Life cycle assessment of pulp and paper production – A Portuguese case study <i>Andreia Santos, Ana Barbosa-Póvoa, Ana Carvalho</i>	809
143. Modelling and Analysing Supply Chain Resilience Flow Complexity <i>João Pires Ribeiro and Ana Barbosa-Póvoa</i>	815
144. A model-based approach to design miniaturised structured packings for highly efficient mass transfer in gas/liquid multiphase flows <i>Daniel Sebastia-Saez and Harvey Arellano-Garcia</i>	821
145. Preliminary economic ranking of reactive distillation processes using a navigation method <i>Rahma Muthia, Aloijsius G.J. van der Ham, Anton A. Kiss</i>	827
146. Multi-scale system modelling under circular bioeconomy <i>Miao Guo</i>	833
147. An Integrated Reactive Separation Process for Co-Hydrotreating of Vegetable Oils and Gasoil to Produce Jet Diesel <i>Miriam García-Sánchez, Mauricio Sales-Cruz, Teresa López-Arenas, Tomás Viveros-García, Alberto Ochoa-Tapia, Ricardo Lobo-Oemichen and Eduardo S. Pérez-Cisneros</i>	839
148. Understanding the dynamic behavior of Semicontinuous distillation <i>Pranav Bhaswanth Madabhushi, Edgar Iván Sánchez Medina and Thomas Alan Adams II</i>	845
149. Integrated Solvent-Membrane and Process Design Method for Hybrid Reaction-Separation Schemes <i>Yuqiu Chen, Evangelia Koumaditi, John Woodley, Georgios Kontogeorgis, Rafiqul Gani</i>	851
150. Exergy efficiency based design and analysis of utilization pathways of biomasses <i>Hongliang Qian, Weiwei Zhu, Chang Liu, Xiaohua Lu, Georgios M. Kontogeorgis, Rafiqul Gani</i>	857
151. Systematic tool for sustainable synthesis and design of flexible processes and supply chains under uncertainty <i>Klavdija Zirngast, Žan Zore, Lidija Čuček, Zorka Novak Pintarič, Zdravko Kravanja</i>	863

152. Processing Systems Synthesis with Embedded Reliability Consideration <i>Akos Orosz, Zoltan Kovacs, Ferenc Friedler</i>	869

Preface

This volume of the Computer-Aided Chemical Engineering series puts together a selection of the contributions presented at the 28th European Symposium on Computer-Aided Process Engineering (ESCAPE28), held in Graz, Austria, from June 10th to 13th, 2018.

This 28th event of the ESCAPE series is a continuation of the conferences under the auspices of the CAPE Working Party of the European Federation of Chemical Engineering. The conference has been organised since 1992, starting with two meetings in 1992 in Denmark and France, then having one event annually since then. Hosts to the conference have been Ireland (1994), Slovenia (1995, 2016), Greece (1996, 2011), Norway (1997), Belgium (1998), Hungary (1999, 2014), Italy (2000, 2010), Denmark (1992, 2001, 2015), The Netherlands (2002), Finland (2003, 2013), Portugal (2004), Spain (2005, 2017), Germany (2006), Romania (2007), France (1992, 2008), Poland (2009), and the United Kingdom (2012). Having organised the event in 1993, Graz takes on the torch of research and knowledge exchange with organising ESCAPE28.

ESCAPE28 is jointly organized by TU Graz and TU Wien (Austria), and the Scientific Coordination Team also spans Brno University of Technology (Czech Republic). The vision was to collaborate in organizing the event, which - besides traditional themes - also offers a platform for topics that were not explicitly mentioned in the two previous editions of ESCAPE: food, (bio-)pharma, bioresources, and the open science movement.

The themes of ESCAPE28 have been selected after a comprehensive discussion with the CAPE Working Party members and the scientific community. These include: Model Development and Simulation; Methods, Software and Tools; Open Science Movement and Education; Process Synthesis, Process Design and Life Cycle Modelling; Process Operation and Control; Bioresources, Bioprocesses and Biomedical Systems; Environment and Energy; Food, (Bio-)Pharma, and Fine Chemicals. The individual topics within these overarching themes have been formulated for allowing researchers from CAPE-related sciences to present their results and exchange valuable knowledge and experience.

ESCAPE28 attracted 321 contributions from five continents (Europe, Americas, Africa, Asia and Australia), and the International Scientific Committee (ISC) selected 163 oral presentation out of these contributions. 4 plenaries given by renowned experts from academia and industry, as well as 16 keynotes, given by leaders in their field, rounds up the scientific program. Putting together all this would have been impossible without the help of nine topic coordinators, as well as the 96 members of the ISC. We are deeply thankful for timely and careful review by these committees, as well as their invaluable help in suggesting plenary and keynote speakers.

We hope that the contributions in this edition of Computer Aided Process Engineering shine bright as illustrations of the current state of the art in their respective field.

Resilient Design and Operations of Chemical Process Systems

Jian Gong, Fengqi You^{*}

Cornell University, Ithaca, New York, 14853, USA

Abstract

Resilience in response to disruption events is critical to the economic performance of process systems, but this concept has received limited attention in the literature. We propose a general framework for resilience optimization to incorporate an improved quantitative measure of resilience and a comprehensive set of resilience enhancement strategies for process design and operations. The proposed framework identifies a set of disruptive events for a given system, and then formulates a multiobjective two-stage adaptive robust mixed-integer fractional programming model to optimize the resilience and economic objectives simultaneously. The model accounts for network configuration, equipment capacities, and capital costs in the first stage, and the number of available processes and operating levels in each time period in the second stage. A tailored solution algorithm is developed to tackle the computational challenge of the resulting multi-level optimization problem. We demonstrate the applicability of the proposed framework through applications on a shale gas processing system.

Keywords: resilience, process design and operations, superstructure optimization.

1. Introduction

Resilience is the ability to mitigate hazards and minimize the reduction in the quality of life (Bruneau et al., 2003). A resilient system is always capable of absorbing a portion of the impacts from disruptive events and recovering to the original state rapidly. A resilient plant could move fast and smoothly from one operating condition to another and dealt effectively with disturbances (Morari, 1983). A relevant concept of resilience was flexibility (Grossmann et al., 2014) which can help predict the probability of feasible operation for a design (Straub and Grossmann, 1990). Another relevant concept was reliability, which described the failure rate due to equipment aging (Rajagopalan et al., Thomaidis and Pistikopoulos, 1995). As resilience deals with safety and operability, the worst-case realization of disruptive events is of paramount importance. However, resilience was not quantified explicitly as an intrinsic property of the system.

In this work, we propose a general framework for resilience optimization with three steps. First, a preliminary risk assessment is performed to identify the disruptive events and the numbers of failed processes for the identified disruptive events. Then a multiobjective two-stage adaptive robust mixed-integer fractional programming (ARMIFP) model is formulated to maximize the resilience under the worst-case realization of disruptive events, and to minimize the total capital cost. To tackle the computational challenges from the multilevel structure and the nonlinear objective function, a tailored global optimization method is proposed by integrating the inexact parametric algorithm and the column-and-constraint generation algorithm. The applicability of the proposed framework is illustrated through the superstructure optimization of shale gas processing and natural gas liquids (NGL) recovery processes.

2. General framework for resilience optimization

We propose a general framework for resilience optimization that incorporates the quantitative measure of resilience and the five resilience enhancement strategies. There are three steps in the proposed resilience optimization framework. In the first step, a preliminary risk assessment is performed for a given system. A set of disruptive events are identified, and the related information, such as the number of failed processes in the given system and the recovery time of each process, is used as input parameters in the second step to formulate a multiobjective two-stage ARMIFP model. In the third step, the multiobjective two-stage ARMIFP problem is solved by a tailored global optimization method that integrates the parametric algorithm and the column-and-constraint generation algorithm.

2.1. Novel quantitative measure of resilience

$$\text{Resilience} = \frac{\sum_{w=0}^{t_n-t_0-1} [F(t_0 + w \cdot ti) \cdot ti]}{[F(t_0) \cdot (t_n - t_0)]} \quad (1)$$

where $F(t) = \sum_k [\omega_k \cdot M(t)_k]$, $M(t)_k$ and ω_k are the flow rate and the weight of product k , respectively; ti is the length of each time period.

We propose a novel quantitative measure as in (1). The disruptive events occur at t_0 and the time horizon is $[t_0, t_n]$. The denominator calculates the accumulated system performance from t_0 to t_n and the numerator calculates the accumulated system performance in the same period but assumes that no disruptive event occurs. This quantitative measure accounts for recovery time and performance degradation simultaneously. Moreover, as the quantitative measure is normalized by the accumulated system performance without disruptions, the resilience analysis results can be compared among distinct process systems. The failed processes of a given system can be reused only if they are fully repaired and tested. Therefore, system performance remains the same in each time period, and the system performance functions are step-wise functions.

2.2. Uncertainty set

$$\sum_{i \in ID_d} SI_{i,d} \leq \Gamma_d \cdot (1 - \varepsilon_d), \quad \forall d \quad (2)$$

$$\sum_{i \notin ID_d} SI_{i,d} = 0, \quad \forall d \quad (3)$$

The availability of process i after the occurrence of disruptive event d is modeled as an uncertain 0-1 variable $SI_{i,d}$. $SI_{i,d}$ is equal to one if the operating units in process i fail after the occurrence of disruptive event d , and 0 otherwise. Given the same operating conditions, parallel operating units are assumed to show the same availability after the occurrence of disruptive event d . Additionally, constraints (2) and (3) are introduced to provide an upper bound of the number of failed processes in the given system. Γ_d denotes the number of failed processes of disruptive event d based on historical records or simulation results. As a decision-maker may consider it too conservative to hedge against the realization where Γ_d processes fail, a tolerance level ε_d is introduced to adjust the degree of conservatism of the optimal solution. Since a disruptive event may influence only a set of processes, the summation in constraint (2) are limited to a subset of sections ID_d . The processes not in subset ID_d are fixed to be 0 as enforced by constraint (3). Uncertainty set U is formed by constraints (2) and (3).

2.3. Model formulation and tailored solution algorithm

Given the definition of resilience and uncertainty constraints, a multiobjective two-stage ARMIFP model is developed for resilient design and operations (Ning and You, 2017b, Ning and You, 2017a, Shang et al., 2017). The decisions are determined sequentially in two stages (Shi and You, 2016, Yue and You, 2016). The first-stage decisions, including network configuration, equipment capacities, and capital costs, are determined before the occurrence of the disruptive events; the second-stage decisions, including the number of available processes and operating levels in each time period, are determined after the occurrence of the disruptive events. There are two objective functions in the general form of the proposed model (shown below). The first objective is to maximize the resilience under the worst-case realization of the availability of process units, and the second objective is to minimize the total capital cost of the given system.

$$\begin{aligned} & \max_{C1} \min_U \max_{C2} \text{ Resilience} \\ & \min_{C1} \text{ Total capital cost} \end{aligned}$$

where $C1 = \{\text{network design; equipment capacity constraints; capital cost evaluation}\}$;

$C2 = \{\text{recovery constraints; operating level constraints}\}$.

Since the proposed multiobjective two-stage ARMIFP model has a multilevel structure, it cannot be handled directly by any off-the-shelf optimization solvers. Additionally, due to the combinatorial nature and nonconvexity stemming from the mixed-integer terms and the fractional objective function, the optimization problem is challenging to solve (Gong and You, 2017). To tackle the computational challenge, we employ a tailored optimization algorithm to efficiently solve this ARMIFP problem (Gong et al., 2016). Specifically, the nonlinear, nonconvex fractional objective function in the ARMIFP is tackled by a parametric algorithm (Zhong and You, 2014) that solves a sequence of auxiliary mixed-integer linear programming (MILP) problems.

3. Case study

The application of the proposed resilience optimization framework is illustrated through the superstructure optimization of shale gas processing and NGLs recovery processes (He and You, 2014, He and You 2016). Figure 1 shows a superstructure that integrates 108 possible process designs for shale gas processing and natural gas liquids recovery processes (Gong et al., 2017). The superstructure consists of four sections, namely acid gas removal, dehydration, NGLs recovery, and sulfur recovery (Yang and You, 2017). The correlation parameter $ri_{i,d}$ is equal to 1 and the tolerance level ϵ_d is equal to 5% for all disruptive events. A total of 4 case studies are considered: Case studies 1–3 involve only one disruptive event with 2, 4, and 6 failed processes, respectively, while Case study 4 involves two disruptive events with 3 and 2 failed processes in the first and second disruptive events, respectively.

All computational experiments are performed on a DELL OPTIPLEX 7040 desktop with Intel(R) Core(TM) i7-6700 CPU @ 3.40GHz and 32 GB RAM. The solution procedure is coded in GAMS 24.8.5 (Rosenthal, 2016), with CPLEX 12.7 used as the MILP solver. The relative optimality tolerances for the inexact parametric algorithm and the column-and-constraint generation algorithm are 10^{-6} .

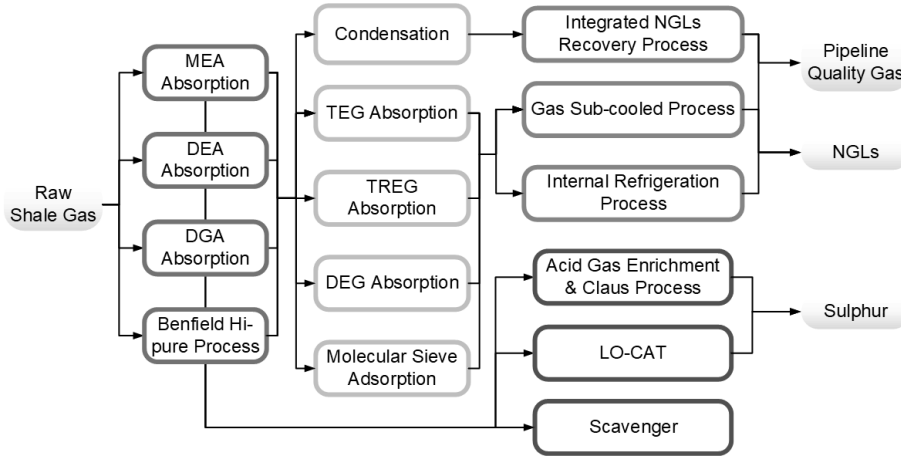

Figure 1. Superstructure of shale gas processing and NGLs recovery processes.

The optimal solutions and the selected optimal process design are plotted in the Pareto-optimal curve in Figure 2. Since the shale gas processing and NGLs recovery processes form a tandem system, the entire system will be disrupted even if only one process in the system fails. In order to operate after the occurrence of disruptive events, backup processes must be built for all the operating processes simultaneously regardless of the number of failed processes. Although four different cases have been considered in this application, the optimal solutions and the optimal objective function values are the same across all the case studies, and only one Pareto-optimal curve is exhibited in Figure 2.

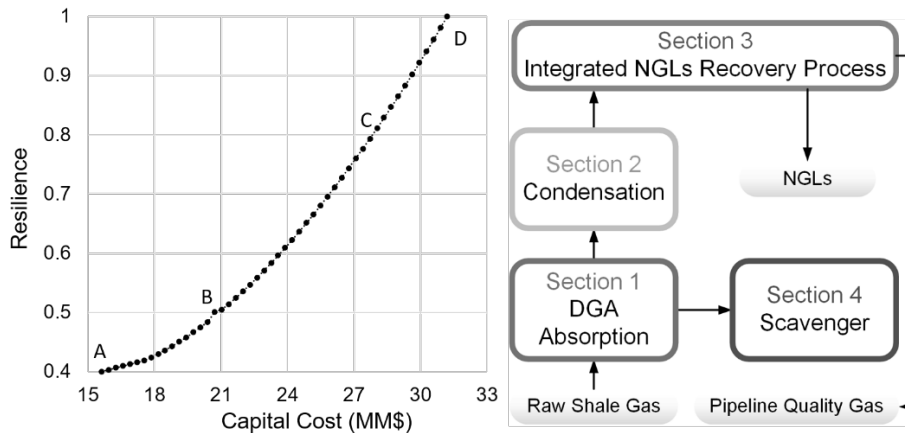

Figure 2. Pareto-optimal curve and optimal process design.

The most resilient solution demonstrates a resilience of 1 and a capital cost of \$31.22 MM, while the most cost-effective solution demonstrates a resilience of 0.4 and a capital cost of \$15.61 MM. There is a tradeoff between the two competing objective functions. A resilience of 1 for the most resilient solution means that the production rate is not affected by the disruptive events, but such an ideal performance corresponds to the highest capital cost, which is twice the cost of the most cost-effective solution. All the optimal solutions the same technologies/processes, namely diglycolamine (DGA) adsorption in the acid gas removal section, condensation in the dehydration section,

integrated NGLs recovery process in the NGLs recovery section, and scavenger in the sulfur recovery section. The resilience of a process system would be higher if additional products can be generated in the same process system. However, the technology alternatives that generate additional sulfur in the sulfur recovery section are not selected by the optimal process design, because of the relatively high capital costs of these technology alternatives. Although the selected scavenger process does not generate a sulfur product, the capital cost of this process is much lower. Therefore, the resilience will be higher if the saved capital cost is invested in alternative resilience enhancement strategies, such as employing multiple parallel processes. Overall, the optimal process design selects technologies that enhance resilience by either directly generating products or by saving capital investment for other resilience enhancement strategies.

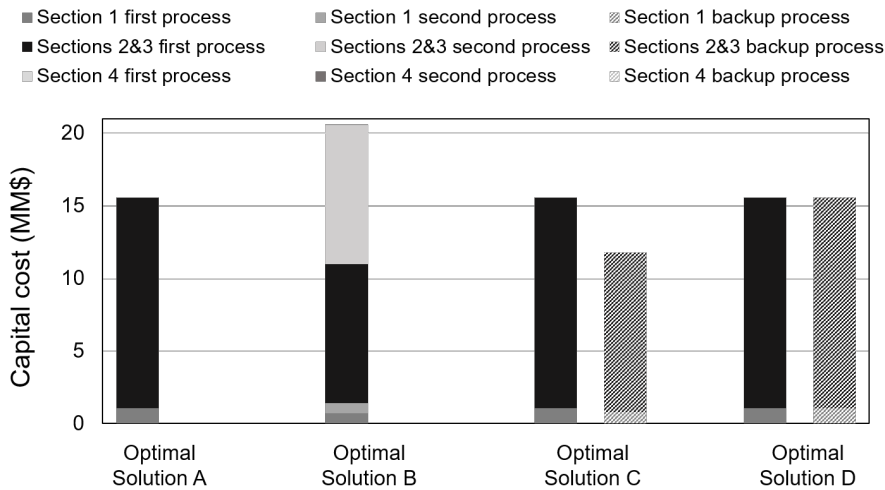

Figure 3. Capital cost breakdowns of the optimal solutions.

The breakdowns of capital costs of the optimal solutions A, B, C, and D are presented in Figure 3. The integrated dehydration and NGLs recovery process contribute to over 90% of the total capital cost. It is noted that the optimal solution B employs two parallel operating processes for the integrated dehydration and NGLs recovery process, while backup processes are built for all the sections in the optimal solutions C and D. The results also indicate that employing parallel processes can lead to a higher resilience with a low capital investment, but backup processes is desirable with higher capital investment.

4. Conclusions

We proposed a general framework for resilience optimization to incorporate the quantitative measure and the resilience enhancement strategies. The framework involves developing a multiobjective two-stage ARMIFP model, and solving the optimization problem with a tailored solution algorithm. The applicability of the proposed resilience optimization framework was illustrated through the superstructure optimization of shale gas processes. The optimal process design selected DGA adsorption, condensation, integrated NGLs recovery process, and scavenger. The maximum resilience ranged from 0.4 to 1, while the minimum capital cost ranged from \$15.61 MM to \$31.22 MM.

Abstract

Process systems engineering (PSE) skills are imperative for the success of the chemical enterprise in a competitive and ever-changing world. Unfortunately, the importance of developing these skills is not always understood or accepted in industry or academia. Thus, engineers early in their careers sometimes have a steep learning curve applying PSE tools, and some may not be fully aware of the discipline and its possibilities.

This presentation will cover the author's perspective on key PSE skills to develop as part of the toolbox of successful engineers given ongoing trends. Developing and enhancing these key skills would enable the chemical enterprise to become more effective, sustainable, and innovative. Some of the skills to be discussed include sustainability evaluations, molecular design, process and supply chain modelling, process control and optimization, relevant data analytics, amongst others.

The talk will incorporate experience obtained through 20+ years of work from the following viewpoints: industrial PSE practice and research, development of technical engineering leaders in the chemical enterprise, and academic formation of new engineers at both graduate and undergraduate level.

The talk will provide perspective of some actions that can be taken by industry and academia to better prepare engineers in training for the demands of the chemical enterprise. When engineers are versed on the right tools, the challenges currently face by PSE become the opportunities of the innovators of tomorrow.

COSMO-RS: From Quantum Chemistry to Fluid Phase Thermodynamics

Andreas Klamt^a

^a*COSMOlogic GmbH & Co. KG, and Inst. of Physical and Theoretical Chemistry,
University of Regensburg, Imbacher Weg 46, 51379 Leverkusen, DE*

klamt@cosmologic.de

Abstract

Thermodynamic data is the fundament of any process design. While accurately measured experimental data almost always is the most reliable source of information for the thermodynamic data required for process design, there are many situations in which this data is not available. In such situations predictive models are required. Correlative models as NRTL or SAFT, or group contribution methods as UNIFAC are the traditional approaches for property prediction in chemical engineering. Correlative methods require some experimental data for exactly the compounds and mixtures under consideration and only extrapolate to other state points. UNIFAC extrapolates to new compounds, but only if the compounds are well describable by the additive group concept and do not have major intramolecular interactions.

For structurally really new and demanding compounds, robust predictions require sound physical concepts for the description of the molecular interactions. The Conductor-like Screening Model for Realistic Solvation, COSMO-RS, is the most fundamental of such models, combining the sound quantum chemical polarity information with the efficient concept of surface segment interactions, also known as quasi-chemical approach. Thus, it provides reliable predictions for pure compound vapor pressures and mixture activity coefficients.

COSMO-RS has been initially published more than 20 years ago, and meanwhile it has become a popular method in academia and industry. The talk will cover the basic concepts of the method, its potential and limitations, and outline several extensions and new application areas which have opened up by the various methodological improvements developed during the past 20 years.

Multi-Parametric Optimization in Smart Manufacturing & Process Intensification

Efstratios Pistikopoulos^a

^a*Texas A&M University, Texas A&M Energy Institute, 1617 Research Pkwy, College Station, TX 77845, US*

stratos@tamu.edu

Abstract

Smart Manufacturing and Process Intensification are major initiatives in the US and worldwide in which process systems engineering core areas, such as modelling, optimization, control and data analytics, play key role. In Smart manufacturing real-time optimization and on-line control based on big data analytics and modelling efforts constitute important challenges. In Process Intensification the in-silico modelling, synthesis and optimization of operable and safe process intensification alternatives constitutes a key research direction.

Multi-parametric optimization provides a complete map of solutions of an optimization problem as a function of, unknown but bounded, parameters in the model, in a computationally efficient manner, without exhaustively enumerating the entire parameter space. In a Model-based Control framework, multi-parametric optimization can be used to obtain the governing ‘control laws’ – the optimal control/optimization variables as an explicit function of the state variables/parameters. This offers opportunities to (i) significantly accelerate and facilitate real-time/on-line optimization solution strategies - in the context of smart manufacturing applications, and (ii) effectively enable the systematic integration of operability criteria in the synthesis and optimization steps - in the context of process intensification.

In this presentation, we will first provide a historical progress report of the key developments in multi-parametric optimization and control. We will then describe PAROC, a systematic framework and prototype software system which allows for the representation, modelling and solution of integrated design, operation and advanced control problems – with focus on sustainable energy systems, smart manufacturing and process intensification.

Abstract

Life Cycle Assessment or LCA is a technique to evaluate and analyse environmental impacts through the entire life cycle of products and its associated processes. In order to evaluate environmental impacts and develop sustainable processes, LCSoft has been developed as a tool for LCA calculations that also integrates with other tools such as process simulation & design software, economic analysis and sustainability analysis. Apart from normalization, sensitivity analysis, uncertainty estimations, alternative comparison and eco-efficiency evaluation are also provided as results. In this paper, new Life Cycle Impact categories (LCIA) methodologies and new interpretations are added in order to improve performances, application range and flexibilities. ReCiPe, including midpoint and endpoint impacts, is added into LCIA method selection, water scarcity footprint and ecological footprint are added as a new feature of interpretation. Also, LCSoft can estimate water scarcity footprint and ecological footprint in different countries and periods of time. Finally, LCA calculations for bioethanol production from cassava rhizome and a carbon dioxide conversion process are validated by comparing with SimaPro, which is another LCA software. The results show that the new LCIA methodologies and LCA interpretation of LCSoft has the ability to evaluate environmental impacts of biochemical and petrochemical processes.

Keywords: Life Cycle Assessment, Life Cycle Inventory, Sustainable process design, Environmental footprint

1. Introduction

For decades, the increase of world population along with the growth of industries caused the increase of demand in natural resources. Policies are being implemented to prevent the reduction of natural resources and focus on environmental issues. Therefore, the assessment of environmental impacts has become an important issue to improve and develop new as well as existing processes. One of the most popular techniques that are widely used around the world is life cycle assessment, also known as LCA.

Currently, several commercial software are available to evaluate LCA, such as, SimaPro (Goedkoop et al., 2016), Gabi (PE, 2012), and Umberto (Ifu Hamburg GmbH, 2016). Although commercial tools for LCA are available, for sustainable process design a number of additional software are needed to obtain an overall perspective of the designed process. For this purpose, LCSoft (Chavewanmas et al., 2017) has been developed as a tool for LCA calculations for chemical and biochemical processes that also integrates with other design and analysis tools, such as, PROII (process

simulation), ECON (economic analysis, Saengwirun, 2011) and SustainPro (sustainability analysis) (Carvalho et al., 2013).

The new version of LCSOFT calculates the Life Cycle Inventory (LCI) as well as LCIA by using a systematic calculation strategy consisting of retrieval of appropriate system data, data of substances involved and process utility data (such as, consumptions of steam, electricity, and water) and the corresponding models. LCSOFT calculates and evaluates environmental impacts organized in different impact categories, which depend on the use of specific LCIA methodologies (General Impact Categories, ILCD 2011 midpoint, ILCD 2011 endpoint, ReCiPe midpoint and ReCiPe endpoint) that are currently available. LCSOFT provides the following impacts and factors: acidification, global warming potential, ozone depletion, particulate matter, photochemical oxidant formation, human toxicity, freshwater ecotoxicity, terrestrial ecotoxicity, marine ecotoxicity, ionising radiation, terrestrial eutrophication, freshwater eutrophication, marine eutrophication, water depletion, fossil depletion, water resource consumption, energy resource consumption for midpoint impact categories and ecological system, human health, resource depletion for endpoint impact categories as well as carbon footprint. The potential environmental impacts are calculated by using characterization factors of specific LCIA methodologies. The new characterization factors in LCSOFT are able to cover a wide range of chemical substances and the implemented model is also able to handle multiple products because of the use of predictive group contribution-based models. Several optional interpretations now available in LCSOFT consist of normalization, sensitivity analysis, uncertainty estimations, alternative comparison and eco-efficiency evaluation. In order to evaluate the impact of water and ecological resource consumption at different periods and locations, a water scarcity footprint and an ecological footprint are also now calculated.

2. Description of New Features in LCSOFT

Two of the features developed for LCSOFT are briefly described below.

2.1 New LCIA methodologies

Midpoint and endpoint impact categories are provided in the new version of LCSOFT, compared to the previous, which only calculated the midpoint impact. In order to broaden the application range of usage, ReCiPe and ILCD endpoints are included in the LCIA methodology. Normally, midpoint impact focuses only on single environmental problems. For other environmental problems, midpoint indicators are transformed by multiplication with characterization factors and aggregation of each environmental problem to higher levels, also known as endpoints. Also, each midpoint and endpoint of ReCiPe are classified in terms of individualist (short term), hierarchist (consensus model) and egalitarian (long term). The LCIA methodologies currently available in LCSOFT are listed in Table 1.

Table 1: LCIA methodologies in LCSoft

Impact level	LCIA methodologies in LCSoft	
	Previous version	Latest version
Midpoint	General Impact categories ILCD 2011	General Impact categories
		ILCD 2011
		ReCiPe (Egalitarian)
		ReCiPe (Individualist)
Endpoint		ReCiPe (Hierarchist)
		ILCD 2011
		ReCiPe (Egalitarian)
		ReCiPe (Individualist)
		ReCiPe (Hierarchist)

2.2 New interpretation and analysis options

To ease the communication with users, new interpretation and analysis options have been added. In addition to carbon footprint, which is defined as the total set of greenhouse gas emissions expressed in terms of carbon dioxide equivalent, LCSoft calculates other environmental footprints: water scarcity footprint (Boulay et al., 2017) and the ecological footprint. The water scarcity footprint shows the impact score of consumed water per kg product, which is compared with data from different countries and time periods. Ecological footprint is defined as the area used to support population and industrial consumption. Water scarcity footprint is calculated by Eq. (1).

$$Water\ Scarcity\ Footprint = Water\ consumption \times Characterization\ factor \tag{1}$$

The ecological footprint (Global Footprint Network, 2013) shows, in terms of global hectares, how much area is needed to produce all resources, instead of it being consumed, and absorb the waste generated from all activities.

LCSoft also provides options for analysis of sensitivity and uncertainty in the calculated impacts, as well as alternative comparison. Sensitivity analysis is calculated by perturbing each parameter to study the effect on the impacts. Uncertainties in the calculated impacts are obtained through the available variations in the system data.

3. Case Study

Here, LCA for two processes are calculated and compared with results from SimaPro.

Case-1: A process for production of bioethanol from cassava rhizome as the feed stock is assumed to be located in Thailand. The data (mass and energy flows) for this evaluation, are taken from simulation results (Mangnimit, 2013). The LCA for this process is evaluated in terms of environmental impacts calculated by LCSoft and SimaPro using the same simulation data and LCIA methodology, ReCiPe (H) methodology. LCA results from both programs for different environmental impacts calculated on the basis of 1 kg of pure ethanol produced are listed in Table 2.

Table 2: Comparison of bioethanol result with the ReCiPe (H) methodology

Case-2: Carbon dioxide capture and utilization (CCU) processes make an effort to reduce carbon dioxide emissions by converting them into useful chemicals. Dimethyl carbonate is one of those high value chemical selected in this work for production by a CCU process. The LCA calculated for this process is also compared with SimaPro (see Table 3). Also, for this case study, the water scarcity footprint and ecological footprint are calculated. For these footprint calculation, location of the process is an important factor because there are differences in climate, geography, resources and time-period. The plant location is assumed to be in Denmark and the results of the footprint calculations are given in Table 4.

4. Conclusions

The latest version of LCSoft covers a broader application range for users, more LCIA methodologies are included and also impacts sub-level, including midpoint and endpoint are calculated. Environmental impacts from case study results confirm that LCSoft, integrated with design and analysis software tools, has the ability to efficiently evaluate biochemical, petrochemical, chemical and related processes. In addition, new interpretation results connected to, water scarcity footprint and ecological footprint are helpful additions to get a sound overall picture with respect to sustainability.

Abstract

In this work, a one-dimensional model of a low-pressure reverse osmosis (LPRO) membrane process has been developed using an augmented model previously developed by the same authors to analyse the rejection of N-nitrosamine from wastewater. The model, based on the principles of the solution-diffusion coupled with the concentration polarization theory, is validated using experimental data of N-nitrosamine rejection from the literature for three different types of membranes in an RO process. Finally, detailed simulation of the LPRO process is carried out for variety of operating conditions such as inlet feed flow rate, pressure, feed concentration, and temperature.

Keywords: Wastewater Treatment, Low Pressure Reverse Osmosis (LPRO), Distributed Modelling, Simulation, N-nitrosamine Rejection.

1. Introduction

The population growth is one of the important factors that drives the exploitation of other alternatives to ensure potable water supply around the world. In the last few decades, wastewater has become a supplementary source of high quality recycled water and a number of techniques including membrane and oxidation based processes have been explored to treat the wastewater (Farré et al., 2011). NDMA (N-nitrosodimethylamine) is one of the most highly toxic compounds in N-nitrosamine family, which has been classified as a carcinogenic compound to human (Fujioka, 2014). To minimize the risk of releasing NDMA into the recycled water, several treatment approaches has been implemented, such as adsorption on activated carbon, hydrolysis, metal complexation, ozonation (Lee et al., 2005). Particularly, ultraviolet radiation-hydrogen peroxide advanced oxidation process (UV/H₂O₂) is considered as the efficient standard treatment procedures used for N-nitrosamine removal from recycled water (Steinle-Darling et al., 2007).

The interest to use the RO process as a treatment method has increased in response to avoid the need for costly conventional methods in addition to satisfy the increasingly stringent limits of N-nitrosamine concentration. Flat sheet membranes are preferred for laboratory scale experiments to illustrate the intrinsic membrane properties with respect to permeate flux and separation efficiency. To the best of authors' knowledge, the distributed modelling of a flat sheet membrane under low pressure for the rejection of wastewater solutions has not been reported in the peer review literature. Fujioka (2014)

used the irreversible thermodynamics model (lumped version) to predict and simulate the rejection of N-nitrosamines in LPRO membranes. Al-Obaidi et al. (2016) developed a one-dimensional model based on the irreversible thermodynamics model to simulate the rejection of N-nitrosamine compounds but using a high-pressure spiral-wound RO process. In general, LPRO membranes are typically used for water reclamation applications (Fujioka., 2014). This is due to low concentration of impurities that can be found in wastewater compared to seawater. This in turn requires much lower values of operating pressure with the consideration of lower energy consumption in addition to lower cost of filtration. Most importantly, the outputs of Fujioka (2014) experiments show that N-nitrosamine rejection and recovery of low-pressure membrane (40 cm²) (small-scale RO system) and high-pressure membrane (7.9 m²) (pilot-scale of three RO modules in series) are 37-52% and 31-54% respectively. Note, in high pressure system pressure around 40-45 atm is used while in low pressure system pressure around 5-12 atm is used. In this work, the removal of a suite of three N-nitrosamines by three different LPRO membranes under different conditions is considered using a one-dimensional model based on the concepts of solution-diffusion model. The model is validated against experimental data gathered from the literature. Reliable design of membrane systems depends heavily on the understanding of the interaction of different parameters, which model based simulation can provide easily and cheaply compared to time-consuming experimental studies and therefore is the focus of this study.

2. Modelling of Spiral-wound Reverse Osmosis

A one-dimensional model includes the physical properties equations has been earlier developed for a spiral-wound RO system by Al-Obaidi et al. (2017) for the removal of chlorophenol and based on solution-diffusion model. Their work provides the basis for the development of a distributed model for a flat sheet LPRO in this work to estimate the rejection of N-nitrosamine. The new model equations are presented in Table 1.

The model equations of Al-Obaidi et al. (2017) are moderated to be compatible with the assumption of no pressure drop along the x-axis (assuming zero friction parameter). Therefore, several equations were included in the proposed new model. Eq. (9) used to calculate the mass transfer coefficient $k_{(x)}$. Eq. (10) is used to predict the viscosity parameter $\mu_{b(x)}$. The dependency of diffusivity parameter of N-nitrosamine solute on feed temperature (T_b) is approximated using Eq. (13). The diffusivity parameters at 20 °C for each N-nitrosamine are reported in Table 2. The calculation of solute concentration $C_{b(x)}$ along the feed channel is conducted using the proposed correlation of Eq. (14). Furthermore, the effect of temperature variation on both water permeability A_w and solute permeability B_s coefficients are described in Eqs. (19) and (20) respectively. Interestingly, the model developed can be used for other pollutants by providing the proper mass transfer coefficient and viscosity correlation for the given pollutant. A simulation model was developed for a flat-sheet LPRO membrane element that describe the variation of all variables with spatial dimensions using the gPROMS.

3. Experiments of Fujioka (2014)

Fujioka (2014) used a laboratory bench-scale filtration system of a flat sheet LPRO element to remove N-nitrosamines from its aqueous solutions, which consists of a rectangular stainless-steel membrane cell that holds a flat-sheet membrane of 4 cm x 10 cm of width and length respectively with a channel height of 2 mm. Three thin film composite LPRO membranes listed in Table 2 are separately packed into the membrane cell for different experiments. The experiment was carried out by introducing 250 ng/L

of each target N-nitrosamine. The feed was pumped at a constant volumetric flow rate of $3.36\text{E-}6 \text{ m}^3/\text{s}$. The temperature was kept at $20\pm 0.1 \text{ }^\circ\text{C}$. More details about the experiments can be found in Fujioka (2014). The characteristics of the membranes used are given in Table 2. The transport parameters for N-nitrosamines through these membranes and its feed concentrations and diffusivity parameters at $20 \text{ }^\circ\text{C}$ are given in Table 3.

4. Model Validation

Fig. 1 depicts the comparison of the model predictions of N-nitrosamine rejection of NDMA, NMEA and NDEA and experimental data of Fujioka (2014) for the specific LPRO membranes. The operating conditions of the experiments are as follows: inlet feed concentration of each N-nitrosamine and feed pressure of each membrane is listed in Table 3, inlet feed flow rate of $3.36E-5$ m³/s and feed temperature of 20 °C. Generally, Fig. 1 shows that the predicted values of the model are in a good agreement with experimental ones. Furthermore, LPRO membranes have poor rejection for NDMA in comparison to NMEA and NDEA. Also, it is expected that the low rejection of NDMA is largely due to its effective diffusion through these membranes.

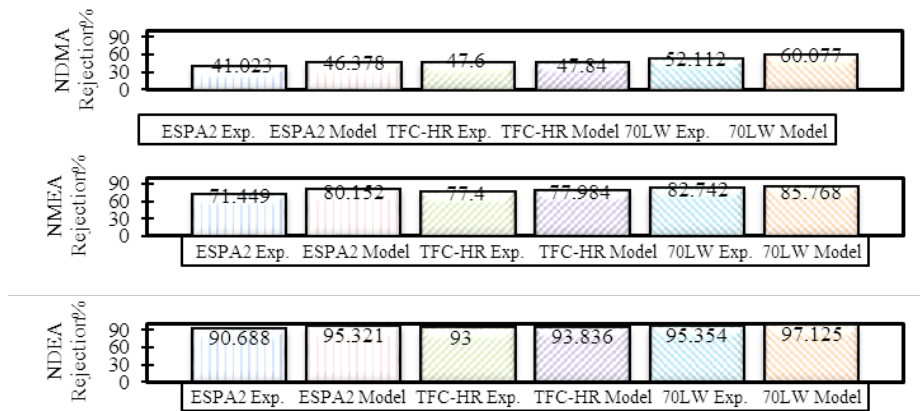

Fig. 1. The comparison of experimental results and model predictions of three types N-nitrosamine rejection by three LPRO membranes (ESPA2, TFC-HR and 70LW)

Fig. 2 shows the variation of feed concentration of NDMA and wall membrane concentration respectively at operating conditions of $3.38E-09$ kmol/m³, $3.36E-05$ m³/s 6.0237 atm and 20 °C for TFC-HR membrane. The concentrations are increased due to the permeated water passing through the membrane.

5. Effect of Operating Parameters on N-nitrosamine Rejection

5.1 Effect of Inlet Feed Concentration

The effect of inlet feed concentration variation from 250 to 1000 ng/L on steady-state rejection was tested by Fujioka (2014) at constant operating conditions of $3.36E-5$ m³/s, 6.0237 atm, 20 °C and for three representative nitrosamines, NDMA, NMEA and NDEA. Fig. 3 shows that the operating feed concentration has a negligible effect on N-nitrosamine rejection. Also, the model can give an accurate estimation of N-nitrosamine rejection at different feed concentration.

5.2 Effect of Feed Temperature

Fig. 4 shows that the operating temperature has a substantial impact on N-nitrosamine rejection, which is dropped due to an increase in feed temperature. The simulation results show that an increase in feed temperature increases N-nitrosamine permeability coefficient, which readily causes a reduction in N-nitrosamine rejection. It can be

mentioned that the model tends to only underestimate N-nitrosamine rejection at high feed temperature. Apparently, this might be attributed to an inaccurate estimation of the transport membrane parameters at such temperature.

5.3 Effect of Inlet Feed Pressure

The effect of inlet feed pressure on NDMA rejection while other variables remain constant can be distinguished through the simulation study shown in Fig. 5 where the pressure is increased from 6 to 10 atm at constant operating feed flow rate, concentration, and temperature of $3.36\text{E-}5 \text{ m}^3/\text{s}$, $3.38\text{E-}9 \text{ kmol/m}^3$ and $20 \text{ }^\circ\text{C}$ respectively for membrane type TFC-HR. It is clearly noted that the rejection parameter increases due to an increase in operating pressure since the water flux increased has diluted the permeate.

5.4 Effect of Inlet Feed Flow rate

The effect of the inlet feed flow rate on N-nitrosamine rejection is shown in the simulation results of Fig. 6 at 250 ng/L , 6.0237 atm , $20 \text{ }^\circ\text{C}$. The variation of feed flow rate from $3.36\text{E-}5$ to $9.8\text{E-}5 \text{ m}^3/\text{s}$ causes a little increase in rejection parameter, which might be attributed to decrease in wall concentration that causes an increase in water flux and decreases permeate concentration. Please note, the study of Fujioka (2014) does not include the impact of feed pressure and feed flow rate on N-nitrosamine rejection.

6. Conclusions

In this work, a one-dimensional model is developed for the low-pressure RO (LPRO) membranes considering the removal of three N-nitrosamine from wastewater. The findings of simulation results were compared to experimental one and shows a good match. The influence of operating parameters was investigated on the process performance. The study shows that inlet feed concentration and flow rate have no apparent impact on N-nitrosamine rejection in comparison to inlet feed pressure and temperature, which have clear influence. Also, the removal of N-nitrosamines is quite correlated to the type of membrane used. Thus, the membrane selection is one of the priorities to be considered in N-nitrosamine removal.

Abstract

This work focused on the simulation of an industrial system of formaldehyde absorption columns. For this purpose, a rate-based stage model of the system subjected to study was developed in *gPROMS[®] Modelbuilder 4.2.0* and the simulation results compared with the operational values. The results are mainly in accordance with the plant data. The columns temperature and composition profiles generated by the model will be validated in future work.

Keywords: Simulation, Model development, Absorption Columns, Formaldehyde.

1. Introduction

Formaldehyde is produced on a large scale due to its many applications as a raw material in industrial and end-use products. One of its main production processes consists of the methanol partial oxidation using an iron-molybdenum oxide catalyst. In this process, a mixture of air and lean methanol is vaporized and passes through a fixed bed multitubular reactor, the product gas stream is sent afterwards to a system of absorption columns with water, represented in Figure 1. The gaseous stream coming from the reactor enters the base of column T-1 and goes through two sections of random packing with two sieve trays in between, followed by a second column T-2 with bubble-cap trays that include internal coils in contact with the liquid. Process water is added at the top of T-2. In the first column, the formaldehyde aqueous solution (formalin) is collected with a concentration of around 55% and in the second column with a concentration of 35%.

The aim of this work was to develop a model that described the behaviour of the above-presented absorption system. The model will be used together with a previously developed model of an industrial reactor for formaldehyde production by Braz et al. (2017) to simulate the entire formaldehyde production unit. The final process model will allow a better understanding of the system as a whole and find the optimal operating conditions that reduce waste and increase the production profitability.

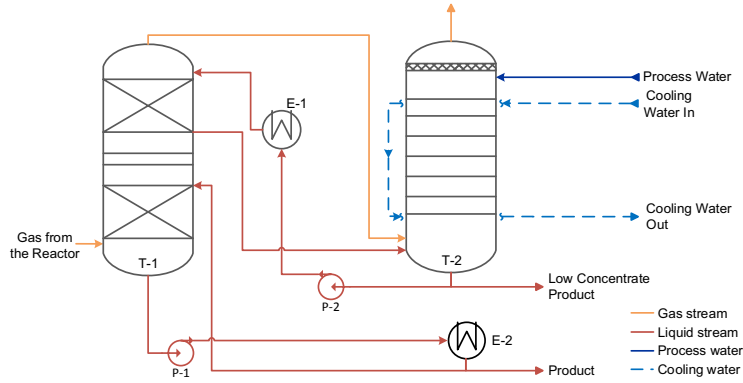

Figure 1 – Scheme of the industrial absorption system.

The design and optimization of formaldehyde absorbers is highly complex, mainly due to the reactions occurring in the liquid phase and the exothermicity of the process. According to Hasse & Maurer (1991), formaldehyde reacts with water to form methylene glycol by reaction (1).

With kinetics:

$$r_1 = k_1 \left(C_F C_W - C_{WF_1} / K_1 \right) \quad (2)$$

$$K_1 = \left(\frac{C_{WF_1}}{C_F C_W} \right)_{eq} \quad (3)$$

Methylene glycol then polymerases to poly(oxymethylene) glycols by a series of reversible reactions, according to equation (4).

$$r_n = k_n \left(C_{FW_1} C_{FW_{n-1}} - C_{WF_n} C_W / K_n \right) \quad (5)$$

$$K_n = \left(\frac{C_{WF_n} C_W}{C_{WF_1} C_{WF_{n-1}}} \right)_{eq} \quad (6)$$

The good apparent solubility of formaldehyde in water is, in fact, the good solubility of methylene glycol, and the capacity of the solution to accommodate poly(oxymethylene) glycols. Like most gases, formaldehyde itself is only mildly soluble in water.

2. Model development

The rate-based stage model was chosen as the method to model the absorption columns. According to Kenig & Seferlis (2009), this approach is a more consistent modelling method when considering reaction and transport kinetics. The mass and energy balances for each phase were written separately for a stage, which represents either a tray or a

packed segment of a column unit. The differential equations were then numerically integrated for the total packed height. The mass transfer at the interface is described using the two-film model, Figure 2.

Figure 2 – Two_film model for the stage description.

The model major assumptions are: (1) The absorption system operates in steady-state; (2) A plug-flow regime is considered for both liquid and gas phase, i.e. there is no axial dispersion for mass and heat transfer; (3) The absorption column operates adiabatically; (4) The packing is fully wetted, i.e. the interfacial area is the same for mass and heat transfer; (5) There is only gas to liquid mass transfer of water and formaldehyde; (6) The liquid in the distributor above the bottom packing of column T-1 and at the bottom of both columns is ideally mixed and the heat and mass transfer between liquid and gas is negligible.

2.1. Differential balances in the gas and liquid phases

Considering the above assumptions, the mass balances for the components in the gas and liquid phases are defined by equations (7) and (8), respectively.

$$0 = -\frac{d}{dz}(y_i G) - N_{i,g} a^I A_c \quad \sum_i y_i = 1 \quad (7)$$

$$0 = \frac{d}{dz}(x_i L) + \left[N_{i,l} a^I + \phi_l \sum_{j=1}^{n_{\max}} \nu_{i,j} r_j \right] A_c \quad \sum_i x_i = 1 \quad (8)$$

Where, n_{\max} represents the largest polymer considered. The energy balances for the gas and liquid phases are:

$$0 = -\sum (y_i G C_{p,i,g}) \frac{dT_g}{dz} - q_g a^I A_c \quad (9)$$

$$0 = \sum (x_i L C_{p,i,l}) \frac{dT_l}{dz} + \left[q_{i,l} a^I + \phi_l \sum_{j=1}^{n_{\max}} r_j (-\Delta H_{R,j}) \right] A_c + Q_{\text{loss}} \quad (10)$$

In the case of column T-1 $Q_{\text{loss}} = 0$. For trays, the differential terms of equations (7) to (10) become finite differences and the balances are converted to ordinary differential equations. The correlations to calculate the holdup of the liquid, ϕ_l , were taken from Billet & Schultes (1993) for the packed sections and from Bennett et al. (1983) for the tray sections. Q_{loss} in column T-2 was taken from a previous master thesis by Branco (2014).

2.2. Equations for the film region

In the film region, the mass transport is normal to the interface and simultaneous with the reactions. The differential components balance is given by equation (11).

$$D_{i,l} \frac{d^2 C_i}{dx^2} = - \sum_j \nu_{i,j} r_j \quad (11)$$

$$x = 0 : C_i = C_{i,l}$$

$$x = \delta_l : N_{ix} = 0 \Rightarrow \frac{dC_i}{dz} = 0$$

2.3. Physical and chemical parameters

The mass transfer coefficients, $k_{i,g}$ and $k_{i,l}$, and the specific gas-liquid interfacial area, a^l , were calculated from the correlation taken from Onda et al. (1968) for packed columns and from AIChE (1958) for tray columns. The reaction rate and equilibrium constant for the hydration reaction (2) were taken from Winkelman (2003) and for the polymerization reaction (4), were taken from Hahnenstein et al. (1994) and Hahnenstein et al. (1995).

2.4. Vapour-liquid equilibria

The thermodynamic equilibrium at the gas-liquid interface was calculated by equation (12). Values for $\gamma_j P_i^s$ were taken from Winkelman (2003).

$$y_i P = \gamma_j P_i^s x_i, \quad i = F, W \quad (12)$$

2.5. Percentage of formaldehyde in the liquid

Since free formaldehyde is present in the liquid in traces quantities, the percentage of formaldehyde that is absorbed by the liquid is calculated by equation (13), considering an overall fraction of formaldehyde, \tilde{x}_F , that includes the formaldehyde converted in the formation of the methylene glycol and its polymerization, using equation (14).

$$W_F = \frac{\tilde{x}_F M_F}{\tilde{x}_F M_F + (1 - \tilde{x}_F) M_W} \quad (13)$$

$$\tilde{x}_F = \frac{x_F + \sum_{i=1}^{n_{\max}} i x_{WF_i}}{1 + \sum_{i=1}^{n_{\max}} i x_{WF_i}} \quad (14)$$

3. Results and discussion

The absorption system presented in Figure 1 was simulated using data supplied by the licensor of an industrial unit for formaldehyde production as input values of the model. The temperature and the formaldehyde mass percentage profiles are presented in Figure

3. Although these profiles were not yet compared with the real plant data, the simulation results are in agreement with what would be expected.

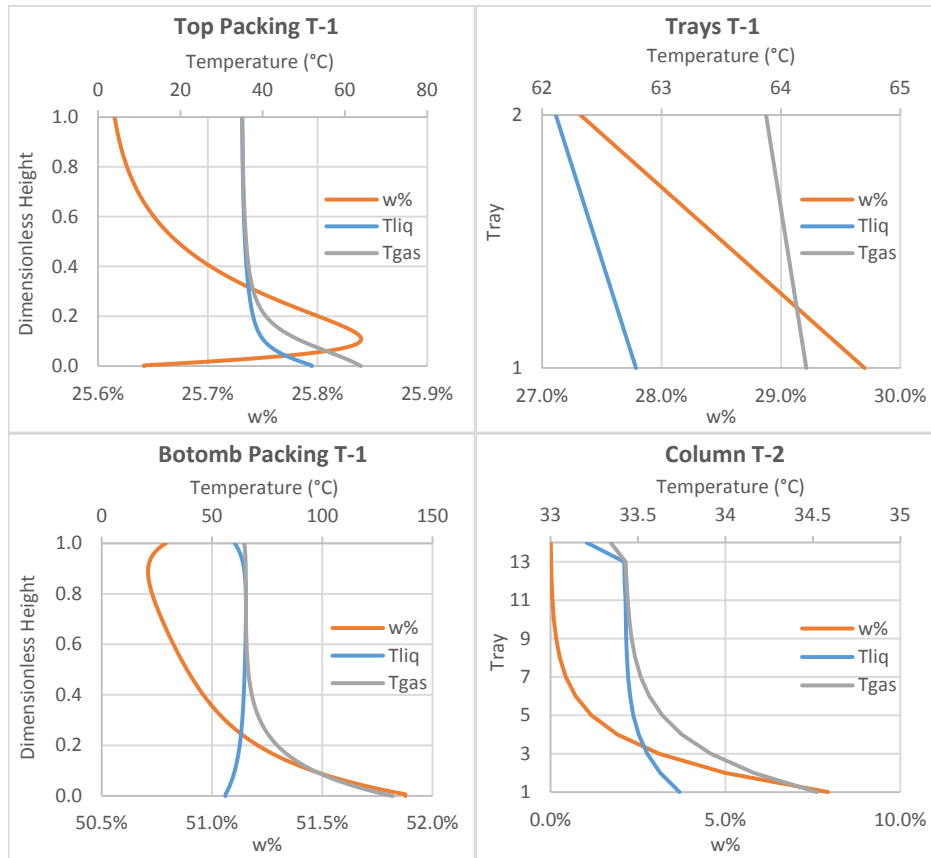

Figure 3 - Temperature and formaldehyde mass composition profiles of the absorption system.

Table 1 compares the simulation results with the typical values from the industrial unit and presents the absolute relative deviation between them, calculated by equation (15). Note that the T_{liq} from the bottom of column T-2 is not the temperature of the liquid after the first tray, but the temperature after mixing with the liquid coming from the top packing of column T-1. The simulation results are in general within the typical ranges of the plant operation values, presenting absolute relative deviations below 6.5%.

$$\varepsilon_{rel} = \frac{|x_{operational} - x_{simulation}|}{x_{operational}} \times 100 \quad (15)$$

Table 1 – Simulation results compared with the typical operational values.

	Typical operational values	Simulation	ε_{rel} (%)
W% bottom of T-1	50-58	51.9	5.8
T_{liq} bottom of T-2 (°C)	52-56	51.9	3.9
T_{gas} top of T-2 (°C)	22-38	33.2	6.4
% of Recovered HCHO	98-100	100	1

4. Conclusions

In this work, a first model of a formaldehyde absorption system was developed in *gPROMS*[®] and the simulation results were compared with typical operational data. The simulation results are in agreement with the operational data with absolute relative deviations below 6.5%. The compositions and temperature profiles of the absorption columns obtained by the model will be posteriorly validated using results from the industrial unit.

In future work, the authors intend to include the absorption and reaction of methanol in water and use the final model in the simulation and optimization of the complete formaldehyde production unit.

Abstract

Industrial processes employing homogeneous catalysis face the difficulty of an economic recovery of the catalyst. In order to be able to design an optimal process route, a comprehensive understanding of the separation process is essential. In this work, the gravity-driven separation of a multi-phase system composed of water, 1-dodecene, and a non-ionic surfactant, is investigated. Within the employed ranges of temperature and phase composition, this system exists in a three-phase configuration, consisting of an aqueous, an organic, and a surfactant-rich middle phase. Following the reaction step, a complete separation of the aqueous phase, in which the expensive rhodium catalyst is dissolved, is essential. Extensive experiments have been carried out to determine the drop size distribution (DSD) of the disperse phases using an endoscopic measurement technique. Based on these experimental data, a Computational Fluid Dynamics (CFD) model employing the Euler-Euler multi-fluid framework coupled with the Extended Quadrature Method of Moments (EQMOM) for the solution of the population balance equations (PBEs) for each disperse phase is implemented using OpenFOAM. Within the framework of this CFD-PBE model, a buoyancy-induced coalescence model, which has been previously shown to accurately predict the degree of separation, has been employed. This multi-fluid CFD-PBE model has been used for simulating the separation of the three-phase system in a double-wall glass tank. The time-evolution of observed phase heights is used to fit the model parameters of the coalescence kernel. Subsequently, this numerical model has been used for simulating the gravity-driven separation in a horizontal settler equipped with a coalescer. The predictions of this numerical model are in good agreement with the experimentally observed values.

Keywords: gravity separation, population balance, method of moments, coalescer, multi-fluid

1. Introduction

Hydroformylation is an important industrial process for the conversion of long-chain alkenes to aldehydes. In this process, homogeneous catalysis is often employed due to its better performance and higher selectivity (Fang et al., 2011). However, this process path is also accompanied by

the problem of catalyst leaching which can make the process economically impracticable (Müller et al., 2015). The choice of recovery methods is also of essence since severe process conditions may be detrimental to the catalyst efficiency as well as to the environment (Peddie et al., 2017). A gravity-driven separation process is often employed in such cases owing to its simplicity and low cost of operation (Panda et al., 2017). In this light, an understanding of the separation process in general, and coalescence in particular, is critical to design an optimal process route. In recent years, there have been multiple investigations of drop coalescence in separating liquid-liquid systems (Frising et al., 2006; Liao and Lucas, 2010; Kamp and Kraume, 2016). Noik et al. (2013) reported the combined coalescence and sedimentation characteristics of a water-in-oil emulsion under the effect of gravity. In addition, a one-parameter model based on batch-settling data was also proposed for the process. However, the model assumes a mono-size droplet distribution as an initial condition. More recently, Mazumdar et al. (2017) investigated the effects of phase composition and surfactant concentration on the gravity-driven separation kinetics of oil-water emulsions. They reported the time-evolution of drop-size distributions in different layers of the emulsion and concluded that the concentration of surfactant in the system greatly influenced the coalescence mechanism. Panda et al. (2017) studied three-phase flow in a continuously-operated gravity settler with the help of Computational Fluid Dynamics. They reported a reduction in the thickness of the dispersion layer with increasing droplet diameter. However, their model only considered a constant droplet diameter for each dispersed phase.

The use of CFD coupled with the population balance equation (PBE) is an effective method in the solution of dispersed multiphase flows (Favero et al., 2015). Of the multiple available solution algorithms for PBE, the method of moments is perhaps the most frequently utilized one. Such moment-based methods convert the PBE to a set of transport equations of integral moments of the associated number density function. Thus, transport equations for just the moments are solved rather than for the full distribution. However, an additional closure condition is required in most practical cases for which a quadrature method of moments (QMOM) is often employed (McGraw, 1997; Marchisio et al., 2003). A number of quadrature-based moment methods (QBMMs) have been proposed in recent literature, for example Sectional Quadrature Method of Moments, SQ-MOM (Attarakih et al., 2009) and Extended Quadrature Method of Moments, EQMOM (Yuan et al., 2012). In particular, EQMOM is a notable method as it improves upon traditional QMOM by utilizing a continuous function instead of a Dirac delta function in the quadrature approximation which results in greater robustness as well as computational efficiency (Pigou et al., 2017).

In the present work, the separation process of a non-ionic surfactant containing water-oil emulsion is investigated through a coupled CFD-PBE Eulerian multi-fluid approach. Within the employed ranges of temperature and surfactant concentration, this mixture exists as a three-phase system consisting of an organic, an aqueous and a surfactant-rich (bicontinuous) middle layer (Hohl et al., 2016). This specific configuration is of particular interest as the presence of a distinct bicontinuous phase allows for better separation, as well as faster separation times. The open source CFD toolbox OpenFOAM 4.1 (Weller et al., 1998) has been used to simulate flow behavior in addition to an EQMOM-based PBE solution for each Eulerian dispersed phase (OpenQBMM, 2016). A buoyancy-driven coalescence model based on the one proposed by Prince and Blanch (1990) has been used to model droplet-droplet interactions. The results obtained using this approach seem promising and a good agreement with experimental data can be achieved, as discussed later. This multi-fluid framework makes it possible to simulate multiphase flows with independently-evolving drop-size distributions. The ultimate intention of the present work is to enhance our knowledge of gravity-driven separation processes in emulsion systems.

2. Multiphase model

The employed multiphase model is based on the solution of averaged mass and momentum transport equations for, both, continuous (organic) as well as dispersed (bicontinuous, aqueous) Eu-

lerian phases as shown in Eqs. (1) and (2), respectively. This means that each phase i , having a density ρ_i , viscosity μ_i and volume fraction α_i , has its own unique velocity \vec{u}_i . As opposed to the Euler-Lagrangian approach, the Euler-Euler multi-fluid method has the advantage of lower computational cost. The efficiency is especially noticeable for simulations with higher dispersed phase fraction. At the same time, however, a choice of appropriate closure terms is critical. In the present study, the effects of drag, surface tension and porous medium are included in the momentum equation as additional terms $\vec{F}_{D,i}$, $\vec{F}_{S,i}$ and $\vec{F}_{P,i}$, respectively. Surface tension is assumed to be constant and drag forces on the dispersed phase are calculated based on the model of Schiller and Naumann. A more detailed description of the model parameters can be found in our previous work (Misra et al., 2017).

$$\frac{\partial}{\partial t}(\alpha_i) + \vec{u}_i \cdot \nabla \alpha_i = 0, \quad i = 1 \dots N_{phase} \quad (1)$$

$$\frac{\partial}{\partial t}(\rho_i \alpha_i \vec{u}_i) + (\rho_i \alpha_i \vec{u}_i \cdot \nabla) \vec{u}_i = -\alpha_i \nabla p + \nabla \cdot (\mu_i \alpha_i \nabla \vec{u}_i) + \rho_i \alpha_i \vec{g} + \vec{F}_{D,i} + \vec{F}_{S,i} + \vec{F}_{P,i} \quad (2)$$

An additional set of moment transport equations given by Eq. (3) for each dispersed phase are also solved. EQMOM is used in order to close the source term \vec{S}_i^k on the right hand side of the equation. As Marchisio et al. (2003) have noted, the use of two quadrature nodes to describe the time evolution of the drop-size distribution is usually sufficient. Thus, transport equations for the first k integral moments of the distribution m^k have been solved in the present case. The initial values of the moments have been obtained from experimental data of Hohl et al. (2016). Moreover, a buoyancy-driven coalescence kernel $\beta(d, d')$ as given by Eq. (4) has been used to describe droplet-droplet interactions in each dispersed phase (Prince and Blanch, 1990; Misra et al., 2017). This approach models binary coalescence of droplets with diameters d and d' approaching each other with a relative velocity u_{rel} . The relative velocity of approach can be obtained based on the Sauter mean diameter and the velocity of the dispersed phase. The term u_{crit} is the only model parameter and can be determined from batch experiments (Noïk et al., 2013).

$$\frac{\partial}{\partial t}(m_i^k) + \nabla \cdot (m_i^k \vec{u}_i) = \vec{S}_i^k, \quad i = 2 \dots N_{phase}; k = 0 \dots 2N_{node} \quad (3)$$

$$\beta(d, d') = \left[\frac{\pi}{4} (d + d')^2 u_{rel} \right] \exp \left[\frac{-u_{rel}}{u_{crit}} \right] \quad (4)$$

2.1. Implementation in OpenFOAM

The OpenFOAM solver *multiphaseEulerFoam* (Wardle and Weller, 2013) already provides a multi-fluid Eulerian framework. Moreover, the OpenQBMM library (OpenQBMM, 2016; Passalacqua et al., 2018) implements solution of moment transport equations for OpenFOAM using QMOM as well as EQMOM closures. However, to the best knowledge of the authors, a coupled implementation of the two methods in a multiphase system has not yet been released. In order to implement the aforementioned model, the class *phaseModel* in *multiphaseEulerFoam* was modified to include a member function of the type *populationBalanceModel*. This ensures that the OpenQBMM library utilizes the phase velocity for transport of quadrature nodes using the buoyancy-driven coalescence kernel as defined by Eq. (4). Coupling between the two algorithms is achieved by adding a new member function to the *diameterModel* class which evaluates the Sauter mean diameter of the dispersed phase as a ratio of the third and second moments of the distribution. In order to ensure a physical solution, user-defined upper and lower limits have been set on the calculated diameter values. Finally, a source term is appended to the file *UEqns.H* through the *fvOptions* framework which enables a run-time selection of sources or constraints on the momentum transport equations. In this manner, the effect of porous media on flow based on the Darcy-Forchheimer relation has been included in the solver. The mesh non-orthogonality has a significant influence on the

Figure 1: History of phase separation in time, starting from homogeneous conditions. Experimentally-measured phase boundaries (black lines) and computed volume fraction of the bicontinuous phase (color plot).

quality of the solution, regardless of the number of grid points in the mesh. Further, the choice of the time step size is also critical as the moment transport equations impose an additional stability restriction.

3. Results

3.1. Calibration of the buoyancy-driven coalescence kernel

Preliminary experiments to calibrate the model parameter u_{crit} were carried out in a double walled glass tank (DN 150, $H/D = 1$). Starting with a completely mixed system ($t = 0$), the initial drop-size distribution as well as the change in phase heights with time was recorded. A two-dimensional CFD-PBE simulation for the same configuration was performed, and a best-fit value of the parameter u_{crit} has been determined by repeating the simulations for different values of u_{crit} . The range of values considered for u_{crit} has been based on similar approaches reported in literature. In this manner, a good fit of the predicted separation profile with experimental data could be obtained with $u_{crit} = 10^{-5}$ m/s. While it is possible to fit u_{crit} for each phase independently, a single value for both dispersed phases has been set. Since the coalescence kernel only accounts for phase properties in an indirect manner (Misra et al., 2017) and the rheological properties of the bicontinuous and aqueous phases are similar, this is a reasonable assumption to make. Fig. 1 shows a comparison of the predicted phase separation profile of the bicontinuous phase (color) using 3 different u_{crit} values with experimentally observed phase boundaries (black lines). It is noteworthy that a ten-fold change in u_{crit} results only in a relatively small change in the predicted phase separation profile of the organic phase. At the same time, an influence on the separation characteristics of the dispersed phases is evident. However, a hundred-fold increase in u_{crit} leads to a noticeable change in the predicted separation time of the the organic phase as well.

3.2. Simulation of separation in a horizontal settler

Following the determination of u_{crit} , the solver is used to simulate separation in a continuously-operated settler. The real settler is modular and has one inlet for the reaction mixture, and three outlets for the separated products as depicted in Fig. 2. The initial condition is a completely mixed system with a fixed inlet flow rate and a Neumann boundary condition at the outlets. In a previous work, a simplification of the settler with only two outlets was investigated (Misra et al., 2017) and is, therefore, also presented here for a comparison. In the following discussion, the terms "top" and "bottom" outlets refer to the common outlets in both settler geometries. Figures 2a and 2b show the volume fractions of the bicontinuous phase in the settler at $t = 4$ s and $t = 7$ s, respectively. Unlike the top and bottom outlets, the third outlet begins in the center of the settler.

Figure 2: Volume fraction of the bicontinuous phase at different times in two different settler geometries as predicted by the buoyancy-driven coalescence kernel (color plot).

As is evident from the figure, the inclusion of a third outlet pipe in the settler geometry changes the separation profile inside the settler. This is expected as the pipe acts as an internal baffle. However, Figure 3 enunciates that this observed difference inside the settler does not affect the predicted volume fractions of the aqueous and bicontinuous phases at the bottom outlet. Moreover, the predictions of the model in both the cases are quite close to the experimentally observed values.

Although the employed coalescence kernel only approximates the several competing physical phenomena affecting droplet coalescence with the aid of a single lumped parameter, it is still able to predict the separation remarkably well. However, as can be observed in Figure 3, the model tends to slightly overestimate the degree of separation. But this is an acceptable drawback of using a single-parameter coalescence kernel. Since the presence present coalescence kernel does not account for the effects of surfactant concentration and temperature on separation, its direct application to a wide range of operating conditions is limited. An extension of the present model based on further experiments is planned for future work.

4. Conclusions

In this contribution, a multi-fluid CFD-PBE framework has been implemented in OpenFOAM to describe the gravity-driven separation process in a three-phase system. A buoyancy-driven coalescence kernel is used to describe droplet-droplet interactions in each dispersed phase. The effect of surfactant on coalescence has been incorporated in the lumped model parameter u_{crit} . This parameter is set to 10^{-5} m/s for both dispersed phases, based on the best-fit of preliminary investigations of batch separation experiments in a cell. Subsequently, this numerical model is used to simulate three-phase flow in a continuously operated horizontal settler. The predictions obtained from the model are in good agreement with the experimental observations. While the

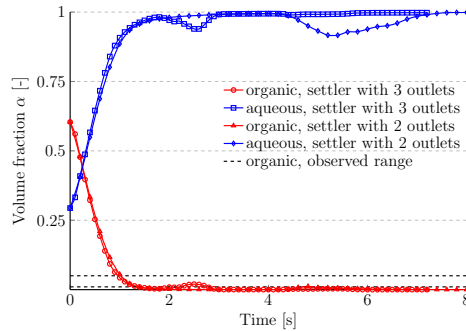

Figure 3: Time-evolution of volume fractions of organic and aqueous phases at the bottom outlet of the settler. The two horizontal dashed lines represent the upper and lower bounds of the organic phase volume fraction observed experimentally during the measurement campaign and are not associated with the time axis (color plot).

proposed framework is flexible, the choice of coalescence kernel still plays a critical role. In the present work, the employed one-parameter coalescence kernel has the advantage of reducing the model complexity. At the same time, it also prevents the model from being applicable to a wider range of operating conditions. A generally-valid coalescence model should take into account the effects of local surfactant concentration and temperature. Thus, further work on coalescence modeling is essential to explicitly incorporate the effects of phase properties as well as process conditions.

Comparative Life Cycle Assessment of Ethylene from Wet Shale Gas and Biomass

Minbo Yang, Xueyu Tian, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

This paper presents comparative techno-economic and environmental analyses of three ethylene manufacturing pathways based on wet shale gas, corn stover, and corn grain. A distributed-centralized processing network that consists of distributed ethane/bioethanol production and centralized ethylene manufacturing is employed for each of the three pathways. Based on the detailed mass and energy balances and life cycle inventory results, we conduct techno-economic and life cycle analyses to systematically compare the economic and environmental performances of the three pathways. The results indicate that the shale gas-based pathway is the most attractive due to the lowest breakeven ethylene prices; however, it leads to the highest greenhouse gas emissions. On the contrary, the corn stover-based pathway results in the lowest greenhouse gas emissions but the highest breakeven ethylene prices.

Keywords: shale gas, corn stover, corn grain, breakeven price, greenhouse gas emissions.

1. Introduction

Ethylene is the most important building block for the chemical industry (Zimmermann and Walzl, 2009). In recent decades, advancements of hydraulic fracturing and horizontal drilling have resulted in a boom of the U.S. shale gas production (Gao and You, 2017), which provides a tremendous increase in the yield of ethane for ethylene production (DeRosa and Allen, 2015). Taking into account the non-renewability of fossil fuel-based feedstocks for ethylene production, dehydration of bioethanol derived from renewable biomass demonstrates significant potential for ethylene production (Zhang and Yu, 2013). In the U.S., corn grain serves as the leading feedstock for bioethanol production. Besides, producing bioethanol from cellulosic biomass, such as corn stover, is of increasing interest, as corn stover not only is an abundant agricultural residue but also can avoid controversies over food versus energy (Ou et al., 2014). Based on the aforementioned feedstocks, manufacturing ethylene may result in different economic performances and environmental impacts (He and You, 2015). For judicious selection of feedstocks for ethylene production, it is necessary to systematically compare ethylene manufacturing from these feedstocks under the same conditions from economic and environmental perspectives.

In this work, we perform comparative techno-economic and environmental life cycle analyses for three ethylene production pathways. We consider a distributed-centralized processing network that combines distributed ethane/bioethanol production with centralized ethylene manufacturing for the three pathways. High-fidelity process simulation models are developed for processing steps including shale gas processing,

ethane steam cracking to ethylene, and bioethanol dehydration to ethylene. The three ethylene production pathways are modeled considering five different ethylene production scales. Next, we conduct techno-economic and environmental life cycle analyses for the three ethylene production pathways. The economic performances of the three ethylene production pathways are compared in terms of breakeven ethylene prices. The life cycle environmental impacts of ethylene manufactured via the three pathways are compared in terms of GHG emissions, which are of special interest in both academia and industry.

2. Distributed-centralized ethylene manufacturing

Figure 1 and Figure 2(a) and (b) illustrate the block flow diagram for ethylene production based on wet shale gas, corn stover and corn grain, respectively.

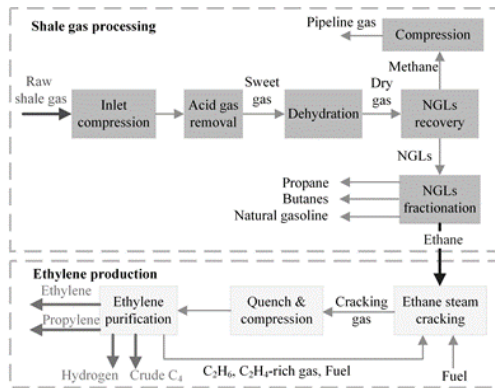

Figure 1. Block flow diagram for manufacturing ethylene from wet shale gas

2.1. Shale gas-based ethylene production

In the shale gas processing step, raw shale gas is first pressurized to satisfy the downstream operating conditions and maximize the recovery of natural gas liquids (NGLs) (Kidnay et al., 2011). The pressurized shale gas is then introduced into an acid gas removal unit to remove acid components. In the following dehydration unit, the water content in shale gas is reduced to prevent hydrate formation. Next, the obtained dry gas is sent to a cryogenic separation unit to recover NGLs (Gong et al. 2017). The resulting methane-rich gas is compressed and sent out as pipeline gas. The recovered mixture of NGLs is fractionated into ethane, propane, butanes, and natural gasoline in an NGLs fractionation unit (He and You, 2014). In the ethylene production step, ethane derived from shale gas is cracked in cracking furnaces first. The cracking gas from furnaces is then quenched and pressurized. Finally, in an ethylene purification unit, the cracking gas is separated into ethylene, ethane, and other byproducts (Yang and You, 2017).

2.2. Corn stover-based ethylene production

This process consists of two processing steps: bioethanol production from corn stover and ethylene production from bioethanol. In the bioethanol production step, corn stover is first delivered to a feed handling unit consisting of weighing and uploading stations, queuing storage, and conveyors. In the following pretreatment and conditioning unit, corn stover is pretreated with dilute sulfuric acid to liberate hemicellulose sugars and

break down biomass, and ammonia is then added to the pretreated slurry to adjust its acidity to be suitable for enzymatic hydrolysis. Next, the resulting hydrolysate is sent to an enzymatic hydrolysis and fermentation unit, where a cellulase enzyme is used for enzymatic hydrolysis. The hydrolyzed slurry is then fermented to convert cellulose and xylose into bioethanol. The required cellulase enzyme is produced on-site in an enzyme production unit using glucose as the primary carbon source. In a production recovery section, the resulting beer is separated into bioethanol, water, and residual solids via distillation and solid-liquid separation. Wastewater streams generated during bioethanol production are gathered and treated by anaerobic and aerobic digestion in a wastewater treatment unit. Solids and biogas from product recovery unit and wastewater treatment unit are combusted to produce HP steam, which is used to generate electricity and satisfy the process heat demand. Detailed process flowsheets for the production of bioethanol from corn stover are available in the literature (Humbird et al., 2011). In the ethylene production step, bioethanol derived from corn stover is first dehydrated into ethylene, water, and other byproducts. Next, the dehydration reactor effluent is quenched and pressurized. Finally, the effluent is sent to an ethylene purification unit, where it is separated into ethylene, water, and others.

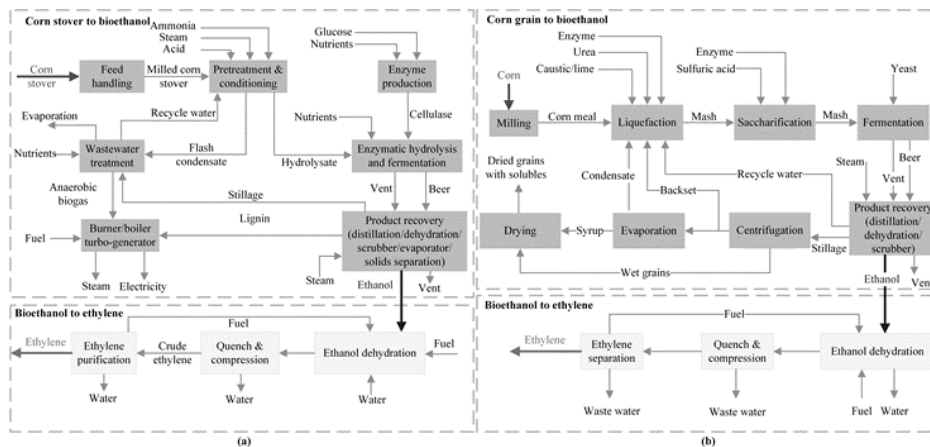

Figure 2. Block flow diagram for manufacturing ethylene from biomass

2.3. Corn grain-based ethylene production

In the bioethanol production step, corn is first conveyed to grain-cleaning equipment and then milled to fine meal by hammer mills. Next, the corn meal is sent to a liquefaction unit, where it is mixed with water and alpha-amylase. Also, caustic and lime are added to provide suitable acidity and calcium for the alpha-amylase, and urea is consumed to supply nitrogen for the downstream yeast fermentation. Maltose and higher oligomers are produced from corn starch using the alpha-amylase enzyme in the liquefaction unit. The resulting mash is introduced into a saccharification unit and mixed with gluco-amylase and sulfuric acid to create sugars. After saccharification, the mash is cooled and then fed to four continuous cascade fermenters with yeast added. Bioethanol and carbon dioxide are produced during the yeast fermentation. In a product recovery unit, bioethanol is obtained from the whole beer by distillation, scrub, and dehydration. The conserved stillage is partially evaporated and then fed to a centrifugation unit. A part of the thin stillage from the centrifugation unit is recycled as backset to the liquefaction unit, and the rest is concentrated to syrup in the following

evaporation unit. Finally, the wet grains from the centrifugation unit and the syrup from the evaporation unit are dried and sent out as distiller's dried grains with solubles (DDGS). Detailed information for the production of bioethanol from corn grain can be found in the literature (Wallace et al., 2005). The ethylene production step in the corn grain-based pathway is the same as that in the corn stover-based pathway described in the previous subsection.

2.4. Distributed-centralized processing network for ethylene production

We consider the distributed-centralized processing network as in He and You (2016) for shale gas and in You and Wang (2011) for biomass processing, we assume that ethane is first produced at several distributed shale gas processing plants and transported to a centralized ethane cracking plant by trucks. In the typical shale gas production process, multiple shale gas wells are drilled at a well pad. Raw shale gas extracted from shale gas wells is gathered at a well pad and transported to a nearby gas processing plant by pipelines. The distributed-centralized processing network is also employed for manufacturing ethylene from corn stover and corn grain. Bioethanol is first produced at several distributed ethanol plants, and then transported to a centralized ethylene plant by trucks. The average transportation distances for the upstream feedstocks are calculated based on the distributed-centralized processing network. The average transportation distances for the downstream feedstocks are assumed to be 100 km.

3. Techno-economic and life cycle analyses results

For systematic comparisons, we consider five different ethylene production scales for each pathway, namely, 1,000 kt/y, 800 kt/y, 600 kt/y, 400 kt/y, and 200 kt/y, according to commercial capacities of ethylene plants. In terms of the distributed ethane/bioethanol production, on each ethylene production scale, three cases are analyzed considering different numbers of distributed shale gas processing/bioethanol plants, i.e. 5, 10, and 15. Therefore, 45 ethylene production cases are investigated in this work.

3.1. Economic analysis

The breakeven prices of ethylene manufactured via the shale gas-based pathway, corn stover-based pathway, and corn grain-based pathway are evaluated and compared in Figure 3. For each of the three ethylene production pathways, the breakeven ethylene price increases as the ethylene production scale decreases and the number of distributed shale gas processing/bioethanol plants increases. On each ethylene production scale, the shale gas-based pathway results in the lowest breakeven ethylene prices. The breakeven prices of ethylene produced via the corn grain-based pathway are notably higher than that of ethylene produced via the shale gas-based pathway by 21%~284%. The corn stover-based pathway leads to the highest breakeven ethylene prices, which are 2.4~6.3 times of the breakeven prices of ethylene produced via the shale gas-based pathway. Also, we find that the breakeven ethylene prices of ethylene manufactured via both the corn stover-based pathway and the corn grain-based pathway are higher than the market ethylene price. This means that the corn stover-based pathway and the corn grain-based pathway have no economic advantage for ethylene production currently. On large ethylene production scales, the shale gas-based pathway could result in lower breakeven ethylene prices than the market ethylene price. Such results indicate that manufacturing ethylene from ethane-rich shale gas on large scales is cost-effective. In summary, the shale gas-based pathway is more competitive than from both the corn stover-based pathway and the corn grain-based pathway regarding the breakeven ethylene prices.

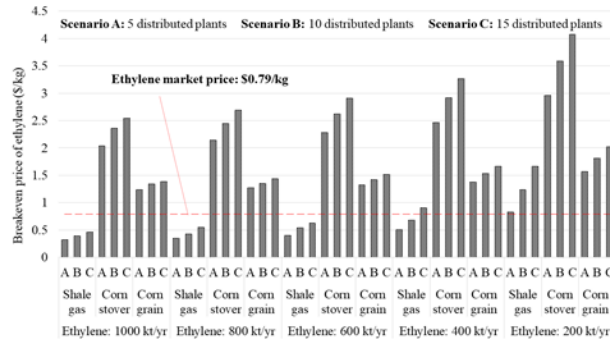

Figure 3. Breakeven prices of ethylene manufactured from ethane-rich shale gas, corn stover, and corn grain.

3.2. Environmental analysis

The environmental impacts of manufacturing ethylene from ethane-rich shale gas, corn stover, and corn grain are systematically analyzed following the LCA approach. The objective of this LCA study is to evaluate and compare the life cycle environmental impacts of ethylene manufactured via the shale gas-based pathway, corn stover-based pathway, and corn grain-based pathway. The functional unit of this LCA study is defined as 1 kg of ethylene manufactured at the plant gate. The impact category to assess the life cycle environmental performance of manufacturing ethylene via the three pathways is dedicated to GHG emissions. The environmental burdens are allocated using the economic value-based allocation method.

Regarding each of the three pathways, differences among the net GHG emissions of ethylene produced on different scales are insignificant, as illustrated in Figure 4. This is because the GHG emissions contributed by feedstock transportation are negligible compared with the total GHG emissions across the product life cycle. The net GHG emissions of ethylene produced via the shale gas-based pathway are positive. In comparison, the corn stover-based pathway and the corn grain-based pathway could result in negative net GHG emissions of ethylene, due to the sequestration of renewable carbon. Such results indicate that the corn stover-based pathway and the corn grain-based pathway are more advantageous over the shale gas-based pathway for ethylene production in terms of the net GHG emissions.

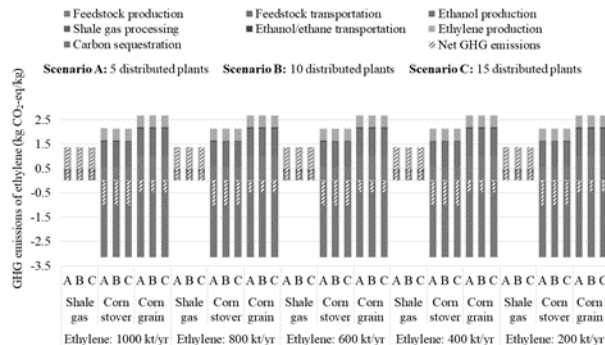

Figure 4. Life cycle greenhouse gas emissions of ethylene manufactured from shale gas, corn stover, and corn grain.

4. Conclusions

We conducted techno-economic and life cycle analyses for distributed-centralized ethylene production based on three feedstocks on five different scales. The shale gas-based pathway showed the best economic performance, but led to the highest net GHG emissions of ethylene. In comparison, the corn stover-based pathway was more competitive than the other two pathways in terms of the net GHG emissions of ethylene, although it resulted in the highest breakeven ethylene prices. The corn grain-based pathway was pinched between the other two pathways regarding both the breakeven ethylene prices and the net GHG emissions of ethylene.

Abstract

The quality of process optimization depends on model parameters. The use of operating data from mini-, pilot or production plants can help to improve model agreement with operation. To support the design of experiments (DoE) in plants with many operability limitations a model-based DoE was implemented into a flowsheet simulator. In this contribution, the implementation of the method is described and its use for the identification of kinetics is demonstrated for a cumene process.

Keywords: model-based design of experiments, process simulation, multi-criteria optimization.

1. Introduction

The validity of simulation and optimization results based on flowsheet simulation models depends significantly on the quality of these models and their model parameters. The estimation and validation of the parameters is based on experiments that, depending on the complexity of the process, can be cost- and time-intensive. Especially experiments in integrated mini-, pilot or production plants are very expensive. The goal of model-based design of experiments (DoE) is to determine a set of experiments that yields the highest information content, which here means the lowest uncertainty in the model parameters. Since integrated processes are usually modeled in flowsheet simulators, an integration of DoE methods in such simulators is obvious and beneficial. In this contribution, the experience gained by the integration of methods of model-based DoE into BASF's flowsheet simulator CHEMASIM for steady state processes are described. The methods are generic in the sense that in principle any other flowsheet simulator could have been used.

2. Theory: Design of experiments for parameter estimation using process simulation

Often parameter estimation is based on the minimization of a sum of weighted least-square residuals

$$\min_p \sum_{i=1}^{N_e} \sum_{j=1}^{N_m} r_j(p, x_i)^2 \quad \text{with } r_j(p, x_i) = \sqrt{w_{i,j}} \left(\frac{\tilde{y}_{i,j} - y_j(p, x_i)}{\sigma_{\tilde{y}_{i,j}}} \right) \quad (1)$$

Herein $r_j(\mathbf{p}, \mathbf{x}_i)$ denotes the residue of the j -th measured property $\tilde{y}_{i,j}$ and depends on the parameter vector \mathbf{p} (with N_p elements) and the design variable vector \mathbf{x}_i of the i -th experiment. $y_j(\mathbf{p}, \mathbf{x}_i)$ is the model prediction, $w_{i,j}$ a weighting factor and $\sigma_{\tilde{y}_{i,j}}$ the standard deviation of the measured property $\tilde{y}_{i,j}$. N_e and N_m are the number of experiments and measured properties. For unconstrained least squares problems, the Fisher information matrix (FIM) F (dimension $N_p \times N_p$) can be estimated based on an initial estimate of the parameter vector \mathbf{p} (cf. e.g. Schittkowski, 2007a)

$$F = \sum_{i=1}^{N_e} J(\mathbf{p}, \mathbf{x}_i)^T J(\mathbf{p}, \mathbf{x}_i) \quad (2)$$

with the Jacobians $J(\mathbf{p}, \mathbf{x}_i)$ (dimension $N_p \times N_m$)

$$J(\mathbf{p}, \mathbf{x}_i) = \left((\nabla_{\mathbf{p}} r_1(\mathbf{p}, \mathbf{x}_i))^T; \dots; (\nabla_{\mathbf{p}} r_{N_m}(\mathbf{p}, \mathbf{x}_i))^T \right) \quad (3)$$

Herein $\nabla_{\mathbf{p}} r$ denotes the gradient of the residual with respect to the parameters \mathbf{p} . The covariance matrix C , which is the inverse of the FIM F , shows how reliable the parameter estimates are and is also used to estimate confidence intervals of parameters. Therefore, the FIM (respectively the covariance matrix) is a good measure of the information content of designed experiments. A number of scalar functionals on the FIM F serve as quality indicators of experimental designs (cf. e.g. Franceschini and Macchietto, 2008), for example:

- A-criterion: $\text{trace}(F^{-1}) = \sum_{i=1}^{N_p} \frac{1}{\lambda_i}$
- D-criterion: $\det(F^{-1}) = \prod_{i=1}^{N_p} \frac{1}{\lambda_i}$

λ_i are the eigenvalues of the FIM. These criteria can be used as objectives to be minimized in a subsequent step to identify optimal designs.

The foundation of the implemented methods is the automated calculation of the Fisher information matrix (FIM). For this purpose, analytical first derivatives have to be available for example via algorithmic differentiation. When for optimization of the designs gradient-based optimization solvers are used, derivatives of the scalar measure of the FIM with respect to the experimental design variables \mathbf{x} are needed. Here the use of numerical derivatives is possible, but in general it is prohibitive to use numerical differentiation in both steps due to the accuracy. In this work, the DoE results are generated using integrated optimization solvers (NLPQLP, NLP-LSQ and MISQP from Schittkowski (2007b, 2009) and Exler et al. (2012)). A further requirement for the implementation of DoE and parameter estimation into a flowsheet simulator is the possibility to run one simulation model with different operating conditions for the experiments in a sequence and to collect data. This is necessary for the setup of the objective for the optimization either for the parameter estimation according to Eq. (1) or for the design of several experiments with the Fisher Matrix according to Eq. (2). This possibility was already realized in CHEMASIM in a previous work (Asprion et al., 2015).

This approach was developed and validated using simple analytical model functions and transferred to a cumene process as an example for a realistic industrial case study. For this process, a comparison between two strategies for the determination of kinetics are shown: The first strategy uses the negative trace of the FIM to be minimized besides the minimization of the operational expenditures (OPEX) in a multi-criteria optimization

(Bortz et al., 2014) to identify an interesting point. The negative trace of the FIM (also called A*-criterion, see Schittkowski 2007a) is used as measure of information content, since the FIM for only one design is (in most cases for $N_p > 1$) singular. Around this point a statistical design is used. The other strategy is to solely optimize a scalar measure of the Fisher information matrix (A-criterion) to estimate the designs. For both strategies, operational limitations like for example loading ranges are taken into account as constraints of the optimization.

3. Application: Design of Experiments for a Cumene process

For an application test an available simulation model for a cumene process (Asprion et al., 2017) has been used. As shown in Fig.1 the process model includes a tubular reactor which is modeled with ten segments with an initial kinetic model for the formation of cumene and the side product p-di-isopropyl-benzene (DIPB). This model was used for the design of the plant and is the basis of the design of experiments. Details of the design, costs and operability limits (used as constraints) are given in Asprion et al. (2017).

Figure 1: Design variables for the experiments are the operating variables (shown with gray font) of the cumene process. The measurements used in the sum of least squares for the determination of the kinetics are shown in the gray boxes.

The ranges of the operating variables which are used in the optimization of both strategies are given in Table 1.

Table 1: Range of the operating variables for the design of experiments. This range is used in the multi-criteria optimization step before applying the statistical DoE and for the optimization of the A-criterion in the model-based DoE.

	$T_{in}/^{\circ}\text{C}$	p to b	RR_1	$\ln(CR_1)$	RR_2	$\ln(CR_2)$	load
min	340	0.2	0.1	-12	0.1	-12	0.6
max	400	0.9	1	-1	1	-1	1.2

The results of the multi-criteria optimization (minimization of -trace F and OPEX) are shown in Fig. 2. Obviously, there is one dominated solution included, which emphasizes the need to start optimization from different initial values. Furthermore, the obtained Pareto-frontier is partly non-convex probably caused by active constraints and/or bounds on the variables. Starting from a typical operating point with low OPEX in the right corner, there is a huge trade-off in the information content (measured by -trace F) by increasing only a little the OPEX, before OPEX increases significantly,

while the additional gain in information content remains small. Therefore, a solution in the so-called Pareto “knee” was chosen. Starting from this point, a statistical design in a closed vicinity (operating variables at selected point and ranges see Table 2) has been setup using a fractional factorial design scheme, which leads to 8 experimental designs.

Figure 2: Results of the multi-criteria optimization: ○ Pareto points, ● dominated point, ✕ selected point as basis of a statistical DoE.

Table 2: Results of the operating variables of the cumene process for the selected point (cf. Fig. 2). Statistical design of experiments is based on a fractional factorial design using the min and max values. Italic values of the variables were already on lower or upper bounds and were not varied.

	$T_{in}/^{\circ}\text{C}$	p to b	RR_1	$\ln(\text{CR}_1)$	RR_2	$\ln(\text{CR}_2)$	load
selected	340	0.641	0.1	-1	0.428	-9.92	0.755
min	340	0.6	0.1	-1	0.4	-10.5	0.7
max	340	0.68	0.1	-1	0.45	-9.5	0.8

For the model-based DoE 8 parallel experiments with 7 operating variables (in total 56 variables) have been used to minimize the A-criterion (subject to in total 176 constraints). For both designed experimental plans “virtual” experiments with the model assuming a different kinetic (called “true” to distinguish from the kinetic used for the design). For the statistical design simulations for 7 and for the A-criterion simulations for 6 design points converged. The remaining ones failed. This behavior is conceivable for real experiments as well: Designs based on an initial guess of the parameters might fail as well because reality is different from the supposed model and limitations prevent to run an experiment. To the inlet stream conditions and the measured molar concentrations and temperatures of the reactor noise based on a normal distribution with standard deviations (1% for the total molar flow to the reactor, $\sigma_x=10^{-4}$ mol/mol and $\sigma_T=1$ K) has been added. For the parameter estimation, the inlet conditions are set and only the measured data (cf. gray boxes in Fig. 1) of the reactor are used in the least squares Eq. (1) with $w_x=w_T=10^{-4}$.

In Table 3 the parameters of the kinetic models based on the Arrhenius ansatz

$$k_i = k_{0,i} \cdot \exp\left(-\frac{E_{A,i}}{RT}\right) \quad (4)$$

used for the initial design and for the virtual experiments (“true”) as well as the estimated parameters based on the statistical and A-criterion design are given. Herein k denotes the kinetic, k_0 the pre-exponential factor, E_A the activation energy, R the universal gas constant. Instead of estimating the parameters k_0 and E_A of the i -th reaction directly, factors F_1 and F_2 initially set to 1 have been introduced

$$k_i = \exp(F_{1,i} \cdot \ln k_{0,i}) \cdot \exp\left(-\frac{F_{2,i} \cdot E_{A,i}}{RT}\right) \quad (5)$$

with the following ranges: $F_{1,1} \in [-3;15]$; $F_{1,2} \in [-3;30]$; $F_{2,1}$ and $F_{2,2} \in [0.1;20]$.

Table 3: Kinetic model parameters of the cumene (1) and p-dipb (2) reaction for different models: design - was used for plant design and design of experiments, “true” - is the kinetic model used for generating the virtual plant experiments, statistical and A-criterion – estimated parameters based on these experimental designs

model	$k_{0,1}$ / (l/mol)	$E_{A,1}$ / (J/mol)	$k_{0,2}$ / (l/mol)	$E_{A,2}$ / (J/mol)
design	2.8E+07	104251	2.32E+09	146873
“true”	1.054E+08	111546	6.101E+08	139577
statistical	2.208E+08	115773	1.275E-01	14687
A-criterion	2.513E+08	116160	6.207E+06	114756

These kinetic models are also shown in Figure 3 for temperatures between 340 and 440°C for the cumene and the p-dipb reaction (cf. Fig. 1). As can be seen, the estimated kinetics for the cumene reaction for both designs are in good agreement with the “true” kinetics, but for the p-dipb reaction the estimated kinetics based on the A-criterion design is much better than for the statistical design. The remaining deviations are caused by the noise as a comparison to the results without noise have shown (not presented here).

Figure 3: Comparison of the different kinetic models for the cumene (1, left) and the p-dipb (2, right) reaction: — “true” model, ... initial design model, -- estimated model based on statistical design around selected point from MCO and - - estimated model based on A-criterion design.

Comparisons of the outlet molar fractions of the virtual experiments and the predictions of the estimated kinetic models are shown for both designs in Figure 4. As can be seen there is more variance in the data for the A-criterion design.

Figure 4: Reactor outlet concentration: full symbols are results of virtual experiments based on “true” kinetic model. Hollow markers with lines are results of estimation of kinetic parameters to this data. Left: based on statistical design, right: based on A-criterion design. O, ●: cumene, △, ▲: benzene, ◆, ◇: dipb, ■, □: propane

This is also true for the temperature profiles of the different designs as can be seen in Figure 5. This higher variance of the data reduces the impact of noise and improves parameter identifiability. There is a good agreement between the models with the estimated data and the virtual experiments.

Figure 5: Reactor temperatures: symbols are results of virtual experiments based on “true” kinetic model. Lines are results of adjustment of kinetic parameters to this data. Left: based on statistical design, right: based on A-criterion design.

4. Conclusions and Outlook

The example of the cumene process has shown how a model-based design of experiments implemented into a flowsheet simulator helps to identify kinetics in an experimental setup with operability limitations. The method and the workflow of the two experimental plans as well as the results will be discussed in the presentation.

Following aspects will be considered for future improvements of the implementation:

- Automatic initialization strategies for the optimization
- Extension of existing experimental designs
- Use of singular value decomposition and estimation of parameter identifiability (Lopez et al., 2015, Schittkowski, 2007a)
- Robust design by considering uncertainties in initial parameter guesses
- User support in problem formulation

Abstract

This study investigated a numerical simulation of a column packed bed using silica gel. This bed is either stationary or steadily rotating, leading to different operation-regeneration schemes. Although models of these systems have already been developed and fitted with available data, they require large number of costly and time-consuming experiment to be applicable. Therefore, the development of a fundamental predictive mathematical model is necessary. The present model is a one-dimensional numerical solution of the conservation equations for heat, water vapor, and adsorbed water inside the silica gel desiccant under the constraint of local equilibrium between the two phases, which is characterized by fundamental sorption isotherms. The system of a non-isothermal adiabatic under constant pressure containing heat and mass transfer phenomena between vapor and solid phases are considered. The numerical results show good agreement with a maximum root of mean square of errors of 6.6% and 9.6% for exit air temperature and humidity, respectively

Keywords: Adsorption, Packed bed, Desiccant, Dehumidification.

1. Introduction

Adsorption process has been used in various applications, for example, in purification processes, whereby a packed bed filled up with solid desiccant material is used to remove the impurity of the adsorbate. The most widely used materials in the adsorption processes are silica gel, activated alumina and zeolite. The choice of the material depends on the type of application to be used. Silica gel is considered as good alternatives and commonly used in air dehumidification systems due to its high performance in the removal of water vapor. It is non-toxic, non-flammable, non-reactive and stable with ordinary usage. One of the advantages of using silica gel desiccant packed bed is the low operating cost. It also does not pollute environment, and can be generated using low temperature. Silica gel desiccant is widely used in applications like food drying, air conditioning, storage of chemical and pharmaceutical products, etc.

Dehumidification is related to physical adsorption. It is an exothermic process. This involves the transfer of water vapor from the humid air onto the solid desiccant surface due to vapor pressure different between the air and the desiccant surface. It is a function of operating temperature with the degree of adsorption decreasing as

Nomenclature	
A_b	bed cross section area [m^2]
a	volumetric surface area [m^2/m^3]

temperature increases. After the desiccant adsorbs moisture, it is usually desorbed or reactivated by heating. Isothermal dehumidification process is an ideal for applying to small systems. An adiabatic (non-isothermal) process is a common process that can occur with a heat insulating system.

In this study, the numerical model for heat and moisture transfer in the non-isothermal packed bed is described and analyzed. The objective of the present theoretical study is to investigate the desiccant bed dynamics during adsorption process and predict the influence of design parameters, such as air velocity and inlet air humidity for adsorption processes without the need of measured data. The model has been validated using the experimental data found in open literatures. The simple explicit finite difference method is applied to solve the model numerically.

2. Theoretical

2.1. Mathematical modeling

The physical system considered in this analysis is illustrated in Fig. 1. The moisture and energy conservation law are applied to the incremental volume of desiccant packed bed of spherical silica gel particles with a height of dz . To simulate the moisture and heat transfer processes in the desiccant packed bed, the following assumptions are used:

- (i) The bulk air stream contains only water vapor as adsorbate.
- (ii) The desiccant particles are porous spheres of uniform diameter d_p .
- (iii) Average bed porosity is assumed at all locations in the packed bed.
- (iv) The pressure drop along the bed is negligible, thus air velocity is constant.
- (v) The variation of humidity in radial direction is neglected.
- (vi) The heat transfer through the bed is along the z -direction only, and column wall is assumed to be adiabatic wall.
- (vii) The dispersion of moisture along axial direction of the bed, which is less than the convective mass transfer in the bed, can be neglected.
- (viii) Lumped capacitance method is adopted for moisture and energy balances.

Applying the moisture balance on the air stream through the bed, the equation of the gas phase moisture balance is:

Fig. 1. Physical model for adsorptive packed bed.

$$-v \frac{\partial(\rho_a w_a)}{\partial z} = \rho_a \varepsilon \frac{\partial w_a}{\partial t} + \rho_s (1-\varepsilon) \frac{\partial q}{\partial t} \quad (1)$$

In the solid phase, the accumulation of moisture in the silica gel particles can be represented as the amount of water vapor transferred from the bulk air stream to particles as shown in eq. (2).

$$\frac{\partial q}{\partial t} = \frac{h_m a}{\rho_s (1-\varepsilon)} (w_a - w_s) \quad (2)$$

Substituting Eq. (2) into Eq. (1), and rearranging, the equation of gas phase moisture balance is as follows:

$$\frac{\partial w_a}{\partial t} = -\frac{\dot{m}_a}{\rho_a \varepsilon A_b} \frac{\partial w_a}{\partial z} - \frac{h_m a}{\rho_a \varepsilon} (w_a - w_s) \quad (3)$$

For simplification, the moisture balance is implemented on incremental volume of spherical desiccant particles. Thus, the moisture content in the solid phase is given by,

$$\frac{\partial q}{\partial t} = \frac{\dot{m}_a}{m_s} (w_{a,z} - w_{a,z+dz}) \quad (4)$$

Applying the energy balance to the following air stream, the gas phase energy equation can be expressed as,

$$\frac{\partial T_a}{\partial t} = -\frac{\dot{m}_a}{\rho_a \varepsilon A_b} \frac{\partial T_a}{\partial z} + \left(\frac{ha}{\rho_a c_a \varepsilon} + \frac{c_v h_m a}{\rho_a c_a \varepsilon} (w_a - w_s) \right) (T_s - T_a) \quad (5)$$

The solid phase energy balance equation is derived by applying the energy conservation law as follow:

$$k_b \frac{\partial^2 T_s}{\partial z^2} + H_A h_m a (w_a - w_s) + ha (T_a - T_s) = c_s \rho_s (1-\varepsilon) \frac{\partial T_s}{\partial t} \quad (6)$$

Where the first term in the left-hand side is the heat transferred by conduction, the second term accounts for the heat released during adsorption (or heat adsorbed during desorption) and the third term represents the convective heat transferred from/to the air stream.

Eqs. (3)-(6) have the following initial and boundary conditions during adsorption processes:

$$\begin{aligned} T_a(z, t=0) &= T_{a0}, & T_s(z, t=0) &= T_{s0}, & w_a(z, t=0) &= w_{a0}, & q(z, t=0) &= q_0, \\ T_a(z=0, t) &= T_{a,in}, & w_a(z=0, t) &= w_{a,in}, & \frac{\partial T_s}{\partial z} \Big|_{z=0} &= \frac{\partial T_s}{\partial z} \Big|_{z=L} &= 0 \end{aligned}$$

2.2. Auxiliary data

In this study, the average silica gel particle diameter and density are 3.88 mm and 1,200 kg/m³, respectively. The bed porosity has been taken as 0.31 for bed spherical particles. The cylindrical column diameter is 0.13 m. The physical properties used by Pesaran and Mills (1987) and Kafui (1994) are as followed:

$$\text{Thermal conductivity} \quad k_b = k_a^\varepsilon k_s^{1-\varepsilon} \quad (7)$$

$$k_s = 0.37 + 0.97q + 0.0014T_s \quad (8)$$

$$\text{Specific heat of silica gel} \quad c_s = 4,186q + 921 \quad (9)$$

$$\text{Specific heat of humid air} \quad c_a = 1,884w_a + 1,004(1-w_a) \quad (10)$$

$$\text{Specific heat of water vapor} \quad c_v = 1,859 + 0.382T_a \quad (11)$$

$$\text{Heat of adsorption} \quad H_A = \begin{cases} 1,000(3,500 - 12,400q) & q \leq 0.05 \\ 1,000(2,950 - 1,400q) & q > 0.05 \end{cases} \quad (12)$$

$$\text{Convective heat transfer coefficient} \quad h = 1.60\rho_a v c_a Re^{-0.42} \quad (13)$$

$$\text{Convective mass transfer coefficient} \quad h_m = 1.70\rho_a v Re^{-0.42} \quad (14)$$

The equilibrium isotherm of water-silica gel system for regular density silica gel is

$$RH_s = 100(0.0078 - 0.05759q + 24.16554q^2 - 124.478q^3 + 204.226q^4) \quad (15)$$

After calculating RH_s and the bed temperature (T_s), the equilibrium moisture content of air adjacent to the particle surface (w_s) is calculated using the following expression:

$$w_s = \frac{0.622RH_s \times P_{sat}(T_s)}{P_a - RH_s \times P_{sat}(T_s)} \quad (16)$$

The relation between water vapor pressure and temperature from Antoine equation is

$$\ln P_{sat} = 16.3872 - \frac{3,885.70}{T_s - 42.980} \quad (17)$$

3. Numerical procedure

The nonlinear partial differential equation, moisture and energy balance of gas and solid phase as Eqs. (3)-(6), have been solved using explicit finite difference method. Computer codes are developed using programming MATLAB to obtain the result of the numerical model. Time step of 1.0 s and grid size of less than 1.0 mm with total 100 grid points have been used. The numerical procedure starts with the parameters definition and initialization for all variables. Finally, the variables w_a , q , T_a and T_s at the current grid point are calculated.

4. Numerical results

Fig. 2. illustrates the comparison between results of this numerical model and experimental data reported by Pesaran and Mill, 1987, which shows the variation of exit air temperature and humidity with time for adsorption processes. Regular density silica gel is packed in the desiccant bed. The height of the bed is less than 0.15 m to avoid pressure drop effects. The time of successful experiment is about 30 min. It can be seen that the present model results are consistent with the measured data. It is a maximum root of mean square of errors of 6.6% and 9.6% for exit air temperature and exit humidity, respectively. For the adiabatic model, there is an acceptable error that is

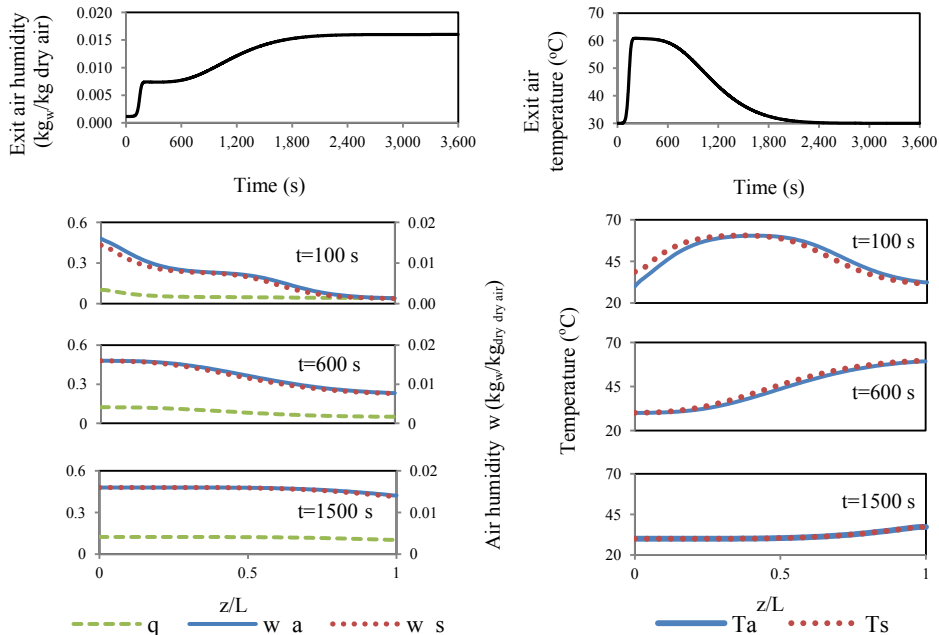

$L=0.0775$ m, $v=0.21$ m/s, $T_{a,in}=23.3$ °C, $w_{a,in}=0.01$ kg_w/kg_{dry air}, $q_0=0.0417$ kg_w/kg_s

Fig. 2. Variation of exit air temperature and exit air humidity with time.

due to heat transfer through packed bed’s wall during the experiment. The heat adsorption in packed bed has caused high deviation of isothermal model.

Fig. 3. shows the simulated results of axial variation of humidity, bed water content and temperature profile along the column. Top two graphs present exit air humidity and temperature. For 100 s, there is no change at the exit air humidity and temperature. However, air humidity, bed moisture and heat have been accumulated along the bed length. Later on, the developed humidity, moisture and temperature have moved toward the exit. Humidity and moisture have been increasing smoothly, while temperature wave has moved out by the air convection cooling. As the bed saturates, there is no humidity and temperature difference along the column.

Inlet air condition has been investigated and presented in Fig. 4. The results are

$L=0.1$ m, $v=0.5$ m/s, $T_{a,in}=30.0$ °C, $w_{a,in}=0.016$ kg_w/kg_{dry air}

Fig. 3. The axial distribution variation of desiccant bed during adsorption process.

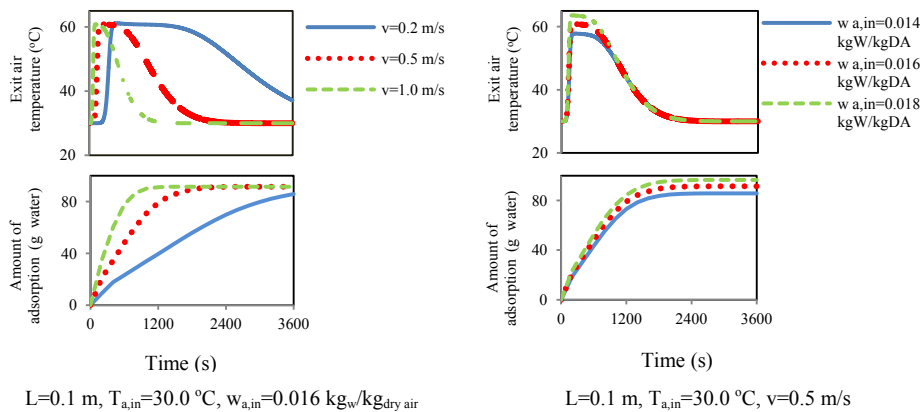

Fig.4. Effect of inlet air humidity and air velocity on exit air temperature and amount of adsorption.

consistent with the experimental data from A.E. Kabeel (2009). Initially, the rate of adsorption is high and gradually decreases when the adsorbent begins to saturate. The exit air temperature rises sharply due to the initial high heat of adsorption, which raises the temperature of bed particles and consequently heats up the air stream by convective heat transfer. When the bed temperature increases, the adsorption capacity decreases, resulting in the decline of heat released and a gradual decrease in the exit temperature. Different inlet humidity has a predictable amount of water adsorption and exit air temperature. In conclusion, the exit air temperature depends on the moisture content adsorbed. As the silica gel saturates, the exit air temperature will equal to the inlet air temperature. However, if the silica gel is still adsorbing moisture, the exit temperature will increase as a result of heat of adsorption.

5. Conclusions

A general numerical model for simulating transient heat and moisture transfer in silica gel packed bed has been presented and validated by comparing with experimental data from public literature reviews. The result of this numerical model is consistent with the experimental data and can accurately explain the physical properties existing in the bed. It can also forecast adsorption capacity by varying the independence variables, such as inlet air humidity and air velocity. The increasing of heat released from adsorption significantly reduces the adsorption capacity. If this numerical model, which is used as a basis for designing adsorption packed bed system, can be designed to reduce the temperature in packed bed, the efficiency of adsorption process will improve.

Abstract

Many factors affect the growth of microalgae among which temperature and light intensity are amongst the most important factors. While these two factors heavily influence the growth in outdoor microalgae cultures such as open ponds, they also have a significant correlation in this environment which makes studying their effects separately rather difficult. A method has been introduced in this paper which models the effect of temperature on long-term growth of microalgae based on the assumption that the effect of light and temperature are independent and can be separated. This method was obtained by binning the data and using the derivatives of the growth to eliminate the effect of light. For this study, long-term growth of *Tetraselmis* sp. grown in Murdoch University, Perth, Australia was used. The result showed that the calculated temperature function is similar to what has been reported in the literature for other types of microalgae. Although raw data did not show any decline in growth at high temperatures due to the increase in light exposure, the proposed model successfully demonstrated this effect and confirmed that elevated temperature can lower the growth of microalgae.

Keywords: microalgae, growth model, outdoor cultivation, temperature function

1. Introduction

Microalgae have attracted the attention of many researchers due to its high potential in production of various chemicals. From pharmaceuticals to nutrition and cosmetic industries as well as wastewater treatment, microalgae showed to be valuable source for wide range of applications (Acién et al. 2014). However, despite the beneficial characteristics, it is still pursuing the path to industrialization. One of the critical steps in this route is clear understanding of microalgal behavior from mathematical point of view. Design and control of a system is not feasible as long as there is not a clear formulation of the system's behavior. When it comes to microalgae production, one of the most important parameters to understand is growth which ultimately facilitates calculation of production rate and other economical values. Growth, in form of specific growth rate, has been subject to numerous studies and effect of various parameters including light, temperature, and nutrients have been investigated. However, there is still a noticeable lack of studies for outdoor cultures from modelling perspective (Béchet et al. 2013).

Mass production of microalgae is only possible in outdoor systems. Given the different nature of indoor and outdoor systems, data acquired indoor does not seem reliable to explain the behavior of an outdoor system. Hence, modelling based on outdoor data seems crucial. This paper specifically focuses on the effect of temperature on the growth of microalgae for which experimental data for growth of *Tetraselmis* sp. in an outdoor open pond is used. When it comes to outdoor data, there is little to control over factors that affect the growth. Temperature, likewise, is rarely controlled as it significantly increases the operating cost of a pond. Hence, the two influential parameters, light and temperature, vary continuously which makes studying the effect of solely one of them challenging. Moreover, these two factors have a strong correlation which makes separating their effect even more difficult. Figure 1 shows the correlation between daily light and pond temperature. However, this correlation is not strong enough to make an accurate prediction of one based on the other and hence it is critical to extract their individual effects from data for better analysis.

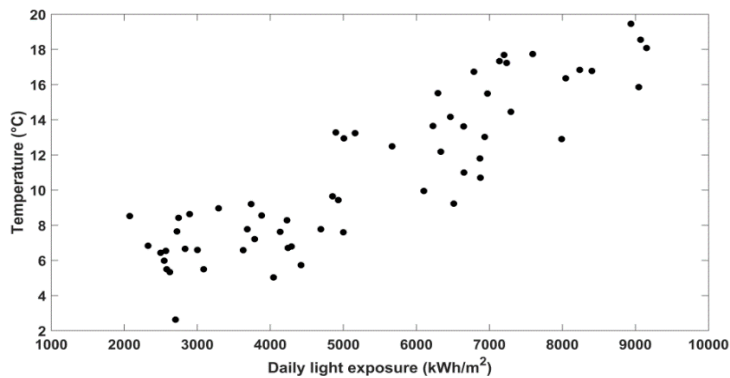

Figure 1 Temperature of the pond against total daily light exposure

Modeling and extracting the effect of temperature from outdoor data is essential since it helps in understanding the difference between the behavior of algal cells in indoor and outdoor cultures, and a pathway to more accurate prediction of growth based on weather conditions. Moreover, understanding the effect of temperature can be useful for cultures that have a temperature control system, which facilitates the optimization of temperature for better growth.

2. Methodology

2.1. Experiments

The data for this study was obtained by Isdepsky (2015) in Murdoch University Algae R&D Centre, Perth, Australia. As part of a long-term feasibility study, *Tetraselmis* sp. was grown in 1 m² open air raceway pond for a period of 20 months (from January 2009 to August 2010). The pond (2 m by 0.5 m) was divided into two channels and the culture was circulated continuously using a paddlewheel at 18 rpm which created a flow of approximately 0.2 m/s. The culture was maintained in a semi-continuous way using a dilution frequency of three times per week.

Light intensity data was collected from Murdoch University Weather Station (<http://www.met.murdoch.edu.au>). Using this data, total daily light exposure was calculated. Pond temperature measurements were collected during the experiments.

2.2. Numerical modeling

Light intensity and water temperature are very closely related in an outdoor culture. Therefore, to make the analysis of data possible, researchers often assume that their effects are independent of each other. Each factor is used to calculate an efficiency function which varies between zero and one. Multiplication of these functions is used frequently in the literature to describe the combined effect of light and temperature (Bordel et al. 2009, Bernard and Rémond 2012, Franz et al. 2012):

$$\mu = \mu_m f(I) g(T) \quad (1)$$

In Eq.(1), μ is specific growth rate, μ_m is theoretical maximum specific growth rate, and $f(I)$ and $g(T)$ are efficiency functions for light and temperature, respectively. The goal is to identify the temperature function, which is difficult since we do not have any information regarding light function either. However, assuming $f(I)$ is independent of temperature, the partial derivative of specific growth rate can be easily calculated:

$$\frac{\partial \mu}{\partial T} = \mu_m f(I) g'(T) \quad (2)$$

Now, by dividing Eq.(2) by Eq.(1), the terms μ_m and $f(I)$ will be cancelled out and hence removed from the calculations.

$$\frac{1}{\mu} \frac{\partial \mu}{\partial T} = \frac{g'(T)}{g(T)} = (\ln(g(T)))' \quad (3)$$

Although using the derivatives are theoretically simple, when it comes to using actual data other issues will appear. To properly calculate the derivatives, data at various temperatures are required for each light intensity value. Unfortunately, data from outdoor cultivation systems are not acquired under such controlled condition, and are far from the ideal form due to errors caused by sudden weather changes and being exposed to atmosphere and many more. One way to tackle this issue is by choosing small ranges of light intensity within which it is fair to assume the effect of light is negligible. Thus, any change in the growth would be due to temperature variations and fitting a line through data using regression can estimate the value of derivatives.

The integration of Eq.(3) results in the following equation:

$$\int_{T_{ref}}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT = \int_{T_{ref}}^T (\ln(g(T)))' dT \quad (4)$$

In Eq.(4) T_{ref} is the reference temperature which is arbitrary. Therefore, by selecting T_{opt} as the reference temperature and solving the integrals Eq.(5) will emerge:

$$\ln\left(\frac{g(T)}{g(T_{opt})}\right) = \int_{T_{opt}}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT \quad (5)$$

T_{opt} is the temperature at which $g(T)$ reaches its maximum value of one and can simplify the equation to the following form:

$$\ln(g(T)) = \int_{T_{opt}}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT \quad (6)$$

The values for $\frac{1}{\mu} \frac{\partial \mu}{\partial T}$ can be obtained from data; however, since the value of T_{opt} is not known, integration cannot be performed. Using an arbitrary temperature (T_0), which is set to be lowest temperature in the dataset, Eq.(6) is transformed to Eq.(7) :

$$\ln(g(T)) = \int_{T_0}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT - \int_{T_0}^{T_{opt}} \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT \quad (7)$$

The first integral can be solved easily using the data. The value of the second integral is still unknown but it is constant and independent of temperature, since both upper and lower bounds are fixed temperatures. Let the value of the second integral be γ_0 . Using the maximum value of both sides of Eq.(7), the value can be determined:

$$\max(\ln(g(T))) = \max\left(\int_{T_0}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT - \gamma_0\right) \quad (8)$$

Knowing that γ_0 is constant and also the maximum value of $g(T)$ is one (or maximum value of $\ln(g(T))$ is zero):

$$\gamma_0 = \max\left(\int_{T_0}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT\right) \quad (9)$$

Eq.(9) shows that the value of the second integral in Eq.(7) is the maximum of the first integral. Therefore, first the integral should be solved using T_0 and all temperatures in the dataset, then the maximum value is γ_0 . Finally, the temperature function can be determined using Eq.(10):

$$g(T) = \exp\left(\int_{T_0}^T \frac{1}{\mu} \frac{\partial \mu}{\partial T} dT - \gamma_0\right) \quad (10)$$

3. Results and discussion

The data was classified into eight groups based on daily light exposure from 2,000 to 10,000 kWh/m² to make sure each group contains at least three data points while keeping the range of light exposure narrow and maintaining validity of assumptions. Within each group a linear regression was used for relationship between the specific growth rate and temperature to estimate the value of $\frac{1}{\mu} \frac{\partial \mu}{\partial T}$ in Eq.(3). The results are summarized in Figure 2. The calculated points follow a clear trend except for one instance associated with light range of 7,000 to 8,000 kWh/m² (Figure 2a). While the values are decreasing with temperature, at this data point (labelled in Figure 2a) there is a sharp increase. This issue occurs because all of the groups experienced a temperature range of

over 2.5 °C (Figure 2b), while for this specific group (7,000 to 8,000 kWh/m²) the range did not exceed 0.5 °C, and there were only three data points available. The combination of

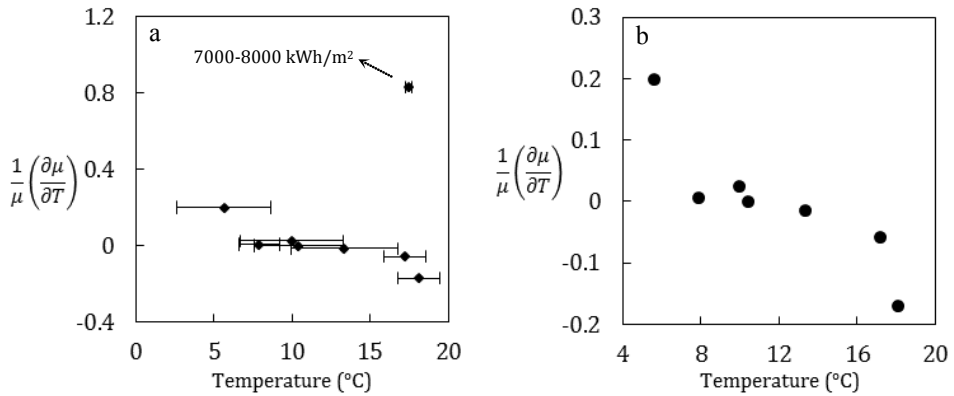

Figure 2 (a) Value of the derivative function for all group and their temperature range (b) Value of the derivative function for all groups, excluding the outlier.

these two factors aggravates the effect of any small error in the data and hence deteriorates the reliability of the result from this group. Therefore, it was decided to flag this point as an outlier and remove it from the rest of the calculations.

Figure 2b also shows that the temperature ranges overlap in certain areas, which produces multiple values at some temperatures and makes integration operation unfeasible. Therefore, where multiple values existed, an average of them was used in the calculation.

After calculating the value of $\frac{1}{\mu} \frac{\partial \mu}{\partial T}$ for all temperatures, numerical integral of the dataset was calculated from $T_0=2.6$ °C to temperature T. As shown in Eq.(9) the value of γ_0 is the maximum of integration which is calculated to be 0.9456 and was inserted into Eq. (10) to find the temperature function ($g(T)$).

Figure 3 The calculated temperature functionality of growth

Figure 3 shows the final form of $g(T)$ which represents the effect of temperature factor on the growth. The shape of the function is similar to what is reported for other types of microalgae in the literature (Bernard and Rémond 2012). The growth is lower at low temperatures and it increases rapidly until it approaches T_{opt} where it reaches the maximum value and then drops thereafter. Here the growth is maximized at $T = 13.2$ °C which is T_{opt} . It is worthwhile to mention that this value is a daily average and does not mean that at this temperature the growth is maximized, but it shows that on the days

with average temperature of 13.2 °C the growth was at its highest value. The result shows the behavior of the culture under a wide range of temperature. Although, it does not cover the minimum and maximum temperature, at which no growth takes place, it describes the change in growth based on the sole factor of temperature in the range that is commonly experienced by the culture in the location of experiments.

4. Conclusion

A numerical modeling approach was presented to describe the effect of temperature on the growth of microalgae for long-term outdoor cultivation systems and decoupled it from light exposure. The effect of temperature was assumed to be independent of light intensity, which made separation of its effect from other factors possible. This effect was represented in form of a function for which the values were calculated within the temperature range of experiments. The result showed a fairly smooth function which to a good extent had a similar shape to the previous reported functions based on indoor data. In other words, the effect of average daily temperature in outdoor cultures seem to be very close to the effect of temperature in controlled indoor experiments. However, due to differences in the conditions of indoor and outdoor experiments there are a few distinctions between the result of this paper and temperature functions based on indoor experiments. For instance, in indoor experiments the temperature function usually is skewed. They tend to increase rather slowly with temperature and after reaching the maximum value decrease rapidly. But the result of this study shows the temperature function is rather symmetrical (Figure 3) and resembles a Gaussian distribution function, a function which has been used before by Franz et al. (2012) to describe the effect of temperature on the growth of microalgae.

Although a look at the raw data did not show any negative effect due to high temperature, this method managed to unravel this effect successfully. The results, however, heavily depend on availability of extensive data. As experienced in one instance, the lack of sufficient data in one of the groups can result in highly unreliable values.

Moreover, this model was based on half-monthly data for long-term cultivation in an open pond. More frequent data, enables us to do the analysis on a more accurate and more detailed scale, which can result in a more robust model. But despite these limitations, the presented framework resulted in a model that describes the temperature functionality of growth with a high quality. Additionally, instead of relying on controlled indoor experiments, it uses the data from long-term cultivation in real outdoor condition, which makes applying it to simulate an outdoor culture more reliable.

Abstract

This study assesses the stability of nanofluids using a computational modelling technique based on Lagrangian particle tracking. A multiphase liquid-solid model is used where the motion of embedded nanoparticles in the suspended fluid is treated by an Eulerian-Lagrangian hybrid scheme with fixed time stepping. This technique enables various multiscale forces, whose characteristics (length and timescales) are quite different, to be established. The system under consideration consists of 50 nm Al₂O₃ ceramic nanoparticles at various volume fractions ranging between 1.0 and 5.0% suspended in fluids of different density ratios, including water with homogeneous temperature distributions from 5 to 95 °C. The simulation results demonstrate the effectiveness of the technique, with predictions elucidating the role of Brownian motion, particle collision and DLVO forces, and their influence on the level of nanoparticle agglomeration. The nano-aggregates formed are found to play a key role in the thermal behaviour of the nanofluid at various particle concentrations, with predictions in agreement with theoretical and experimental results obtained in similar studies. The results of the work are used to consider the heat transfer characteristics of nanofluids and their potential applications.

Keywords: Nanofluids, stability, thermal conductivity, thermal energy storage

1. Introduction

Both heat transfer fluids and thermal energy storage media are commonly used as thermofluids in large-scale power generation units, including solar thermal and nuclear plants. However, the poor thermal properties of many fluids (e.g. water, oil, ethylene glycol and molten salt) are a major limitation in developing more energy-efficient power generation processes. New methods have recently been introduced to improve their thermal heat transfer properties by doping them with small concentrations of selected nanoparticles (ranging in size from 10 to 100 nm) to form so-called nanofluids. Work in this area has therefore received increased attention in recent years, with extensive experimental and computational research having been carried out (Wang and Mujumdar, 2008a,b). The reported enhancement in heat transfer characteristics obtained using different types of nanoparticles such as metal oxides, non-metallic and carbon nano-tubes is described in the literature, with substantially higher thermal conductivities found. The most significant is for samples containing aluminium-trioxide (Al₂O₃) nanoparticles with volume fractions ranging between 1.0 and 2.5%, for which increases

in thermal conductivity of between 2 and 36% (Choi and Eastman, 1995; Wang and Mujumdar, 2008a,b) have been obtained.

For numerical simulations, most researchers have dealt with nanofluids as a single-phase fluid rather than a two-phase mixture (Wang and Mujumdar, 2008a). The single-phase approach assumes that continuum principles are still valid for fluids with suspended nano-sized particles following the flow, and as such is much simpler and computationally less expensive than explicitly accounting for both phases. The alternative two-phase modelling approach clearly better describes the separate phases, but this approach is not commonly found in the literature due to its computer run-time limitations. The latter technique is to be preferred when modelling nanosuspensions, as it is able to describe the key mechanisms and dynamic processes involved in such multi-phase fluids and their flows, such as nanoparticle clustering, aggregation and thermal property enhancement.

This paper describes the model used, and evaluates the key dynamic forces involved in nanofluids, demonstrating some results and findings. General conclusions are also drawn on the model's capabilities and its potential applications.

2. Computational Setup

The numerical multiscale model applies a Lagrangian particle tracking approach to investigate the dynamics of, and heat transfer mechanisms in, nanofluids. The three-dimensional computational region examined consists of a $1\mu\text{m}$ cube filled with stagnant water. This volume element is composed of a collection of 50 nm- Al_2O_3 spherical nanoparticles (40-2000 in number) that are injected uniformly across the domain. The motion of the embedded nanoparticles in the fluid is treated using an Eulerian-Lagrangian hybrid scheme with fixed time stepping. Two directions (x and z) use periodic boundary conditions while the third y direction limits are treated as walls. The particle equations of motion are integrated using the fourth order Runge-Kutta algorithm with a very small time step, $\Delta t = 10^{-11}$ s. The dynamic properties of both phases are coupled to the ambient temperature of the fluid suspension, that being water at 5 to 95 °C.

3. Model Description

The motion of each nanoparticle is described using the Langevin equation (Sloan et al, 2012), where the translational velocity of the i -th particle is obtained from the principle of conservation of linear momentum, using:

$$m_p \frac{\partial \mathbf{v}_i}{\partial t} = \mathbf{F}_i \quad (1)$$

where,

$$\mathbf{F}_i = \mathbf{F}_i^C + \mathbf{F}_i^e + \mathbf{F}_i^v + \mathbf{F}_i^f + \mathbf{F}_i^B \quad (2)$$

Here, m_p and \mathbf{v}_i are the mass and the transitional velocity vector of the i -th nanoparticle, respectively. \mathbf{F}_i^C is the particle contact force, \mathbf{F}_i^e is the electric double layer repulsive force, \mathbf{F}_i^v is the van der Waals attractive force, \mathbf{F}_i^f is the fluid force and \mathbf{F}_i^B is the random Brownian motion force. Other body forces such as gravity and buoyancy are found to be negligible for all length and time scales, since their magnitudes are much smaller than the aforementioned surface forces. The present model simulates the dynamics and

mechanisms responsible for nanoparticle aggregation, including particle collisions and DLVO (theory named after Derjaguin, Landau, Verwey, and Overbeek) inter-particles forces (Israelachvili, 2011), and the fluid force and Brownian motion as random forces. Particle collisions are resolved using a soft sphere approach as described by the Hertzian normal contact theory (Timoshenko and Goodier, 1970). The model describes the collision force between the i -th and j -th sphere in the normal unit direction, \mathbf{n}_{ij} , according to the approach of Fujita and Yamaguchi (2008). For the estimation of inter-surface forces, the DLVO theory is used, with surface separations down to 5 nm. This consists of a repulsive electric double layer exerted between the two spheres, together with an attractive van der Waals force that can be expressed mathematically as:

$$\mathbf{F}_i^e + \mathbf{F}_i^v = \sum_j (f_{ij}^e + f_{ij}^v) \mathbf{n}_{ij} \quad (3)$$

The magnitude of the electrostatic repulsive force exerted on two homogeneously charged spheres can be determined by Derjaguin's approximation (Israelachvili, 2011) using:

$$f_{ij}^e = -\frac{64\pi a n k_b T \theta^2 e^{-\kappa H_{ij}}}{\kappa} \quad (4)$$

and for the attractive van der Waals force:

$$f_{ij}^v = \frac{Aa}{12H_{ij}^2} \quad (5)$$

where a is the radius of a sphere, n is the number density of electrolyte ions, k_b is the Boltzmann constant, T is the temperature of the suspension, θ is the polarizability factor, κ is the inverse of the Debye length, H is the inter-surface distance between spheres and A is the Hamaker constant. The magnitude of the van der Waals force is limited below a maximum value to prevent divergence when the inter-surface distance becomes zero. For the Brownian force exerted on the spherical nanoparticles, the components are modelled using a Gaussian white noise process given by Kim and Zydney (2004):

$$f^B = \xi \sqrt{\frac{12\pi a \mu_f k_b T}{\Delta t}} \quad (6)$$

in which ξ is the coefficient of Stokes drag for a sphere and μ_f is the fluid dynamic viscosity. To determine the magnitude of the fluid force responsible for nanoparticle aggregation in a quiescent system, the following Stokesian equation is applied:

$$f^f = -6\pi a \mu_f V \quad (7)$$

The above nanofluid dynamic model is further coupled to a thermal energy model to predict the overall heat transfer properties of the system. The applied model works on the basis of inter-particle distances which are tracked at every time step in the simulation. The thermal model has also been coded to precisely determine the volume of aggregates formed at each time step, using a depth-first search method to iterate through aggregated particle chains and clusters. The applied technique considers both aggregation kinetics (responsible for the formation of particle percolation pathways) and Brownian motion (responsible for the induced micro-convection). These physical phenomena are found to be responsible for the effective thermal conductivity, k_{eff} , in nanofluids, as noted by Prasher et al. (2006), and can be expressed mathematically as:

$$k_{eff} = (1 + ARe^m Pr^{0.333} \phi) \left\{ \frac{[k_{ag} + 2k_{bf} + 2(k_{ag} - k_{bf})\phi_{ag}]}{[k_{ag} + 2k_{bf} - (k_{ag} - k_{bf})\phi_{ag}]} \right\} k_{bf} \quad (8)$$

where Re is the Brownian Reynolds number, Pr is the Prandtl number, and A and m are constants determined from experiment. Additionally, k_{ag} and k_{bf} represent the thermal conductivity of aggregates and the base-fluid, respectively. The particle volume fraction is given as ϕ for a primary particle and as ϕ_{ag} for aggregated particles that are characterized by their radius of gyration R_a , determined using the depth-first search method.

4. Results and Discussion

Different simulations were performed using the model described, with results analysed to elucidate the forces and mechanisms responsible for nanoparticle dynamics, aggregation and subsequent thermal property enhancement. First, the spontaneous ordering process of the particles in the suspension was examined, followed by clustering and agglomeration with time. Different time step snapshots of the simulations are presented in Fig. 1.

Figure 1. Representation of spherical 50nm Al_2O_3 particles in $1\mu m$ cubic-cell filled with water showing: a) homogenous distribution of particles; b) formation of clusters; and c) nano-aggregation.

The model allows the size of the different forces exerted on nanoparticles in a suspension to be predicted, with Fig. 2 giving the various multiscale forces plotted as a function of the normalized inter-surface distance, H , and the particle radius, a . These predictions indicate the magnitude of the various forces exerted on the particles in the test cell which drive particle aggregation. They also illustrate that when enough distance is maintained between nanoparticles, the effects of both the fluid (drag) and Brownian random motion forces dominate over other contributions as these forces are dependent on the velocity of the nanoparticles and interactions between the particles and the fluid. As the inter-surface distance between particles diminishes, the electric double layer (EDL) repulsive force starts to have a significant effect on the nanoparticles. When two particles are close to colliding, the attractive van der Waals force (VDW) starts to become dominant over all others. After a collision of two nanoparticles, the repulsive force increases rapidly and matches well with the attractive force. This change in the magnitude of the forces with inter-particle distance leads to the conclusion that every single force noted has to be considered in the dynamic modelling of nanofluids. The values noted in Fig. 2 are in excellent agreement with similar results in the literature

(Sloan et al, 2012; Fujita and Yamaguchi, 2008). The present model has been validated against experimental thermal conductivity data obtained in some of the studies described earlier, with good agreement found. This validation will be the subject of future publications. The model can also determine the number of nanoparticle collisions and the volume of each agglomerate formed in the system, with Fig. 3 giving predictions of the average number of inter-particle collisions occurring with time at different volume concentrations.

Figure 2. Quantitative assessment of various forces driving aggregation in nanofluids.

Figure 3. Collisions of particles in nanofluids as a function of particle volume concentration.

Figure 4. Mean free path (----) and number of aggregates (—) at different volume fractions.

Figure 5. Enhancement in thermal conductivity of Al₂O₃-water nanofluid with temperature.

It is clear from Fig. 3 that the average number of collisions increases as a function of nanoparticle volume concentration. Very few collisions take place when the system concentration is 1 vol%. However, above 3 vol%, the system enters a regime where both collision and agglomeration begin to take place more frequently. Mean free path results corresponding to the results in Fig. 3 are given in Fig. 4, leading to the same conclusion. Hence, at 3% volume fraction, the mean free path clearly decreases with time due to collisions and agglomeration taking place in the system. Such dynamic forces also govern the thermal behaviour of nanofluids, with a direct relationship between the normalized thermal conductivity and temperature at different volume fraction of particles evident in the results of Fig. 5. The results for the thermal

conductivity demonstrate an almost 13% increase with time for a 5 vol% Al₂O₃ nanofluid, as is evident in Fig. 5. These predictions were performed for the given range of temperatures 25 to 85 °C, and shows that further enhancement is expected due to increases in kinetic energy and hence in the fluid and Brownian motion forces. The increasing number of collisions and aggregation with time and concentrating indicates the effect of direct particle contact and the agglomerates' percolation effects on the conductivity. The observed combined effects of convection and conduction of thermal enhancement in nanofluids has been reported by Prasher et al. (2006), and is of the same magnitude. It predicts a linear relationship between the thermal conductivity, temperature and volume fraction. All these results support the use of nanofluids in thermal energy storage applications.

5. Conclusions

Key variables related to the stability and thermal conductivity of nanofluids have been examined using multiscale simulation. The model enables the prediction of various dynamic forces, and gives quantitative predictions of the magnitude of those forces, including their role in particle aggregation. It has also been found to perform well in comparison with similar studies, and provides confirmation of the effect of particle size and concentration on the thermal conductivity of the system. Future work will extend the model's application to include other fluids such as molten salts (used for thermal energy transfer and storage applications), and to flow situations by coupling the tracking approach with direct numerical simulations.

Abstract

Water, as everybody knows, is a limited and fragile resource. In fact, water faces several challenges in the future due to the increase of population, pollution, climate change, etc. To overcome these problems, some concepts linked to sustainable development such as “Industrial Ecology” have emerged. The concept of industrial ecology is defined as a group of companies, close in proximity to each other, who cooperate with the objective of sharing resources such as energy, water or services in order to act in a more efficient way and more respectfully to the environment. However, environmental impacts of such organizations are still difficult to identify and the impacts on the local environment could be very different from a larger surrounding ecosystem such as a watershed. The aim of this work consists in defining the optimal configuration of EIP in the watershed so that impacts of industrial activities are minimized considering a large-scale system. This study develops a multiobjective optimization based approach by combining two models. The first one consists of the optimisation of the water networks of clusters of companies to make them work as eco-industrial parks where a multi-objective optimisation approach is used. Secondly, the impact of this ecological strategy/policy is studied at a bigger scale: the Garonne watershed, in France modelled through a Material Flow Analysis (MFA). This model helps to track and measure the quality of the water, before and after the implementation of the eco industrial parks. In each scenario studied, there is a significant reduction of the pollutant concentration, proving the benefits of the implementation of an industrial ecology policy at a larger scale. Depending on which industrial area is transformed into an EIP, one can observe a diminution of the pollutant concentration up to 70% at the estuary.

Keywords: eco-industrial parks, multi-objective optimization, watershed scale, Material Flow Analysis

1. Introduction

Water is a fragile, precious and limited resource and is not only important for domestic or sanitary purposes, but every human economic activity relies on the existence of this element. In addition, leaving the human scope, every marine and terrestrial ecosystem depends on water somehow. This fact underlines the huge importance of this resource. Nevertheless, many recent reports have demonstrated that water is in danger. Indeed,

there is a clear evidence that in many rivers and aquifers there has been a reduction in its water quantity and quality. Water scarcity is a problem in many countries and many ecosystems have been modified until a point of no return. One of the most prominent problem is the pollution caused by agriculture and industry. This situation can cause significant damages, not only to ecosystems, but also to humans.

In conclusion, most of the problems evoked have a human origin and as a result, governments and society in general must act to reverse this situation. Efficiency in water use must be increased, technology must be developed and in this situation, research has an important role, because there are still many questions to answer and strategies to establish.

All this concern about resources in general, not only water, led to the birth of a great deal of new concepts such as sustainable development or industrial ecology. Industrial ecology consists of understanding human industrial activities as a natural ecosystem (Frosh and Gallopoulos, 1989). Indeed, a natural ecosystem represents equilibrium, sustainability and the use of every resource in the most efficient way as possible, reducing consumption and waste. One of the most important ideas in implementing Industrial Ecology is to establish eco-industrial parks. An eco-industrial park can be understood as a group of facilities in the same geographic region that try to optimise the use of energy, water and raw material flows, looking for economic benefits for all of them and for a better environmental performance (Lowe, 1997). Nevertheless, among all the eco-industrial parks that have been built, most of them are working in sub-optimal conditions because they have been built somehow, spontaneously. In other words, gradually some improvements were introduced, but a complete industrial park reconfiguration was never established.

The objective of this research is to introduce the conception of robust mathematical methods to design eco-industrial parks while taking into account the effects of such a policy at a bigger scale: the watershed scale. In order to convince the industries owners to be a part of these changes and to obtain real profits from them through a multiobjective optimization.

2. Objectives and methodology

During this research, several EIPs are going to be established within a region, from existing facilities or existing industrial areas. The reconfiguration of these facilities into eco-industrial parks is going to be limited to their water networks. The idea is to investigate deeply the impact of this politic at a bigger scale, the scale of the whole watershed. The objectives of this work are summarized below:

- To model a watershed. A Material Flow Analysis (MFA) to track and measure the quality of the river water is developed based on Lopez-Diaz et al. (2015).
- To develop a multi-objective optimization model for the water networks reconfiguration.
- To study the impacts of these changes on the watershed.
- To look for data to apply, specifically, this model to the Adour-Garonne watershed in France.

According to Figure 1, the two models interact with firstly the run of the MFA model to obtain the parameters of the watershed without the eco-industrial park's effects. Then, in the optimization model (MILP), the data related to water network of the industries are changed to make the industries work as eco-industrial parks. Finally, the results of the EIPs reconfiguration are loaded again into the MFA model to obtain the effects of these

modifications in the watershed, following the methodology developed by Lopez-Diaz et al. (2015).

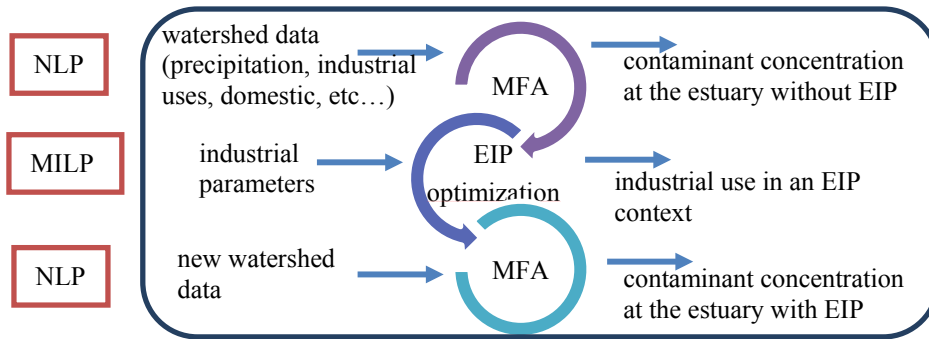

Figure 1. Methodology used in this study

3. Material Flow Analysis

The river flow along the watershed is modeled through a Material Flow Analysis (MFA), so its quality can be studied before and after the reconfigurations of the eco-industrial parks. To start with, the river is divided into several parts (Figure 2). The main parts are going to be called reaches and the secondary sections will be the tributaries. In general, this model is going to consist of some mass balances per reach and tributary, this allows to solve several consecutive small problems rather than a big non-linear one, more difficult to solve. This problem is formulated as a Non-Linear Problem (NLP) that has been solved within GAMS environment with DICOPT solver. Its most important variable is the pollutant concentration at the final disposal. With the changes on this variable before and after the establishment of the eco-industrial park their effects on the environment will be evaluated.

Figure 2: Decomposition of the river basin in reaches and tributaries (from Lopez-Diaz, 2015)

4. Multi-objective optimization of eco-industrial parks

As it has been showed in the previous figure, within a single watershed there can be several industrial parks or clusters of companies. Moreover, these industrial complexes are constituted by individual plants modelled as a group of process sources (i) and process sinks (j) to be reconfigured as EIP. Besides, a regeneration to clean the water

that has been used is added. This unit can be called an interception unit as well. The interception unit consists of several interceptors (int).

The superstructure defines the whole set of available solutions in a network so that all the possible links between units can be seen. For instance, the water used by a process unit leaves the sources to be used again in a process sink if some conditions, in relation to quality, are achieved. This water can also be sent to the regeneration unit. Furthermore, the flow leaving the sources can be sent directly to the environment without any previous treatment if the concentration constraints are respected. The process sinks can receive water from the sources, the interception unit or from fresh water sources directly. Finally, the interception unit is constituted by several interceptors, as it has been mentioned before. Each interceptor receives used water from process sources, it cleans the water and it can send it, either to the environment or to other process sinks so the water can be used again.

The companies that constitute the industrial parks are going to be working on their own at the beginning. With this methodology, all the plants characterized by their sources, sinks and interceptors are going to start working together, by sharing their water networks. For example, the water of one source of one specific plant can feed any sink of any plant; it can go to any interceptor of the industrial complex, etc. This way, the industrial plants will integrate an eco-industrial park. This optimization step will give a new optimal topological configuration of the water network as a solution by minimizing the total cost and environmental impact (fresh water consumption).

The problem is formulated as an MILP and solved within GAMS environment with CPLEX solver. The main equations are mass balances for each sink, source and interceptors, the total cost and environmental functions and more constraints that complete the model (Boix et al., 2012).

5. Case study: the Garonne watershed in France

5.1. Description of the case study

In this study, four possible eco-industrial parks are considered to be placed in the Garonne watershed. To model the Garonne watershed firstly, it is necessary to divide the watershed into different sub-watersheds, as the MFA model requires. Secondly, some information about the watershed was needed for each partition that had been done, for example the precipitations rate, industrial, residential and agricultural discharges, losses, usages, initial flows, etc.

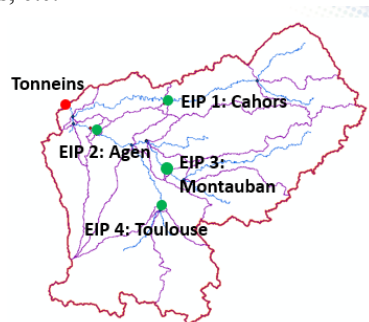

Figure 3: Garonne watershed

To reach this purpose, a model is developed in ArcSWAT (Arnold et al., 2012) for the watershed of Garonne. The watershed has been divided into 22 sub-basins and the final disposal has been placed in Tonneins. Also, it has been decided to place the possible eco-industrial parks in Toulouse, Montauban, Cahors and Agen (Figure 3). Firstly, with all this information, the MFA model for the Garonne watershed with normal industrial parks (without any collaboration) was developed and the concentration of pollutant at the final disposal is obtained: 2.03 ppm. Then, the multi-objective optimization of all the four industrial parks is carried out and the information obtained in relation to the pollutant concentration and the wastewater is introduced again into the MFA model to evaluate the changes in the pollutant concentration.

5.2. Reconfiguration of industrial parks into EIP by multi-objective optimization

In this study, four possible eco-industrial parks are considered to be placed in the Garonne watershed. For each of them a multi-objective optimisation process has been carried out. The optimisation variables were fresh water, regenerated water, number of connections, total cost and the pollutant concentration expelled to the environment. To solve this problem, for each eco-industrial park a Pareto front has been drawn and, from this set of optimal solutions, the optimal TOPSIS solution has been chosen. In order to illustrate this step, Figure 4 represents one of the four EIP Pareto fronts that have been built; the figure is related to EIP n°1 and represents the fresh water consumption (environmental objective) with the regenerated water (economic objective) for several number of connexions.

Figure 4: Pareto Front of the EIP 1

5.3. Environmental impacts of EIP policy at the watershed scale

Several strategies were studied: first, only one of the four EIP is working while the others stay as classical industrial parks, then some combinations of them and finally all of them are working at the same time. All these configurations were then compared to the pollutant concentration at the final disposal, without any eco-industrial park in the watershed. Figure 5 summarizes the results obtained during this study where the pollutant concentration at the final disposal is reported for the different strategies explored.

Some important results must be underlined:

- A global diminution of the pollutant concentration at the estuary is observed for every strategy of EIP development

- Each EIP does not have the same effect on the overall watershed, for example, EIP 3 leads to a greater reduction than EIP 4. This is mainly because EIPs have different sizes and are located at different places in the watershed what causes different environmental impacts.

Figure 5: Pollutant concentration at the final disposal under several strategies of EIP development

6. Conclusions

As a general conclusion, it must be highlighted that the implementation of industrial ecology strategies is always interesting. The development of eco-industrial parks reduces pollution and studying the eco-industrial parks effects on a bigger perspective or scale, such as the scale of a whole watershed. This study helps us to understand their influence or beneficial impacts in a better way and the strategy developed aims at implementing this strategy with a higher performance. The optimal location for these eco-industrial parks in the watershed has a major influence in their final environmental impact. Nevertheless, this task is not completely finished. Some improvements can be added to both models, the EIP's model and the MFA model. Starting with the first one, this model can be enhanced by making the code multi-pollutant, the cost equations can be improved, other ways of introducing the ecological effects into the code or more ecological parameters could be studied. Moreover, the eco-industrial park concept can be extended by sharing not only water but also more resources such as energy or other materials.

Coke Formation Model in Crude Oil Furnace for Maintenance Scheduling

Amata Anantpinijwatna

Department of Chemical Engineering, Faculty of Engineering, King Mongkut's Institute of Technology Ladkrabang, 1 Chalongkrung Rd., Lat Krabang, Bangkok, TH-10520, Thailand

amata.an@kmitl.ac.th

Abstract

A crude oil distillation unit (CDU) is one of the most important unit in petroleum industry. Its main function is to separate the crude oil into many kinds of petroleum products. Generally, the CDU's design includes the crude oil preheater, which are either cabin or vertical cylindrical furnace, for adjusting the crude feed properties and increasing feed temperature. Carbon coking inside the furnace during the preheating process leads to accumulating of the coke, deteriorating of the product quality, increasing of the pressure drop across the furnace, and increasing of the energy consumption. The de-coking process is normally executed on demand based on the measured heat loss or performed every fixed period of time. However, due to the different rate of coke formation of various crude oil grades, as well as the difference in cost of product, process operation, and maintenance operation; both on-demand and fixed maintenance practices are not optimal method for de-coking. Model of the coking rate and accumulation inside of the furnace could be a useful tool for scheduling the de-coking. The model includes the balance equations for the heat generated, the heat transfer in forms of convection and radiation, the changes of the temperature and the amount of crude oil and coke, the constitutive equations for the coke formation and accumulation, and the conditional equations for optimization of the de-coking schedule. The model parameters are fitted to the data provided by the refinery in Thailand with absolute average deviation below 3%; the operation and maintenance costs are also estimated from the financial activity report of the similar sources. It is found that with different sources of crude oil, the optimal furnace maintenance schedules are different. The improvements, in term of cost per maintenance, are found to be 15 - 34% depending on the operation scenario. Although, the initial results look promising and the initial goal is accomplished, the application of the model toward multiple crude oil feed for better operation is under development.

Keywords: Modelling, Crude Oil Furnace, Coke Formation, Scheduling, Optimization

1. Introduction

A crude oil distillation unit (CDU) is one of the most critical and important unit in petroleum industry. Its main function is to separate the crude oil into many kinds of petroleum products (Motlaghi et al., 2008). General design of the CDU includes the crude oil preheater, which are either cabin or vertical cylindrical furnace, for adjusting the crude feed properties and increasing the feed temperature (Jegla et al., 2011; Pelini, 2008). The crucial issue found in the furnace is carbon coking, which occurred at the

inner-side of the crude oil tube in the furnace during the preheating process. The carbon coking and coating of the inner tube leads to the coke accumulating, the product quality deteriorating, the pressure drop increasing across the furnace, the energy consumption increasing, and the tube wall carbonization corroding (Jegla et al., 2011). Therefore, occasional de-coking of this furnace is required.

Generally, the de-coking is executed on demand based on the measured heat loss, or performed every fixed period of time (Towfighi et al., 2002). However, due to the different rate of coke formation of various crude oil grades, as well as the difference in cost of product, process operation, and maintenance operation; both on-demand and fixed maintenance practices are not optimal method for de-coking. Modelling of the coke's formation and accumulation rates at the inner tube of the furnace could be a useful tool for optimizing, predicting, and scheduling the de-coking period.

2. Model Development

The model has been developed with the modelling methodology proposed by Cameron and Gani (2011) based on the typical cabin furnace shown in Figure 1A.

2.1. Furnace Model

The furnace increases the temperature of the crude from 231 °C to 362 °C; consisting of 5 natural gas burners at the bottom. The crude is fed into the upper convection section, receiving the heat from the convection and radiation of the combusted gas, and raising the temperature to 288.5 °C. The heated oil is then passed through the bottom radiation section where the radiation directly from the burner flame is the main source of the heat; in this section, the crude temperature is increased to 362 °C.

The models for both convection and radiation sections have been developed similarly as presented in Figure 1B. The system consists of the heat transfer to the crude by convection as displayed in equations 1 - 3. It is worth mentioned that the coke inner

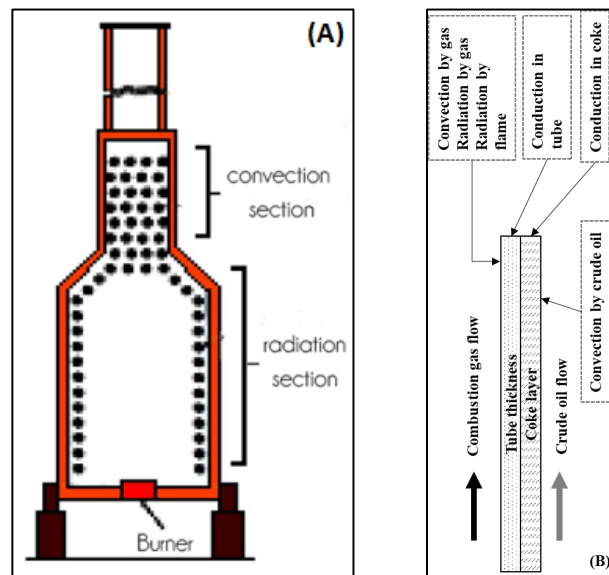

Figure 1. A: typical cabin furnace configuration (KLM Technology Group, 2013) and B: Representation of the radial cut of the system

tube radius ($r_{Co,i}$) is calculated from the amount of coke formed described in the next section.

$$Q_C = m_c c_C^p (T_{C,i} - T_{C,o}) \quad 1$$

$$A_{Co,i} = 2\pi r_{Co,i} L_{Co} \quad 2$$

$$T_{Co,i} = \frac{Q_C}{h_C A_{Co,i}} + T_{C,o} \quad 3$$

The heat transfers through the coke layer and the tube wall by conduction are displayed by equations 4 - 6.

$$T_{w,i,t} = T_{Co,o,t} = \frac{Q_C x_{Co,t}}{k_{Co} A_{w,i}} + T_{C,i} \quad 4$$

$$A_{w,o} = 2\pi r_{w,o} L_w \quad 5$$

$$T_{w,o,t} = \frac{Q_C \Delta x_w}{k_w A_{w,o}} + T_{w,i,t} \quad 6$$

And the outside tube wall heat transfers by the convection from the combusted gas and the radiations from the combusted gas and the flame are described with the equation 7, where the first term is only considered in the radiation section calculation.

$$Q_{r,t} = \frac{\sigma(T_f^4 - T_{w,o,t}^4)}{\frac{1 - \varepsilon_w}{\varepsilon_w A_{w,o}} + \frac{1}{A_f F_{ij}}} + h_g A_{w,o} (T_g - T_{w,o,t}) + \frac{\sigma(T_g^4 - T_{w,o,t}^4)}{\frac{1 - \varepsilon_w}{\varepsilon_w A_{w,o}} + \frac{1}{A_g F_{ij}}} \quad 7$$

As already discussed, the radius of the coke inner tube ($r_{Co,i}$) and the convective length of the coke ($x_{Co,t}$) are changing by time, depending on the amount of the coke formed throughout the operation, which is discussed in the next section.

2.2. Coking Mechanism

From the work of Towfighi et al. (2002), there are 3 mechanisms for coke formation in the furnace: catalytic coking, polyaromatic condensation, and radical coking.

2.2.1. Catalytic coking

Typical furnaces consist of iron, chromium, and nickel which behave catalysts-like; where the hydrocarbon is chemisorbed and react into crystalline filament on the metal surface as shown in Figure 2A.

2.2.2. Polyaromatic condensation

As displayed in Figure 2B, some polynuclear aromatics are produced by trimerization reaction; then these aromatics are dehydrogenated and condensed as tar droplets or soot particles onto the surface of the furnace.

2.2.3. Radical coking

At the interface between the coke and the crude, the unsaturated molecules can react with the remaining free-radical position of the coke, following with the decomposition and dehydrogenation reaction. Thus, resulting in the growing of the aromatic structure and regenerating of the free-radical molecules and sites, as shown in Figure 2C.

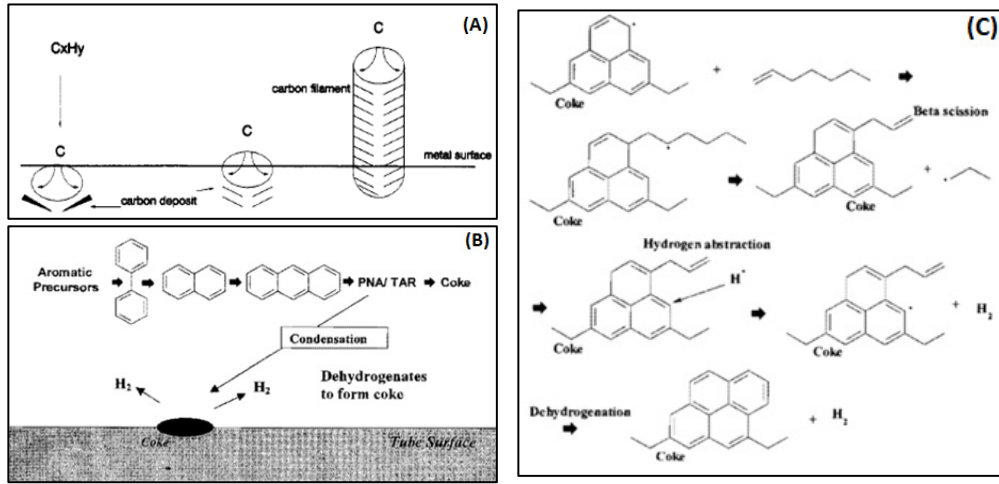

Figure 2. Coking mechanisms (Towfighi et al., 2002)

The rate of the coke formation is described by non-elementary reaction rate law, where the rate constant follows the Arrhenius equation, as displayed in equations 8 - 10.

$$k_{m,n} = Ae^{\frac{-E_{a,m,n}}{RT_{av}}} \quad 8$$

$$r_{m,n} = k_{m,n} C_m^{\alpha_{m,n}} \quad 9$$

$$x_{Co,t} = \frac{r_{m,n} MW_m t V}{\rho_{Co} \cdot A_{tu,i}} \quad 10$$

The composition of the crude is also considered to have an effect to the formation rate of the coke. In this study, the crude is divided by the cut-point temperature into 5 compositions as shown in Table 1.

The compositions of the crude are calculated from equation 11, where the volume average boiling points (VABP) are estimated from Figure 3.

$$VABP = \frac{T_0 + 4T_{50} + T_{100}}{6} \quad 11$$

Table 1. Crude category and their cut-point temperature (Uppaluri, 2010)

Crude Composition Category	Cut-point temperature (K)
Naphtha	Less Than 463.71
Kerosene	463.71 - 552.04
Light Gas Oil (LGO)	552.04 - 594.26
Heavy Gas Oil (HGO)	594.26 - 633.15
Residue	More Than 633.15

Figure 3. Total boiling points by volume of the crude generally used in Thailand (Thai Customs Department, 2016; Uppaluri, 2010)

3. Results

The data for the coke formation and accumulation inside the furnace and the furnace configuration are taken from various researcher (Bayat et al., 2012; Chaibakhsh et al., 2015; Coletti and Macchietto, 2011; Jafari Nasr and Majidi Givi, 2006; Jegla et al., 2011). Figure 4 shows the comparison between the measured data and the model predicted amount of the coke accumulation inside the furnace; the overall absolute average deviation is less than 3% with maximum deviation below 15%.

The regressed parameters are then utilized for the optimization of the crude oil furnace maintenance scheduling. As presented in Figure 5, the cost of natural gas consumed as fuel for the fixed maintenance schedule is undoubtedly highest, since the scheduling maintenance period tend to be longer than the optimum period; while the proposed optimum scheme costed the lowest since it could predict accurately the maintenance period. On the other hand, the expense of the routine maintenance scheduling is the lowest amongst all schemes because there will be no extra “urgent” scheduling involved; however, the optimum scheduling requires not much more maintenance cost

Figure 4. Comparison between the calculated coke amount (line) and the measured coke amount (dotted) inside the furnace tube

Figure 5. Comparison of the involved cost between the different operation scheme

compare to the on-demand scheduling. Moreover, the sum of the operation and maintenance cost of the optimum case is by far lower than the other cases.

4. Conclusion

In this work, the time-dependent lumped model of the coke formation in the furnace of the CDU has been developed. The model parameters have been regressed and validated with the measured data from various sources. The model has been then applied for the optimization of the furnace maintenance scheduling; around 20% of the operating and maintenance cost could be saved with the optimum operation scheme.

Although, the objective of this model development has been achieved; further study on the one or two dimension models and their applications are desired, since they could provide more detailed option for the maintenance and operation.

Microbubbles coalescence during transport in vertical channel flows

K.S. Asiagbe^{*}, M. Fairweather, D.O. Njobuenwu, M. Colombo

School of Chemical and Process Engineering, University of Leeds, Leeds LS2 9JT, UK

**pmksa@leeds.ac.uk*

Abstract

Large eddy simulation coupled to a Lagrangian bubble tracker, previously developed to study two-way coupled turbulent bubbly flows in channels, is extended to cover four-way coupling. The bubble tracker accounts for bubble collisions with a hard-sphere model and bubble coalescence using a film-drainage model. Upward and downward vertical channel flows of water at shear Reynolds numbers of 150 and 590 are examined, with air bubbles of diameter $d_b = 220 \mu\text{m}$ dispersed within the flows. Turbulence is found to significantly impact the level of bubble interaction, increasing the number of collisions and coalescences, but at the same time also increasing the number of collisions that do not result in a coalescence event (coalescence efficiency). The different behaviour of the bubbles, and the impact it has on the turbulence field in the two flow configurations examined, also plays a major role in the coalescence process. The paper demonstrates the capabilities of the overall model for predicting coalescence in bubbly flows, and its ability to model flows of industrial relevance such as enhanced oil recovery, fermentation processes etc, the results from which are also of value in increasing our understanding of such flows

Keywords: Eulerian-Lagrangian, microbubbles, coalescence, turbulent flow

1. Introduction

In many processes that rely on bubbly flows, such as those that use bubble column reactors and mixing equipment, mineral processing, fermentation, and oil and gas transportation and treatment, interfacial transfer is mainly governed by the interfacial area density. This drives exchanges of mass, momentum and energy between the phases and evolves continuously as a function of the bubble size distribution. In turbulent flows, most of the changes that occur within the flow result from bubble collision, coalescence and break-up that follow from interactions between the bubbles and the turbulence field. At present, knowledge of these processes is still limited and no general agreement on a commonly accepted modelling framework has been reached. This study has considerable industrial relevance such as enhanced oil recovery, fermentation processes, mineral processing etc.

In the present paper, a bubble collision and coalescence model is introduced into a Lagrangian bubble tracking routine previously developed to study bubbly flows in channels (Asiagbe et al., 2017). In this routine, individual bubble trajectories are deterministically predicted, differently from in Eulerian-Eulerian methods, where phases are treated as interpenetrating continua and, consequently, the behaviour of individual bubbles, including their position, velocity and the size of each bubble, is not

directly known. In this work the continuous phase flow field is predicted using large eddy simulation (LES), the use of which, when coupled to a Lagrangian bubble tracking routine, is less demanding computationally than studies based on direct numerical simulation. LES is, however, of sufficient accuracy when contrasted with the more commonly used Reynolds-averaged Navier-Stokes approach to allow confidence in using its predictions to understand and reliably predict bubbly flows that are of industrial importance. This is largely because in LES, accurate turbulence field predictions are obtained through full simulation of large scale anisotropic turbulent motions, with only the smaller scale isotropic motions having to be modelled.

In the tracking routine, the bubbles are assumed to be non-deformable and momentum coupled with the fluid, and are treated as pointwise spheres. The overall model is applied to vertical upward and downward channel flows of water at shear Reynolds numbers of 150 and 590. At the beginning of each simulation, air bubbles with $d_b = 220 \mu\text{m}$ are uniformly dispersed in the channel. With the aim of improving current understanding of, and the ability to predict, bubble coalescence, the impact of turbulence, and the different behaviour of bubbles in the two channel flow configurations noted, the rate of collision and coalescence is carefully analysed and discussed.

2. Computational Methods

LES was adopted to compute the continuous phase flow field. In LES, the fluid flow is divided into large scale turbulent motions, which are resolved by the computation, and small, sub-grid scale (SGS) fluctuations by use of a filtering operation. The flow field was calculated by integrating the mass and momentum balance equations, with results made dimensionless using the half-channel height, h , the fluid density, ρ , and the shear velocity, u_τ , defined as the square root of the ratio of shear at the wall, τ_w , to the fluid density. The SGS stress arising from the top-hat filtering operation on the Navier-Stokes equations was modelled using the Germano dynamic model (Germano et al., 1991).

The trajectory of each microbubble was tracked in a Lagrangian framework using the following equation of motion:

$$\frac{d\mathbf{v}}{dt} = \left(1 - \frac{\rho_l}{\rho_b}\right)g + \frac{\mathbf{u} - \mathbf{v}}{\tau_b} C_{SN} + C_L \frac{\rho_l}{\rho_b} [(\mathbf{u} - \mathbf{v}) \times \boldsymbol{\omega}] + \frac{\rho_l}{\rho_b} \frac{D\mathbf{u}}{Dt} + \frac{\rho_l}{2\rho_b} \left(\frac{D\mathbf{u}}{Dt} - \frac{d\mathbf{v}}{dt}\right) + \boldsymbol{\chi}_{sgs} \quad (1)$$

In Eq. (1), the terms on the right-hand side represent the different forces acting on the bubble motion, which are the gravity/buoyancy, drag, shear lift, pressure gradient and added mass forces, respectively. The final term, $\boldsymbol{\chi}_{sgs}$, represents the effect of SGS velocity fluctuations on the bubble motion which was determined using a stochastic Markov model (Bini and Jones, 2008). Subscripts l and b depict the liquid and bubble, respectively. τ_b is the bubble response time, expressed as $\tau_b = \rho_b d_b^2 / 18\mu$, with d_b the bubble diameter and μ the fluid viscosity. C_{SN} and C_L represent the drag and lift coefficients. C_{SN} modifies the Stokesian drag force for large bubble Reynolds numbers (Schiller and Naumann, 1935) and is equal to $(1 + 0.15 \text{Re}_b^{0.687})$. The lift coefficient C_L is a function of the flow Reynolds number and was calculated using the model of Legendre and Magnaudet (1997). The bubble position vector $\mathbf{x}_b = (x_b, y_b, z_b)$ was obtained by further integration of Eq. (1).

Deterministic, inter-bubble collisions were assumed to be binary (Breuer and Alletto, 2012) and modelled using a hard-sphere approach. For modelling the coalescence process, the film drainage theory proposed by Prince and Blanch (1990) was adopted. In the film drainage model, the coalescence process is divided into three steps: (i) two bubbles collide and trap a small amount of liquid between them; (ii) while both bubbles stay in contact, the liquid film drains out to a critical thickness and (iii) ruptures, leading the bubbles to coalesce. Otherwise, the bubbles bounce off one another without coalescing. The constraint for coalescence to occur is that the duration of the contact time of the bubbles must be sufficiently long for the liquid film to drain. For bubble coalescence, the contact time is expressed by $\tau_{ij} = (C_c R_{ij}) u_n^{-1}$, where R_{ij} is the equivalent bubble radius, given by $R_{ij} = 2.0(2/d_{b1} + 2/d_{b2})^{-1}$, u_n is the relative approaching velocity in the normal direction, and C_c is the deformation distance as a fraction of the effective bubble radius; a value of 0.25 gives the best agreement with experimental data (Sommerfeld et al., 2003). The film drainage time is given as $t_{ij} = (R_{ij}^3 \rho_l / 16\sigma)^{0.5} \ln(h_0/h_f)$, with the initial film thickness h_0 for air-water was set to 1.0×10^{-4} m, the final film thickness before rupture h_f was set to 1.0×10^{-8} m, (Prince and Blanch, 1990), and σ is the surface tension. The properties of the new bubble after coalescence were calculated from a mass and momentum balance. During coalescence, the total bubble volume was conserved and the bubble diameter after coalescence obtained from $d_{b,new} = (d_{d1}^3 + d_{d2}^3)^{1/3}$.

3. Computational Conditions

The computational domain employed was a vertical channel with the z , y and x axes in the streamwise, spanwise and wall normal directions, respectively. The dimensions of the computational domain was set to $4\pi h \times 2\pi h \times 2h$ for $Re_\tau = 150$ case, and $2\pi h \times \pi h \times 2h$ for the $Re_\tau = 590$ flow. The grid nodes were uniformly distributed along the y and z axes and non-uniformly in the wall-normal direction, giving a total of $128 \times 128 \times 129$ nodes. Periodic boundary conditions were imposed in the streamwise and spanwise directions, with no-slip boundary conditions enforced at the channel walls for the liquid phase, and elastic collisions assumed between the bubbles and the channel walls.

Air bubbles with diameter $d_b = 220 \mu\text{m}$ and density $\rho_b = 1.3 \text{ kgm}^{-3}$ were injected uniformly into fully-converged single-phase flow solutions at shear Reynolds numbers of $Re_\tau = 150$ and 590, with the liquid phase kinematic viscosity and density set to $\nu = 10^{-6} \text{ m}^2\text{s}^{-1}$ and $\rho = 1000 \text{ kgm}^{-3}$. The bubble volume fraction was $\Phi_v = 10^{-3}$ (corresponding to 226,662 bubbles for the $Re_\tau = 150$ case and 56,647 for the $Re_\tau = 590$ flow), high enough for the microbubbles to affect the continuous phase flow field as well as permitting significant bubble-bubble interactions. Simulations were performed for both upward and downward vertical flow configurations. The total flow time for the bubbles was 30 s for the $Re_\tau = 150$ and 3 s for the $Re_\tau = 590$ flows (corresponding to at least 12 passes through the channel in each case).

4. Results and Discussion

Bubble mean streamwise velocity and normalised concentration predictions from the simulations in the wall-normal direction at both Reynolds numbers, and for upflow and downflow conditions, are shown in Fig. 1. A clear distinction between the upflow and downflow velocity profiles is evident at $Re_\tau=150$. Having a much lower density, the

bubbles move faster than the fluid in upflow and, for the same reason, are slower in downflow. This difference is much smaller in the $Re_\tau=590$ flow as the fluid velocity is much higher. However, the relative velocity between the bubbles and the fluid remains almost constant, being mainly a function of the bubble diameter exerted through the drag force. The bubble concentration at $Re_\tau=150$ is mainly affected by the lift force that pushes the bubbles towards the wall in upflow and away from the wall, and towards the centre of the channel, in downflow. At $Re_\tau=590$ the lift force effect remains dominant but the bubble segregation is greatly reduced because of the enhanced mixing promoted by the higher levels of turbulence.

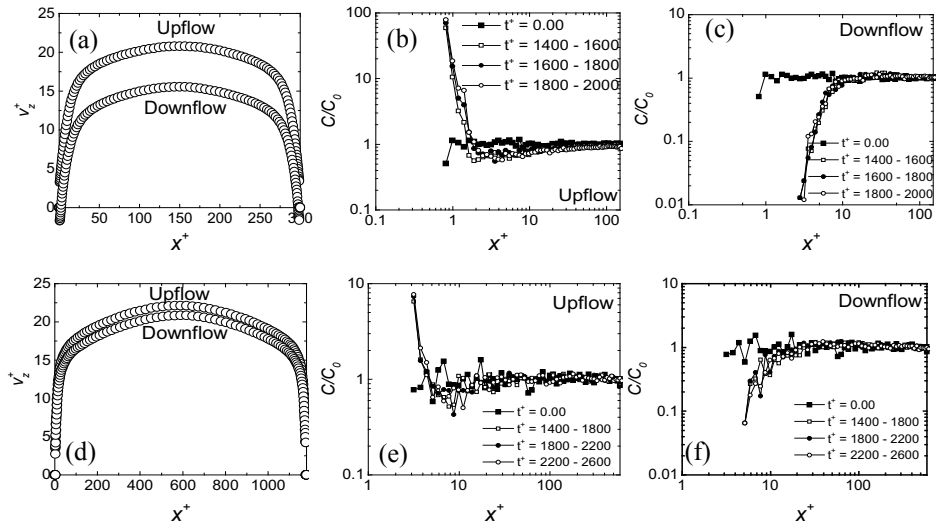

Figure 1. Bubble velocity statistics for four-way coupled vertical channel flows: (a) and (d) bubble mean streamwise velocity profiles; (b), (c), (e) and (f) bubble wall-normal concentration profiles; (a), (b) and (c) $Re_\tau=150$; (d), (e) and (f): $Re_\tau=590$.

Microbubble interactions are considered in Fig. 2, which shows normalised (by the initial number of bubbles) bubble collisions and coalescences, and the formation of larger bubbles, in upflow and downflow, for the two Reynolds number cases. Figure 2(a) and (d) show bubble collisions, whilst (b) and (e) gives coalescence events. Figure 2(c) and (f) shows the distribution of different bubble sizes with time (where (2) signifies a bubble formed from the coalescence of two bubbles of original size $220 \mu\text{m}$ (1), etc.). Note that some bubble sizes have been omitted from the latter plots for clarity, although the formation with time of increasingly larger bubbles is evident. It is immediately clear that, at $Re_\tau=590$, the higher levels of turbulence increase bubble interaction and, consequently, the number of coalescence events. Additionally, the number of multi-sized bubbles formed is higher than for the lower Reynolds number case, with the largest bubbles also forming at the higher Re_τ . However, turbulence also impacts on the bubble contact time, which decreases with the level of turbulence. Therefore, the coalescence efficiency decreases at $Re_\tau=590$, with a significant number of collisions not resulting in coalescence (cf. Fig. 2(a) and 2(b)).

It has been observed that bubbles tend to increase turbulence levels in upflow and decrease them in downflow (Molin et al., 2012), and this was confirmed in the present work. Therefore, the number of collisions is greater in upflow, as well as the number of coalescences. Because of the lower turbulence levels in downflow, the decrease in coalescence efficiency at $Re_\tau = 590$ noted above is limited to the upflow case and is not observed for the downflow.

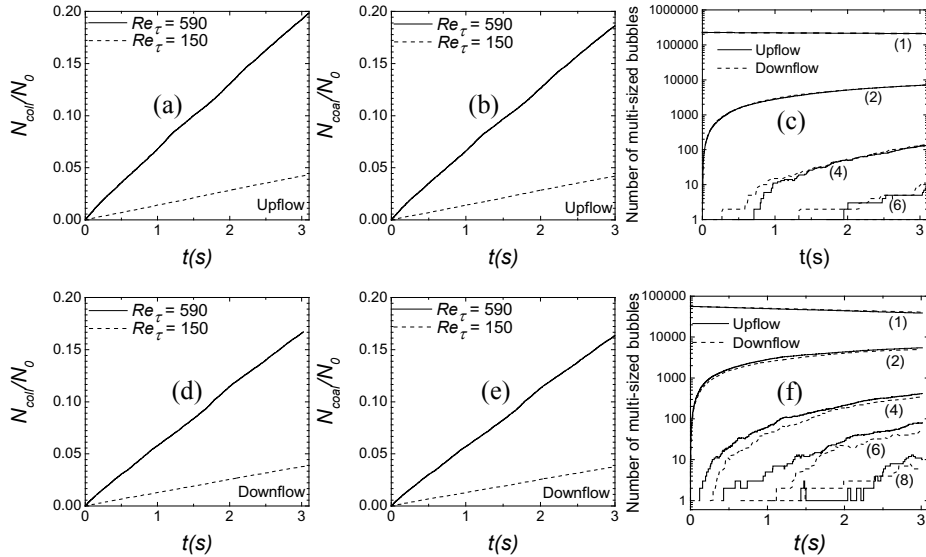

Figure 2. Normalized number of bubble collision, (a) and (d), and coalescence, (b) and (e) events, and bubble size distribution, (c) and (f) with time: (c) $Re_\tau = 150$; (f) $Re_\tau = 590$.

Figure 3. Normalized total number of collisions (a) and coalescences (b), and instantaneous distribution of collisions and coalescences across the channel at $t = 28$ s in upflow (c) and downflow (d), for the $Re_\tau = 150$ flow.

The $Re_\tau = 150$ flow simulation was extended to $t = 30$ s and the results are presented in Fig. 3. These confirm that the greatest number of collisions, and coalescences, is found in the upflow case. At the same time, the coalescence efficiency is reduced because of the higher turbulence level in upflow (Fig. 3(a)). For the latter case, the number of collisions is observed to deviate from a linear trend at around 10-15 s. The spatial distribution of collisions and coalescences in Fig. 3(c) and (d) help to explain this trend. Because of the lift force segregating bubbles near the wall in upflow, a larger number of them are located in regions of high turbulence, resulting in enhanced bubble interaction with respect to the downflow, where the majority of the bubbles are in the lower turbulence central region of the channel. However, although the coalescence rate remains higher, the bubbles experience lower contact times in those regions of high turbulence, and again not all collisions in the upflow case result in coalescence (Fig. 3(a)).

5. Conclusions

Four-way coupled simulations of bubbly flows in channels have been performed using a Lagrangian bubble tracking routine that includes bubble collision and coalescence, coupled to large eddy simulation of the liquid phase. Vertical upward and downward flows of water at shear Reynolds numbers of 150 and 590 were simulated, with air bubbles initially of 220 μm diameter. A greater number of collision and coalescence events occurs at $Re_\tau = 590$ due to enhanced bubble mixing and interaction promoted by high levels of turbulence. For the same reason, the associated lower bubble contact time resulted in a reduced coalescence efficiency than for the lower Reynolds number case. More collisions and coalescences, but at a reduced efficiency of coalescence, occur in upflow than in downflow, due partially to bubbles increasing the turbulence level in upflow but reducing it in downflow. The lift force affects the bubble distribution, pushing bubbles towards the highest turbulence regions near the wall in upflow, whereas in downflow the bubbles are concentrated in lower turbulence regions in the centre of the channel. Overall, the results demonstrate the potential of the overall model for predicting bubble behaviour in these types of flow. Future developments will enable full predictions of bubble size evolution with the introduction a model of bubble break-up.

Abstract

Recently, we developed a new kinetic model for the methanol synthesis from H₂, CO₂ and/or CO using a commercial Cu/ZnO/Al₂O₃ catalyst (Seidel et al., 2017), where different active surface species for CO and CO₂ hydrogenation and dynamic changes of the catalyst morphology were taken into account. This effect is crucial for the description of the dynamic transient behavior. The model is therefore suitable for evaluating new applications in chemical energy storage, where strongly varying feed ratios of CO and CO₂ are possible (Raeuchle et al., 2016). The model parameters were fitted to steady state and dynamic experimental data for varying CO/CO₂ feed ratios (Vollbrecht, 2007) using global optimization. Identifiability was studied using the profile-likelihood method. In the present contribution, the effect of catalyst deactivation observed during the experiments is explicitly taken into account. For that purpose different catalyst activity levels are considered and parameters are refitted to the experimental data to achieve better quantitative prediction. Further, the influence of possible additional side reactions is discussed.

Keywords: renewable resources, methanol synthesis, kinetics, catalyst deactivation

1. Introduction

Methanol is important for the chemical industry. It can be used as a starting material for paraffins, olefins or various organic chemicals like acetic anhydride and as fuel. It is produced continuously in large amounts from synthesis gas using Cu/ZnO/Al₂O₃ catalysts. The reaction network

comprises three main reactions, i.e. hydrogenation of CO and CO₂ as well as the water-gas shift reaction according to Eq. (1)-(3). With the upcoming focus on renewable resources as basis for energy supply, methanol becomes an important energy carrier in addition to its relevance as chemical industrial raw material. Excess wind or solar energy can supply an electrolysis for hydrogen, which reacts with CO/CO₂ to methanol for chemical energy storage. If an energy deficit occurs, methanol can be converted back into electrical energy. This results in a more flexible grid and more efficient usage of renewable resources. In this case the methanol reactor will face strongly varying ratios in the feed, where established kinetics are insufficient (Raeuchle et al.,

2016). These changing requirements were recently summarized by Kalz et al. (2017). In contrast to established kinetics (Bussche and Froment, 1996; Graaf et al., 1988), the proposed novel Langmuir-Hinshelwood kinetic for the methanol synthesis takes dynamic changes of catalyst morphology into account (Seidel et al., 2017). The model is able to reproduce steady state and dynamic data over a large range of CO/CO₂ feed ratios from previous experiments (Vollbrecht, 2007). For long term operation the catalyst deactivation has to be considered. In this paper, two approaches for deactivation are investigated. Furthermore, possible side reactions and their influence on catalyst activity are discussed.

2. Kinetic Model

The recently developed Langmuir-Hinshelwood kinetics describe the reactions Eqs.(1)-(3) with the following rate expressions:

$$r_1 = k_1 p_{\text{CO}} p_{\text{H}_2}^2 \left(1 - \frac{1}{K_{\text{P1}}} \frac{p_{\text{CH}_3\text{OH}}}{p_{\text{CO}} p_{\text{H}_2}^2} \right) \Theta^\ominus \Theta^{\otimes 4} \quad (4)$$

$$r_2 = k_2 p_{\text{CO}_2} p_{\text{H}_2}^2 \left(1 - \frac{1}{K_{\text{P2}}} \frac{p_{\text{CH}_3\text{OH}} p_{\text{H}_2\text{O}}}{p_{\text{CO}_2} p_{\text{H}_2}^3} \right) \Theta^{*2} \Theta^{\otimes 4} \quad (5)$$

$$r_3 = k_3 p_{\text{CO}_2} \left(1 - \frac{1}{K_{\text{P3}}} \frac{p_{\text{CO}} p_{\text{H}_2\text{O}}}{p_{\text{CO}_2} p_{\text{H}_2}} \right) \Theta^* \Theta^\ominus \quad (6)$$

The corresponding relative amounts of free surface centers will be denoted by Θ^\ominus for oxidized centers, Θ^* for reduced centers, and Θ^{\otimes} for hydrogen. Temperature dependence of the rate constants is described by the reformulated Arrhenius equation with six additional parameters ($\beta_1 - \beta_6$ for \tilde{k}_i & \tilde{E}_A) (Vollbrecht, 2007).

$$\Theta^\ominus = \left(1 + \underbrace{K_{\text{CO}} p_{\text{CO}}}_{\beta_{11}} + \underbrace{K_{\text{CH}_3\text{OH}}^\ominus p_{\text{CH}_3\text{OH}}}_{\beta_{12}} + \underbrace{K_{\text{CO}_2}^\ominus p_{\text{CO}_2}}_{\beta_{14}} \right)^{-1} \quad (7)$$

$$\Theta^{\otimes} = \left(1 + \underbrace{\sqrt{K_{\text{H}_2}} \sqrt{p_{\text{H}_2}}}_{\beta_7} \right)^{-1} \quad (8)$$

$$\Theta^* = \left(1 + \underbrace{\frac{K_{\text{H}_2\text{O}} K_{\text{O}}}{K_{\text{H}_2}} \frac{p_{\text{H}_2\text{O}}}{p_{\text{H}_2}}}_{\frac{\beta_{10} \beta_9}{\beta_7^2}} + \underbrace{K_{\text{CO}_2} p_{\text{CO}_2}}_{\beta_{13}} + \underbrace{K_{\text{CH}_3\text{OH}}^* p_{\text{CH}_3\text{OH}}}_{\beta_8} + \underbrace{K_{\text{H}_2\text{O}} p_{\text{H}_2\text{O}}}_{\beta_9} \right)^{-1} \quad (9)$$

The unknown parameters $\beta_1 - \beta_{14}$ were fitted to steady state experiments using global optimization (Seidel et al., 2017). Results are given in Tab. 1. Equilibrium constants $K_{\text{P1}} - K_{\text{P3}}$ are taken from Skrzypek et al. (1994); Vollbrecht (2007).

2.1. Extension to a variable fraction of reduced and oxidized surface centers

A fixed amount of reduced and oxidized surface centers was not able to explain transient effects, as seen in (Choi et al., 2001; Muhler et al., 1994; Nakamura et al., 2003; Peter et al., 2012) after feed changes. Therefore, a conversion of reduced to oxidized and vice versa was considered. Following

the work of Ovesen et al. (1997) the amount of reduced and oxidized centers was reformulated for a variable amount:

$$\tilde{\Theta}^{\ominus} = (1 - \phi) \cdot \Theta^{\ominus} \quad \tilde{\Theta}^* = \phi \cdot \Theta^* \quad (10)$$

where the fraction of reduced centers is denoted as ϕ and under transient conditions described by the following dynamic equation (Seidel et al., 2017):

$$\frac{d\phi}{dt} = k_1^+ \left(y_{\text{H}_2}(1 - \phi) - \frac{1}{K_1} y_{\text{H}_2\text{O}} \phi \right) + k_2^+ \left(y_{\text{CO}}(1 - \phi) - \frac{1}{K_2} y_{\text{CO}_2} \phi \right). \quad (11)$$

The additional rate constants were fitted to transient data (Vollbrecht, 2007). This dynamic equation allows the kinetic model to take the dynamic catalyst morphology changes by oxidation and reduction into account.

3. Catalyst deactivation

The developed Langmuir-Hinshelwood kinetics was fitted to experimental data without considering a deactivation especially due to sintering of the catalyst during the experiments. To account for the impact of possible deactivation, two deactivation models are considered and implemented in Eq.(4)-(6). The parameter estimation was done again for each deactivation model in the same way as in stated in (Seidel et al., 2017).

3.1. Model from experimental data

The first approach was formulated by Vollbrecht (2007) and assumes a deactivation of the catalyst only over time which gives the following equation:

$$a(t) = a_0 \exp(-k_s(t - t_0)) \quad (12)$$

The deactivation constant $k_s = -6.274 \times 10^{-4} \text{h}^{-1}$ is estimated from the decrease of methanol yield under identical experimental conditions at different time points. The steady state results and the corresponding parameters are given in Fig. 2 and Tab. 1.

3.2. Temperature dependent model

This model was formulated by Hanken (1995), it takes the impact of the temperature on the deactivation process into account.

$$\frac{da}{dt} = K_d \exp\left(-\frac{E_D}{R} \left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) a^5 \quad (13)$$

The parameters are given with $T_{ref} = 513 \text{K}$, $E_d = 91 \times 10^3 \text{Jmol}^{-1}$ and $K_d = 4.39 \times 10^{-3} \text{h}^{-1}$. The steady state results and the corresponding parameters are given in Fig. 2 and Tab. 1. The difference over time and experiments between both deactivation models is pictured in Fig 1. The Vollbrecht model assumes a loss of 30% over all experiments and the Hanken model gives a loss of 20%. In both cases the parameter estimation could be done using global optimization strategies (GAMS, 2013; Sahinidis, 2014). As expected the parameter values shift, but stay in the same order of magnitude as without catalyst deactivation. Largest deviations are observed for β_4 , β_{10} and β_{12} . The profile likelihood method was used to investigate the structural identifiability for the parameters in both cases (Raue et al., 2014). It was shown that in both cases catalyst deactivation has no influence on structural identifiability, which is discussed in detail in Seidel et al. (2017).

Figure 1: Activity over time as described by the models of Vollbrecht (2007) and Hanken (1995) at $T = 523 \text{K}$.

Figure 2: Steady state experiments (blue) with deactivation model by Vollbrecht (2007)(red) and deactivation model by Hanken (1995)(black).

4. Additional Side Reactions

During the dynamic experiments of Vollbrecht (2007), small amounts of CO_2 were measured at the output of the reactor for a pure CO/H_2 feed. This formation of CO_2 in the reactor has two possible reasons. The first possibility is the existence of side reactions and the second is a proceeding reduction of the catalyst. Vollbrecht (2007) mentioned various side reactions in his work for a commercial $\text{Cu}/\text{ZnO}/\text{Al}_2\text{O}_3$ catalyst which are listed in Tab. 2. It is obvious that all reactions contain at least one carbon compound which is not part of the methanol synthesis Eq. (1)-(3). However, these products were not detected in the experiments with the applied method (gas chromatography with ion-molecular-reaction mass spectroscopy). For some quantification we refer to Asinger (1986). The last side reaction to consider is the Boudouard reaction. In the experimental investigated temperature and pressure range, the reaction equilibrium lies on the side of carbon dioxide. In this case carbon would stay on the catalyst and would lead to a coking process that decreases the activity of the catalyst. A possible way to examine the influence of the Boudouard reaction is a stoichiometric consistency analysis (Felder and Rousseau, 1986). In a first step, the Boudouard reaction is neglected and the rank of the stoichiometric matrix in Tab. 3 is two. According to Tab. 4 CH_3OH and CO_2 are suitable key components and the reaction rates of all other components are calculated from the measured reaction rates of the key components. Results in Fig. 3 show good agreement between measured and calculated reaction rates of the nonkey components. If the Boudouard reaction is added, the rank of the stoichiometric matrix is 3. Therefore H_2 is added as a suitable third key component. This however, leads to a large differences

Table 2: Possible additional side reactions on a $\text{Cu}/\text{ZnO}/\text{Al}_2\text{O}_3$ catalyst (Asinger, 1986).

Table 1: List of estimated parameters with Vollbrecht model, Hanken model and no deactivation.

Unknown parameter	Estimated Vollbrecht	Estimated Hanken	Estimated no deactivation	Units
β_1	-4.5543	-4.5144	-4.7636	-
β_2	26.7823	26.2079	26.1883	-
β_3	-2.8991	-3.0118	-3.4112	-
β_4	6.0614	5.3356	3.4470	-
β_5	-5.3857	-5.5203	-5.7239	-
β_6	23.2372	22.5643	23.4744	-
β_7	1.2075	1.2446	1.1665	bar ^{-1/2}
β_8	0	0	0	bar ⁻¹
β_9	0.0043	0.0043	0.0297	bar ⁻¹
β_{10}	1.5018×10^4	1.4297×10^4	1.60×10^3	-
β_{11}	0.1284	0.1362	0.1362	bar ⁻¹
β_{12}	0.0514	0.000	0	bar ⁻¹
β_{13}	0	0	0	bar ⁻¹
β_{14}	0.0725	0.06	0.04712	bar ⁻¹

between measured and calculated reaction rates for the nonkey components, also illustrated in Fig. 3, indicating that the network with Boudouard reaction is not consistent with the experimental data. It is therefore conjectured that the measured CO₂ formation for a pure CO/H₂ feed is due to reduction of the catalyst which in the longer term can also result in a reduced catalyst activity.

Table 3: Stoichiometric matrix for standard model and with Boudouard reaction.

Species	r_1	r_2	r_3	$r_{Boudouard}$
CO	-1	0	1	-2
CO ₂	0	-1	-1	1
H ₂	-2	-3	-1	0
CH ₃ OH	1	1	0	0
H ₂ O	0	1	1	0
C	0	0	0	1

Table 4: Element-Species-Matrix for standard model and with Boudouard reaction.

Species	C	O	H
CO	1	1	0
CO ₂	1	2	0
H ₂	0	0	2
CH ₃ OH	1	1	4
H ₂ O	0	1	2
C	1	0	0

5. Conclusion

A kinetic model for methanol synthesis, which considers strongly varying CO/CO₂ feeds was extended with two different models describing catalyst deactivation. This results in a more precise kinetic model and improves the prediction for long term operation. Both accordingly extended models yield similar parameter values with some differences to our previous model without deactivation especially for β_4 , β_{10} and β_{12} . It is further suggested that for a pure CO feed, catalyst activity might also be lowered by catalyst reduction that is caused by CO₂ formation. Hence it is confirmed that a long term operation with pure CO feed is not reasonable. Further, CO₂ formation is caused by side reactions but seems to be small. The developed kinetic model explicitly accounts for dynamic changes of the catalyst morphology but has moderate complexity, therefore it provides a good basis for further studies on reactor dynamics and operation.

Abstract

The Middle East is a hydrocarbon-rich region. Nonetheless, the majority of its natural gas reserves are ultra-sour in nature. Previously these resources were left untapped; but latest technology advances and growing energy security concerns have motivated the exploitation of such resources. Ultra-sour gas processing is particularly very energy intensive and generates noteworthy greenhouse gas (GHG) emissions during its whole lifecycle (e.g., from well-extraction to grid transmission). This study aims to quantify in detail the ultra-sour gas well-to-electricity transmission GHG emissions in terms of per kilowatt hour (kWh) delivered. This is, the GHG emissions involved in delivering one kWh of electricity produced from ultra-sour gas. A mathematical model of a power generation infrastructure was developed in GAMS®; whereas a simulation model for gas transportation and treatment was developed in ProMax®. The two aforementioned models together with engineering principles were employed in the present study. The United Arab Emirates is considered as case study. The results indicate that GHG emissions associated with ultra-sour gas-based power averages 564 g CO₂ eq./kWh delivered. This is over 11% larger than average US conventional gas-based power. Likewise, gas processing and electricity production account for more than 92 % of the lifecycle emissions.

Keywords: Greenhouse Gas, Life cycle assessment, Electricity generation, Optimization, Simulation.

1. Introduction

In most Middle Eastern countries the power generation capacity is dominated by fossil fuels; being gas one of the most important fuels (Betancourt-Torcat and Almansoori, 2015). Although most of these countries possess significant gas reserves, the majority of the untapped reserves are ultra-sour in nature (very high concentration of acid gases). The region features one of the highest electricity consumption rates in the world (Energy Information Administration, 2015). Accordingly, the countries in the region have been forced or plan to develop its unconventionally ultra-sour gas resources.

Although natural gas is commonly regarded as a relatively clean energy feedstock, it still represents a significant focus of greenhouse gas (GHG) emissions. For instance, the United Arab Emirates (UAE) is currently developing nuclear and renewable power capacities to increase the country's energy mix and reduce GHG emissions (Almansoori

and Betancourt-Torcat, 2015). In general, the literature on GHG emissions lifecycle for both ultra-sour gas resources and UAE's electricity sector is very scarce. For instance, the processing of ultra-sour gas featuring H_2S concentrations exceeding 20% is very unique; the first type of such development was recently inaugurated in the UAE in late 2016. Therefore, due to the high concentration of acid gases (particularly H_2S) in the country's gas reserves, and the highly energy-intensive processes employed to sweeten the ultra-sour gas, conducting a lifecycle assessment of the UAE's electricity sector is needed and is novel. To the authors' knowledge the level of detailed accounted in this analysis in terms of the power system, gas processing, and gas transmission simulations for the UAE cannot be found in any other study. Moreover, currently this is the only analysis covering these rarely ultra-sour gas resources.

ProMax® was used to simulate the upstream ultra-sour gas transportation and treatment processes, while an optimization mathematical model developed in the General Algebraic Modeling System (GAMS®) (Almansoori and Betancourt-Torcat, 2015) was used to illustrate the downstream gas combustion at UAE's power plants along with the electricity transmission and distribution. Unlike the inventory method, the proposed modeling-based approach allows conducting uncertainty analyses on key process parameters with major effects on the GHG emissions lifecycle. This is required to understand the environmental impacts of the cradle-to-grave UAE's electricity sector. This work is organized as follows: Section 2 presents the assessment methodology. Section 3 presents a case study of the UAE. Concluding remarks are presented at the end of this work.

2. Methodology

In the present work the lifecycle assessment method was employed to estimate the GHG emissions of ultra-sour gas electricity generation. The employed framework corresponds to those of the International Organization for Standardization (ISO) methodology reported in ISO 14040/44 (International Organization for Standardization, 2006). This study accounts for the GHG emissions associated with CO_2 , CH_4 , N_2O , and SF_6 . The analyzed well-to-transmission (WTT) lifecycle is given as follows: 1) extraction of ultra-sour gas, 2) raw gas collection and transfer to gas treatment facilities, 3) raw gas treatment, 4) sweet gas transfer to power plants, 5) gas combustion at power plants, and 6) electricity transmission and distribution.

The GHG emissions related to gas extraction and electricity transmission and distribution are estimated based on typical values reported in the literature (Skone et al., 2012). Likewise, fugitive and venting emissions for upstream processes are estimated according to guidelines for gas transmission and storage (Interstate Natural Gas Association of America, 2005). Moreover, all energy forms and GHG emissions from gas pipeline transmissions and treatment are calculated using a simulation model built in ProMax® v3.2. Most of the lifecycle GHG emissions are associated with energy consumption during operations. In gas extraction most of the energy is spent in drilling, generating GHG emissions. Also, some episodic natural gas emissions occurred in the well during gas extraction.

Then, the natural gas is sent to surface processing, where it is sweetened, dehydrated, and compressed for pipeline transmission. The ultra-sour gas is treated/sweetened using di-glycol amine (DGA) as solvent. The energy consuming units in this stage are: coolers (cooling water and electricity), reboilers (low and high pressure steam), pumps

(electricity), condensers (cooling water), and compressors (electricity). The wet sweet gas is dehydrated while the acid gases are sent to the sulfur recovery units.

In sulfur recovery, steam is generated contributing to meet part of the steam requirement in gas processing. The units consuming energy in sulfur recovery are condensers (cooling water) and re-heaters (high pressure steam). To estimate the amount of fuel gas required to produce process steam, it is assumed that the gas first combines with air and then combust in a burner. The heat generated is used to boil water and generate high and low pressure steam. The average emission per slandered of fuel gas was found to be approximately 66.7 g CO₂ eq./scf.

Part of the produced dry sweet gas can also be combusted onsite to generate electricity. The electricity requirements for the cooling water loop can be estimated using the cooling water flowrate (\dot{V}). This can be done calculating the power demands in pumps and cooling tower fans. The power for cooling water pumps ($Power_{pump}$) is given as:

$$Power_{pump} = \frac{\dot{V} \Delta P}{\eta} \quad (1)$$

where ΔP is the pressure drop and η is the pump's efficiency. Moreover, the power requirements in tower fans ($Power_{tower}$) can be estimated as:

$$Power_{tower} = \dot{V} (Area) Surface \quad (2)$$

where $Area$ is the tower fan's effective area, and $Surface$ is the fan's surface area.

To estimate the GHG emissions of dry sweet gas transfer from the currently only existing ultra-sour gas processing facility at Al Hosn Gas (Abu Dhabi Gas Development Ltd., 2016) to the different power plants' stations (main five stations) through the pipeline network, it was required to find: the pipeline lengths between the gas processing facilities and the power stations, the number of compression stations, and required compression power. The first compression station is considered to compress the sales gas from 330 psig to 1300 psig; whereas the remaining compression stations compress the gas from 500 to 1300 psig. This study considers the gas compression stations to be powered by the domestic electricity grid.

On the other hand, the GHG emissions of UAE's electricity generation system as well as power transmission and distribution were obtained from a proven GAMS® model (Almansoori and Betancourt-Torcat, 2015). The model is a Mixed Integer Linear Programming (MILP) formulation. The set of decision variables includes: types of power plants, number of power plants, plants' operating capacities, and plants' location. The model takes into account potential structural decisions through discrete (integer) variables to find the most suitable combination of power plants for a geographical area. The power production balance by type of power plant is given as follows:

$$EP_p = IE_p IC_p CF_p, \quad \forall p \quad (3)$$

where EP_p is the quantity of electricity produced by the p^{th} power plant, IE_p is an integer variable that denotes the number of plants p selected for the power structure, whereas IC_p and CF_p are model's parameters denoting the installed capacity and capacity factor

of the p^{th} power plant, respectively. The GHG emissions generated by the power plants can be estimated as:

$$EG_{e,p} = EP_p AEF_{e,p}, \quad \forall e, p \quad (4)$$

where $EG_{e,p}$ is the amount of emission e generated by plant p , and $AEF_{e,p}$ is a parameter representing the air emission e produced by the p^{th} power plant. The total balance of gas consumed (TNG) by the gas-based power plants (g) can be estimated as follows:

$$TNG = \sum_p IE_p NG_p, \quad p = g \quad (5)$$

where NG_p is the amount of natural gas consumed by the gas-based (g) power plants. The model's simulation results show an average gas volume of 7.78 scf of gas/kWh of power delivered, and an average GHG emission of 409.8 g CO₂ eq./kWh delivered. Finally, the average GHG emissions of electricity transmission and distribution were taken from the literature: 3.2 g CO₂ eq./kWh delivered (Skone et al., 2012).

3. Results and Discussion

The United Arab Emirates was taken as Case Study because is pioneering the development of ultra-sour gas facilities where the concentration of H₂S is much higher than that of CO₂. This is a rare characteristic which can only be found in the Middle East region. The natural gas considered in this study corresponds to that of a typical UAE ultra-sour gas reserve. This type of resource accounts for an annual production of 184 billion cubic feet (bcf) of natural gas; which currently represents roughly 20% of the gas consumed by the UAE power sector. The production of ultra-sour gas is expected to increase significantly in the near-to-medium term future. Table 1 shows a typical composition for ultra-sour natural gas produced in the UAE.

Table 1. Typical composition for ultra-sour natural gas in the United Arab Emirates (Abu Dhabi Gas Development Ltd., 2016).

Components	Mole %
H ₂ S	22
CO ₂	10
C1	54
C2	4
C3+	5
H ₂ O	5

ProMax® v3.2 was used to estimate the utilities (e.g., high/low pressure steam, cooling water, and electricity) required in the treatment of ultra-sour natural gas. The processing of ultra-sour gas requires a significant amount of energy (three to four times higher than conventional gas) per unit of sweet gas yield. This is explained by the fact that as the amount of H₂S in the feed gas increases so does the absorption facility utility requirements. This since more acid gases must be removed by the absorber leading to higher recirculating solvent flowrates. Therefore, the power consumed to cool and pump the regenerated solvent back into the absorber, as well as the steam used to regenerate the alkanolamines increases. Both energy forms (i.e., steam and electricity) account for

the majority of the utilities consumed in the absorption plant. Likewise, more sulfur must be processed by the sulfur recovery units. Moreover, the sweet gas product net recovery rate for ultra-sour gas is around 50 % (after internal fuel consumption); which is very low. For example, the net recovery rate for conventional gas resources is typically higher than 80 % in volume. The electricity requirements for the cooling water loop were estimated using Eq. (1)-(2). The GHG emissions values for ultra-sour gas processing are reported in Table 2. The values are given in terms of per standard cubic feet (scf) of net dry sweet gas yield.

Table 2. Greenhouse Gas emissions involved in ultra-sour natural gas processing.

Type of Utility	GHG emissions (g CO ₂ eq./scf)
High Pressure Steam	0.8
Low Pressure Steam	2.8
Electricity	10.8
Overall Energy Consumption	14.4

From the table it can be clearly noticed that around 75 % of the GHG emissions are due to electricity consumption. The WTT GHG emissions life cycle of UAE’s domestic ultra-sour gas electricity generation can be estimated as the summation of the GHG emissions from the six stages. Table 3 displays the single components of the GHG emissions life cycle for electricity produced from ultra-sour natural gas in the UAE. The GHG emissions were calculated using the 100 year global warming potential.

Table 3. Single GHG emissions for domestic ultra-sour electricity generation in the United Arab Emirates.

Type of Utility	GHG emissions (g CO ₂ eq./kWh)
Raw gas extraction	10 ± 7
Raw gas collection and transfer	0.2
Raw gas treatment/processing	112 ± 8
Sweet gas transfer	29 ± 9
Gas combustion – Power plants	409 ± 29
Electricity distribution and transmission	3 ± 1

As shown in Table 3, raw gas processing and electricity generation account for more than 92 % of the total GHG emissions in the life cycle. Figure 1 shows a comparison between the GHG emissions life cycles of ultra-sour gas electricity generation in the UAE and different power generation options in the United States (Skone et al., 2012). As shown in the Figure, the GHG emissions of ultra-sour gas electricity generation in the UAE are approximately 6% and 11% higher than the averages for the United States’ shale gas and conventional gas, respectively. Nevertheless, it is worth pointing out that the GHG emissions corresponding to UAE’s ultra-sour gas electricity generation place in the middle range of global values according to the literature (e.g., 416-730 g CO₂ eq./kWh). This since the majority of the UAE’s current power fleet is composed of gas-fired combined cycle plants; which are comparatively more efficient than other gas-based plants.

Figure 1: Comparison between the GHG emissions lifecycles of ultra-sour gas electricity generation in the UAE and different power options in the United States.

4. Conclusion

The results of the analysis show that UAE's ultra-sour gas electricity generation is more emission intensive than most gas-based power options employed in the United States. This because significant amounts of energy must be consumed during ultra-sour gas processing in addition to the very low sweet gas yield. Also, sour gas processing and electricity production account for over 90 % of the total GHG emissions.

Abstract

Packed beds of monosized spherical particles in cylindrical confined walls are simulated using DigIDEMTM, LIGGGHTS[®] and blenderTM. Parameter studies to characterise the influence of the cylinder-to-particle diameter ratio and the filling speed on mean bed porosity are conducted for all three approaches. It is shown that the results obtained for bed configuration are in agreement with experimental results. A clear trend illustrating the influence of filling speed on mean bed porosity is presented. Moreover, new insights on local packing structure are revealed.

Keywords: random packed beds, bed porosity, filling speed, cylinder-to-particle diameter ratio.

1. Introduction

Packed beds are widely used within the chemical and pharmaceutical industry for numerous applications in all kinds of variations and come in a wide range of sizes. In principle, spherical particles were incorporated to form packed beds generally described as being random. However, the formation of an underlying order in the arrangement of the spheres in the bed, especially when using cylindrical containers, is widely accepted throughout the scientific community. This results in an inhomogeneous void space distribution across the packing. In fixed-bed reactors this leads to uneven velocity distributions, expressed by regions of fast channel flow on the one hand and dead zones on the other hand. As a consequence, problems evoke concerning heat and mass transfer. Further, the particle arrangement affects the mean bed porosity. It can easily be shown by error propagation of the respective correlations that small variations in mean bed porosity influence the pressure drop across the bed by a factor of about four. Since pressure drop is directly related to energy consumption, this is of major importance for industry. It is thus decisive to know the influence of parameters on the degree of order and on the mean bed porosity of packed beds.

The radial porosity profile as a function of the distance from the tube wall serves as a well established tool to describe order effects in packed beds. Experimental data, limited to a small selection of investigated cylinder-to-particle diameter ratios $\frac{D}{d}$ and incorporating different experimental techniques, were for example presented by Giese et al. (1998) and Mueller (2010). Altogether, it is shown that spheres order themselves in concentric rings starting from the tube wall. This is indicated by minima in the radial porosity profile at half sphere diameters and maxima at sphere

diameter multiples from the confining wall. However, this trend is not perfect: firstly, the amplitude of the porosity oscillation decreases with higher wall distance, indicating smaller degrees of order towards the tube centre. Secondly, the extrema are shifted closer to the tube wall than expected as the concentric rings of spheres intertwine and thus reduce the radial positions of the extrema away from integral multiples of half the particle diameter.

Experimental studies were performed concerning the dependency of mean bed porosity $\bar{\epsilon}$ and cylinder-to-particle diameter ratio $\frac{D}{d}$, for example by de Klerk (2003) as well as Benyahia and O'Neill (2005). A fast decrease of the mean bed porosity until reaching a constant value at $\frac{D}{d} > 10$ was generally observed and described by correlations. In this work, Benyahia and O'Neill's correlation for packed beds of spheres as given in Eq. (1) was representatively chosen.

$$\bar{\epsilon} = 0.390 + \frac{1.740}{\left(\frac{D}{d} + 1.140\right)^2} \quad \text{for } 1.5 \leq \frac{D}{d} \leq 50 \quad (1)$$

Further parameters possibly influencing bed porosity include filling procedure, material properties and deviations from the commonly assumed ideal geometrical properties. For example Afandizadeh and Foumeny (2001) investigated the difference between fast and slow filling of spheres into cylinders, resulting in a smaller bed porosity when particles were filled slower. Their findings were verified by Pottbäcker and Hinrichsen (2017).

Here, an attempt is made to characterise the influence of the cylinder-to-particle diameter ratio and the filling speed on the mean bed porosity using three different numerical simulation tools.

2. Methodology

The software packages DigiDEMTM (Caulkin et al. (2009)), LIGGGHTS[®] (Kloss et al. (2012)) and blenderTM (Blender Foundation (2015)) are used to generate packed beds of monosized spherical particles in cylindrical confined walls.

DigiDEMTM is a voxelated particle simulation software incorporating a digital packing algorithm based on the Monte Carlo Approach whilst explicitly considering physical interaction forces similar to the discrete element method (Caulkin et al. (2009)). In particular, DigiDEMTM uses the spring-dashpot contact force model between overlapping voxels. The particles are introduced at a random position along the cylinder cross sectional area at the upper end of the container where the number of particles added at each time step varies based on the available space within the cylinder. Thus a maximum filling speed, similar to experimental pouring, is obtained. The simulation finishes after reaching a set final time which is selected such that the cylinder is completely filled with spheres and the particles are at rest in the resulting bed.

LIGGGHTS[®] is a particle simulation software using the discrete element method. Details on the applied Hertz-Mindlin contact model can be found in Jahani et al. (2015) and Kloss (2016). To investigate the influence of the filling speed, particles are introduced above the cylinder at random positions across the cylinder diameter. The insertion rate is kept constant while the number of particles introduced at each insertion instance is varied. To examine the influence of $\frac{D}{d}$, particles are introduced at grid points in a plane above the cylinder with small random variation of the position about the grid points (cf. Boccardo et al. (2015) filling strategy 3). The number of particles is adjusted such that a square with a maximum number of particles per side fits into the considered cylinder. The total kinetic energy of the system is used as stopping criteria to determine whether the particles are at rest.

blenderTM is a computer graphics software used for animation movies and computer games. Boccardo et al. (2015) were the first to apply this software to the generation of packed beds. Particle deposition in blenderTM is achieved by integrating the Bullet physics library (Coumans (2015)). The simulation loop is based on collision detection and rigid body dynamics components (Coumans (2015); Bender et al. (2014)). After collision detection the contact points are handled and the collisions resolved. The particle velocity is updated and in the subsequent time integration the

Table 1: Parameters used for packing generation.

parameter	DigiDEM TM	LIGGGHTS [®]	blender TM
cylinder-to-particle diameter ratio, $\frac{D}{d}$ (-)	2 - 9	2 - 14	2 - 14
cylinder height-to-particle diameter ratio (-)	30	approx. 30	approx. 30
particle density (kg m^{-3})	3000	4000	4000

coefficient of restitution (-)	0.7	0.7	0.7
coefficient of friction (-)	0.3	0.3	0.3

resulting new particle position evaluated. Particles are positioned above the cylinder as single particles, a pair of particles, in triangle, rhombic and cross arrangement, as squares of 3x3 and 4x4 as well as in a honeycomb structure to investigate the influence of the filling speed. For simulations concerning $\frac{D}{d}$, particles are introduced at random positions across the cylinder diameter one at a time with minimal time between two insertions. The simulation times are chosen such that the particles are at rest in the resulting bed.

Geometry and material settings used for the packing generation simulations are provided in Tab. 1. Parameter studies to characterise the influence of the filling method and the cylinder-to-particle diameter ratio are conducted for the three approaches and compared to literature.

3. Results and Discussion

First, the obtained packed bed structures of all three simulation approaches are compared to experimental data. Two packed beds with $\frac{D}{d} = 8$ and $\frac{D}{d} = 5.6$ are selected as there is experimental data available by Mueller (2010) to characterise the packing structure.

In Fig. 1 (a) and (b) scatter plots of the sphere centre positions are depicted accordingly. Fig. 1 (a) compares the simulated results from all three applied software packages with experimental data, showing the results in the four quarters respectively. It can be seen that the outermost ring is almost perfect, whereas the order of the packing is decreasing towards the centre. Nonetheless, four complete rings with a stack of single spheres in the centre are visible. In case of $\frac{D}{d} = 5.6$, shown in subfigure (b), the positioning in rings is more pronounced as compared to the packing with $\frac{D}{d} = 8$. Small deviations between the software packages can be seen, where the second ring from the wall appears to be least ordered for the results obtained with LIGGGHTS[®].

These observations are reflected in the corresponding radial porosity profiles displayed in subfigures (c) and (d). Overall, for the packed bed with $\frac{D}{d} = 8$ (subfigure (c)) a perfect agreement of all three simulations and the experimental data from literature could be obtained. As expected, the first minimum in the radial porosity profiles appears at an exact position of half a sphere diameter from the containing cylindrical wall and the first maximum at a distance from the wall of one particle diameter. In addition, the amplitude of the porosity oscillations decreases towards the centre of the packing. In contrast to this, subfigure (d) depicting the bed with $\frac{D}{d} = 5.6$ shows generally less but still good agreement between simulated and experimental results. The radial porosity profiles of the simulated packings show less damping as compared to the experimental data. This deviation is especially distinct close to the cylinder centre. As opposed to the other two software packages, the results obtained with LIGGGHTS[®] are extraordinary close to the experimental data at the outermost one and a half particle diameters from the wall. Further into the bed, the LIGGGHTS[®] profile strongly approaches the other two simulated curves. The first minimum and maximum are once more at the expected positions whereas there is a perceptible shift in position of the following extrema between experimental and simulated data. Especially the last minimum is shifted away from the centre for the simulated results as compared to the experimental data. Consequently, a duct at the centre of the cylinder can be observed in the simulated data which is considerably more pronounced as compared to the experimental data.

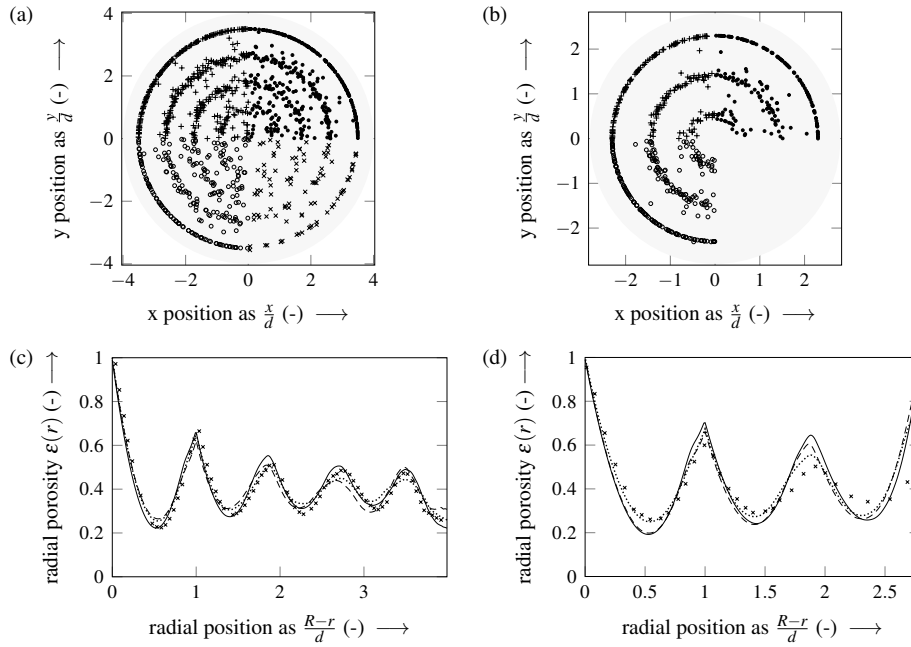

Figure 1: Scatter plots of sphere centre points and radial porosity profiles for beds with $\frac{D}{d} = 8$ (a,c) and $\frac{D}{d} = 5.6$ (b,d), simulated with DigiDEMTM (+ and —), LIGGGHTS[®] (• and), and blenderTM (◦ and ---); experimental data by Mueller (2010) for $\frac{D}{d} = 8$ (×).

Comparing the position of the minima corresponding to the third ring of spheres from the wall for both diameter ratios shown reveals different degrees of shifting. In case of $\frac{D}{d} = 8$ the minimum of the third ring is at a radial position of $2.25 \cdot d$ whereas for the packed bed with $\frac{D}{d} = 5.6$ the corresponding value is about $2.3 \cdot d$ for the simulated and $2.4 \cdot d$ for the experimental data. The positions of these extrema would be $2.5 \cdot d$ in an ideal packing, but due to intertwining rings of spheres the extrema positions are shifted towards the confining wall. This occurring deviation in the positions of the minima is worth being investigated further.

In Fig. 2 results showing the influence of $\frac{D}{d}$ on the mean bed porosity are provided for all three simulation approaches and compared to the correlation by Benyahia and O'Neill (2005). A good agreement between the simulated results and the correlation is presented. The data points obtained by simulation of beds with $\frac{D}{d} = 2$ are in perfect agreement with the correlation as well as an analytical solution presented by Govindarao et al. (1992). The following group of values from $\frac{D}{d} = 2.2$ to 2.8 are very similar for all numerically obtained data and close to the correlation. For $\frac{D}{d} = 3$ an apparent minimum can be identified for all three simulation approaches. This refers to a very dense packing based on one concentric ring at the wall with a stack of spheres in the centre of the cylinder. The experimental data by de Klerk (2003) shows a similar minimum. In the following, the data depicted in subfigures (a) and (b), representing DigiDEMTM and LIGGGHTS[®] respectively, show similar courses close to the correlation with values slightly above the predicted. The data obtained by simulation with blenderTM, presented in subfigure (c), shows a considerably steeper initial slope. As a result, the mean bed porosity is significantly below the other simulation results and the correlation from $\frac{D}{d} = 3$ and beyond, whereby an earlier but faster levelling off is observed. Altogether, the results obtained with blenderTM are slightly below the correlation.

Experimental studies by Afandizadeh and Fomeny (2001) and Pottbäcker and Hinrichsen (2017)

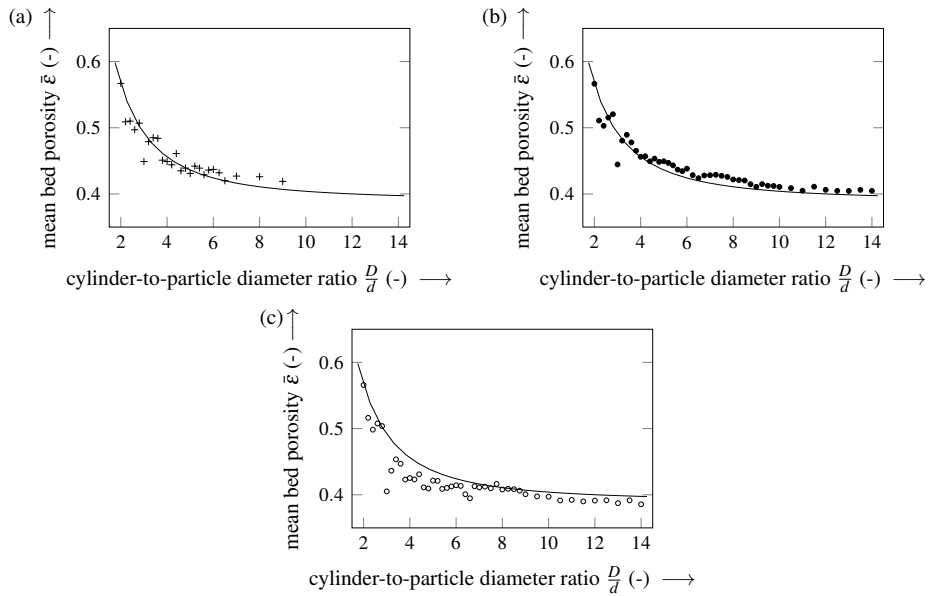

Figure 2: Mean bed porosity as a function of $\frac{D}{d}$, simulated with (a) DigiDEMTM (b) LIGGGHTS[®] and (c) blenderTM, compared to correlation of Benyahia and O'Neill (2005).

indicate an influence of the filling speed with a significantly lower mean bed porosity for slow filling as compared to poured beds, where the difference in both procedures is the amount of particles filled to a container within a given time. Here, the influence of filling speed, expressed as number of spheres per insertion layer, on the mean bed porosity of packed beds with $\frac{D}{d} = 6.25$ is simulated with LIGGGHTS[®] and blenderTM as presented in Fig. 3. It is apparent from both subfigures that the simulated bed porosities increase with filling speed, which is in line with the expected trend. For comparison, experimental bed porosity values are provided for poured beds, beds obtained by single particle dropping and subsequently densified beds (Pottbäcker and Hinrichsen (2017)). It would have been expected that at high filling speeds the porosity values should approach the experimental results for poured beds whereas at low filling speeds porosities close to single dropping should be obtained. Despite trying to establish comparable settings for the different simulation approaches, LIGGGHTS[®] overestimates whereas blenderTM underestimates the bed porosity at fast filling conditions.

Figure 3: Mean bed porosity as a function of filling speed for beds with $\frac{D}{d} = 6.25$, simulated with (a) LIGGGHTS[®] and (b) blenderTM; experimental porosities for loose (---), dense (.....) and densified (-.-.-) beds shown for comparison (Pottbäcker and Hinrichsen (2017)).

4. Conclusions

All three applied software packages, although being based on different numerical methods, are well suitable to generate random packed beds of spheres. The results match the trends known from experimental studies. However, small differences in the obtained results are identified. Further, it could be shown that mean bed porosities simulated with DigiDEMTM and LIGGGHTS[®] are well in accordance with the experimental correlation of Benyahia and O'Neill (2005) for a wide range of $\frac{D}{d}$. Adequate consistency can be obtained using blenderTM, whereby slight deviations are balanced by considerably faster simulation times. Hence, blenderTM may be the tool of choice for initial assessments. A clear trend concerning the influence of filling speed on mean bed porosity was revealed. As a consequence, the filling speed could be utilised to adjust the bed porosity and thus for example the pressure drop of a packing. Moreover, the remarkable spread in the obtained mean bed porosities when varying the filling speed indicates that more care should be taken when designing numerical packed bed simulation set-ups as small changes may result in significant porosity deviations. This should be kept in mind when drawing conclusions from numerical simulations for technical applications.

Superimposing both influences of cylinder-to-particle diameter ratio and filling speed on the bed porosity as well as the influence of material properties are currently under investigation.

Abstract

The importance of accurate thermodynamic models, capable of describing vapor-liquid and liquid-liquid equilibria, is generally acknowledged for the design of chemical processes. However, the parameterization of thermodynamic models and the development of chemical processes are usually treated as two different disciplines. More importantly, the objectives of each discipline do not necessarily align. While the quality of a thermodynamic model is often judged purely on the basis of its average mean deviation from experimental data, process design aims at minimizing the overall process costs, assuming that the underlying thermodynamic models (especially model parameters) are reliable/accurate. Assessing the uncertainty of the thermodynamic model parameters is the link between both disciplines. However, this link is rarely established, and even the effect of the consideration of uncertainties in parameter regression by means of a deterministic process design is rarely investigated. Within this work this effect was taken into account for vapor-liquid equilibrium modeling and optimal design of a distillation column. The results indicate the necessity of a consistent consideration of uncertainties both during parameter regression and process optimization. Furthermore, the results highlight that a special treatment of experimental data and uncertainty information is required for specific applications (e.g. distillation of tangent pinch systems) in order to obtain reliable results in process design.

Keywords: Thermodynamic equilibria, Parameter regression, Optimization, Distillation

1. Introduction

Thermodynamic data is required for a wide variety of applications in the chemical industry including the development, design, planning, and operation of processes. Especially phase equilibrium modeling is one of the most important fundamental sciences for process development in the chemical industry (Zeck & Wolf, 1993). It provides the basis for a model-based evaluation of a variety of separation processes, such as e.g. distillation and liquid-liquid extraction, and enables the evaluation of individual process concepts by means of flowsheet simulations. The availability of accurate thermodynamic models and corresponding parameters for a wide range of chemicals are the foundation of today's accelerated process development by means of process simulators. This circumvents a good number of previously required time consuming and expensive experiments. A famous quote of Roger Sargent states that

“design methods have been developed to such a point that any plant design can be carried through with confidence, provided the requisite basic data is available.” (Doherty et al., 2016). Today, this optimistic statement of Sargent is for sure more realistic than 60 years ago. However, the necessary confidence and even more a quantification of the level of confidence is still a challenge. One possibility to deal with uncertainty related to this basic data is to perform a robust process design. Thereby, the process specifications will be met for all probable variations of the property parameters considering a quantification of their uncertainty. Interestingly, Sargent was also one of the pioneers in the area of process design under uncertainty and specifically robust optimization approaches, more than 20 years after his previously quoted statement (Grossmann & Sargent, 1978). Today, in order to deal with uncertainty related to thermodynamic property models, methods like robust optimization or two-stage stochastic optimization become increasingly popular (Steimel & Engell, 2016). Nevertheless, these methods are not the state-of-the-art in application and uncertainty is almost always estimated, instead of properly propagated from the experimental data through parameter regression. One potential reason for this is the missing information on uncertainties (or their quantification) in published experimental data. This was recently documented by the results of the working party on thermodynamics and transport properties of the EFCE, which evaluated information from 28 chemical engineering companies (Hendriks et al., 2010). They specifically pointed out that quality is more important than quantity. An essential step in quantifying this quality by a regular reporting of uncertainties in thermochemical experimental data was established by the National Institute of Standards and Technology (NIST) through the concept of dynamic data evaluation more than 10 years ago (Frenkel et al., 2005).

In order to motivate the necessity of a consistent consideration of uncertainties, this work presents an investigation of the effect of different uncertainty considerations in parameter regression on a deterministic process design of distillation processes. Therefore, different objective functions for the parameter regression are taken into account, followed by an optimization-based process design for different product specifications. Various systems with different degrees of non-ideality are considered. It is shown that significant deviations in process design may occur from marginal deviations in equilibrium modeling: These can be caused by minor modifications of the parameter regression, especially the way uncertainties are considered. The results mandate a stronger integration between the disciplines of thermodynamics, fluid separations and process systems engineering in order to consider the effect of uncertain experimental data on process design already at the level of thermodynamic modelling.

2. Methodology

The methodology that is applied in the current study is illustrated in Figure 1. At first adequate experimental data, including reported uncertainty information is selected. Next, the parameters of a thermodynamic model for the free enthalpy (G^E -model), in this case the non-random two liquid (NRTL) model are regressed against the experimental data, using selected objective functions. Finally, an economic process optimization of a distillation column for different product specifications is performed.

2.1. Data acquisition

For the subsequent evaluation suitable vapor-liquid equilibrium (VLE) datasets with uncertainty information need to be selected from the NIST TDE as a first step.

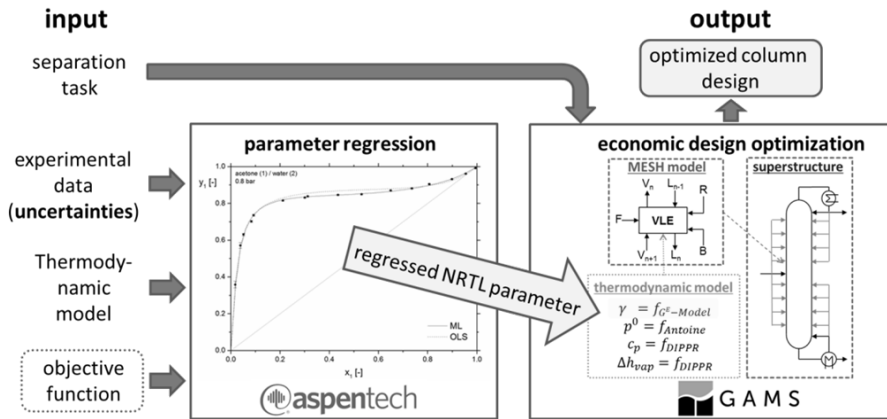

Figure 1: Illustration of the applied method for evaluating the effect of uncertainty consideration in parameter regression on the final process design.

Only datasets that contain a sufficient amount of data points, with full information on pressure, temperature, both compositions, as well as information on standard deviations for each measurement were considered. Although the NIST TDE provides a significant number of binary VLE datasets, yet, only a limited subset satisfies these constraints. Unfortunately, mostly default values for standard deviations are considered. These relative values are based on literature estimates and assume e.g. an error estimate of 1% for the vapor mole fraction (Sandler, op. 2015). The effect of these default values is briefly addressed in the subsequent subsection.

2.2. Parameter regression

While a proper choice of the thermodynamic model is important, even for the best available model the effect of uncertainties in the experimental data can result in significant uncertainties in the model parameters (upon regression based on these data) and a subsequent process design (Xin & Whiting, 2000). As one of the industrially most applied G^E models, the NRTL model is selected and the a_i and b_i parameters (Aspen nomenclature) are regressed to the selected VLE datasets. The NRTL c parameter is fixed according to the suggestions in ASPEN Plus® (Schefflan, 2017). Parameter regression is performed by means of the available regression methods in ASPEN Properties. In order to evaluate the effect of considering the uncertainty information, different objective functions are considered.

The statistically most reliable parameter estimates are obtained by means of a maximum likelihood estimation (MLE). Assuming that all measurements are independent of each other and that the measurement noise follows a Gaussian distribution with zero mean, the MLE can be obtained by a weighted least squares minimization, for which the weights are equivalent to the standard deviation of the measurement (Beck & Arnold, op. 1977). In ASPEN Plus® the MLE considers all compositions, the temperature and the pressure:

$$\min \sum_{i=1}^{N_{dp}} \left[\left(\frac{p_i^{est} - p_i^{exp}}{\sigma_{p,i}} \right)^2 + \left(\frac{T_i^{est} - T_i^{exp}}{\sigma_{T,i}} \right)^2 + \sum_{j=1}^{N_c-1} \left(\frac{x_{i,j}^{est} - x_{i,j}^{exp}}{\sigma_{x,i,j}} \right)^2 + \sum_{j=1}^{N_c-1} \left(\frac{y_{i,j}^{est} - y_{i,j}^{exp}}{\sigma_{y,i,j}} \right)^2 \right] \quad (1)$$

Since, the standard deviation of the liquid phase composition is usually zero, this term is often not considered. In case all standard deviations are equal, the method simplifies to the so called ordinary least squares (OLS) minimization (Beck & Arnold, op. 1977). Among others, *OLS* is also a possible objective function in ASPEN Plus® (Schefflan, 2017). However, this option presents a weighted least squares minimization that takes into account the reported standard deviation for the temperature and a relative error of 1% for the vapor composition:

$$\min \sum_{i=1}^{N_{dp}} \left[\left(\frac{T_i^{est} - T_i^{exp}}{\sigma_{T,i}} \right)^2 + \sum_{j=1}^{N_c-1} \left(\frac{y_{i,j}^{est} - y_{i,j}^{exp}}{0.01 \cdot y_{i,j}^{exp}} \right)^2 \right] \quad (2)$$

It therefore does not comply with the textbook definition of OLS and is rather equivalent to the MLE without the pressure and liquid composition, and default relative deviation for the vapor composition. Thus, a comparison between results obtained by both objective functions allows for an evaluation of the effect of considering reported uncertainty information for the vapor phase or a default estimate of a relative 1% error. The latter is not an accurate estimate of the variance of the measurement, but it introduces strong bias to measurements at small compositions, such that measurements close to pure components are fitted more accurately to the measurement value.

2.3. Rigorous economic optimization of a distillation column

The regressed parameters are further evaluated in a rigorous economic optimization of a separation by means of a distillation column for different separation tasks. Therefore, a superstructure optimization based on an equilibrium tray model, including sizing and costing correlations is performed in GAMS. Refer to the article of (Skiborowski *et al.*, 2015) for a detailed description of the models and the applied optimization approach. In the optimization the determined parameters are considered as deterministic values, while the process design is determined by minimizing the total annualized costs (TAC).

3. Results

Within this work three close-boiling, four azeotropic, and five tangent pinch systems were investigated. After parameter regression (Aspen properties) the NRTL was used as thermodynamic model within process optimization (GAMS), considering different product specifications (taking into account an equimolar saturated liquid feed mixture of 10 mol/s). Product specifications with high purities of 99 – 99.9 mol% were assumed for the close boiling and tangent pinch systems, while the product specifications for azeotropic systems were adapted to the azeotropic composition.

Table 1: Results of the parameter regression for both objective functions for selected systems.

System	BVLE [Nr]	p [bar]	T - AAD%		K ₁ - AAD%		K ₂ - AAD%	
			MLE	OLS	MLE	OLS	MLE	OLS
1: isopropanol/water	120	1.013	0.04	0.20	1.3	0.9	1.8	1.3
2: acetone/water	120	0.8	0.60	1.60	0.8	1.5	6.3	9.4
3: methanol/nitromethane	006	1.013	0.45	0.45	1.4	2.0	3.1	3.0
4: acetone/water	122	1.013	0.39	0.42	3.8	3.5	4.8	5.6
5: n-propanol/n-butyl acetate	003	1.013	0.05	0.65	2.0	1.3	7.5	2.1
6: acetonitrile/p-xylene	001	1.013	0.37	0.76	3.6	3.2	6.0	5.1

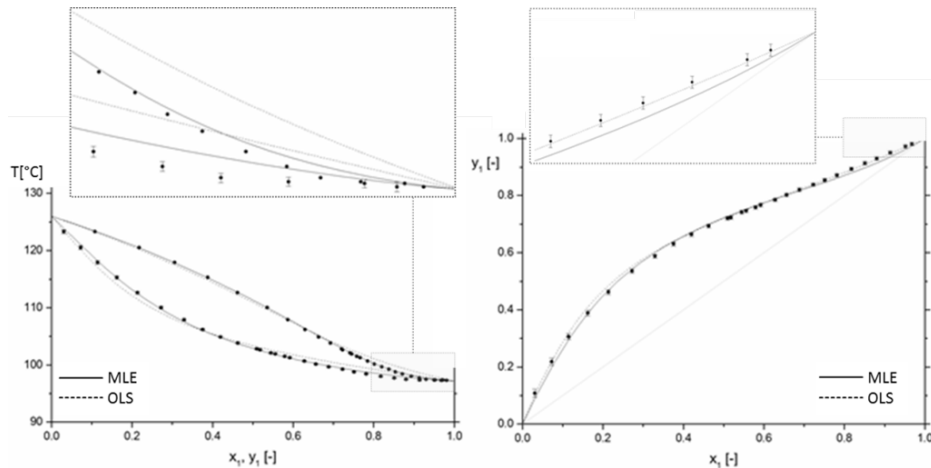

Figure 2: Illustration of the fit of the VLE model prediction according to the MLE and OLS objective function, for the binary the n-propanol/n-butyl acetate system.

In general, the results of the parameter regression in terms of the average absolute deviation (AAD%) are comparable for both objective functions. This is illustrated for a selection of the considered systems and the AAD% values for the temperature and the distribution coefficients (K) of both components in Table 1. Additionally, the specific dataset for the binary VLE data (BVLE) in the NIST TDE and the pressure are given. The subsystems selected are either azeotropic or tangent pinch systems, which show the comparably largest deviations in the subsequent process design results. The regression results for all narrow boiling systems show an excellent “goodness of fit” and are hardly distinguishable for both objective functions. This applies also for the selected subsystems with respect to the AAD% values, as well as corresponding T-xy and x-y diagrams. Deviations between the resulting VLE predictions and experimental data become apparent upon close up investigations. Especially in case of the tangent pinch systems the parameters fitted in accordance with the MLE objective function provide a better fit to the temperature and the T-xy diagram, while the OLS provides smaller deviations in terms of the K -values and accordingly the yx-diagram. This is illustrated for the n-propanol/n-butyl acetate system in Figure 2, which represents one of the largest visible deviations between the fits using the two objective functions.

While the deviations in VLE modeling are close to negligible, the differences in the resulting process designs can be substantial. Figure 3 illustrates the deviations between the resulting process designs in terms of relative deviations of the TAC. The small deviation in the VLE prediction for the n-propanol/n-butyl acetate systems results in a deviation in the subsequent process design that exceeds a factor of two in TAC for the highest product purity specifications of 99.9 mol%. Taking into account the deviation between the OLS and MLE fit for the yx-diagram in Figure 2 it can be suspected that the MLE results in a severe overdesign of the column, since the VLE equilibrium line of the model runs closer to the 45° degree line as indicated by the experimental data. However, there is no clear trend, as the differences in terms of TAC of an optimized design can go both ways. Nevertheless the trend towards higher deviations for higher purities is the same for all tangent pinch systems (4-6), whilst for the azeotropic systems one of the designs becomes infeasible (Inf) due to small differences in the azeotropic composition. Consequently, the differences in these cases are also significant.

Figure 3: Resulting deviations in the TAC of the optimized process design for different product specifications for each of the listed binary systems (cf. Table 1).

4. Conclusion and Outlook

The results of this work highlight the importance of the choice of the objective function and the way uncertainties are considered in parameter regression. It is illustrated that severe differences in the subsequent process design can even result from minor deviations in the consideration of uncertainties (taking into account reported standard deviations or a default relative deviations). Especially small deviations in very narrow boiling regions of systems with non-constant relative volatility, such as azeotropic or tangent-pinch systems are of superior importance for the design of distillation processes. Thus, these regions have to be described with extreme accuracy in order to avoid process misdesign. Future work needs to evaluate if process design under uncertainty can avoid such misdesign without severely conservative overdesign.

Abstract

Microgels based on poly(*N*-isopropylacrylamide)- and poly(*N*-vinylcaprolactam) can be synthesized by precipitation polymerization. To get a better insight into the kinetics of the microgel synthesis, a model-based approach is pursued. Herein, the approach proposed by Janssen et al. (2017) is extended to the terpolymerization system. The kinetic model for a two-phase terpolymerization is combined with parameter values from quantum mechanical calculations. The remaining unknown parameter values are estimated from experimental data using reaction calorimetry and Raman spectroscopy. Acceptable agreement of simulation and experimental measurements is obtained. The prediction of the gel phase growth is combined with the consumption of comonomers and the cross-linker *N,N'*-methylenebis(acrylamide) to predict the average distribution of comonomers, thus giving insight into the microgel structure. The resulting particle structures indicate uniform *N*-vinylcaprolactam and *N*-isopropylacrylamide compositions in the core and an outer layer with a high *N*-vinylcaprolactam fraction, while the cross-linker distribution decreases from core to shell.

Keywords: Method of moments, kinetic modeling, microgels, polymerization

1. Introduction

Precipitation polymerization is a commonly used method to synthesize poly(*N*-vinylcaprolactam) (pVCL)- and poly(*N*-isopropylacrylamide) (pNIPAM)-based microgels and copolymer microgels thereof (Pich and Richtering (2011)). Monomers and the cross-linker *N,N'*-methylenebis(acrylamide) (BIS) are initially dissolved in water. The thermal initiator 2,2'-azobis(2-methylpropionamide) dihydrochloride (AMPA) initiates the free radical polymerization. Due to low solubility of the growing polymer chains in water, the radicals precipitate to form small precursor particles. The particles continue to grow by both, aggregation as well as ongoing polymerization. Propagation of growing radicals with the pendant double bonds (PDB) of cross-linker lead to the formation of stable microgel particles.

In batch polymerization, the distribution of comonomers and cross-linker within the microgels is determined by the reaction kinetics. Balaceanu et al. (2013) reported for microgels from pVCL and pNIPAM uniform internal structures, although NIPAM is the more reactive monomer. Model-based approaches can help understanding the driving forces of the microgel synthesis and give

insight into their internal composition. Hoare and McLean (2006a) predict the local distribution of functional groups in pNIPAM-based microgels from reaction rate constants in a solution polymerization model. Further, they propose an approach for controlling the local polymer composition in multi-component systems (Hoare and McLean (2006b)). However, solution polymerization models simplify the system as they neglect any mass transfer mechanisms between the phases. The preferential accumulation of one monomer in the gel phase can equally cause an inhomogeneous copolymer composition. To elucidate the underlying phenomena causing the particle structures, models should address the distinction of the two-phase system and mass transfer mechanisms.

Precipitation polymerization models, such as proposed by Arosio et al. (2011) for a different polymer system, focus on the impact of mass transfer among the phases and predict the reaction locus. In Janssen et al. (2017) we propose a precipitation polymerization model for pVCL-based microgels. Thereby, the gel phase is determined to be the primary reaction locus due to a short critical chain length and an accumulation of monomer and cross-linker in the gel phase. Different cross-propagation reaction rates for VCL and BIS (Kröger et al. (2017)) cause an inhomogeneous cross-linker distribution in the particles.

In this contribution, we adapt our approach (Janssen et al. (2017)) to the terpolymerization precipitation of VCL, NIPAM and BIS. The model is fitted to previously published and new experimental data and applied for a rough prediction of the particles internal structure.

2. Modeling of Precipitation Terpolymerization

In Janssen et al. (2017) we describe the synthesis of pVCL-based microgel by precipitation copolymerization model with two phases. Mass balances for all reaction species are formulated, whereas the primary chains of polymers are balanced applying the terminal model and the method of moments. Mass transfer between the phases is described for small molecules by phase equilibrium with distribution coefficients D and for polymer by precipitation of the radicals at a finite critical chain length η . The key feature of this approach is that the high number of unknown parameter values is reduced by the use of reaction rate constants and distribution coefficients calculated from transition state theory and COSMO-RS. In this contribution, we apply this approach to a model for the terpolymerization of VCL (1) and NIPAM (2) with the cross-linker BIS (3).

Few alterations are applied to the model in order to reduce the number of parameter values to be estimated and decrease the model complexity without loss of information. These alterations are: 1.) Constant initiator efficiencies $f_i = 0.6$ in liquid and gel phase, which is a mean efficiency for azo-initiators. 2.) Cross-linking in the liquid phase is neglected ($f_{\text{pdb}}^l = 0$) while in the gel phase, cross-linking reactions are assumed to be equally limited by the formation of the polymer network, resulting in one cross-linking efficiency factor f_{pdb}^g . 3.) Termination rate constants k_t^g in the gel phase represent the apparent rate constants which account for diffusion limitation (k_{diff}^g). They are linked to the termination rate constants of the liquid phase by $k_t^g = (k_t^l k_{\text{diff}}^g) / (k_t^l + k_{\text{diff}}^g)$ (Buback et al. (1992)). 4.) The gel phase volume, V^g , is calculated from the pure polymer densities ρ and 50 w% water. The volume of the liquid phase, V^l follows from $V^{\text{tot}} = \text{const} = V^l + V^g$. 5.) The liquid phase serves as initiation phase, due to a small critical chain length and $D > 1$. To calculate the mass flow by precipitation, first the pseudo-homopolymerization approach (Storti et al. (1989)) and then the quasi-steady state assumption (QSSA) for radicals are applied. Thus, the $n_C(\eta - 1)$ differential equations for n_C comonomers are replaced by $n_C + 1$ algebraic equations.

Quantum mechanical calculations (QMC): The chain propagation rate constants k_p with the corresponding reaction enthalpies ΔH_R are calculated by transition state theory depending on the composition of both phases: For the liquid phase infinite dilution and for the gel phase a composition of 50 w% polymer and 50 w% water is assumed. The corresponding parameter values are used as listed in Kröger et al. (2017) and Janssen et al. (2017). VCL and NIPAM cross-propagation

rate constants are calculated accordingly for the liquid phase ($k_{p12}^l = 47.3 \text{ m}^3(\text{mol s})^{-1}$, $k_{p21}^l = 620.0 \text{ m}^3(\text{mol s})^{-1}$) and the gel phase ($k_{p12}^g = 19.6 \text{ m}^3(\text{mol s})^{-1}$, $k_{p21}^g = 315.7 \text{ m}^3(\text{mol s})^{-1}$). The unknown distribution coefficient for NIPAM is calculated with COSMO-RS ($D_{M_2} = 2.52$).

Experiments: All experiments are performed in a Mettler Toledo RTcal 0.5 L real-time calorimeter in isothermal control mode at 70 °C and ambient pressure. The reactor is filled with 0.3 L water and all reaction species, monomers (homo- and copolymerization: 0.106 molL⁻¹ VCL or NIPAM; terpolymerization: 0.053 molL⁻¹ VCL and NIPAM) with or without cross-linker BIS (2.5 mol% of monomer) are dissolved as well as the stabilizer Cetyltrimethylammoniumbromide (CTAB, 1 w% of monomer). Before the reaction, the reactor is purged with nitrogen. 0.1 g thermal initiator AMPA is added. The experiment runs for 1.5-2 h after initiation before it is terminated. Calorimetry and Raman spectroscopy are performed simultaneously. VCL and BIS experiments are used as published in Janssen et al. (2017). In-line Raman spectra are evaluated with Indirect Hard Modeling (IHM) according to the methods described in Meyer-Kirschner et al. (2016) and Meyer-Kirschner et al. (Submitted) to determine monomer mass fractions w_{M_i} of VCL and NIPAM. Despite purging, the experimental data reveal an inhibition phase right after initiation, which is removed for parameter estimation and comparison with simulation data.

The remaining unknown parameter values for initiator distribution coefficient D_1 , termination rate constants k_t^l , k_{diff}^g , and cross-linking efficiency f_{pdb} are determined by parameter estimation. The experimental data from Raman spectroscopy and the model are linked by the weight fraction balance for the monomers VCL and NIPAM:

$$\frac{dw_{M_i}}{dt} = \frac{MW_{M_i}}{m_{\text{tot}}} \left(-V^l \sum_{j=1}^3 (k_{pji}^l + k_{fmji}^l) c_{\lambda_0}^l c_{M_i}^l - V^g \sum_{j=1}^3 (k_{pji}^g + k_{fmji}^g) c_{\lambda_0}^g c_{M_i}^g \right). \quad (1)$$

Thereby, the termination rate constants influence w_{M_i} only indirectly by affecting the radical concentrations c_{λ_0} . In addition, reaction calorimetry provides information on the overall polymerization progress. The enthalpy transfer rate of the reaction, Σ_R , represents the heat released at constant temperature by the exothermic propagation reactions of monomer and cross-linker:

$$\Sigma_R = \sum_{p=1,g} \sum_{i=1}^3 \left(\sum_{j=1}^3 \left(-\Delta H_{Rij} V^p k_{pij}^p c_{\lambda_0}^p c_{M_j}^p \right) - \Delta H_{Ri3} V^p f_{\text{pdb}} k_{pi3}^p c_{\lambda_0}^p c_{\text{pdb}}^p \right). \quad (2)$$

It also accounts for the consumption of BIS and reactions of the PDBs, while the BIS concentration is below the detection limit of the utilized Raman spectrometer and therefore cannot be measured directly. Thus, both measurement techniques complement each other.

3. Results

Modeling and parameter estimation with the maximum likelihood method are both performed with gProms version 4.2.0 on a 64-bit Intel Core i3-3225 CPU with 3.3 GHz running Windows 7. The parameter values are estimated sequentially and transferred, beginning with homopolymerizations of VCL and NIPAM, followed by their copolymerizations with BIS, respectively, and last terpolymerization of VCL, NIPAM and BIS.

3.1. Homo- and Copolymerization of VCL and NIPAM

The model with parameter values from QMC is evaluated for polymerization reactions of pure VCL and NIPAM. Figure 1a shows the enthalpy transfer rate Σ_R calculated from measurements in comparison to the results with the fitted model. Σ_R is plotted over time, whereas $t = 0$ s corresponds to the moment of initiation in simulation and for experiments is located after the observed inhibition phase. Both curves, VCL and NIPAM, show a good agreement of the fitted model with

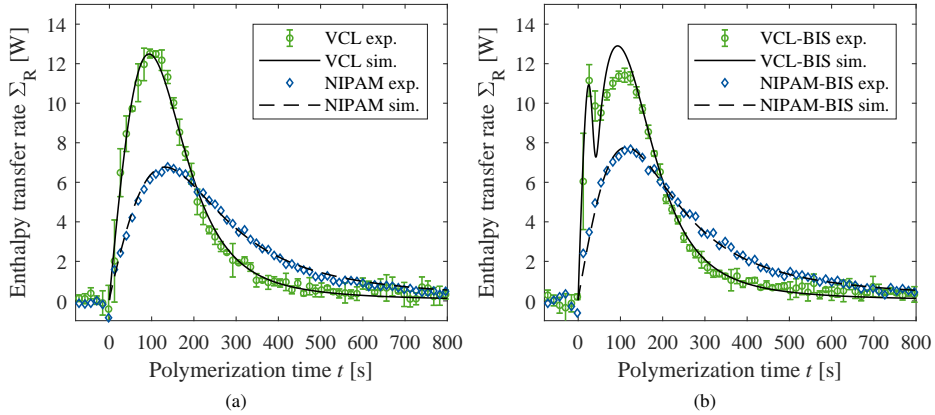

Figure 1: Comparison of experiments and fitted model for (a) homopolymerizations and (b) copolymerizations with BIS in terms of Σ_R .

experimental data.

The experimental data shows that the overall polymerization of VCL proceeds faster than of NIPAM, as Σ_R for VCL increases faster after initiation and obtains its maximum after 100 s while the curve for NIPAM obtains its significantly lower maximum after 150 s. This is counter-intuitive, as the calculated k_p (Kröger et al. (2017)) indicate a faster propagation rate for NIPAM. However, the estimated k_t to fit the experimental data differ significantly. A low estimated value $k_{diff}^g = 3.54 \cdot 10^{-2} \text{ m}^3(\text{mol s})^{-1}$ for VCL dominates k_t^g , expressing a significant diffusion limitation of the termination reaction. This accelerates the overall polymerization reaction. For NIPAM, the higher estimated $k_{diff}^g = 9.89 \cdot 10^3 \text{ m}^3(\text{mol s})^{-1}$ suggests that the termination reaction is less affected and the overall polymerization reaction proceeds slower.

Figure 1b depicts the results of the fitted model in comparison to experimental data for copolymerizations with the same amount of cross-linker. For both reaction systems, the parameter values from QMC can be employed to calculate the reaction progress, as the experimental data can be fitted with good agreement. For VCL-BIS, the first maximum in the Σ_R measurement results from the faster consumption of cross-linker, represented by higher cross-propagation reaction rate constants (Janssen et al. (2017)). Note that the improved fit for VCL-BIS results from a reevaluation of the experimental data regarding the inhibition phase. Σ_R for NIPAM-BIS on the other hand does not indicate such inhomogeneous consumption.

The estimated k_{diff}^g for both reactions differ significantly. A good fit for VCL-BIS is only obtained, when individual diffusion limitations for the termination reactions are introduced ($k_{diff11}^g < k_{diff13}^g < k_{diff33}^g$). For NIPAM-BIS, a constant k_{diff2}^{g*} for the different termination reactions is sufficient, but it needs to be determined for reactions with different cross-linker concentrations individually. Then, k_{diff2}^{g*} decreases with increasing cross-linker concentration, causing the overall polymerization to proceed faster. Thus, for the system of NIPAM-BIS, diffusion limitation depends on the cross-linker concentration, whereas for the VCL-BIS system, the monomer VCL itself, e.g., by steric limitation of the molecular structure, causes a limitation of the termination reaction.

3.2. Terpolymerization

The model is applied to the terpolymerization system. Thereby, the observations from copolymerization are incorporated in terms of the fitted parameter values: while k_{diff11}^g and k_{diff13}^g are

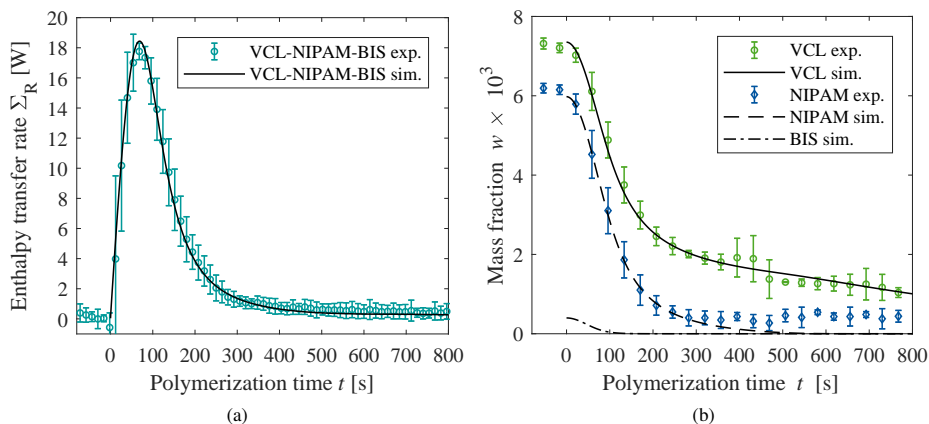

Figure 2: Comparison of experiments and simulation with fitted model for terpolymerization in terms of (a) enthalpy transfer rate from calorimetry and (b) monomer mass fractions from Raman spectroscopy. BIS concentration is below the detection limit and hence cannot be determined from in-line spectra. Time $t = 0$ s denotes the initiation.

transferred as previously estimated, the k_{diff2}^{g*} is estimated again due to the different composition. Figure 2a shows good agreement between Σ_R determined from experiments and the fitted model. The maximal enthalpy transfer rate is significantly higher (> 18 W) than for the copolymerizations and the overall reaction proceeds fast. For the fitted model, this results from high k_{p12} and k_{p21} in combination with low estimates for k_{diff12}^g and k_{diff2}^{g*} . Hence, the overall reaction is accelerated. The comparison of the measurements of the mass fractions w_M of VCL and NIPAM with the fitted model is illustrated in Figure 2b. NIPAM is consumed slightly faster than VCL. Still, high VCL cross-propagation rate constants and the preferential accumulation of VCL in the gel phase ($D_{M1} > D_{M2}$) promote the consumption of VCL in the presence of NIPAM and BIS. After 300 s, w_{M2} is below $1 \cdot 10^{-3}$ and thereby in the size range of the prediction error of the chemometric model (Meyer-Kirschner et al. (Submitted)). With the combination of both measurements, the cross-linker consumption can be predicted with the fitted model.

The comonomer consumptions in combination with the predicted gel phase growth provide a rough prediction of the internal microgel structure, as illustrated in Figure 3. The instantaneous copolymer fraction F_{CM} represents the reaction rate fractions of the comonomers in the gel phase and V^g is predicted from the mass transfer due to phase equilibrium and precipitation. The instantaneous BIS mole fraction declines over the radius. As the cross-linker is incorporated in the polymer network, the instantaneous radius represents the maximum range of its position in the microgel, indicating a higher cross-linked core. The instantaneous

Figure 3: Instantaneous comonomer mole fraction compared to the instantaneous normalized radius.

mole fractions of VCL and NIPAM are mostly constant over the radius, though the faster NIPAM consumption results in a higher NIPAM fraction. For the normalized radius close to unity, VCL is the only monomer left. Hence, the final microgels have a core with radially uniform composition of VCL and NIPAM and a thin outer corona of pure pVCL. The prediction of the microgel structure agrees with the uniform distribution of VCL and NIPAM described by Balaceanu et al. (2013).

4. Conclusion

In this contribution, we extend our precipitation polymerization model for VCL-based microgels (Janssen et al. (2017)) to the synthesis of microgels based on pVCL and pNIPAM. Parameter values from QMC are employed to reduce the number of unknown parameter values. The unknown termination rate constants are estimated from experimental data for increasing system complexities. Thereby, substantial differences in the termination rate constants are observed for homo- and copolymerizations of VCL and NIPAM: A lower termination rate for VCL causes the overall reaction to proceed faster, despite its lower propagation rate constants. For terpolymerization, the overall polymerization proceeds faster due to high propagation reaction rates and low termination rate constants. Thereby, NIPAM is consumed slightly faster due to its higher propagation rate constants. In agreement with previous experimental observations, the prediction of the internal microgel structure shows a radially uniform distribution of the comonomers VCL and NIPAM.

Abstract

Organic solvent nanofiltration (OSN) is a promising technology for an energy-efficient separation of organic mixtures. However, due to the lack of suitable models that allow for a quantitative prediction of the separation performance in different chemical systems OSN is rarely considered during conceptual process design. The feasibility of OSN is usually determined by means of an experimental screening of different membranes. Further experiments are conducted for a selected membrane in order to determine membrane specific parameters for a model-based description of the separation performance for a specific mixture. Obviously, this classical approach is experimentally demanding. The effort in identifying a suitable membrane in the first step could be significantly reduced if a theoretical evaluation of the separation performance was possible. The current article proposes an automatic method for the determination of a suitable predictive model for a given membrane, taking into account a limited set of experimental data. Specially, the rejection of different solutes in a specific solvent is modeled based on a set of physical and chemical descriptors. The proposed approach is based on a combination of genetic programming and global deterministic optimization, allowing for the identification of innovative models, including non-linear parameter regression. The predictive capability of the generated models is validated on a separate data set. The identified models were able to predict the rejection of different components in the considered case studies with a deviation from the experimental values below 5%.

Keywords: organic solvent nanofiltration, model identification, data-driven approach, prediction

1. Introduction

Separation processes in the chemical industry are commonly dominated by energy-intensive thermal separations like distillation (Sholl and Lively (2016)). Especially pressure-driven membrane processes, such as organic solvent nanofiltration (OSN), offer a high potential for significantly improving the energy efficiency, since phase transitions and high operating temperatures are avoided (Marchetti et al. (2014)). Recent developments in solvent stable polymeric membranes allow for the application of OSN in a variety of industrial sectors, ranging from pharmaceuticals to petrochemicals and food industry (Lutze and Górak (2016)). However, despite the large prospect of OSN, it is rarely considered during conceptual process design as reliable predictions of the separation performance in different chemical systems are not available yet. In order to facilitate an effective consideration during conceptual design, a model-based description of the separation characteristics of the membrane is indispensable. Common models for OSN separation are solution-diffusion or pore-flow models (Marchetti et al. (2014)). However, these models require experimentally determined model parameters for each component in the system. Hence, the implementation of OSN is often linked to expensive and time-consuming screening experiments. Moreover, some

experimental results comply best with the pore-flow model, whereas others can be described better by solution-diffusion models or a combination of both (Marchetti et al. (2014)). Thus, it is not possible to determine which model type is more suitable for OSN in general. Obviously, a general mechanistic model would be desirable for the prediction of the separation performance. However, such an approach is yet a long-range target that is extremely challenging, due to the strong interactions between the solute(s), the solvent(s) and the membrane material.

In order to allow for a predictive description of the membrane performance, Bhanushali et al. (2001), Geens et al. (2006) and Darvishmanesh et al. (2009) developed different models to describe the permeation of a pure solvent, each based on a number of molecular descriptors, such as the viscosity or the surface tension. These models allow for the evaluation of the solvent flux. A prediction of the separation performance, especially the rejection of different solutes, was not reported so far. Furthermore, the proposed models are based on a fixed structure and membrane-specific parameters, resulting in strong variations in the quality of the prediction for different membranes.

Since the number of available polymeric membranes for OSN is yet limited, tailored model structures for each membrane type are a feasible option. However, the complexity of determining an optimal model structure and parametrization represents a much more complicated problem than a mere parameter identification for a fixed model. In order to solve this problem, an optimization-based data-driven approach is proposed. The method utilizes a combination of genetic programming (GP) and deterministic global optimization for the identification of optimal parameters, in order to automatically identify models with linear as well as nonlinear parameters. While the capability of the method to identify predictive models for pure solvent flux was demonstrated in a previous work (van den Bongard et al. (2017)), the current work illustrates that also models for the separation performance can be derived by such an approach.

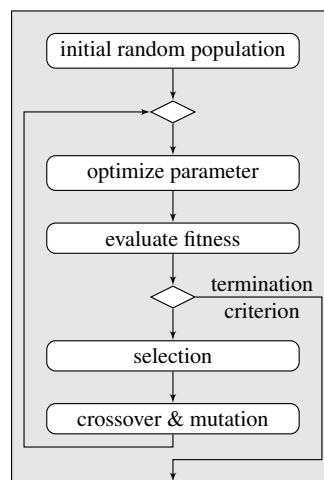

Figure 1: Structure of the GP approach

2. Optimization-based approach for model identification

The optimization-based approach for model identification utilizes a combination of GP and global deterministic optimization in order to derive a model structure and the corresponding parametrization, which reproduces a set of experimental data in the best way. For modeling OSN rejection, different descriptors that account for physical and chemical properties of the solutes and the solvent are correlated, taking into account experimentally measured rejection data of different components solved in the same solvent. The identification of the best parameter values for each model candidate is performed by means of global deterministic optimization. As measures for the mutual solubility descriptors based on the Hansen and Hildebrand solubility parameters of the components are used, since these were identified as suitable measures (Darvishmanesh et al. (2011); Zeidler et al. (2013)). As descriptors for physical and chemical properties of the solute and the solvent different parameters like molar mass, viscosity, density and surface tension are used which were found to be useful in different investigations (Bhanushali et al. (2001); Darvishmanesh et al. (2011)). In total 34 different descriptors for each solute-solvent combination are considered.

The GP approach is used for the identification of the model structure and it builds on the work of Madár et al. (2005). The different steps of the algorithm, which are implemented in Matlab[®], illustrated in Figure 1, are explained in further detail in the following subsections. An important feature of the current approach, which stands out in comparison to other automated model learning

algorithms, like the ALAMO approach of Cozad et al. (2014), is the ability to generate models that are nonlinear in the parameters. Therefore, a differentiation between linear and nonlinear regression models is considered in the embedded parameter optimization step, which utilizes a global deterministic solver in case of a nonlinear regression problem. The quality of the model candidates is evaluated based on an information criterion, rather than the least squares functional and the identifiability of the parameters is evaluated in a final postprocessing step.

2.1. Model representation in GP

The structure of each model candidate is represented by a tree with a predefined maximum tree depth. Figure 2 illustrates the basic structure of a tree with a maximum tree depth of 3. Each node of a tree represents either a function or a descriptor. However, the bottom positions in the tree (position 4, 5, 6 and 7 in figure 2) have to represent a descriptor. Besides the previously described descriptors a number of user-defined functions are available ($+$, $-$, $*$, $/$, exp , log , $\sqrt{\quad}$), allowing for the construction of linear and nonlinear models. The trees are translated to a single-equation model for which parameters are introduced for every node that represents a function. However, additional restrictions directly eliminate obviously correlated parameters. Finally, an additional parameter is added to the model as a constant. For models with only linear parameters additional restrictions are considered for the integration of parameters.

Figure 2: Tree with tree depth 3

2.2. Initial population

For all model candidates in the initial population and each type of node a random selection between the sets of descriptors and functions is performed. The final depth of the tree for each of these model candidates may therefore be smaller than the maximum depth, since nodes below a descriptor position do not contribute to the final model. In order to enforce a subset of models with maximum trees depth, 10% of the model candidates in the initial population are completely filled with functions and descriptors are only allowed for the bottom layer of the tree. The size of the initial population was set to 500 individuals.

2.3. Parameter optimization

Depending on the type of model either a linear or nonlinear parameter regression needs to be performed. The optimal parameter values for a linear regression problem are determined directly in Matlab[®] evaluating the first order optimality condition for the sum of squares functional by means of the matrix inversion. For a nonlinear regression problem, a global optimization problem has to be solved. Therefore, the model structure as well as the corresponding values of the included descriptors and the experimental data are passed from Matlab[®] to the general algebraic modeling system GAMS, where the nonlinear regression problem is solved to global optimality applying the solver ANTIGONE. In general, the parameter regression is performed only for a subset of the available experimental data. The remaining data is allocated as a test data set and a validation data set, which are not used for the parameter regression, but for fitness evaluation and the subsequent model validation.

2.4. Evaluation of fitness

In order to obtain reliable and useful models for performance prediction in OSN, two aspects are important. First, the experimental data has to be reproduced such that the goodness of fit is an important criterion. Second, an accurate fit of the model parameters is also important to

avoid overfitting with too many parameters. Thus, the fitness function should account for the quality of the fit as well as the number of parameters. Consequently, an information criterion is considered and in specific, the Akaike information criterion (AIC) is used in this work (Burnham and Anderson (2004)). The fitness function is evaluated for the training as well as the test data set, which provides also information about the predictive quality of the model.

2.5. Selection of Individuals

Based on the fitness evaluation, the GP continues with the generation of a new population, starting with the selection of model candidates that are considered for the application of reproduction, crossover and mutation operators. In order to preserve the best model structures, the best 10% of the current generation are passed to the next generation. The remaining 90% of the next generation are filled with new model structures created by crossover and mutation, whereas the parents for the new individuals are selected based on the tournament method (Affenzeller et al. (2009)). This method randomly selects two individuals out of the current population and the individual with the better fitness is selected as a parent. Consequently, the method is applied once for mutation and twice for crossover.

2.6. Crossover and mutation

For the generation of new model candidates crossover and mutation operators are applied with predefined probabilities. Here, a mutation probability of 80% for the second generation was specified, which further decreases for each generation until reaching a constant level of 20%. The crossover operator is applied opposed to the mutation operator, such that the probability always adds to a total of 100%. A variable mutation probability was used to ensure an exploration phase in the beginning, with a focused exploitation phase in the end. Both operators consider only active nodes in the tree, since nodes on a branch below a descriptor do not contribute to the model. Furthermore, the use of crossover is limited, as it requires trees with corresponding relevant nodes. In that case one of the nodes is randomly selected and the complete branch below that node is replaced by the corresponding branch of the other tree and vice versa. For mutation, again one of the identified nodes is randomly selected and one of the following two options is performed. Either the type of node at the selected position is changed from function to descriptor or vice versa, or it remains the same. Anyhow, the specific type of function or descriptor is modified and selected randomly.

2.7. Termination criterion

The GP approach terminates if the fitness of the best model candidate does not improve for a certain number of consecutive generations, or in case a predefined maximum number of generations has been evaluated. Here, a number of 25 generations was chosen for the evaluation of continuing progress, while the maximum number of generations was set to 75. However, none of the runs reached the maximum number of generations.

2.8. Postprocessing for potential model reduction

While the AIC, which is used as fitness function, already accounts for the number of parameters and avoids overfitting to some extent, it does not guarantee a high parameter precision. In order to evaluate the identifiability of the parameters, a post-processing step is performed for the best identified model after the GP stopped. In this step, the 95% confidence intervals of the parameter estimates are computed and an eigenvalue analysis of the Hessian matrix of the least squares functional is performed (Quaiser and Mönnigmann (2009)). Parameters which are not identifiable based on the given data or which are strongly correlated are eliminated from the model and the remaining model parameters are optimized again, with a subsequent evaluation of the AIC. The postprocessing is repeated until the parameter identifiability is satisfying.

3. Case Study

The proposed optimization-based method was used to identify predictive models for the rejection of different solutes in either toluene or isopropanol (IPA) for a PuraMem® S600 membrane manufactured by Evonik Resource Efficiency GmbH. A data set with 18 solutes for toluene as well as 16 solutes for IPA were considered, including a homologous series of even numbered alkanes, a branched isomer and different aromatic components. Besides the solubility of the solutes in the specific solvent a preferably wide distribution of the property values in terms of the considered descriptors was taken into account. For each of the solvent-solute combinations lab-scale experiments were conducted in a membrane test plant and the permeate and feed compositions were determined by means of gas chromatography. The rejection R was subsequently calculated based on the permeate and feed concentration of the solute according to

$$R = 1 - \frac{c_{\text{Permeate}}}{c_{\text{Feed}}}$$

On the basis of error propagation the relative measurement error of the determined rejections was generally below 2%, whereas the deviation of two consecutive experiments was below 8%. In order to successfully apply a data-driven modeling approach it is indispensable to warrant a good distribution of the data points. Therefore, the allocation of the data points to the training set was not performed randomly, but a high degree of variation, taking into account all descriptors was warranted.

For toluene the training data set consisted of 9 substrates, while 4 additional substrates were allocated to the test and the remaining 5 to the validation data set. For the smaller IPA data set the training, test and validation data set included 8, 4 and 4 substrates respectively.

A maximum tree depth of 3 was found to be sufficient, since a larger tree depth did not improve the results. In order to evaluate the stochastic nature of the GP approach 20 consecutive runs were performed for each solvent. Furthermore, additional 20 runs were performed with a restriction to model structures that are linear in terms of the parameters. A comparison of the results of the different runs showed that models, which are linear in the parameters, were sufficient for the prediction of the rejection in the investigated cases. For toluene the reproducibility of the results by repeated runs was also satisfying, producing most of the times model candidates with an equivalent fitness. However, especially for the case of the rejection in IPA different models were identified in various runs with fluctuating fitness. Consequently, the optimization-based approach still needs improvement in order to consistently identify the best model candidate. Nonetheless, the best identified models are able to describe the experimental data in all three data sets for both solvents with very high accuracy. The excellent agreement between the best models and the experimental data is illustrated in the parity plots in Figure 3 and 4. Herein, the training data is represented by circles, the test data by squares and the validation data by triangles. The dashed lines indicate an absolute deviation of 5% between experimental and calculated value. For both solvents only for one component out of each validation data set (deviation of 9 – 11%) a deviation of 5% is exceeded. For the best model candidates a sufficient parameter precision was validated, based on the confidence intervals and eigenvalue information, taking into account only the training data. The best model for the rejection in toluene

Figure 3: Rejection toluene

$$R_{\text{toluene}} = -52091.29(\pm 4681.91) \cdot \frac{d_{\text{eq,Solute}}}{M_{\text{Solute}} + M_{\text{Solvent}}} + 193.21(\pm 13.37)$$

includes only descriptors for the size of the solvent and solute molecule, i.e. the equivalent molecular diameter d_{eq} and the molar mass of the corresponding molecule M . Besides the determined model parameters, also the information on the 95% confidence interval is listed in the brackets.

4. Conclusion

The current article proposed an optimization-based approach for a systematic model identification and its application to organic solvent nanofiltration. For the first time rejection models are generated and the results are very promising, showing a high degree of accuracy when compared to the experimental data for two investigated solvents with a broad range of different solutes. These models can further be used to evaluate the applicability of the given membrane for the rejection of specific solutes in the considered solvents. Further work will aim at the extension of the approach towards solvent independent models and the improvement of the optimization approach.

Abstract

An application of machine learning algorithms for the prediction of physical properties of ionic liquids is presented herein. Molecular descriptors obtained from quantum-chemistry calculations (COSMO theory (Klamt, 2004)) containing both structural and energetic information are used as input parameters. In this sense, a set of COSMO-based descriptors is proposed by reduction of the original σ -profile (51 descriptors reduced to 9 bins). A critically evaluated set of viscosity data is used for a large number of ionic liquids (159). Artificial neural networks are then trained for the correlation of liquid viscosity and compared with available tools (QSPR).

Keywords: COSMO descriptors, ionic liquids, viscosity, artificial neural networks

1. Motivation

One of the latest paradigms in chemical engineering science has been product design. In the last decades the number of new specialized chemical products offering new solutions (health care, environmental, process industry. . .) has drastically grown. New promising computer tools have also been developed for the specific task of finding the best molecule for every application (Fung et al., 2016; Gani and Ng, 2015) in the context of Process System Engineering.

Any approximation for chemical products design relies on good physical properties predictions. Many of the current computer-aided process engineering (CAPE) use group contribution methods, specifically developed to estimate from individual to mixture properties. Some examples are Joback model for ideal gas heat capacity, Li-Ma model for vapor pressure of single components, Orrick-Erbar model for liquid viscosity or the well-known UNIFAC model for individual activity coefficients in a liquid mixture.

On the other hand, many efforts have also been made in the field of quantum mechanics in pursuing new procedures and methods for physical properties predictions computationally affordable in chemical engineering applications. The well-known COSMO-RS/SAC (Klamt, 2004; Lin and Sandler, 2002) models founded on the COSMO theory developed by A. Klamt and co-workers are good examples of well-established tools. These methods involves quantum chemical followed by statistical mechanics calculations to compute both pure and mixture thermodynamic properties. In the middle of the procedure, each molecule is characterized through the so-called σ -profile.

This σ -profile or derived properties (COSMO descriptors) have been successfully used in literature (figure 1) as inputs of different quantitative structure property relationships (QSPR) or artificial

neural network (ANN) models for the correlation and prediction of pure thermodynamic properties (i.e. Hansen solubility parameters (Járvás et al., 2011), heat capacities (Zhao et al., 2015) or densities (Palomar et al., 2008)), mixture thermodynamic properties (i.e. activity coefficients (Gonfa et al., 2016), vapor-liquid equilibrium (Bouza et al., 2016) or partition coefficients (Palomar et al., 2008)), and others (i.e. viscosity (Mehrkes and Karunanithi, 2016) or toxicity (Ghanem et al., 2017)). The use of ANN for the correlation of viscosity data from COSMO descriptors as proposed in this work has not been performance until now.

However many efforts have been done to develop good estimation models to predict ILs viscosity (figure 2). Between them, we can find property-based group contribution (GC) models such as the Gardas-Coutinho (Gardas and Coutinho, 2008) model which estimates viscosity from an Orrick-Erbar type equation combining some property information (density and molecular weight) and a GC-based estimation of parameters. On the other hand, the great amount of works in this topic are grounded on pure GC approximation using different kind of models (multilinear regression, support vector machines or artificial neural networks).

None of the previous approximations uses COSMO information as descriptors. Therefore, the main objective of our work is the development of different estimation methods for the prediction of both thermodynamic and transport properties of pure ILs. These methods will all start from a small set of shared molecular descriptors (derived from the σ -profile of the components) which allows for the design of molecules by the solution of the non-linear optimization problems where the properties are part of the objective functions and the σ -profiles descriptors the design variables.

In this first work, we use a reduced version of the σ -profile as the input of an artificial neural networks model for the correlation and prediction of pure IL viscosity. This reduction in the number of descriptors is required to decrease the number of fitting parameters in the model.

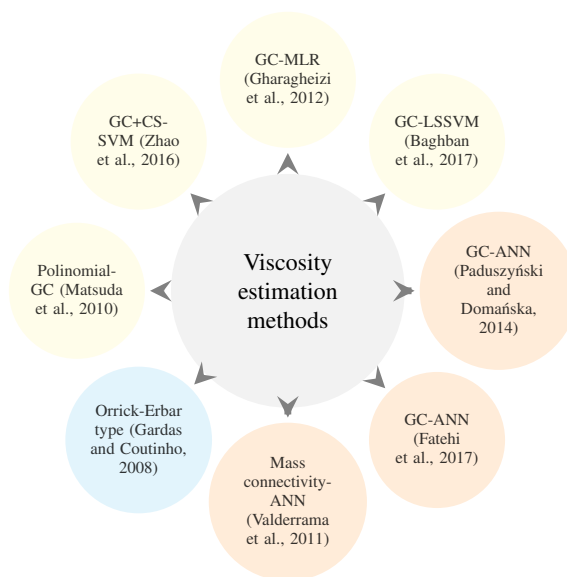

Figure 2: Literature methods for ionic liquids viscosity estimation. SVM-MLR based (yellow), physical property based (cyan), ANN based (orange)

2. Data obtention and ANN training

2.1. Viscosity dataset

The viscosity of ILs is a complicated property to predict because of the high discrepancy between existing data. We can find in literature both intracomponent discrepancy (different values for the same component) and intercomponent discrepancy (incoherent values for a family of compounds) (Valderrama et al., 2011). These highly different values of viscosity have motivated the development of a reliable database named ILUAM (Ferro et al., 2018) where all the available viscosity data was mined, critically evaluated and finally implemented in a commercial process simulation tool (AspenOne). The ILUAM database contains information of both σ -profile of ILs and a set of thermodynamic and transport properties of ILs statistically curated for a large number of compounds.

Thus, ionic liquids viscosity dataset is obtained from the extended version of the ILUAM database (ILUAM01-(CA)-RB). In this database all the experimental viscosity data for regressing the parameters (A and B) of the Andrade equation were obtained from the NIST Standard Reference Database ILthermo (NIST). All the data collected were filtered prior to the statistical fitting in order to ensure information of liquid phase measurements in a pressure range between 50 and 150 kPa (almost atmospheric pressure). All the IL data included in ILUAM01-(CA)-RB have been previously curated, ensuring enough viscosity data for each compound (minimum number of viscosity points = 5) and coherence between them (minimum fitting quality of $R^2=0.98$). In this work, only the viscosity information at 303 K is taken. A total number of 159 ILs viscosity points are used (the subset of ILs whose σ -profile was also available). The dataset was then divided into train (75%) and test (25%) sets.

2.2. COSMO descriptors

An increase in the number of descriptors used in the model results in a higher number of weights to be fitted (each descriptor is connected to each neuron in the hidden layer so an increase in one

descriptor involves an increase of # neurons weights to fit). Therefore, the ILs σ -profiles contained in the ILUAM01-(CA)-RB database were discretized reducing the number of descriptors from 51 (one $P(\sigma)$ for each screening charge σ) to 9 bins (figure 3) as proposed by Palomar et al. (2008).

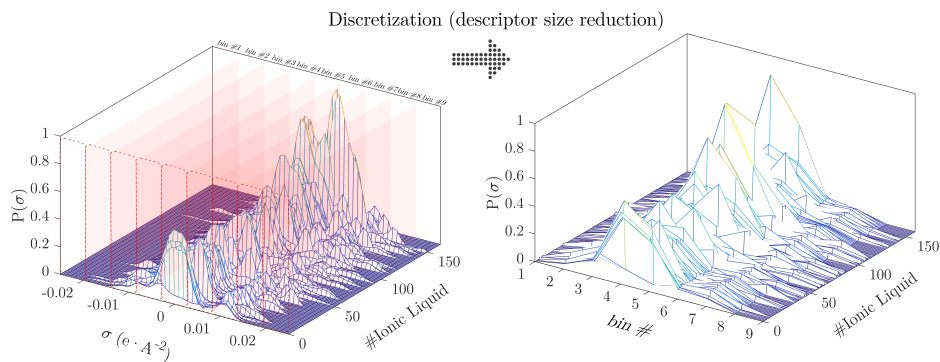

Figure 3: σ -profile information used as descriptors. Left, original information with 51 descriptors. Right, bin discretization with 9 descriptors

2.3. Artificial neural network

A typical feed forward structure (figure 4) is considered as proposed by other authors in similar works (Valderrama et al., 2011; Fatehi et al., 2017; Padaszyński and Domańska, 2014). A \tanh activation function is used in all the neurons. The size of the hidden layer is determined by using k-fold cross validation and preliminar trainings.

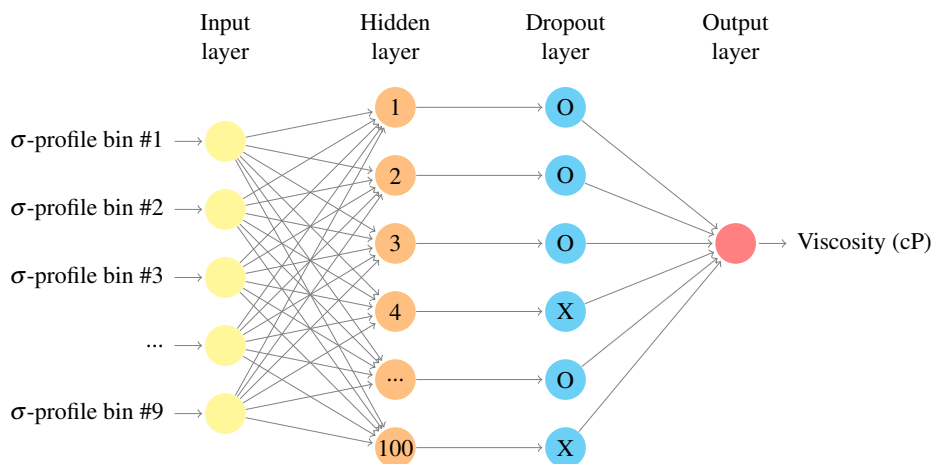

Figure 4: Feed forward ANN structure proposed

Figure 5: k-fold cross validation results

Figure 6: ANN preliminary training

2.4. Training

Once input-output data have been taken, the ANN model was trained using Tensorflow under Keras. Every ANN was trained using the Adam optimizer (Kingma and Ba, 2014) which is a gradient-based optimizer based on adaptive estimation of moments. Overfitting is minimized by using dropout fraction of the units to drop equal to 0.3.

In figure 5 the mean squared error (MSE) of the test set averaged over the 10 folds is depicted. In our case, 10 folds were chosen not showing better results in layers bigger than 100 neurons. By training individual ANNs in the range 3-300 neurons (weight initialized randomly 100 times) during 10^5 epochs, we obtained similar results. The calculated MSE of both training and test sets (figure 6) suggested no improvements for hidden layers with more than 100 neurons.

The weights of the 100 neurons ANN were randomly initialized 100 times. For the best initial point, we trained the ANN during 10^6 epochs. The results of the ANN performance are shown in figure 7 (MSE training set 0.00724, MSE test set 0.00725). For comparison, the estimation of the viscosity of 50 ILs was also carried out with the QSPR model (using COSMO-derived descriptors) available in the COSMOTermX (COSMOTerm, 2017) package.

Figure 7: Ionic liquids viscosity modelling using ANNs

3. Conclusions

ANN and COSMO descriptors have been successfully used to fit and predict ILs viscosities. Accuracy was checked by comparing with existing QSPR tools. The final ANN model showed no overfitting and low deviations in terms of MSE.

A CFD investigation of the effect of particle sphericity on wellbore cleaning efficiency during oil and gas drilling

Emmanuel I. Epelle, Dimitrios I. Gerogiorgis*

School of Engineering (IMP), University of Edinburgh, Edinburgh, EH9 3FB, UK

D.Gerogiorgis@ed.ac.uk

Abstract

In all drilling operations in the oil and gas industry, the generation and eventual distribution of formation rock cuttings along the wellbore constitutes a major concern to operational feasibility and profitability. The nature of the annular geometry/wellbore trajectory, rheological properties of the non-Newtonian carrier fluid and physical properties of the cuttings are also very important to consider, particularly in the design stage. Cuttings encountered in practical operations are hardly of a perfectly spherical geometry; however, the ease of mathematical description due to this simplifying assumption is prevalent in most CFD modelling studies. This decreases the accuracy of simulated flow behaviour as far particle-particle and particle-fluid interactions are concerned. We address this challenge by modifying the Syamlal-O'Brien (SO) interphase exchange coefficient in the Eulerian-Eulerian model. This modification yields a better representation of the actual flow dynamics during cuttings transport. Our results show increased transport velocity of non-spherical particles compared to particles of perfectly spherical shape. The relatively complex wellbore geometry (in deviated drilling) considered reveals a key finding: there is greater particle deposition at the inclined-to-vertical (upper) bend, relative to other sections in the CFD flow domain.

Keywords: Computational Fluid Dynamics (CFD), sphericity, drag, drill cuttings.

1. Introduction

It is vital to understand the flow behaviour of drill cuttings carried by a non-Newtonian fluid in an annular geometry for successful design, efficient operation, and optimisation of the drilling process (Gerogiorgis et al, 2015). Drillers often control variables such as the penetration rate, fluid velocity and inner pipe rotation to obtain the best possible transport conditions; however, the application of advanced CFD methods for flow prediction guarantees better informed decisions. Although several experimental (Han et al, 2010; Osgouei, 2010) and computational (Rooki et al, 2015; Epelle and Gerogiorgis, 2017) efforts have sought to understand the impact of these factors on the overall transport efficiency, a widely recognised difficulty in particle transport modelling that has not been adequately addressed is the concept of particle sphericity. The assumption of perfectly spherical particles in most CFD models could yield inaccuracies in the predicted cuttings transport efficiency. In this work, this challenge is addressed by accounting for the particle sphericity as a means of increasing modelling accuracy. A modified interphase momentum exchange coefficient is implemented to better capture the particle-fluid interactions using the Eulerian-Eulerian model; thus, providing further insight into the actual dynamic particle behaviour during wellbore drilling and cleaning.

2. Drag Modification

Very few empirical correlations exist for the drag coefficient on a non-spherical single particle as well as multi-particle suspension systems. They are usually formulated either from experiments or Direct Numerical Simulations. However, our modification of the Syamlal-O'Brien drag model involves a re-definition of the particle diameter (in terms of the sphericity) in the interphase exchange coefficient. A direct application of the sphericity to the exchange coefficient ensures the particle shape is considered at conditions of high particle concentration (Gidaspow, 1994, Sobieski, 2011). The relative ease of implementation of this modification (Eq. 2 & 5) in the SO model influenced our choice of model relative to that of Gidaspow. Essentially, the need of a switch/blending function to ensure a smooth transition between conditions of high and low particle concentration is not necessary when using the SO model.

$$K'_{sl} = \eta K_{sl} \quad (1) \quad \text{Re}_s = \frac{\rho_l d_s |\vec{v}_s - \vec{v}_l|}{\mu_l} \quad (6)$$

$$d_p = \psi d_s \quad (2) \quad A = \alpha_l^{4.14} \quad (7)$$

$$\eta = \frac{1}{\psi} \quad (3) \quad C_D = \left(0.63 + \frac{4.8}{\sqrt{\text{Re}_s / v_{r,s}}} \right) \quad (8)$$

$$K_{sl} = \frac{3\alpha_s \alpha_l \rho_l}{4v_{r,s}^2 d_s} C_D \left(\frac{\text{Re}_s}{v_{r,s}} \right) |\vec{v}_s - \vec{v}_l| \quad (4) \quad \begin{array}{l} \text{for } \alpha \leq 0.85 \\ B = 0.8\alpha_l^{1.28} \end{array} \quad (9)$$

$$K'_{sl} = \frac{3\alpha_s \alpha_l \rho_l}{4v_{r,s}^2 d_p} C_D \left(\frac{\text{Re}_s}{v_{r,s}} \right) |\vec{v}_s - \vec{v}_l| \quad (5) \quad \begin{array}{l} \text{for } \alpha > 0.85 \\ B = 0.8\alpha_l^{2.65} \end{array} \quad (10)$$

$$v_{r,s} = 0.5(A - 0.06 \text{Re}_s + \sqrt{(0.06 \text{Re}_s)^2 + 0.12 \text{Re}_s (2B - A) + A^2}) \quad (11)$$

In this CFD model summary, K_{sl} and K'_{sl} denote the actual and modified interphase exchange coefficients of the SO model, respectively (Fluent, 2017), v_s and v_l are the velocities of the solid and liquid phases, α_s and α_l are the volume fractions of the solid and liquid phases, and ρ_s and ρ_l are the solid and liquid phase densities, respectively. Moreover, η is the drag modification factor, ψ is the particle sphericity (the ratio of the surface area of a sphere with the same volume as the particle, to the surface area of the actual particle), d_s is the volume-equivalent diameter (the diameter of a sphere having the same volume as the non-spherical particle), d_p is the modified particle diameter, Re_s is the relative Reynolds number, $v_{r,s}$ is the solid phase terminal velocity, μ_l is the liquid phase viscosity, and C_D the drag coefficient as per the definition of Dalla Valle (1948).

3. Simulation Parameters and Annular Flow Geometry

Table 1. Simulation input parameters

Drill pipe diameter, d_{pipe} (m)	0.113
Wellbore diameter, d_{wb} (m)	0.180
Computational length, L (m)	2.340
Cuttings diameter, d_s (m)	0.002 and 0.008
Cuttings density, ρ_s ($\text{kg}\cdot\text{m}^{-3}$)	2800
Sphericity, ψ	0.5, 0.75, 1.0
Drilling mud composition	0.5% CMC Solution
Drilling mud density, ρ_l ($\text{kg}\cdot\text{m}^{-3}$)	1000
Consistency index, K ($\text{Pa}\cdot\text{s}^n$)	0.5239
Flow behavior index, n	0.60
Fluid circulation velocity, v_l ($\text{m}\cdot\text{s}^{-1}$)	0.8
Cuttings inlet velocity, v_s ($\text{m}\cdot\text{s}^{-1}$)	0.5
Flow regime	Laminar – Unsteady state
Drill pipe rotation, Ω (rpm)	100
Hole eccentricity, e	0.6

Figure 1. Dimensions of annular flow geometry with mesh properties adopted.

Transient simulations were run using the finite volume formulation with a time step of $5 \cdot 10^{-4}$ and a tolerance factor of 10^{-4} in the Ansys Fluent solver (17.1). Statistical averages of flow properties were performed over the entire converged time steps. Total simulation run time was approximately 8 days using the University of Edinburgh's high performance computing facility (Eddie mark 3 – Scientific Linux 7 Operating System)

with 32 CPU cores (2.4GHz Intel®-Xeon® CPU processor) and 64GB of RAM. The geometry is shown in Figure 1.

4. Results and Discussion

The particle velocity, pressure drop and volume fraction profiles averaged over the entire flow domain for a simulation period of 5 seconds are shown in Figure 2.

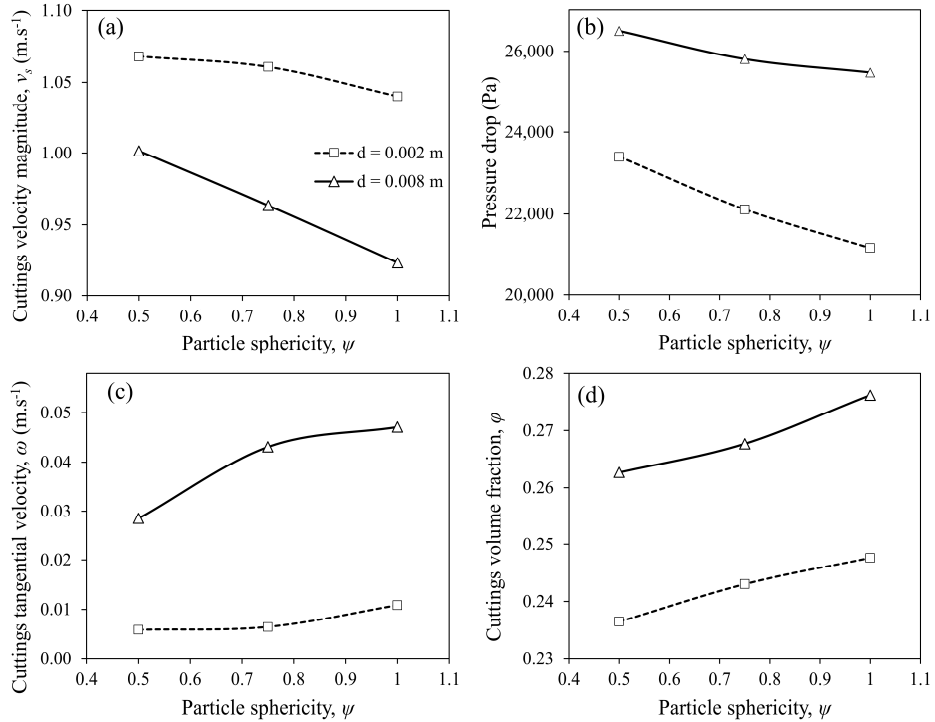

Figure 2. Cuttings velocity, pressure drop and volume fraction for variable sphericity.

It has been shown that non-spherical particles undergo a secondary oscillatory motion when transported in a fluid (Mandø et al. 2007). This tends to reduce its settling velocity compared to perfectly spherical particles (Byron, 2015). The higher settling velocity of spherical particles in the partially inclined geometry considered, is the most probable reason for the increased deposition (volume fraction – Figure 2d) and the reduced velocity in the direction of bulk flow (Figure 2a). Furthermore, spherical particles will tend to roll against the flow direction during transport; the results obtained show that these combined phenomena exhibited by spherical particles, are superior to the frictional resistance posed by the non-spherical particles (due to increased contact area).

Cuttings with diameter of 0.002 m generally travel faster in the annulus than those of 0.008 m (Figure 2a). However, larger particles exhibit stronger tangential motion compared to the smaller particles (Figure 2c). This occurs as a result of the rotating drillpipe which has a higher impact on spherical particles compared to non-spherical particles (Figure 2c). Spherical particles will more readily rotate along the axis of the drillpipe compared to non-spherical particles with a more chaotic flow character.

Interparticle collisions of non-spherical particles coupled with the increased drag forces are the most likely reasons for the higher pressure drop noticed with the non-spherical particles (Figure 2b). Additionally, larger particles will require more transport energy; hence the higher pressure drop and volume fractions (Figure 2d) observed. The impact of drillpipe rotation on the larger particles is further demonstrated in Figure 3 (d-f) and Figure 4. While the 0.002 m particles tend to settle at the lower section of the eccentric annulus, larger 0.008 m particles clearly experience an asymmetric deposition pattern.

Figure 3. Impact of particle diameter and sphericity on solid volume fraction at bends.

Figure 4. Annular flow velocity streamlines for two particle sizes at given sphericity.

The particle streamlines shown in Figure 3 (a & b) indicate that the impact of drill pipe rotation on particle motion in the vertical section of the annulus is much lower compared to the inclined and horizontal sections respectively. This effect was noticed for all particle sphericities considered. Furthermore, this reduced impact of drillpipe rotation due to the transition in the annular geometry coupled with the eccentric configuration of flow are the major reasons for increased particle deposition noticed around the bend (inclined-to-vertical) compared to other areas of the flow domain.

5. Conclusions

By incorporating the particle sphericity into the interphase momentum exchange coefficient of the Syamlal-O'Brien model, we have studied the impact of particle shape on the multiphase flow of drill cuttings in irregular annular geometries. The obtained results show a 5% reduction in cuttings volume fraction between particles of lowest sphericity (0.5) and perfectly spherical particles for both particle diameters considered. As far as the cuttings transport velocity is concerned, the shape of the particle is more influential on larger cuttings compared to smaller-sized cuttings. We also discover that the inclined-to-vertical (upper bend) is the most susceptible location for particle deposition. Drillpipe rotation is seen to have a more pronounced effect on larger particles, especially in the horizontal and inclined regions of the annulus. In the vertical section, the effect of rotation is low; we infer that this phenomena, alongside increased gravitational resistance are the main reasons for increased deposition in the upper bend.

Process network modelling for the assessment of environmental impacts

Raul Calvo-Serrano^a, Gonzalo Guillén Gosálbez^{a*}

^a*Centre for Process Systems Engineering, Imperial College of Science, Technology and Medicine, South Kensington Campus, London SW7 2AZ, UK*

g.guillen05@imperial.ac.uk

Abstract

Environmental databases have recently become an essential instrument in the sustainability evaluation of products. Unfortunately, these repositories still contain a limited number of chemicals and are based on fixed mass flows reflecting static industrial settings that might poorly reflect the characteristics of the facilities one wishes to analyse. To overcome these limitations, we propose a methodology to quantify the life cycle assessment (LCA) impact of chemicals based on a mathematical model of the petrochemical industry coupled with linear programming and allocation methods. Our approach was applied to a network comprising 178 processes and 144 products, generating results consistent with those available in the Ecoinvent database for widely used impact indicators such as Global Warming Potential (GWP) and ReCiPe methodology score. Our method provides estimates of the life cycle impact embodied in chemicals under varying yields and demands, even for products that are missing in standard repositories. Overall, this tool should complement existing databases, extending their capabilities and boosting the widespread use of LCA in the chemical industry by simplifying its application.

Keywords: Process Networks, Life Cycle Assessment, Linear programming

1. Introduction

The chemical industry is currently committed to achieve cleaner and more sustainable standards, a trend that has led to a plethora of environmental evaluation methodologies. Among them, Life Cycle Assessment (LCA) has become the prevalent one, due to its holistic view and versatility as applied to a wide range of processes (Azapagic, 1999; Guillen-Gosalbez et al., 2007). LCA is based on a detailed analysis of all the mass and energy flows exchanged with the environment in all the stages in the life cycle of a product, from the extraction of resources to its final disposal. Unfortunately, this requires large amounts of data, which hampers the application of LCA in cases where such information is hard to gather. Streamlined LCA (SLCA) approaches (Hunt et al., 1998; Wernet et al., 2008) have been proposed to simplify the data required by a standard LCA. The most of them are based on the use of information retrieved from an LCA database as proxy of the “true” data needed. LCA repositories (e.g. Ecoinvent3.3 (Swiss Centre For Life Cycle Inventories, 2017)) have experienced a widespread growth in the recent past. They contain LCA results for a wide variety of products and chemicals that comes from full LCA studies of real facilities while considering their geographical and temporal context. In practice, these results replace the missing data in a LCA study under the

assumption that the databases' references are similar to the ones of the studied process. The use of data from repositories as proxy data presents two main limitations.

First, repositories currently only contain a few hundred chemicals, being possible that the required one may not be available. This is especially true for novel or specialised products and processes. The second limitation is that databases are based on fixed flows and specific processes that might be quite different from the ones implemented by the suppliers in the product's supply chain. To circumvent this limitation, LCA databases tend to rely on uncertainty modelling, mainly by using Pedigree matrices in their different versions (Lewandowska et al., 2004; Weidema and Wesnaes, 1996). These are well-established LCA methodologies that characterize the uncertainty associated with the LCI entries in the database (i.e. feedstocks, emissions and wastes) via probability distributions that depend on the degree of similarity (in terms of geographical, technological and temporal context) between the process under study and the data present in the database and its quality. This approach is therefore based on qualitative items that do not cover the entire range of uncertainties encountered in the chemical industry.

Here, we propose a method to estimate the LCA impact of chemical production processes that aims to overcome the two limitations mentioned above. Our strategy combines a network-based model of the petrochemical industry with mathematical programming and allocation methods. This approach not only relies on a more detailed description of the chemical industry, but also is able to model uncertainties through sensitivity analysis, considering a set of plausible scenarios of the chemical industry. To demonstrate the capabilities of our approach we have assembled a network of petrochemical processes encompassing 178 processes and 144 chemical products, using data gathered from the literature (Rudd et al., 1981).

2. Methods

Our methodology relies on optimising a network of processes so as to generate mass flows consistent with a given industrial production scenario. These flows are later on used to allocate the total impact among the final products. The methodology can be divided into four steps: i) building a process network of the chemical industry; ii) optimising the process network to generate mass flows consistent with a given demand pattern, costs and environmental data; iii) allocating of the network impacts among its products considering the flows generated in step one; and iv) assessing the uncertainty of the results generated in previous steps. These steps are described in detail in the ensuing sections.

2.1. Step 1: Building a process network of the chemical industry

The network contains two types of nodes: technologies (j) and products (i). For simplicity, all the utilities are expressed in Fuel Oil Equivalent Tonnes (FOET) following the original work by Rudd et al. (1981). Technology nodes are modelled as black boxes, each described by mass yields (μ_{ij} , kg of i /kg processed by j), utilities consumption rates (u_j , FOET/kg processed by j) and maximum operational capacity (cap_j , kg processed by j). These parameters are complemented by the utilities' cost (uc , \$/FOET) and their environmental impacts embodied ($LCIA^u$, units of the analysed impact indicator/FOET). Product nodes model inputs and outputs of products. Products can either be feedstocks (FS , inputs not produced by any technology), final products (FP , outputs not consumed by any technology) or intermediates (consumed and produced by one or more technologies in the network).

2.2. Step 2: Deriving a mathematical model based on the network

The network previously assembled is used to assess the LCA impacts of the products involved. To this end, we first determine the optimal production pathways (and thus the mass flows exchanged between technologies) by solving an optimisation model M1. This model seeks to minimise the total production cost (TC) while satisfying a set of product demands (d_i). While other optimisation objectives can be established, here we assume that the minimal production cost pathway is the closest scenario to the current global production pathways. The main decision variables of the model are the mass flow rates of main products in each technology (W_j , kg processed by j). Model M1 is described in the following equations (Eqns.(1 to 5)).

$$\text{Min } TC = \sum_i P_i pc_i + \sum_j W_j u_j uc \quad (1)$$

$$P_i + \sum_{j \in OUT(i)} W_j \mu_{ij} = \sum_{j \in IN(i)} W_j \mu_{ij} + S_i, \forall i \quad (2)$$

$$P_i = 0, \forall i \notin FS \quad (3)$$

$$S_i \geq d_i, \forall i \quad (4)$$

$$W_j \geq cap_j, \forall j \quad (5)$$

$$W_j, P_i, S_i \geq 0$$

In model M1, the objective function (Eq.(1)) minimises the total production cost defined as the addition of all the individual processing costs and all the feedstocks purchased (where pc_i represents the purchasing cost for feedstock i , \$/ kg of i). In the previous formulation, note that the main source of processing cost is the utilities consumption. The mass balance of products is defined in Eq.(2), which enforces to consider the structure of the network via the sets $OUT(i)$ and $IN(i)$. $OUT(i)$ contains the processes j that produce product i , while set $IN(i)$ contains the processes that consume product i . The remaining equations force some logical limitations, such that only feedstocks can be purchased (Eq.(3)), that a demand of final products has to be satisfied (Eq.(4)) and that processes have to operate below their maximum capacity (Eq.(5)). Note that this model can accommodate different objective functions as well as additional constraints in order to reflect the specific details of an industrial setting.

2.3. Step 3: Allocating impacts based on mass flows

With the solution of model M1 (i.e. mass flows W_j^*, P_i^*, S_i^*) it is possible to calculate and allocate the LCA impact values ($LCIA_i^{ln}$) to the different products. These LCIA values are obtained by solving model M2, defined in the following equations (Eqns.(6 to 8)). Note that, if both models M1 and M2 were solved together, the combined model would be non-linear. This would not only translate into higher difficulty to obtain solutions (requiring more computational time), but also lower confidence over the results obtained as global optimality is not always ensured by non-linear model solvers.

$$\sum_{i \in IN^P(j)} \mu_{ij} W_j^* LCIA_i^{In} + u_j W_j^* LCIA^u = \sum_{i \in OUT^P(j)} \mu_{ij} W_j^* LCIA_{ij}^{Out}, \forall j \quad (6)$$

$$P_i^* LCIA_i^{fs} + \sum_{j \in OUT^P(i)} \mu_{ij} W_j^* LCIA_{ij}^{Out} = \sum_{j \in IN(i)} \mu_{ij} W_j^* LCIA_i^{In} + S_i^* LCIA_i^{In}, \forall i \quad (7)$$

$$LCIA_{ij}^{Out} = LCIA_{i'j'}^{Out}, \forall j, \forall i, i' \in OUT^P(j), i \neq i' \quad (8)$$

Model M2 is based on the impact balances in processes (Eq.(6)) and in products (Eq.(7)), where feedstocks ($LCIA_i^{fs}$) and utilities are considered the main source of environmental impact. As previously, the structure of the network is satisfied by using sets $IN^P(j)$ and $OUT^P(j)$ (which include all the products i being consumed and produced by a process j , respectively). In order to allocate the generated impact, here we assume that impact values are proportional to the mass flow of each product. This is satisfied with Eq.(8), which enforces all products generated in a process to have the same relative impact values ($LCIA_{ij}^{Out}$).

2.4. Step 4: Modelling uncertainty

The uncertainty associated to the obtained results is obtained through a sensitivity analysis in some network parameters. More in detail, the considered varying parameters in M1 are the product demands (d_i), utility consumption rates (u_j), and process mass yields of main products (μ_{ij} such that i is the main product of process j). In order to generate coherent uncertainties, these changing parameters are assumed to follow specific probability distributions instead of totally random values.

3. Results and discussion

We illustrate the capabilities of our approach by assessing 15 final products included in the network. As well, we focus on 3 environmental impact indicators: Cumulative Energy Demand (CED, energy consumption), Global Warming Potential (GWP, emission of greenhouse gases), and ReCiPe. Note that, while CED and GWP represent specific environmental footprints, ReCiPe evaluates the total environmental impact. When trying to assess these essentially different indicators with the presented method it is possible to characterise its suitability for different kinds of environmental impact indicators. Following the previous methodology, all the parameters values in M1 (i.e. technology utility consumption rates, u_j , and main yields, μ_{ij}) are obtained from Rudd et al. (1981) for the 178 technologies in the network. The feedstocks purchase cost (pc_i) and the final products' demands (d_i) have been obtained from a wide variety of sources, adapting them for the UK and the year 2016. Regarding the maximum capacities (cap_j), these have been set so the demand can be fully met. The impact embodied in the utilities and feedstocks are retrieved from the Ecoinvent3.3 database accessed via SimaPro8.1 (Pre Consultants, 2014). Considering this data, model M1 contains 406 equations and 458 continuous variables and was implemented in GAMS 24.4. The model was solved in 0.016 CPU seconds with the solver CPLEX 12.6 on an Intel Core i5-4570 3.20 GHz computer. Model M2 features 322 variables and the same number of independent linear equations, being solved with GAMS and CPLEX. Regarding the uncertainty calculation, each uncertain parameter (d_i , u_j and main μ_{ij}) is assigned a specific probability distribution. The demands of the final products are assumed to

follow a normal distribution to account for different market demand patterns. The normal distributions use the demands' nominal values as their mean and standard deviations of 30% of the nominal value in all cases). The utility consumptions are uniformly distributed between 0.75 and 1 times their nominal values, while the main product yields vary between 1 and 1.25 times the nominal product yields. These improvements on the processes' performances is done to compensate potentially outdated parameter values from Rudd et al. (1981) when compared to Ecoinvent3.3.. Uncertainties are quantified via 2,000 random scenarios generated via Monte Carlo sampling on the previously defined probability distributions. Models M1 and M2 are recalculated for each scenario. The obtained results and uncertainties are compared with those available in Ecoinvent3.3 (original values). For each scenario, we then compare the values provided by M2 and the ones from Ecoinvent3.3 in order to finally calculate a relative difference between both. Figure 1 displays the calculated and original impact values (as the mean values obtained from the uncertainty analysis) and their uncertainties as well as the relative difference between both original and calculated results. In all cases, the uncertainties are expressed as 25th and 75th percentiles.

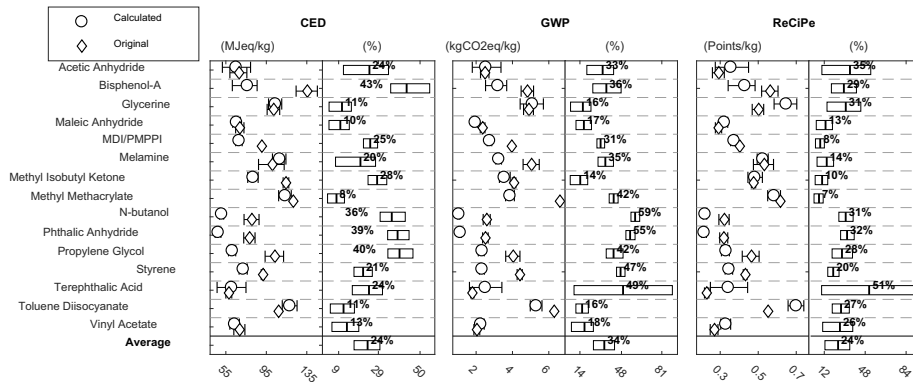

Figure 1, Calculated and original impact values and uncertainties (left) and their relative distances (average and 25th and 75th percentiles, right). Labels indicate the average relative differences.

Three indicators are considered to assess the quality of the results: average relative difference (the lower the better), width of the confidence interval of the difference (the smaller the better), and whether the confidence intervals of the two impact values overlap. In Figure 1, the calculated and original values agree reasonably, with 20-30 % average relative differences. However, since the original values consider additional impact sources and steps in the life cycle, the calculated results tend to be lower than the original values. Also, for some products, the processes selected by the assembled network were different to those considered in Ecoinvent3.3, obtaining notoriously discrepant impact values (as is it the case for Terephthalic Acid or N-butanol). This demonstrates how critical is to have a process network as complete as possible to evaluate as many alternatives as possible and therefore be able to better assess impact values. Looking at the confidence interval of the relative differences, their width is generally proportional to the expected error, with low errors having small uncertainty ranges. Concerning the overlap between confidence intervals, only 18 calculated results match (partially or completely) with their original counterparts.

4. Conclusions

Here we propose a methodology to calculate the life cycle impacts of chemicals based on the use of a petrochemical process network modelled via mathematical programming tools. This approach allows filling data gaps in LCA repositories, potentially producing better estimates based on a detailed and flexible representation of the industry underpinned by a mathematical model based on first principles. This methodology has been applied to a petrochemical network containing 178 processes and 144 products. The results obtained are in good agreement with the ones available in LCA databases, with the error of the estimate varying significantly depending on the product and impact indicator. In the future we aim to update and increase the process network data as well as to consider alternative optimisation objectives and allocation methods, then being possible to study how the changes in the global market may affect the petrochemical production pathways and also their environmental performance. This work has the potential to open up further research on methods for complementing LCA repositories based on a deep knowledge of an industrial sector.

Abstract

In this paper, we present an industrial case study of a batch process; the degradation effect is fouling in heat exchangers which impedes heat transfer and fluid flow during batch production. The degradation increases from batch to batch until the batch reactor is shut down for a scheduled maintenance. That is, there is a periodic pattern in the batch-to-batch data as a result of the degradation. We propose a novel data-driven modeling technique for predicting the evolution of a batch degradation key performance indicator (KPI). This method extends existing algorithms (based on partial least squares, PLS) for the treatment of within-batch data to the present batch-to-batch degradation problem. An existing missing data algorithm for PLS models is employed to predict degradation in future batches. The proposed approach is then applied to the case study, and predicts the evolution of the fouling KPI with respect to the production planning under predefined process operations, which is a basis for optimal scheduling of batch production and maintenance.

Keywords: fouling, batch process, degradation evolution, unfolding approach, multiway PLS

1. Introduction

The performance and efficiency degradation of industrial equipment and assets is inevitable in their life cycles. The assessment of process condition provides information of degradation, and the following optimization of process operations is meant to mitigate the influence of degradation. In some cases, it is necessary to shut down the plant and carry out the maintenance operation for restoration when the degradation reaches a certain degree. Human experience-based maintenance scheduling is not necessarily optimal on account of degradation in production along with other physical and logistical constraints. However, optimal scheduling asks for information about future degradation evolution. Therefore, the development of a predictive degradation model plays a significant role in plant performance optimization in consideration of degradation effects.

A batch reactor is a multi-purpose unit operation that is widely used in process industry to manufacture diverse products. The flexibility of batch processes is the major reason for its popularity in the chemical industry. By using batch production plants industry can easily adapt to market fluctuations and extend their product portfolio to react to customer needs. A multi-product batch process runs in a finite time period. It includes several stages: the raw materials are charged and the initial conditions are set according to the recipe; then the reaction starts and lasts for some time; the product is transferred into a storage tank and the product final quality variables are recorded at the end of this batch. During the batch running period, the process variables such as temperature, pressure, etc. are measured in real-time, and their profiles are called trajectories. These trajectory data are presented in three-way form with time $t = 1, 2, \dots, T$, variable $k = 1, 2, \dots, K$ and batch

$n = 1, 2, \dots, N$, while the initial condition variables and the final quality variables are in two-way form with batch $n = 1, 2, \dots, N$ and variable $k = 1, 2, \dots, K$ (Nomikos and MacGregor, 1994). In comparison with continuous processes, monitoring, control and optimization of batch processes are more challenging. These challenges arise from the problems that are associated with batch processes: absence of steady state (wide operating range) and presence of constraints, irreversible behavior, repetitive nature (Bonvin et al., 2006). In the presented case study, the reaction heat is removed by pumping the reactant through the heat exchangers (HE), and the fouling in the heat exchangers impedes the fluid flow and leads to the increase of the pressure drop across the heat exchanger during the reaction period. As a result, the pressure drop of the heat exchanger is chosen as a fouling indicator for the process (see figure 1). However, the contribution of the fouling towards the real-time pressure drop measurement is hidden and the increasing trend of fouling is masked in the individual batch duration, which results from the variant batch operation conditions. To deal with this problem, the pressure drop measured under selected operation conditions (at the start of the reaction) is considered as the fouling KPI (red star) for each individual batch as figure 1 illustrates. The fouling evolution from batch to batch is then indicated by the fouling KPIs.

As for the degradation prediction in continuous process, a variety of degradation examples using different data-driven modeling approaches (such as support vector machine, neural network, etc.) are found in literature (Sun et al., 2008; Aminian and Shahhosseini, 2008; Riverol and Napolitano, 2005). Due to the characteristic of the batch processes (Bonvin et al., 2006), these approaches do not deal well with the multi-dimension batch data structure. On the other hand, the multiway approach was proposed to solve batch data structure problems by transforming three-dimension data into batch-wise unfolded data, and the multiway PLS approach is then employed in the within-batch modeling to predict the final quality of the individual batches (Nomikos and MacGregor, 1994; García-Muñoz et al., 2003; Wold et al., 2010). As to degradation in batch production, unlike final quality variables barely affected by previous batches, degradation grows from batch to batch. Moreover, degradation prediction usually means to predict degradation evolution in next N batches, and the time horizon for prediction can be longer than one month, while the application of the multiway PLS approach using the within-batch model is only available to predict the final degradation in a single batch.

In this paper, a novel data structure called “campaign” is proposed for the analysis of degradation evolution from batch to batch. A data-driven model is developed based on the unfolded campaign data. Finally, an application of the PLS method and its missing data estimation algorithm enable the prediction of degradation evolution. The paper structure is presented as follows: the proposed approach details are presented in Section 2; the corresponding application on the case study and its results are showing in Section 3; finally, Section 4 draws the conclusions.

2. Method

2.1. The campaign concept in batch processes

In some cases, the batch degradation KPI presents periodic nature as maintenance is carried out to restore its degradation state regularly (see Figure 2). The figure shows the evolution of the fouling KPI in the heat exchanger. Each point represents the fouling degree in an individual batch, and the color and symbol together denote the batch product type from P1 to P9. The product order is planned ahead of time and flexible to modify as necessary. The period between two

Figure 1: Fouling indication by the pressure drop across the heat exchanger

Figure 2: Heat exchanger fouling evolution in batch process and campaigns

maintenance operations is named campaign, which contains a series of batches. The idea of the campaign concept is to capture the dynamics of the degradation evolution. To make effective use of campaign data, further data structure analysis is necessary. The structure of campaign data includes individual batch data firstly, where batch trajectory data have three dimensions: batch, time and variable. Secondly, campaign is a “batch” consisting of a series of batches connected by the degradation evolution.

2.2. Campaign PLS approach and campaign data unfolding method

As one campaign consists of a series of batches, the campaign data structure has four dimensions (campaign, batch, variable and time). The modeling approaches for continuous processes are not applicable to the multi-dimension campaign process, and it requires an unfolding method to transform the multi-dimension campaign data into two-dimension data. In the multiway analysis, the batch-wise unfolding method is developed to transform the three-dimension batch data into two-dimension unfolded data: batch data are extracted horizontally in a time-wise fashion and each batch becomes a single row of data (Nomikos and MacGregor, 1994; García-Muñoz et al., 2003; Wold et al., 2010):

$$X_{batch}^m = [x_{i1}, x_{i2}, \dots, x_{iki}, x_{t1}^1, x_{t2}^1, \dots, x_{tT}^1, x_{t1}^2, x_{t2}^2, \dots, x_{tT}^2, \dots, x_{t1}^{kt}, x_{t2}^{kt}, \dots, x_{tT}^{kt}] \quad (1)$$

where, X_{batch}^m is the unfolded batch data of the m th batch, which includes initial conditions and unfolded trajectories: the initial condition variables x_{ik} , $k = 1, 2, \dots, ki$ is the index of initial condition variables; trajectory data $x_{t_k}^k$, $k = 1, 2, \dots, kt$ is the index of trajectory variables, $t = 1, 2, \dots, T$ is the time index in a single batch.

In a similar methodology, a campaign unfolding method is proposed to obtain 2-dimension unfolded campaign data. The variable and time dimensions are unfolded firstly to obtain the unfolded batch data X_{batch}^m using the batch-wise unfolding method. Then the three-dimension campaign data is unfolded as Figure 3 illustrates, where the campaign data are extracted horizontally in a batch-wise fashion and each campaign becomes a single row of different unfolded batch data. For simplicity, unfolded batch data are presented with the index $k = 1, 2, \dots, K$. Further, the unfolded campaign data are employed for the degradation modeling. To build a degradation model based on campaign data, the outputs are the evolution of degradation KPIs, and the inputs are the unfolded campaign data which contain control and process information of a single campaign.

In this section, PLS is employed for the campaign-based degradation modeling due to its advantage in dealing with a large number of correlated predictor variables and avoiding over-fitting problem. In PLS, the highly correlated data in the input and output space are modeled separately with orthogonal principal components based on multivariate statistical projection, and linear regression

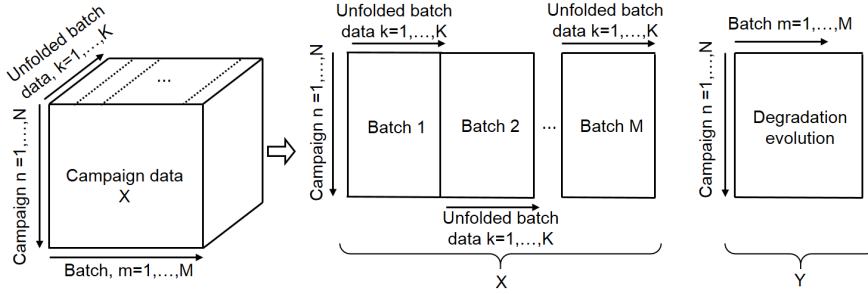

Figure 3: Campaign data structure and unfolding method

is employed on those dimension-reduced principal components (Geladi and Kowalski, 1986; Abdi, 2010). The campaign-based PLS model is:

$$\begin{aligned} X_n &= T_n P^T + E_n, & X_n &= [X_1^n, X_2^n, \dots, X_M^n], & X_m^n &= [x_1^m, x_2^m, \dots, x_{k_1}^m, z_1^m, z_2^m, \dots, z_{k_2}^m] \\ Y_n &= T_n C^T + F_n, & Y_n &= [y_1^n, y_2^n, \dots, y_M^n] \end{aligned} \quad (2)$$

where, $X_n \in \mathbb{R}^{1 \times M(k_1+k_2)}$ is the n th unfolded campaign; the m th unfolded batch data from the n th campaign $X_m^n \in \mathbb{R}^{1 \times (k_1+k_2)}$ are divided into manipulated data z_k^m , $k = 1, 2, \dots, k_2$ and process data x_k^m , $k = 1, 2, \dots, k_1$, while k is the corresponding index; the output $Y_n \in \mathbb{R}^{1 \times M}$ is a series of degradation KPI in a campaign, and the element y_m^n is the degradation KPI of m th batch in n th campaign; $T_n \in \mathbb{R}^{1 \times L}$ is the score of the n th campaign projecting on the principal component, while L is the dimension; $P \in \mathbb{R}^{M(k_1+k_2) \times L}$ and $C \in \mathbb{R}^{M \times L}$ are the model parameters, called loading matrix, which can be estimated through the NIPALS algorithm (Geladi and Kowalski, 1986).

The campaign-based PLS model can be used to estimate the evolution of batch degradation from the known input observations (historical process data and the manipulated data). In the batch fouling example, the manipulated data are exclusively the production planning, that is, the planned production schedule shows which products are going to be produced and the production order. Given the current batch K , the known data X_n^* are $\{X_{1:K}^n, x_{1:k_2}^{K+1:M}\}$, and missing data $X_n^\#$ are $\{x_{1:k_1}^{K+1:M}\}$. The future batch degradation indicators of interest are $\{y_{K+1:M}^n\}$. The missing data estimation approaches for PLS models such as the trimmed score regression (TSR) are meant to provide estimation of final score \hat{T}_n with the known samples X_n^* (the information update to K), and then output \hat{Y}_n is calculated from the estimated score \hat{T}_n . TSR algorithm is proved to be effective in multiway PLS applications (Arteaga and Ferrer, 2002; Nelson et al., 1996; Keivan Rahimi-Adli, 2016).

3. Case study

3.1. Case study description

The case study presents an example of heat exchanger fouling in a polymerization batch process (see the process schematic in Figure 4). This batch process produces multiple water and paper treatment chemicals. The polymerization starts when initiators are added into monomer emulsion in the reactor. The recirculation system works during the reaction, and two parallel heat exchangers help to cool down the reactor. The emulsion flow results in polymer residues depositing in the reactor and the heat exchangers. The fouling in heat exchanger impedes the flow and can even lead to a blockage, and it also decreases the cooling efficiency and prolongs batch duration with less production capacity. Therefore, the cleaning is required to remove the residues in the heat exchanger after running certain number of batches. We focus on the fouling in heat exchangers as it is the short-board of the process.

3.2. Multi-product effects on fouling KPIs

Multiple products in batch process add more complexity to degradation prediction. Different products mean different batch recipes, such as ratios of raw materials, additives and operation conditions, which results in disturbances to fouling KPIs. In figure 2, the fouling KPIs from batch to batch show an increasing trend between two cleanings, especially for the same product type. KPIs with different product type show some biases among them, for example, the green KPIs are relatively larger than the blue KPIs. This is not due to fouling evolution, and it brings more disturbances in degradation modeling. To avoid this, the product biases are calculated by comparing KPIs to some fitted curves of the main product KPIs (P6), and the bias correction is carried out by adding the product-based biases to the KPIs (see the smoothed KPIs in Figure 5).

3.3. Results

The factors that contribute to fouling evolution in heat exchangers include the product recipes and trajectory process variables like temperature, pressure, flowrate, etc. The pressure drop across the heat exchanger is employed as a batch fouling KPI, and the multi-product biases are excluded to obtain smooth increasing fouling KPIs with less disturbances. To model the fouling KPI evolution in the heat exchanger, the unfolded campaign data is obtained using the proposed method. An equally long campaign is a prerequisite for the PLS model, hence the last 30 batches of one cleaning period are collected as one campaign, which includes the dynamics of the fouling evolution. The collected historical data for modeling includes 20 campaigns. 23 input variables are selected from the unfolded batch data, which are production planning variables, landmarks of trajectory data and batch quality data (Wold et al., 2010). The output vector for each campaign includes 30 batch fouling KPIs. The unfolded campaign data X has a row of 460 input variables. The heat exchanger fouling campaign PLS model is developed based on the historical data (20 campaigns), where several campaigns are excluded for cross validation purpose. Based on this model, we can predict fouling evolution in upcoming campaigns of batches by using the missing data estimation method TSR as explained above. We illustrate this using two campaign examples in Figure 6, where three predictions are given using the data up to different stages of the campaign, and compared to the actual fouling KPIs. The first case is $K=1$, which means given observation data up to Batch 1 and the production planning for the whole campaign, one needs to predict the fouling evolution in the remaining 29 batches. Similar for $K=10$ and $K=20$. The fouling KPI predictions in Figure 6 follow the actual KPIs with a smooth increasing curve.

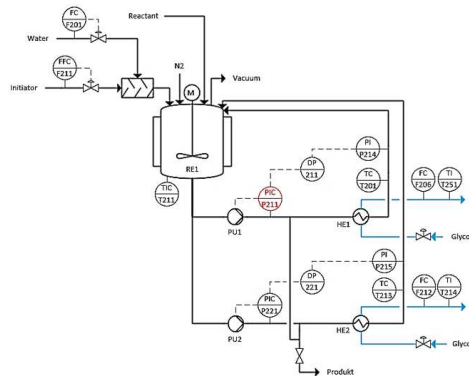

Figure 4: Case study process schematic

Figure 5: Bias corrected fouling indicators

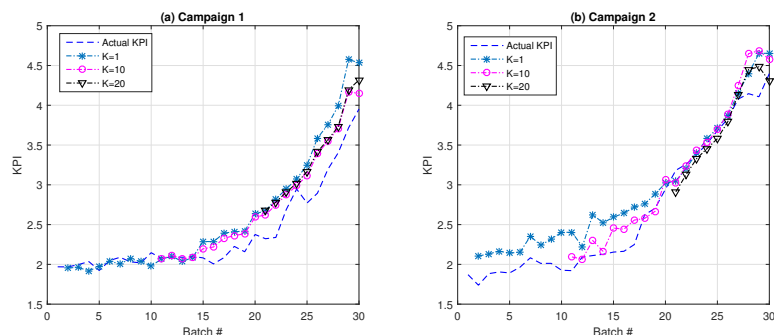

Figure 6: Two fouling KPIs campaign predictions: given information up to Batch $K = 1, 10, 20$

4. Conclusions

This paper focuses on degradation prediction for batch processes with heat exchanger fouling as the case study. To solve the degradation prediction problem, a new “campaign” concept is proposed to structure the batch degradation evolution. Furthermore, an unfolding method is proposed to transform the four-dimension data into two-dimension unfolded campaign data for PLS modeling. The campaign-based PLS approach is then applied in the case study, and the missing data estimation method TSR is employed for the degradation prediction. The validation result illustrates the effectiveness of the proposed campaign PLS approach in predicting heat exchanger fouling evolution, and this fouling predictions can provide further information for better production scheduling and maintenance planning.

Applying New Sustainability Metric in Different Natural Gas Liquid (NGL) Recovery Configurations to Extend Investment Decision and Incorporate Sustainability Analysis

Saad A. Al-Sobhi,* Ahmed AlNouss

Chemical Engineering Department, College of Engineering, Qatar University. Doha, Qatar

saad.al-sobhi@qu.edu.qa

Abstract

Sustainable design is considered as one of emerging research area in process system engineering (PSE) society. It extends the investment decision that focuses mainly on profitability analysis to consider other aspects such as the environmental impact and safety aspects. The sustainability dimensions such as the economic and environmental impact are considered to assess the natural gas liquids (NGL) recovery process using a new sustainability metric referred as the sustainability weighted return on investment metric (SWROIM). It extends return on investment (ROI) concept and makes use of the augmented sustainability metrics and process integration targeting (benchmarking) approaches. We adapted a sequential strategy to assess different NGL configurations. The turbo-expanding separation method and its consequent configurations, the most applicable separation technology in today's gas industry were considered to process 84000 kg/h of natural gas. We used ASPEN HYSYS V9 to simulate six NGL flowsheet configurations. Other ASPEN products such as ASPEN Energy Analyser were utilized to perform other energy saving activities to improve the design of baes case. Considering the economic evaluation first, and using the ROI analysis, IPSI-1 and GSP are competing with the original ISS configuration with 44% and 40% as estimated rate of investment, respectively. After the incorporation of the sustainability metric with some weights (e.g. 0.07 for thermal saving via heat integration and 0.3 for CO₂ emission reduction) as relative importance to economic profit, both IPSI-1 and GSP configurations improved in SWROIM analysis with 47% and 42%, respectively. However, IPSI-2 showed to be promising with 10 %, a percentage incremental in SWROIM analysis in comparison to 8 % in IPSI-1 configuration for 0.45 as CO₂ emission reduction relative importance.

1. Introduction

Recently, sustainable design is considered as one of emerging research area in process system engineering (PSE) society. The sustainable design of industrial processes is the one that leads to economic growth, environmental protection and social prosperity. Many definitions are available to define sustainability. However, the most widely known definition of sustainable development, which has been used as the basis for

many definitions, is that given in the Brundtland Report (Brundtland, 1987): ‘Sustainable development is development which meets the needs of the present population without compromising the ability of future generations to meet their own needs’. Traditionally, chemical engineers are known for designing and operating processes with the focus on material utilization, cost and safety. For over a couple of decades, chemical engineers have been incorporating environment concerns into process design and operation in terms of sustainability (Batterham, 2006). Sustainability has been gaining popularity in chemical engineering education and practice. Figure 1 shows the uptrend in terms of the number of publications from 1999 to 2016 when we consider “chemical engineering design and sustainability” as key words in the search engine Scopus with 329 as a total number of documents.

Figure 1 Uptrend in the number of publications addressing sustainable chemical engineering design from 1999 to 2016.

To extent our previous work, (Al-Nouss et al., 2017) and incorporate the sustainability analysis, we were motivated by the new metric referred to as the sustainability weighted return on investment metric (SWROIM) introduced recently by El-Halwagi (2017). It extends the Rate of Investment (ROI) concept and makes use of the augmented sustainability metrics and process integration targeting (benchmarking) approaches. The new metric was applied on different NGL recovery configurations. The main purpose of NGL recovery unit in gas processing facility is to recover the heavy hydrocarbons to satisfy pipeline gas specifications, safety and operational issues such as these heavier may result in the pipeline blockage when cooled. The advancements in turbo-expansion technology that can recover high values of ethane and propane made it a viable choice in today’s gas plants. Considering the simplest turbo expander scheme for NGL extraction, in this technology the feed gas is cooled in a series of heat exchangers by exchanging heat with residual gas and de-methanizer side stream and bottom reboiler. The partially condensed gas feed is then sent to a high pressure separator. The vapor is

expanded through a turbo-expander to obtain low temperatures, which makes the ethane less volatile, and larger amount of ethane can be recovered at the bottom of the de-methanizer. The expander shaft, which rotates during gas expansion, is coupled with the compressor shaft to utilize the expansion work while simultaneously producing a cooling effect. With the low temperatures at the de-methanizer top, carbon dioxide icing remains a problem. The ISS operational limitation had led to more advances schemes such as Cold residue gas-recycle (CRR), Gas sub-cooled process (GSP), Recycle split-vapor process (RSV), Enhanced NGL recovery process (IPSI-1), Internal refrigeration for enhanced NGL recovery process (IPSI-2). Basically, the GSP, CRR and RSV process schemes focus on improvements at the top side of the demethanizer column and IPSI-1 and IPSI-2 schemes focus on the improvements at the bottom side of the demethanizer column. Therefore, the industry standard single stage (ISS) and its consequently improved configurations are considered for simulation and sustainability analysis.

2. Overall Methodology

The sequential strategy consists mainly of five majors steps.

Step One: Process Simulation: steady state simulation of six NGL process schemes/configurations using ASPEN HYSYS V9 under different operating conditions to estimate material and energy requirements. ASPEN HYSYS, a powerful simulation package, it is used to estimate the material balance and energy balances and help to address what-if analysis and carry out sensitivity analysis.

Step Two: Economic Evaluation: estimate the capital, operational costs using ASPEN Economic Evaluation tool and perform profitability by calculating the total Annualized Cost and ROI as shown in Eq. (1).

$$ROI_p = \frac{AEP_p}{TCI_p} \quad (1)$$

Where AEP is the annual net economic profit and TCI is the total capital investment.

Step Three: Environmental Impact Assessment: estimate the annual carbon emissions in kg/h and the reduction targets in all recovery configurations using ASPEN software embedded CO₂ estimation algorithm.

Step Four: Process Integration and Improvements: perform heat integration techniques to estimate potential energy savings using ASPEN Energy Analyzer. It is an energy management software for performing optimal heat exchanger network design to minimize process energy. Also, the energy intensity before and after heat integration can be estimated.

Step Five: Sustainability Incorporation and Analysis: apply the sustainability metric with some weights as relative importance as ratio to economic profit as shown in Eq. (2).

$$SWROI M_p = \frac{AEP_p \left[1 + \sum_{i=1}^{N_{Indicators}} w_i \left(\frac{Indicator_{p,i}}{Indicator_i^{Target}} \right) \right]}{TCI_p} \quad (2)$$

where i is an index for the different sustainability indicators (other than the annual net economic profit with $i=1,2,\dots,N_{indicators}$). The weighing factor w_i is a ratio representing the relative importance of the i^{th} sustainability indicator compared to the annual net economic profit. The term $Indicator_{p,i}$ represents the value of the i^{th} sustainability indicator associated with the p^{th} project and the term $Indicator_i^{Target}$ corresponds to the target value of the i^{th} sustainability indicator (obtained from process integration benchmarking or taken as the largest value from all projects, or set by the company as a goal).

3. Case Study: Results and discussions

The selected process schemes namely, ISS, GSP, CRR, RSV, IPSI-1 and IPSI-2 were simulated in steady state mode using ASPEN HYSYS V9. Peng Robinson was considered as it is the recommended property fluid package for hydrocarbon system. For brevity, we present the simulated flowsheet for IPSI-1 configurations as shown in Figures (2). All other simulated configurations can be found in our recent work (AlNouss et. al., 2017). After the development of the flowsheets in ASPEN HYSYS, the six different process schemes were assessed based on the economic metric. After obtaining the recoveries values for sales gas, NGL product and the utility requirements using the steady state simulation mode, we activated Aspen process Economic Analyzer (APEA) to estimate the capital cost and annual operational cost in US dollars. By considering the raw materials and products prices, revenues were calculated to estimate

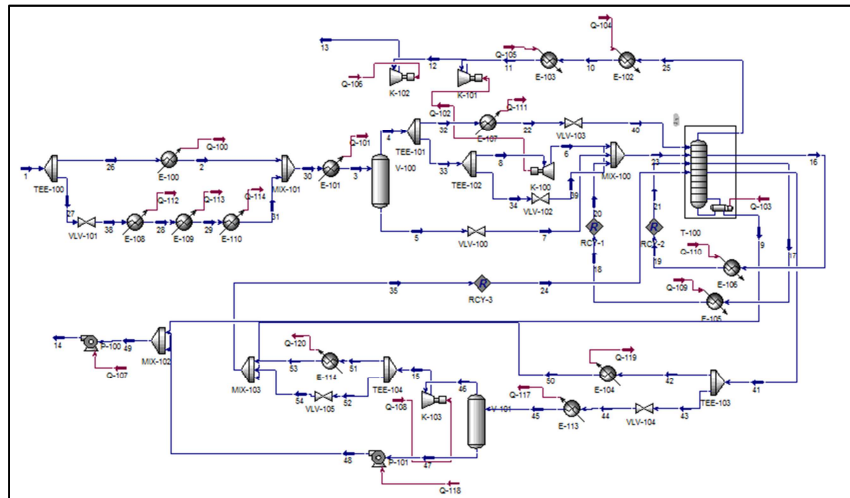

Figure 2 IPSI-1 ASPEN HYSYS flowsheet simulation.

ROI using Eq. (1) to perform the profitability analysis. Table 1 summarizes different economic, energy, and environmental parameters and values after activating the APEA and AEA components. Table 2 presents the targets and relative importance of sustainability indicators for IPSI-1 configuration.

Table 1 Main results from ASPEN Plus, ASPEN Process Economic Analyzer, and ASPEN Energy Analyzer.

	ISS	GSP	CRR	RSV	IPSI-1	IPSI-2

NGL recovery, %	7.49	7.81	7.68	8.00	6.94	8.42

Table 2 Targets and Relative Importance of sustainability indicators for IPSI-1 NGL configuration case study

Sustainability indicator (i)	Target $Indicator_i^{Target}$	Unit	Relative importance as a ratio to economic profit (w_i)
Thermal energy savings (via heat integration)	55,538,358	KW	0.07
CO ₂ emission reduction	702.61	Kg/h	0.30

By using Eq. (2), for all configurations and considering the targets and relative importance of sustainability indicators (e.g. 0.07 for thermal saving via heat integration and 0.3 for CO₂ emission reduction) relative importance as ratio to economic profit, the SWROIM % values are calculated and presented in Figure 3.

Figure 3 ROI and SWROIM for all NGL configurations.

4. Conclusions

The new sustainability metric was applied on different NGL recovery configurations. When considering only the economic factors and profitability criteria, IPSI-1 showed to be the most attractive configuration with 44 % as the highest ROI % next to ISS configuration. However, after incorporating the sustainability aspect, some configurations showed to be promising with 3, 2, 5 %, a higher incremental in SWROIM % analysis in comparison to profitability analysis in the case of GSP, IPSI-1, and CRR configurations, respectively for 0.3 for carbon emission relative importance. For a higher ratio as carbon emission relative importance such as 0.45, IPSI-2 showed a higher incremental percentage in SWROIM analysis to 48 % next to ISS with 69 %.

Abstract

Pretreatment is one of the most important stages for producing advanced bioethanol and bioproducts from lignocellulosic biomass in biochemical-platform biorefineries. Continuous pretreatment using tubular reactors is gaining importance at industrial scale. Mass flow represents a crucial variable to accurately predict pretreatment yields. In order to study realistic flow dynamics, a pilot-scale continuous tubular reactor was designed and built. In this work, a discrete-time surrogate model for the mass flow dynamics is presented. Flow data was carefully acquired for two types of biomass. The model accurately predicts the experimental data.

Keywords: mass flow, residence time, pretreatment, discrete-time modelling, lignocellulosic biomass

1. Introduction

Lignocellulosic biomass (LB) is currently considered as an important material source worldwide and is used for the bioethanol, bioproducts, power and heat production processes (Gupta and Verma, 2015). The bioethanol production process consists on four stages: pretreatment, enzymatic hydrolysis, sugar fermentation and product recovery (Saini et al., 2015). The pretreatment is considered as one of the most challenging stages and its task is to destroy the cellulose lignin matrix to reduce cellulose crystallinity and increase the fraction of amorphous cellulose as shown in Figure 1.

Figure 1: Pretreatment effect over LB (Mosier et al., 2005).

There are several technologies to carry out the pretreatment process depending on the LB's properties. Autohydrolysis has become popular due to its low environmental impact and has been widely

studied to find its optimal operation conditions (Kim et al., 2001; Shekiri III et al., 2014). One of the key variables for predicting autohydrolysis yields using kinetic models (Sidiras et al., 2011) is the mass flow output. According to Roberts (1999), the mass flow output is affected by geometric features of the continuous tubular reactor (CTR), transport phenomena such as backmixing flow or bulk sticking (Nachenius et al., 2015) and the LB's mechanical properties. Several authors have reported different approaches to identify the mass flow inside CTRs. Wan and Hanley (2004) presented a flow pattern prediction method to depict LB behavior inside the CTR. Owen and Cleary (2009) simulated the particles dynamics within the CTR by the discrete element method. In general, these two approaches use LB parameters that are either not reported in the literature or very difficult to measure in a CTR.

2. Equipment Description

The pilot-scale pretreatment CTR of the Energy Futures Laboratory of CINVESTAV Guadalajara served as a platform for carrying out the identification experiments using two biomass types with different physical properties: wheat straw (WS) and corn stover (CS). The CTR schematic diagram is shown in Figure 2. The main equipment parts involved in the pretreatment process are labeled with circled numbers and referenced in Table 1. The CTR task is divided into three phases, each one performing a different type of pretreatment: extrusion (parts 1, 2 and 3), autohydrolysis (parts 4, 5 and 6) and steam explosion (parts 7 and 8).

Figure 2: CTR schematic diagram.

Table 1: Process components from Figure 2.

ID	Device
1	Extruder screw
2	Hopper
3	Extruder's body
4	Screw conveyor
5	CTR body
6	Steam input
7	Discharge valves
8	Discharge box

LB was grinded and soaked before each experiment to improve the mechanical properties of the particles. The prepared LB was fed (by hand) through the hopper into the extruder's body. Flow input data U was acquired by measuring the time it takes to feed a fixed amount of biomass.

The extruder screw conveys and compresses the LB inside the extruder's body as it rotates at a fixed speed ω_1 . The LB filling time is termed cone filling delay (CFD) and represents the delay between LB input and output from the extruder. The extrusion phase aim is to create a dense biomass body in the CTR input to avoid steam from escaping the CTR. Extruder mass output y_E enters the CTR body directly. Once inside, it is transported by the rotation of the screw conveyor at a fixed speed ω_2 which determines the LB residence time (RT) T_R . Finally, LB reaches the discharge point where the discharge valves execute a predefined sequence of opening and closing with a fixed time interval so the biomass is expelled to the receiver box by the pressure difference between the CTR interior and the environment (steam explosion). Mass flow output samples y_R were collected, weighed and registered with a constant sample time T_s . Input and output LB moisture was measured at fixed time intervals.

3. System modelling

Identification runs were carried out and analyzed off-line. Experiments were executed first for the extrusion phase only. Then, experiments were carried out in the complete CTR (three phases) and consisted on registering the system response to an impulse feed of tracer (variables shown in Figure 2). Extrusion and reaction phases were modelled with discrete-time equations due to the sampling procedure according to the areas A and B shown Figure 2, respectively. The light and dark hexagonal blocks represent the corresponding input and output variables, respectively.

The extrusion model was proposed as a second order overdamped discrete transfer function as shown in Eq. (1). Additionally, the CFD phenomenon was considered by including a gain K_1 in the system's output Eq. (2) which depends on the total LB fed $\sum_0^k U(k)$ and the extruder's mass capacity C_e . For the reaction phase model, the CTR body was modelled as a series of n identical continuous stirred tank reactors (CSTR) (Fogler et al., 1999), with $n = 14$ due to the mechanical and geometric CTR characteristics as seen in Figure 3. Each CSTR (i.e. subreactor) mass flow output x_{iR} was modelled as a first order discrete transfer function described by Eqs. (3). The extruder output y_E is the first CSTR input, the first CSTR output x_{1R} is the second CSTR input, and so on. The output of the 14th CSTR x_{14R} is the system output y_R shown in Eq. (4). The total T_R is also divided in 14 equal CSTR delays δ_2 as seen in Eq. (5).

$$x_E(k+1) = \theta_1 x_E(k) - \theta_2 x_E(k-1) + \theta_3 U(k) - \theta_4 U(k-1) \quad (1)$$

$$y_E(k) = K_1(k) x_E(k) \quad (2)$$

$$x_{1R}(k+1) = \theta_5 x_{1R}(k) + \theta_6 y_E(k - \delta_2)$$

$$x_{2R}(k+1) = \theta_5 x_{2R}(k) + \theta_6 x_{1R}(k - \delta_2)$$

$$\vdots$$

$$x_{14R}(k+1) = \theta_5 x_{14R}(k) + \theta_6 x_{13R}(k - \delta_2) \quad (3)$$

$$y_R(k) = x_{14R}(k) \quad (4)$$

$$T_R(k) = \delta_2(k-14) + \delta_2(k-13) + \dots + \delta_2(k-1) \quad (5)$$

Figure 3: CTR body analysis.

Model parameters θ_1 , θ_2 , θ_3 and θ_4 depend on T_s as well as the damping ζ and natural frequency ω_n of the extrusion phase system, while θ_5 and θ_6 are explicit functions of T_s and the reaction phase time constant τ_2 . Expressions for the model parameters θ_i and gain K_1 are given in Appendix A. All parameters were estimated with a PSO algorithm (Liu et al., 2008) to reduce the mean squared error between real data and the model output. For the extrusion model the PSO algorithm was utilized to find the values of ω_n corresponding to a fixed $\zeta = 1.001$ (overdamped) so the system poles produced an output that reproduced experimental results for both LB (WS and CS) as shown in Figure 4. The CTR parameter estimation was divided in two tasks: first, a) parameters ω_{n2} and ζ_2 from an approximation function $\hat{x} = f(\omega_{n2}, \zeta_2, T_s)$ similar to Eq. (1) (second order overdamped transfer function) were estimated to fit the identification experimental data (Figure 5a). Then, b) the 14 τ_2 and δ_2 parameters in Eqs. (3) were estimated to fit the \hat{x} behavior (Figure 5b).

Figure 4: Extrusion phase tracer experiments predictions.

Figure 5: Reaction phase tracer experiment approximation and modelling.

4. Validation results

Figures 6 and 7 show: a) the acquired input signal and b) the comparison between experimental output data and the model output for two typical experiments using WS and CS, respectively. The error signal was analyzed with the method proposed by Zekki et al. (1999), which led to the conclusion that the model is adequate to reproduce experimental behavior in steady conditions.

Figure 6: WS experiment.

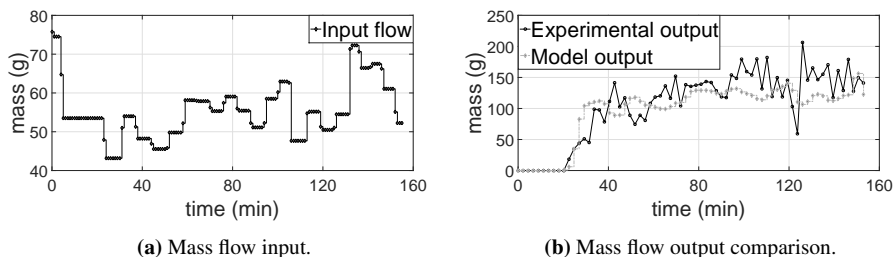

Figure 7: CS experiment.

5. Conclusion

Mass transport inside a CTR is a difficult phenomenon to describe. The identification experiments in a pilot-scale CTR showed that an important variable for mass flow prediction is the input flow. This input flow directly affects the extruder and CTR mass flow output and defines its erratic behavior in steady state conditions. The accurate acquisition of LB input flow allowed to reproduce the mass flow dynamics correctly. Different behaviors occurred for each LB when subjected to the extrusion phase only, but similarities were observed when both LB were subjected to the complete pretreatment conditions (high pressure and temperature). The modeling approach and experimental validation resulted in a set of equations that allow to predict the mass flow in the CTR explicitly. Future work will focus on the effects of different conditions of ω_2 over the mass flow and RT.

Abstract

We investigate the influence of the biodiesel feedstock on the optimal operating conditions of the reactor and the properties of biodiesel produced at those conditions. To this end, we employ a generalized kinetic model to find optimal operating conditions for 4,500 different blends of six major oils *viz.*, Jatropha, Linseed, Olive, Palm, Rapeseed, and Sunflower oil. We then develop meta-models with the characteristics of the different feedstocks as input variables and the solution of the optimization problems as the output variables. We employ Regression tree ensembles in MATLAB to develop these meta-models. Finally, we use these meta-models for predicting the various properties of biodiesel to find the best blend of the considered oils in order to obtain the premium quality biodiesel as per both European (EN 14214) and American (ASTM D6751) standard specifications. We evaluate the weight distribution of these blends for a variety of scenarios. We observe that the optimal oil blend may vary a lot depending on the specifications we impose, thereby emphasizing the significance of such a study in our efforts to bridge the gap between academic research and commercialization of biodiesel.

Keywords: Biodiesel, Feedstock, Kinetics, Meta-model, Optimization

1. Introduction

The hunt for an assortment of energy sources is just about as old as humanity's need for energy. This search has been escalated by an expanding industrialization since the 19th century. The internal combustion engine is a prime example. Even though fuels obtained from fossil sources have been a prime choice since the onset of these engines, biofuels specially biodiesel have also found some interest. This interest has particularly gained momentum in the past few decades due to rapidly increasing energy demand and depletion in fossil fuel resources.

Biodiesel is a non-toxic, biodegradable, and environmentally benign fuel that can be used in diesel engines. The most commonly used method for the production of biodiesel is transesterification. It involves the reaction of the oil with an alcohol in the presence of a catalyst to form fatty acid alkyl ester (biodiesel) and glycerol. Although biodiesel is a promising alternative fuel, its production poses significant challenges due to its higher production costs compared to the petroleum-based diesel. Therefore, it becomes crucial to model and optimize the biodiesel production process to lower costs while meeting the desired property specifications.

The literature is replete with the studies about modelling and optimization of transesterification (Singh et al. (2008); Yang et al. (2016)). It is generally believed that reaction temperature, catalyst concentration, alcohol to oil molar ratio, and reaction time are the significant factors that impact the yield. Recently, statistical methods such as response surface methodology (RSM) (Pinzi et al. (2011b)), Taguchi method (Kumar et al. (2015)), *etc.* have been employed to optimize these factors and study their interactions. However, there is a notable divergence in the optimization results reported in the literature. This further leads to uncertainties in properties of the biodiesel produced at those conditions, thereby making these results unreliable. All this is primarily due to substantial variation in the composition of biodiesel feedstock. Although, a few comparative studies have been reported in the literature, all of them focus on static optimization, thereby neglecting the kinetics of biodiesel production.

The purpose of this study is to investigate the influence of the chosen biodiesel feedstock on the optimal operating conditions of the reactor and the quality of biodiesel. To this end, we use a generalized kinetic model in order to find those optimal conditions with 4,500 different blends of six major oils *viz.*, Jatropha, Linseed, Olive, Palm, Rapeseed, and Sunflower oil as feedstock. We employ three different objective functions to solve these optimization problems. We then develop meta-models with the solutions of these optimization problems as output variables and the characteristics of the feedstocks as the input variables. Finally, we employ these meta-models to identify the best possible blend of the considered oils which is required to obtain the premium quality biodiesel. Overall, the objectives of the current study are as follows,

1. Find optimal operating conditions of the reactor for biodiesel production using different vegetable oils as feedstock.
2. Develop meta-models outlining the effect of different vegetable oils/their blends on the optimal operating conditions of the reactor.
3. Develop meta-models depicting the effect of the different vegetable oils/their blends on the properties of the biodiesel produced using these feedstocks.
4. Use the developed meta-models to find the best possible blend.

The outline of the paper is as follows. In Section 2, we explain the details regarding the kinetic model employed in this study and also provide a brief account of the approximation technique *i.e.* Regression trees ensembles. We explain the methodology adopted for the current study in Section 3. We discuss the results in Section 4. Finally, we present our conclusions in Section 5.

2. Theoretical Background

2.1. Kinetic Model Description

A huge variety of vegetable oils can be used to produce biodiesel. However, most oils consist of 95 - 98 % of triglycerides (TG) with traces of diglycerides (DG), monoglycerides (MG), water, and free fatty acids (FFA). A triglyceride is an ester formed from one molecule of glycerol and three fatty acids. Considering the large variety of fatty acids, these can lead to the formation of a wide range of triglycerides. In our previous study (Chhabra et al. (2017)), we developed a generalized kinetic model based on the reaction scheme of all the glycerides formed by the combination of the five most common fatty acids present in oils *i.e.* oleic, linoleic, linolenic, palmitic, and stearic. Since any vegetable oil can be represented by an arbitrary mixture of these glycerides, our model can be adopted to investigate the product distribution with a vast variety of vegetable oils as feedstocks. We have validated our model for a variety of experimental datasets from the literature. In this study, we employ it to find the optimal operating conditions of

the reactor along with the properties of biodiesel developed at those conditions. The correlations employed to calculate the properties based on the distribution of various ester components in biodiesel have been taken from Pinzi et al. (2011b).

2.2. Regression tree ensembles

The idea of simple regression as a way of making quantitative predictions is well known. In simple regression, a dependent variable, \hat{y} is modeled as a function of multiple independent variables, $x_1, x_2, x_3, \dots, x_N$, where ε is a random noise,

$$\hat{y} = \beta_0 + \beta^T x + \gamma x x^T + \varepsilon \quad (1)$$

However, the number of parameters increases exponentially with increasing number of independent variables. Furthermore, strong nonlinearities among the independent variables enhance the complexity of the problem. Simple regression involves a single predictive formula that holds over the entire data-space. However, in case of large number of independent variables which interact in complex non-linear ways, assimilating a global model can be strenuous. Therefore, an alternative approach is to partition the entire space into small regions, where the interactions are easier to comprehend. The partitioning is continued till we reach a space where we can fit simple models to them. The regression tree ensembles, which are a variant of the decision trees, are based on this principle. There are several advantages associated with them, *i.e.*, the predictions are faster, it is easier to understand which variables are important (by simply looking at the tree structure), and there exist reliable algorithms to implement them. One may refer to Breiman et al. (1984) for a detailed discussion on the same.

3. Methodology

As stated earlier, our aim is to develop meta-models that can help us to comprehend the effect of the feedstock on a) the optimal operating conditions of the reactor, and b) the quality of biodiesel produced at those conditions. To this end, we have employed a three step methodology (as shown in Figure 1). We start with the collection of data to develop these meta-models. In order to achieve that, we solve an optimization problem for a blend from a pool of 4500 blends. This amounts to total 4500 optimization problems. As mentioned in Section 2.1, we employ the generalized kinetic model for performing the optimization. We chose three different objective functions to solve the optimization problems *i.e.* maximization of biodiesel yield, minimization of a property based

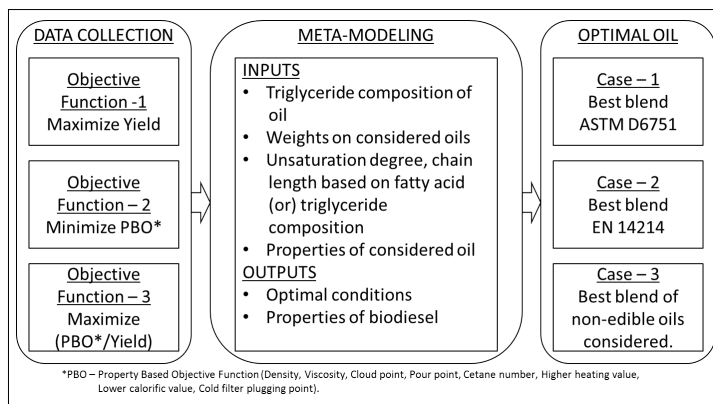

Figure 1: Adopted Framework for the current study.

objective function (considering density, viscosity, cold point, pour point, cetane number, higher heating value, lower calorific value, and cold filter plugging point), and a combination of the two, which is to minimize the ratio of the property based objective function and the yield. We solve each optimization problem by using the "fmincon" function in MATLAB. The computational time for each optimization problem is approximately 100 seconds. We use multiple MATLAB sessions to enhance the computation speed. The decision variables are reaction temperature (293.15 K to 343.15 K), catalyst concentration based on oil (0.2 wt.% to 2.0 wt.%), alcohol to oil molar ratio (2 to 12), and reaction time (2 minutes to 120 minutes). The bounds on the variables are chosen based on the results reported in the literature for optimization of base catalyzed transesterification over the past decade.

Once we obtain the solutions of these optimization problems we move to the second step, which is to develop the meta-models that can predict the effect of a feedstock on the operating conditions of the reactor and the quality of biodiesel obtained using that feedstock. The solution of the optimization problems refer to the set of dependent variables. For the set of independent variables, we need to characterize the feedstock in order to observe their effect on the set of dependent variables. In the past this has been done using the average chain length and the unsaturation degree of the fatty acids that constitute the oil (Giakoumis (2013)). Hence, we use this as one approach to characterize the feedstock. Additionally, we propose four different approaches to achieve the same *viz.* a) triglyceride composition (number of dimensions (N) = 34), b) average chain length, weighted unsaturation degree calculated based on the triglyceride composition of oil (N = 2) c) weights on the considered oils for the different blends (N = 6), and d) properties of oils, *i.e.* viscosity, density, heat capacity, enthalpy of vaporization, and vapor pressure calculated based on the triglyceride composition of oil (Zong et al. (2009)) (N = 5). We develop meta-models for each set of input-output pair and compare the performance on the basis of a normalized error metric, primarily the ratio of the percentage average absolute error in approach "i" to the minimum of the percentage average absolute error. The meta-models are developed using regression tree ensembles in MATLAB R2016b.

Finally, we employ the meta-models developed for predicting the properties of biodiesel to find the best possible blend (or) biodiesel feedstock that can provide the premium quality biodiesel *i.e.* it meets the standard specifications as stated by both Europe (EN 14214) and the United States of America (ASTM D6751).

4. Results & Discussions

The meta-models are as good as the data used to develop them. Therefore, in this study, we ensure that we examine the feedstock composition space as uniformly as possible. In order to achieve this, we consider a significantly high number (4500) of vegetable oil blends for collecting the data. Furthermore, as stated above, we choose three different objective functions for solving the optimization problems with the vegetable oil blends as feedstock. We observe that in the case of maximization of biodiesel yield (Objective Function - 1), the cold flow properties, specifically the Cold point and Pour point of biodiesel calculated at the obtained set of optimal conditions are very different from the standard specification of most of the countries. Similar problems persist in the case of minimization of the ratio of yield to property based objective function (Objective Function - 3). However, in the case of just the property based objective function (Objective Function - 2) we observe that even though the biodiesel yield drops for some of the considered blends, there is a notable improvement in the cold flow properties of the final product. Since the cold flow properties play a vital role in deciding the quality of biodiesel, we adopt the data generated by the latter case for developing the required meta-models.

Once we collect the set of output variables, our next task is to characterize the feedstock in order to obtain the set of input variables. As we discussed in Section 3, we employ five different ways to

Table 1: Error metric comparing the performance of different feedstock characterization approaches(A,B,C,D: Proposed in this study; E: From past studies in the literature).

Response	PAAE = $\frac{AAE}{AR} \times 100$				
	A	B	C	D	E
Reaction temperature, T (K)	1.74	2.14	1.71	2.05	2.12
Density, ρ (g/cc)	0.03	0.08	0.06	0.04	0.09
Viscosity, μ (mm ² /s)	0.91	1.88	0.97	1.46	2.40
Cloud point, CP (K)	0.40	0.74	0.46	0.65	0.74
Pour point, PP (K)	0.46	0.83	0.55	0.73	0.84
Cetane number, CN	0.96	1.82	1.08	1.42	2.55
Higher heating value, HHV (MJ/kg)	0.06	0.14	0.07	0.11	0.17
Lower calorific value, LCV (MJ/kg)	0.06	0.12	0.07	0.10	0.14
Cold filter plugging point, CFPP (K)	0.21	0.43	0.24	0.35	0.53

Table 2: Weight fraction of different oils in the optimal blend.

	Jatropha	Linseed	Olive	Palm	Rapeseed	Sunflower
Case-1	0.0454	0.0159	0.0851	0.6442	0.0115	0.1979
Case-2	0.2074	0.0462	0.0939	0.0828	0.4620	0.1077
Case-3	0.9059	0.0941	0.00	0.00	0.00	0.00

characterize the feedstock (or) Vegetable oil blends. We split the data into two parts, whereby 70% of the data is used for training, while the remaining 30% of it is used for validation of the model. Table 1 shows the percentage average absolute error (PAAE) for the optimal operating conditions and the biodiesel properties.

$$PAAE = \frac{\text{Average Absolute Error (AAE)}}{\text{Average Response (AR)}} \times 100 \quad (2)$$

where $AAE = \frac{1}{1350} \left(\sum_i |y_i - \hat{y}_i| \right)$ and $AR = \frac{1}{1350} \left(\sum_i y_i \right)$. We observe a minimum error of 1.74% in the prediction of reaction temperature. However, no strong correlation was observed for the set of other operating conditions *i.e.* catalyst concentration, alcohol to oil ratio, and reaction time. This may be because the reaction temperature is more significant than any of the other three decision variables. This is in accord with the findings reported in the past (Pinzi et al. (2011a)). We notice a sound agreement between the predictions made by the original model and the meta-models developed for predicting the biodiesel properties (Table 1), which is an excellent result.

Finally, we employ the meta-models developed for predicting the properties of biodiesel to find the optimal blend of the considered vegetable oils in order to produce the premium quality biodiesel. We achieve this optimization using genetic algorithm. The objective is to minimize the property based objective function. The decision variables are the weights on the considered oils. We evaluate the optimal weight distribution for three different scenarios. In the first case, we identify the optimal oil blend needed to produce biodiesel that satisfies the less stringent American specifications (ASTM D6751). In the second case, we identify the optimal oil blend required to produce biodiesel that satisfies the more stringent European specifications. Finally, since there has been lot of opposition against the use of edible oils for the production of biodiesel, we evaluated a scenario where we assume the non-availability of the edible oils. Hence, we aim to determine an optimal blend of Linseed and Jatropha oils in order to produce biodiesel that would meet both American and European specifications. Table 2 shows the optimal distribution of weights whereas Table 3 lists the property values of biodiesel produced using the suggested blends. We observe that the optimal blend obtained for the first case contains around 64% palm oil. Since the biodiesel formed

Table 3: Properties of biodiesel produced using the optimal blends as feedstock.

	ρ (g/cc)	μ (mm ² /s)	CP (K)	PP (K)	CN	HHV (MJ/kg)	LCV (MJ/kg)	CFPP (K)
Case-1	0.87	5.52	273.52	266.38	67.10	42.40	37.66	279.91
Case-2	0.88	5.00	271.24	264.36	58.54	42.08	37.54	271.43
Case-3	0.88	5.00	270.61	263.41	58.24	42.08	37.54	271.46

using palm oil has higher cetane number, the same is reflected in the properties of biodiesel produced using the first blend. However, since the viscosity of biodiesel formed using palm oil is comparatively higher, it fails to meet the specification imposed by EN 14214 (3.5 to 5.0 mm²/s). Therefore as we impose tighter constraints as in Case-2, we record a sharp decrease in the amount of palm oil suggested in the optimal blend, thereby leading to a marked reduction in the Cetane number as well. As per the results of Case-3, the properties of biodiesel are quite similar to the properties of biodiesel obtained using the blend for Case-2. This suggests that it is possible to produce premium quality biodiesel even without the consumption of edible oils. This will definitely bolster the efforts for commercialization of biodiesel production as the use of non-edible oils can significantly reduce the costs associated with the biodiesel production process.

5. Conclusions

In this study, we develop meta-models describing the effect of the characteristics of different feedstock on the optimal operating conditions of the biodiesel reactor and the quality of biodiesel produced at those conditions. We also demonstrate the application of these meta-models in finding an ideal feedstock for the production of premium quality biodiesel and evaluated the solution for a variety of pragmatic scenarios.

Abstract

Reactive Scheduling is a dynamic and stochastic process, where changing circumstances continually force the reconsideration and revision of pre-established plans. The use of rolling horizon frameworks to exploit multiparametric programming techniques has been proposed, in which the optimal decisions are obtained as simple explicit functions of the uncertainty parameters, thus avoiding the need for repetitive solving the optimization problem. However, the main limitation of the proposed method is the increasing computational burden for solving big multiparametric programming problems (e.g., problems with many state variables and/or long prediction horizons). Recently the mixed-integer multiparametric approach based on machine learning has been proposed to solve optimization problems in a faster way. The objective of this work is to investigate the extension of mixed-integer multiparametric technique based in machine learning to deal with both uncertainties and optimal solutions with discrete behaviour and show its application to reactive scheduling problem with bounded uncertainty parameters. The results showed that the proposed methodology is capable of obtaining high accurate estimated optimal solutions, reducing the complexity of the solution procedure and scaling down the computational burden.

Keywords: Reactive Scheduling, Metamodel, Machine Learning.

1. Introduction

In highly dynamic production environments, Reactive Scheduling (RS) seeks to update production decisions in order to improve the profitability through the quick reaction to unexpected events or changes. Therefore, it is very important to consider how uncertainty is coupled with the scheduling process, since many of the parameters that are associated with the scheduling (demand, prices, machine reliability) vary with respect to time and are often subject to unexpected deviations (Li & Ierapetritou, 2007).

The Rolling Horizon (RH) method is commonly used to address RS problems: the involved optimization problem is solved sequentially over successive time intervals, in order to find the optimal decisions to be applied considering the uncertainty that may affect the system over this specific time interval. Recently Kopanos and Pistikopoulos, (2014) have introduced a multiparametric programming Rolling Horizon framework

(mp-RH) for the reactive scheduling problem of systems involving Uncertain Parameters (θ s), considering the θ s space divided by critical regions. Moreover, the Meta-Multiparametric (M-MP) approach has been proposed by (Shokry and Espuña, 2015) in order to solve optimization problems subjected to θ s in much simpler way. Recently, (Lupera, Shokry, Medina-González, Vyhmeister, & Espuña, 2018) have successfully proposed a mixed-integer multiparametric Metamodel (mi-mpM) technique based on machine learning techniques in order to handle general mixed integer optimization problems involving θ s. The objective of this work is to investigate the extension of mi-mpM technique to deal with both θ s and optimal solutions with discrete behaviour.

The rest of the paper will first revise the steps of proposed methodology, and then illustrate its application details to a reactive scheduling problem of a network of combined heat and power units. Then the discussion of the results will be addressed, to end with some concluding remarks.

2. Methodology

Taking in account a system that would involve discrete behaviour of some bounded θ s and the possible existence of mixed integer optimal solutions, the mi-mpM technique based on machine learning is proposed, Figure 1. A detail of the development of this methodology can be found in (Lupera et al., 2018).

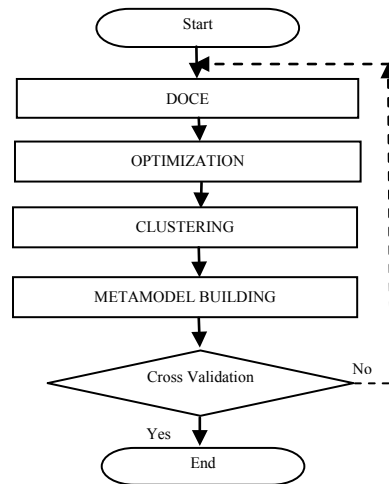

Figure 1. mi-mpM technique flowchart based in Machine Learning

Design of Computer Experiments (DOCE), is an important aspect to be considered when applying mi-mpM, in order to generate N combinations of θ s values. The designs should provide information about all portions of the experimental region. After analyzing several techniques like: Latin Hypercube, Hammersley sequencing, Monte Carlo, Full factorial design. A hybrid technique of Monte Carlo and full factorial design is proposed to ensure that all the portions are included representatively in the experimental region.

3. Case-study (Problem Statement)

This part illustrates the application of the proposed methodology in detail, through its application to a case-study (Kopanos, et al., 2014). This example considers the reactive scheduling problem of an energy system consisting of a CHP unit and a heat storage tank - as shown in Figure 2- over a certain period prediction horizon. The energy system can trade electricity with the main electrical grid, or even receive heat from external sources. More details about this problem can be found in Kopanos and Pistikopoulos (2014).

Figure 2. Representative structure of the energy network.

The resulting scheduling problem under consideration is formally defined in terms of the following items:

- (i) A given scheduling prediction horizon which is divided into a set of uniform time intervals $t \in T: = \{1, \dots, \tau\}$. Time interval t starts (ends) at time point $t - 1$ (t).
- (ii) A set of CHP units $i \in I$ having a ramp up limit ρ_i^+ (>0), a ramp down limit ρ_i^- (<0), a minimum (maximum) electricity production capacity ε_i^{min} (ε_i^{max}), a minimum running (shutdown) time δ_{iup} (δ_{idn}), and a known heat to electricity production ratio μ_i .
- (iii) The CHP units are connected to a heat storage tank with a known heat loss rate η , and minimum and maximum heat storage capacity levels λ_{min} and λ_{max} , respectively.
- (iv) At each time interval $t \in T$, the energy network is characterized by a total heat ζ_h and electricity demand ζ_e , which are considered as uncertain parameters with known bounds.
- (v) Economic parameters, which include the starting up (shutting down) cost ϕ_i (π_i) for each CHP unit $i \in I$, the (penalty) price for acquiring heat ζ_i from external sources, and the electricity purchased (selling) price ψ_i (v_i) from (to) external sources (e.g., main electrical grid). Additionally, α_i and β_i represent the fixed and variable energy production cost coefficients for every CHP unit $i \in I$, respectively.

In this study, we consider that there is an administrator that centrally controls the CHP unit. For every time interval $t \in T$, the key scheduling decisions to be made involve:

- (i) The operating status (startup $S_{(i,t)}$, shutdown $F_{(i,t)}$, in operation $X_{(i,t)}$) of CHP
 - $S_{(i,t)} = 1$, if CHP unit startups at the beginning of time interval $t \in T$; i.e., $X_{(i,t-1)} = 0$ and $X_{(i,t)} = 1$
 - $F_{(i,t)} = 1$, if CHP unit shutdowns at the beginning of time interval $t \in T$; i.e., $X_{(i,t-1)} = 1$ and $X_{(i,t)} = 0$
 - $X_{(i,t)} = 1$, if CHP unit is operating in time point $t \in T$
- (ii) The electricity production level $E_{(i,t)}$ of the CHP unit. If CHP unit is operating (i.e., $X_{(i,t)} = 1$), the upper and lower bounds on $E_{(i,t)}$ parameter are given by:
 - $E_{(i,t)max} = \varepsilon_{i,max}$, and $E_{(i,t)min} = \varepsilon_{i,min}$, respectively. Obviously, if $X_{(i,t)} = 0$, $E_{(i,t)} = 0$ and vice versa.

(iii) The total electricity purchases P_t and sales W_t , and

(iv) The total heat received from (disposed to) external sources Q_t (D_t).

B_t represent the heat storage level before the beginning of time interval $1 \leq t \leq \tau + 1$

$$\begin{aligned} \text{Objective Function} = & \underbrace{\sum_{i \in I} \sum_{t \in T} (\alpha_i X_{(i,t)} + \beta_i E_{(i,t)})}_{\text{energy production cost}} + \underbrace{\sum_{i \in I} \sum_{t \in T} (\phi_i S_{(i,t)} + \pi_i F_{(i,t)})}_{\text{switch on and off cost}} \\ & + \underbrace{\sum_{t \in T} (\psi_t P_t - v_t W_t + \xi_t Q_t + \omega_t D_t)}_{\text{energy purchases and sales}} + \underbrace{\sum_{t \in T} \gamma_{t+1} B_{t+1}}_{\text{inventory cost}} \end{aligned} \quad (1)$$

The total electricity and heat demand of the energy network at every time interval must be fully satisfied, and the optimization goal involves the minimization of total costs for producing and trading energy, as given by equation (1).

4. Illustrative Example

For simplicity and presentation purpose a single CHP unit and single-period prediction horizon, is considered. The parameters about the problem are showed in Table 1.

Table: 1 Data for the CHP Units.

θ_s	range	μ	ε_i^{\min}	ε_i^{\max}	ρ_i^+	ρ_i^-	δ_{iup}	δ_{idn}	Initial conditions
ζ_e	$0 \leq \zeta_e \leq 9$	2.5	2.00	8.00	2.880	-3.600	2	2	$E_{\theta} = 320$
ζ_h	$0 \leq \zeta_h \leq 20$	β	ϕ_t	π_t	λ_{\min}	λ_{\max}	η	α_i	$B_i = 3$
E_{θ}	$E_{\theta} = 0, 2 \leq E_{\theta} \leq 9$	2.226	34	17	0	30	0.05	37.0	$S_{(0,0)} = 1$

According to the proposed methodology, an hybrid technique (Monte Carlo & full factorial design) was used to generate the θ_s domain (ζ_e , ζ_h , E_{θ}) and the optimization problem was solved N times (1500) to obtain the optimal variable (E_t , P_t^* , W_t^* , Q_t^* , D_t^* , B_t^*) and the objective function (Optimum trading cost). The S and F are considered as additional θ_s . As a result, the problems must be solved for all possible combinations of the initial state binary decision (S=0, F=0; S=1, F=0; S=0, F=0; S=0, F=1), which were defined for each optimization. Each θ_s and their corresponding optimal solution form an instance I, and the set of instances make up a database of 831 training instances (I_t) and 669 validation instances (I_v). Based on the optimization results, the E_0 , B_0 and E_1 variables have a discrete behavior in addition to the binary variables (S, F).

5. Results and discussion

Therefore, once the proposed methodology was applied, 3 clusters (A, B, C), 3 metamodels based on optimization to predict the optimal values and 2 classification metamodels were determined. The metamodels' validation results and their corresponding interpolation time to determine a new instance are shown in the Table 2.

Table 2. mi-mpM results.

Metamodel	μ	σ^2	θ_1	θ_2	θ_3	θ_4	RMSE	I_t	Interpolation time (s) per instance
Cluster A	5.95	0.78	16.60	8.53	17.66	8.80	0.065	575	0.0002
Cluster B	8	0	2	2	2	2	0.000	50	0.0002
Cluster C	2.88	3.42E03	1.50	1.90	1.89	-	0.001	206	0.0002

The Figure 3 displays comparative results of the optimum electricity generation and the accumulated trading cost between mp-RH and mi-mpM for 20 consecutive instances of reactive scheduling. Observe that with mi-mpM, the predicted value (E1) have a difference, which have been quantified between 0% and 0.5% respect to mpRH. For other hand, when the objective function (accumulated optimum trading cost) is predicted with mi-mpM, there is a difference of 0.8% with respect to accumulated value obtained with mp-RH. The total execution time per iteration is 0.0002s, the same problem has been solved in 0.0003s by using mp-RH.

Figure 3. Detailed schedule per time interval using mp-RH and M-miMP.

6. Conclusions

The proposed methodology mi-mpM would address the reactive scheduling problems which involve discrete behaviour, with accuracy and computational efficiency.

Abstract

Biomass materials are initially wet containing with a moisture content of app. 25 - 65% which requires a thermal pre-treatment to reduce the moisture to app. 10% and increase the quality of a biofuel. Understanding and optimizing the heat transfer is important in order to decrease the cost of running the equipment. Due to the complexity of moving bed reactors, heat transfer is mainly assessed through experiments and derived empirical correlations that obviously depend on the operating conditions and include a degree of uncertainty. Therefore, the objective of this study is a drying analysis of wet woody particles on a vibrating grate using a DEM-CFD coupling method referred to as eXtended Discrete Element Method (XDEM). In this approach, the particles are resolved as a discrete phase and coupled via heat, mass and momentum transfer to the surrounding gas phase. Thus, the dynamics and thermodynamic behavior of biomass particles during drying is analyzed in detail when exposed to a hot gaseous environment and transported by the vibrating motion of a grate. An outstanding feature of the numerical concept is that each particle in addition to its position and orientation in time and space is described by its thermodynamic state e.g. temperature and reaction progress. Available positions of particles allow determining contact areas between particles and walls for heat transfer. Validation is carried out with experimental data taken from an industrial-scale facility on a vibrating grate dryer in Soil-Concept company in Luxembourg. Under these circumstances, different sizes of particles are employed to predict the final moisture content and density to compare with experiment and show a good agreement between measurements and predicted results. In addition, the influence of inlet gas temperature and velocity, heated-up device temperature and vibrating grate motion on the particle bed mean temperature and moisture content, drying rate and residence time is investigated. At the end, the surface temperature distribution of particles in different instances during drying is visually demonstrated.

Keywords: multi-scale, multi-physics, modeling, renewable energy

1. Introduction

In this DEM-CFD coupling module, all processes inside each particle are described by one dimensional and transient conservation equations of mass and energy. With summing up individual particle processes, the total process is established for the packed bed of particles. The arrangement of particles within the surrounding gas is expressed as void space. In this case, the flow through the void space of the packed bed is modeled as the flow through a porous medium with considering the interaction between the solid-gas phases by heat, mass and momentum transfer (Mahmoudi et al., 2014). Generally, there are three transport phenomena inside a dryer that take place simultaneously during drying as *i*) heat transfer between particle and gas; *ii*) particle transportation; and

iii) water vapor transportation from particle to gas. The heat and mass transfer during transportation of particles inside a dryer highly depends on the surface area and the contact time between particles and gas phase (Mujumdar (2006)).

The vibrating grate dryers studied in this work are a combination of conveying and fluidized bed dryers. That is, the transportation of particles from inlet to outlet is added to fluidization with a gas phase. This enables the vibrating grate dryers to be efficient and powerful drying facilities in the industrial applications. Also the entrainment phenomenon could happen when the grate motion and the gas flow rate are relatively high. In a typical vibrating dryer, the particles are transferred to the dryer where the bottom grate has an oscillatory motion in both vertical and horizontal directions. Simultaneously, the particles face the drying medium which leads to fluidisation and move the particles forward until exiting from the system. Whereby, the particles and gas phase mix properly leading to better heat transfer and consequently better drying. The presented DEM-CFD approach is used to analyze drying of biomass particles on a vibrating grate in this study. Also the motion of particles inside the vibrating grate dryer is modeled in which the particles move forward inside the dryer by oscillatory motion of vibrating grate plate as well as drag force by gas medium.

2. Mathematical modeling

Since the experiment is highly effortful and costly to realize the complex processes in the multi-phase flow systems, a full scale numerical simulation is desired to investigate the solid-gas behavior. In multiphase systems where the particles interact with fluid flow, there are two approaches to describe the behavior of different phases as Eulerian and Lagrangian. The Eulerian approach considers the flow as continuous while the Lagrangian approach tracks the properties of each particle as it traverses in the flow (Faghri and Zhang (2010)). Apart from compatibility with an Eulerian approach for fluid flow, employing this approach for solid phase leads to miss particulates properties during simulation which decreases the accuracy of results. The advantage of XDEM is resolving the continuous fluid phase with Eulerian approach with employing OpenFOAM tool, while Lagrangian approach is implemented to track each entity of the granular material. Fig.1 describes the schematic DEM-CFD coupling modules. The detailed description of mathematical modeling is presented in (Mohseni and Peters (2016)).

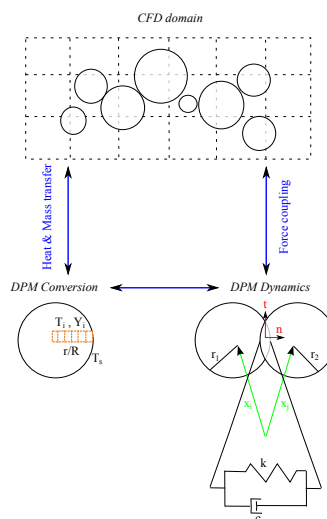

Figure 1: Schematic DEM-CFD modules

3. Result and discussion

Fig.2 shows the industrial scale vibrating grate dryer including the solid-gas inlets and outlets where the system is properly isolated. To heat up the system before drying, the steam is injected into the dryer until the gas temperature inside the dryer exceeds $100\text{ }^{\circ}\text{C}$. Then the biomass feeding starts using a screw feeder which transports the biomass into the dryer with the rate of 100 t/h for 5 s . The feedstock is forest residues. Dryer geometry in *length*, *width* and *height* directions are 7 , 1.5 and 2.2 m , respectively. The case study used for the simulations has the same geometry as the experimental facility except *width* direction. This is to reduce the running time of the simulation, since the temperature gradient is constant in *width* direction, thereby one slice of the dryer (as 0.1 m) is performed in this side. However, two periodic boundary walls are considered to predict the motion of particles properly. The particles are transported through the horizontal axis due to the vibrating motion of the grate and the gas flow drag force. The gas phase medium is the superheated steam which is in direct contact with the particles. The superheated steam enters the dryer and encounters the wet particles. And after heat exchange with particles, the cooled air exits the dryer through two upper outlets. The simulation domain with boundary specifications are illustrated in fig.3. To evaluate the effect of particle size distribution in accordance with the experimental test; and for tracking each particle size to investigate the density and moisture content variation, five different sizes as $5, 10, 15, 20, 25\text{ mm}$ are considered for simulations. This is according to the measured experimental size distribution. For validation, fig.4 compares the mean moisture content of three experiments with simulation prediction. The measurements are carried out in four points at four instances during the experiments. It can be seen that the moisture content values are in a good agreement between experimental and numerical predictions.

Figure 2: Schematic vibrating grate dryer

Figure 3: The simulation domain of vibrating fluidized bed dryer

Figure 4: Validation of moisture content with experiment vs. drying rate

3.1. Instantaneous particle temperature

To evaluate the effect of particle size distribution during drying, the temperature distribution of particles is visually shown in fig.5 at five instances 5, 30, 120, 240, 360s. Fig.5(a) shows the particles falling down onto the grate after 5s. Initial gas temperature inside the dryer is 100 °C and with feeding the particles, inlet gas with temperature 210 °C is injected. With facing the hot gas (210 °C) with fed particles (with 95 °C), the bed temperature starts to increase. And since the particles at the bottom of the bed are in direct contact with the hot gas, the temperature rises faster than the particles through the bed. After 30s shown in fig.5(b), the bed height becomes uniform and the smallest particles move up further due to lower weight. In this moment, the surface temperature of particles reach the saturation status and the smallest particles specially before 1m in the system are dried. Fig.5(c) shows the system at 120s. In this moment, some particles left the dryer in saturation status. This is in accordance with the scope of the experiment as reaching the total moisture under 10 %wb. While at the middle of the vibrating dryer between 3 – 4m, the temperature of small particles reach the gas temperature. Most of the particles after 240s left the domain which is shown in fig.5(d). The particles inside the system still receive energy and the temperature continues increasing. It is clear that only small particles reach the gas temperature. This is due to the smaller size that leads to faster heat transfer from the surface to center of particles. In contrast, the large particles at the end of dryer are dried but the temperature is still under gas temperature.

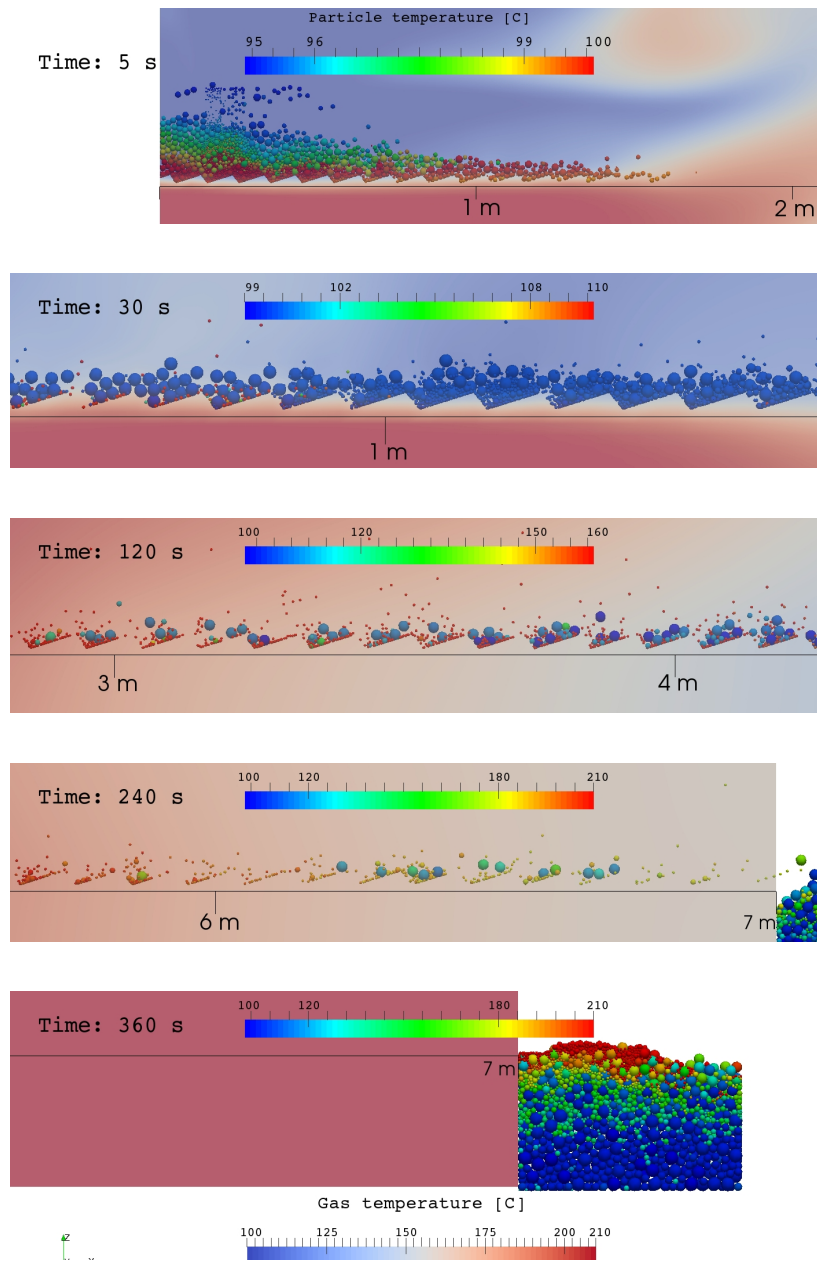

Figure 5: Temperature distribution of particles at different instances in zoomed view

At the end of simulation (360s) shown in fig.5(e), all particles are out of the dryer domain. And the gas temperature is uniformly 210 °C since there is no more solid element for heat transfer. With looking at the exterior bed, it is obvious that the temperature of upper part is close to the gas phase 210 °C while the bottom part has the saturation temperature (100 °C). This is explained as the particles at the top had more residence time and consequently the temperature exceeded the saturation status.

4. Conclusion

In this study, a DEM-CFD coupling approach is applied to evaluate drying of beechwood in a vibrating fluidized bed dryer. The particles are modeled based on discrete element method coupled to the continuous gas phase via heat, mass and momentum transfer using OpenFOAM as a computational fluid dynamics tool. To evaluate the numerical simulation, the experimental work is done via collaborating with Soil-Concept company in Luxembourg. The experiments are carried out in the industrial scale vibrating dryer to measure the moisture content, density and size distribution of materials. The comparison of moisture content at different instances as well as total residence time between experiment and simulation reveal a good agreement. The instantaneous temperature distribution of particles and gas phase are visually presented to examine the effect of size distribution on drying process. It is shown that the small particles are dried faster than large particles since heat is transferred from the surface to core of small particles faster.

Abstract

The Brazilian sugarcane ethanol plays an important role in the country fuel market. It also presents a better strategic position to get the environmental targets established by Brazil at COP21 (in Paris). To reach these targets, the biofuel production needs to be improved to reach ca 50 billion liter of ethanol until 2030. Nowadays, the Brazilian mills seek for increasing the fermentation process efficiency from 83 % to values close to 90 %, making the ethanol raising production feasible. In this context, the present work aims to model the industrial ethanol fermentation unit using a feedforward neural network. A set of industrial data was used for training and validating the neural network. The backpropagation algorithm was used for training the network. It was possible to identify the variables that had a direct impact on the process performance. The better network configuration was able to attain a correlation coefficient value (R-value) of 0.84. Efficiency fermentation values were predicted by the network with good precision during stable process operation. From this information, it is possible to come up with new process modifications which will contribute towards the increase in industrial fermentation efficiency.

Keywords: Neural network, ethanol, fermentation, process efficiency.

1. Introduction

Bioethanol production has become more important not only in national discussions about biofuels but also worldwide once Brazil is committed to reducing greenhouse gas emissions. In Brazil, bioethanol production is a long-established process. Its production process is primarily based on the sugar fermentation (mainly sucrose) from sugarcane juice. After the launch of the Brazilian Alcohol Program (Proalcool, in Portuguese) in 1975, ethanol production increased considerably, from 600 million liter in 1975 to 11.8 billion liter of ethanol in 1986. In harvest 2016/2017, Brazil produced 27.2 billion liter of ethanol (UNICA, 2017). To reach a target established by Brazil at COP 21 in Paris, ca 50 billion liter of ethanol until 2030, several options exist: expansion of cultivation area, improvement in agricultural or in industrial yields, introduction of new industrial processing pathways which include improvements in first (sugars conversion) or second generation (lignocellulosic biomass conversion) ethanol industrial processing (Jonker et al., 2015).

Ethanol can be produced in fed-batch or continuous operation modes with cell recycle (Melle-Boinot process). A typical Brazilian distillery is divided into sectors or units which include: (1) an upfront section, named extraction unit, composed by cleaning and extraction juice; (2) treatment unit, composed by sedimentation and concentration processes to eliminate impurities and adjust the sugar concentration in the juice; (3)

fermentation unit, composed by a set of fermenters, centrifuges and distillation columns, and (4) heat and power unit, composed by the boilers and turbines which produces energy (vapour and electricity to the process). A simplified block diagram illustrating these main process units is illustrated in Figure 01.

Figure 1. Block diagram illustrating the main process units in ethanol production.

Regarding ethanol production process there are in literature many works that focus on describing the fermentation process. Several kinetics models (Oliveira et al., 2017) together with mass balances equations can be used to describe the fermentation process, which means, to describe the profiles of cell, substrate, and product inside the bioreactor throughout the fermentation. The kinetic models seek to describe the inhibitory effects due to substrate, product, and biomass concentrations, common phenomena present in industrial process production. Other models can also include the effect of the medium temperature on kinetic parameters, which brings additional information for better process description. Models based on neural networks have also been used to describe the fermentation process (Mantovanelli et al., 2007). Fonseca et al. (2017) have modelled and simulated the entire fermentation unit which comprises the fermentation vessels, centrifuges, and distillation columns. The fermentation process, operated in fed-batch or continuous mode, was represented by both stoichiometric and kinetic-based fermentation models. There are advantages in using the first one approach instead of that involving reaction kinetics, such as fast convergence and simplicity of modelling and optimization, since dynamic fed-batch models require specialized optimization algorithms (Roubos et al. 1999). However, stoichiometric models typically do not incorporate the aforementioned inhibition effects that could hinder the product output of the reaction. Instead, they rely on previously known information on the substrate conversion rate. The use of neural networks to model the fermentation unit can overcome this difficulty. Using this approach, at the same time that important process variables are introduced into the model (as inputs to the network), the model can be easily solved making it more desirable for use in optimization problems.

The aim of this paper was to model an industrial fermentation unit using neural network approach. The objective is to estimate the process fermentation efficiency based on a set of variables.

2. Methodology

The data released by the industry (a mill located in the São Paulo state, Brazil) comprised 142 operation days from March to September of 2015. A set of 17 variables were monitored daily. These variables were used as input to the network. The selected variables were grouped in sub-sets named: molasse variables (1-total reducing sugars-TRS (%); 2-total soluble solids ($^{\circ}$ Brix); 3-molasse acidity (%); 4-molasse purity), wine variables (5-ethanol titer ($^{\circ}$ GL); 6-yeast concentration (% v/v), 7-wine bacterial contamination (FCU/ml); 8-cell viability (%); 9-residual reducing sugar (%)), fermentation variables (10-waiting time for wine centrifugation (hour); 11-molasse feeding time (hour); 12-fermentation temperature ($^{\circ}$ C); 13-standard deviation of molasse feeding time), and inoculum variables (14-pH of inoculum; 15-yeast treatment time (hour); 16-standard deviation of yeast treatment time; 17-inoculum ethanol titer ($^{\circ}$ GL)).

Figure 02 shows a schematic diagram of the industrial fermentation unit layout. The unit is composed by six fermentation tanks (650 m³ working volume), six pre-fermentation tanks (100 m³ working volume), and three centrifuges (100 m³/h of nominal flow rate). The fermentation unit has a nominal ethanol production of 700 m³ per day.

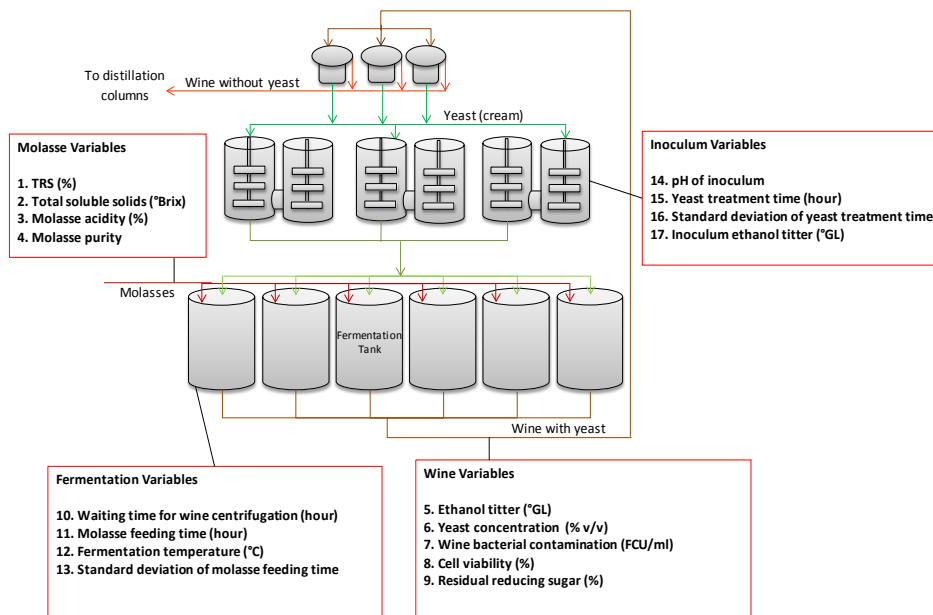

Figure 2. Schematic illustration of the industrial fermentation unit.

A feedforward neural network with one hidden layer was used throughout this work. The log-sigmoid transfer function was employed in the hidden layer neurons. The linear transfer function was used in the output layer. The Levenberg-Marquardt algorithm was used for training the neural network. Before starting the training step, the algorithm randomly distributed the data points into three data sets: training, validating and testing. Then, random initial weights for each network connection are attributed. Each network architecture was trained from different initial condition 2,100 times to assure that a global minimum was found during the training step. All the input data values were

normalized between -1.0 and 1.0. All the steps carried out to find the best neural network architecture was performed taking into account to avoid network overfitting. The mean squared error and the correlation coefficient were the parameters used to choose the best network configuration.

Different sets of input variables and different number of neurons in the hidden layer were evaluated. The best net configuration had eight input variables and seven neurons in the hidden layer. The following variables were used as input: total reducing sugar (TRS, %), ethanol titer ($^{\circ}$ GL) from wine, yeast concentration (% v/v) from wine, wine bacterial contamination (FCU/ml), waiting time for wine centrifugation (hour), molasse feeding time (hour), fermentation temperature ($^{\circ}$ C), and inoculum ethanol titer ($^{\circ}$ GL). Figure 03 illustrates the architecture of the feedforward network used in this work.

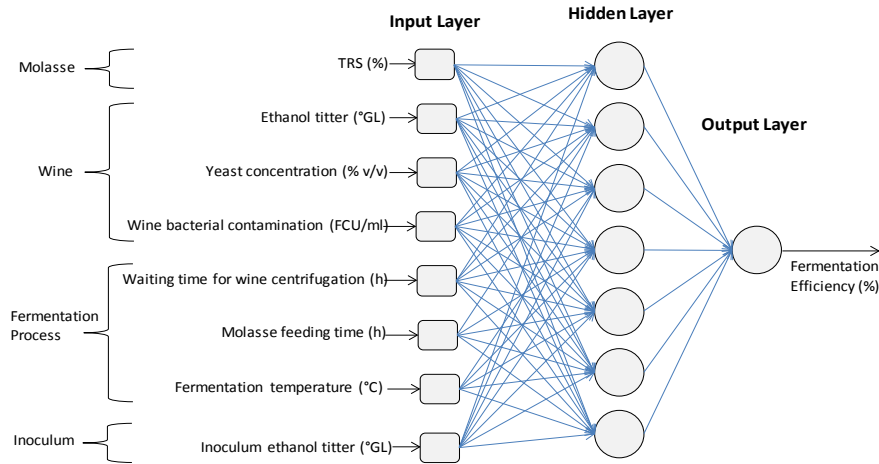

Figure 3. Neural network architecture implemented for simulation of the industrial fermentation unit. The network output is the fermentation efficiency (%).

3. Results and Discussion

Figure 4 illustrates the regression plot of the targets (experimental fermentation efficiency) and the neural network output (estimated fermentation efficiency). It can be seen that the neural network was able to predict with good precision the fermentation efficiency (correlation coefficient, $R = 0.84$). It must be considered that the variables used to estimate fermentation efficiency comprises effects of previous days of operation. It occurs because the industrial fermentation is a continuous process of molasses input and wine output, once there are several fermentation tanks operating in fed-batch mode in synchronized cycles. The correlation coefficient of 0.84 reached for a static neural network could be increased if it was considered a dynamic network with time delay in the input layer.

Figure 5A shows predict and experimental efficiency fermentation values in chronological order of the operation days, from March to September 2015. The relative error is shown in Figure 5B. It can be seen that the mean of the relative error decreases from 72nd to 141st day (1.5 %) when compared to the same value calculated from the

beginning of the harvest (1st to 71st day, 2.9 %). The dry weather (72nd to 141st day) allowed more stable operations. As a consequence, the network gave more accurate responses. Despite this, in this period some points reached relative errors above 5 % due to the occasional breakdown of equipment.

Process variables are collected on the shop floor and analyzed in the laboratory. When process instabilities occur due to rainy days or equipment breakdowns these samples are no longer representative as the sampling procedure was developed for steady state process operation.

Figure 4. Regression plot between the industrial fermentation efficiency values (targets) and the network output.

Figure 5. (A) Fermentation efficiency values (experimental and predicted by the network) in chronological order of the operation days; (B) Error plot between industrial fermentation efficiency values and the network outputs.

4. Conclusions

The neural network was able to model the fermentation unit providing with good precision fermentation efficiency values during stable process operation. This approach showed to be a promising way to circumvent the difficulty in using phenomenological models for process optimization studies. Actually, the decision on the level of model complexity to be used will be a trade-off between modeling effort, quality and quantity of available information and the application of the model.

Once the industrial process variables comprise features from the previous days of operations, the next step to this work would be to evaluate the performance of a dynamic network with time delay in the input layer.

olga.arsenyeva@upb.de

Abstract

Pillow-Plate Heat Exchangers (PPHEs) represent an innovative equipment type, with space-effective, light and pressure-resistant construction. In this work, an experimental study of air cooling by water in small-scale pillow plates was carried out and an analysis of the hydraulic resistance and heat transfer inside the PPHEs was performed based on the experimental data. The correlations for friction factor and heat transfer in PPHEs channels were proposed and validated by the measurements of small-scale PPHEs. The correlation for the heat transfer coefficients in the channel with hot heat carrier is based on the modified Reynolds analogy between heat and momentum transfer; it is valid for fully developed turbulent flow with the Reynolds numbers between 2,000 and 20,000. The deviation of the data predicted by the proposed correlations from the experimental results is within $\pm 10\%$. The experimental data processing was realised using the developed software. The proposed correlations can be applied for the mathematical modelling of PPHE design parameters.

Keywords: pillow-plate heat exchangers, friction factor, thermo-hydraulic performance, heat transfer coefficient.

1. Introduction

Implementation of novel-type heat exchangers in industry requires design approaches based on reliable models for thermo-hydraulic performance. One of the innovative types of heat exchangers is the so-called *pillow-plate heat exchanger* (PPHE). Heat transfer in PPHEs is realised in channels with complex geometry, which are formed by spot-welding of two metal sheets, according to a particular welding spot pattern, and by subsequent expansion using hydroforming. PPHEs show enhanced heat transfer characteristics while keeping pressure loss on the product media side low (Tran et al., 2015). The ease of the production process as well as space-effective, light and pressure-resistant construction characterises this equipment as promising for implementation in industry. However, no reliable models for the heat transfer efficiency estimation in small-scale PPHEs are available.

The previous results on thermal and hydraulic performance of pillow plates available in the literature are given for turbulent flow in large-scale pillow plates with particular geometries, both for inner pillow-plate channel (Tran et al., 2015) and for outer pillow-plate channel (Piper et al., 2016). The data published for the outer channels formed between the pillow plates is limited to only one pillow plate geometry. The data transferability between different pillow-plate geometries is also uncertain. The present

tendency towards compact equipment makes investigation of hydraulic performance of small-scale pillow plates interesting for industrial application. Above all, the correlations for the friction factor and heat transfer coefficients are required. Only based on these correlations, the thermal and hydraulic performance of PPHEs can be determined in line with their geometrical design parameters. We developed an experimental set-up for the determination of pressure drop and heat transfer coefficients in the inner and outer channels of the small-scale PPHEs. Measurements were carried out and the obtained experimental data were analysed and validated using the developed software in Mathcad, which enables numerical evaluation of the obtained set of experimental data as well as determination of the friction factor and heat transfer coefficients for each set. The obtained results allowed the general correlation for heat transfer coefficient and friction factor in the outer pillow-plate channel to be developed using the least square method.

2. Description of experimental set-up

To study the pressure drop in the inner and outer channels of a PPHE, the experimental set-up shown schematically in Fig. 1 was developed. It consists of two cycles, one for water and one for dry air. Water was heated in the thermostat up to 20 °C and pumped to the inner channel of the PPHE. The water flow rate was varied during the experiments between 130 and 900 kg/h and measured using the Coriolis flow and density meter CMF025M (G2). To measure pressure drop in the inner pillow plate channel for water, sensors were installed in the inlet and outlet pipes of the pillow plate. The pressure drop measurements were made using the Rosemount pressure transmitter 3051CD (ΔP_2).

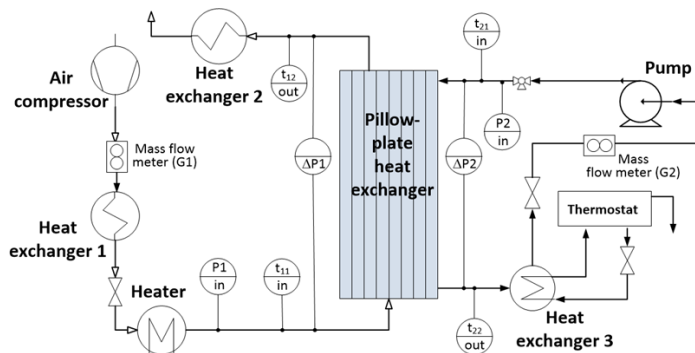

Figure 1. Experimental set-up

Dry air with the temperature varied from 20 to 325 °C was directed to the outer pillow plate channels by an air compressor. The flow rate of the air varying from 40 to 105 kg/h was measured using the Rosemount 8800D vortex flowmeter (G1). The pressure drop was determined with the Rosemount pressure transmitter 3051 (ΔP_1), using sensors installed at the inlet and outlet of the channel. Calibrated B-type thermocouples were used to measure the temperatures of air and water at the inlet and outlet. The total accuracy of the pressure drop experimental measurements was estimated as $\pm 0.10\%$ for water side and $\pm 0.50\%$ for air. The accuracy of flow rate

measurements was $\pm 0.50\%$ and $\pm 0.80\%$ for water and air, correspondingly. To decrease the uncertainty of air flowmeter data, non-ideal gas behaviour was taken into account, and the dry air thermo-physical properties were estimated for each specific gas flow measured. The data acquisition system based on PC running LabVIEW software together with sensors and digital multiplexers was used to process the measured data.

Figure 2. Dimensions of the studied small-scale pillow plate

Table 1. The geometrical parameters of investigated pillow plates

Parameter	Value, mm
d_{ws}	6
h_i	3.5
$2s_L$	42
s_T	36
w_{pp}	230
L_{pp}	530
w_e	30

A specific PPHE sample was manufactured by BUCO Laserplate GmbH (Germany). It consists of two small-scale pillow plates like one shown in Fig. 2. They are made of AISI 304 stainless steel, with the thickness of metal plate equal to 0.8 mm. The main geometrical parameters of the investigated small-scale pillow plates are presented in Fig. 2 and Table 1. The inner-plate expansion of both pillow plates (h_i) was 3.5 mm. The pillow plates were assembled together to compose a heat exchanger with one outer-plate channel for air and two inner-plate channels for water. The distance between the pillow plates (h) was equal to 12 mm. Water was directed inside pillow plate channels. For a better flow distribution inside this small-scale pillow plate, the entrance to the pillow plate was made at the plate side, while the outlet was placed diagonally opposite at the other side (see Fig. 2). The inner diameters of the entrance and outlet tubes were 24.9 mm. Water flowed through two inner pillow plate channels and air through the outer channel in a counter-current mode.

3. Heat transfer coefficients and hydraulic resistance in the PPHE

The thermal and hydraulic performance of PPHE can be estimated using the overall heat transfer coefficient, which can be determined as follows:

$$\frac{1}{U} = \frac{1}{h_1} + \frac{1}{h_2} + \frac{\delta_w}{\lambda_w} + R_f \quad (1)$$

where h_1 and h_2 are the heat transfer coefficients for air and water side of the PPHE, R_f is the thermal resistance of the fouling deposit on the heat transfer surface, δ_w is the thickness of the plate metal, λ_w is the heat conductivity of the plate material.

Eq. (1) can only be applied, if the correlations for both heat transfer coefficients are known. They depend on the fluid physical properties, friction factor and channel

geometry (Klimes et al., 2015). The friction factor in the PPHE channels is determined based on experimental data on pressure loss according to the following relationship:

$$\zeta = \frac{\Delta P \cdot 2 \cdot d_e}{\rho \cdot w^2 \cdot L_{EF}} \quad (2)$$

where d_e and L_{EF} are the characteristic lengths in tangential and longitudinal directions, correspondingly.

The friction factors for hot and cold channels, as well as corresponding heat transfer coefficients were analysed based on the experimental data for the small-scale PPHE with the geometrical parameters of channels, presented in Table 1.

3.1. Friction factor and heat transfer coefficient for the inner pillow-plate channel

The correlation for the friction factor in inner pillow-plate channels, proposed by Arsenyeva et al. (2017), was used:

$$\zeta = 8 \cdot \left[\left(\frac{12 + p2}{\text{Re}} \right)^{12} + \frac{1}{(A+B)^{\frac{3}{2}}} \right]^{\frac{1}{12}}; \quad A = \left[p4 \cdot \ln \left(p5 \sqrt[3]{ \left(\frac{7 \cdot p3}{\text{Re}} \right)^{0.9} + 0.27 \cdot 10^{-5} } \right) \right]^{16}; \quad B = \left(\frac{37530 \cdot p1}{\text{Re}} \right)^{16} \quad (3)$$

where $p1$ to $p5$ are parameters depending on the channel form and determined as follows:

$$\begin{aligned} p1 &= 1,439 \cdot c_1^2 + 256,900 \cdot c_2^2 - 38,450 \cdot c_1 \cdot c_2 - 775.9 \\ p2 &= (2.171 \cdot c_1 + 66.605 \cdot c_2)^{1.077} - 7.868 & p4 &= (0.508 \cdot c_1 + 7.169 \cdot c_2)^{-2.468} + 0.237 \\ p3 &= ((1.239 \cdot c_1)^{-2.284} + 1.109 \cdot c_2) - 0.188 & p5 &= (0.323 \cdot c_1 + 2.646 \cdot c_2)^{14.03} + 4.59 \end{aligned} \quad (4)$$

Here, c_1 is the ratio of the longitudinal distance between the adjacent welding spots to the transversal distance, without considering the welding spot diameter: $c_1 = (2s_L - d_{ws}) / (s_T - d_{ws})$, c_2 is the ratio of the inner expansion of the pillow plate h_i to the diagonal distance between the adjacent welding spots δ : $c_2 = h_i / \delta$.

The heat transfer coefficient was calculated using the dependence suggested by Tran et al. (2015) for the large-scale pillow-plate:

$$\text{Nu}_2 = 0.067 \text{Re}^{0.774} \text{Pr}^{0.338} \quad (5)$$

The characteristic parameters (d_{e1} , f_{CHI} and L_{EF}) in Eqs. (2)-(4) for the inner pillow-plate channel are determined using the relations given in (Tran et al., 2015) and specific geometrical values of the investigated pillow plate (Table 1).

3.2. Friction factor and heat transfer coefficient for the outer pillow-plate channel

The experiments with the outer pillow-plate channel were first carried out at a constant temperature of water and air equal to 20 °C. Afterwards, dry air temperature was varied to estimate the heat transfer coefficients for the outer PPHE channel. The experimental data for different Reynolds numbers are shown in Figure 3. For accurate estimation of the heat transfer and hydraulic parameters in the outer pillow-plate channel at varied dry air temperature and pressure along the channel length, the relations for dry air thermo-

physical properties were taken from the literature, namely, the correlation for density from Picard et al. (2008), the correlation for viscosity from Lemmon and Jacobsen (2004) and the air heat capacity and heat conductivity from Melling et al. (1997).

The obtained experimental data for friction factor and heat transfer were compared with those for tubes (Fig. 3a, line 2). The Blasius equation for the friction coefficient in a turbulent flow inside a smooth pipe was used:

$$\zeta = 0.3164 \cdot \text{Re}^{-0.25} \tag{6}$$

The experimental results on the hydraulic resistance obtained at constant temperature are in good agreement with Eq. (6) (Fig. 3a, line 2). The experimental data in the outer PPHE channel at varied temperature can be approximated using the following correlation:

$$\zeta = 0.7155 \cdot \text{Re}^{-0.361} \tag{7}$$

The data for the large-scale outer pillow-plate channel both for friction factor and heat transfer coefficient from Piper et al. (2016) are presented by line 1 in Fig. 3a. The heat transfer coefficients in tubes were determined using the Sieder and Tate equation (see Green and Perry, 2008):

$$\text{Nu} = 0.027 \cdot \text{Re}^{0.8} \cdot \text{Pr}^{1/3} \tag{8}$$

For the prediction of heat transfer in the outer PPHE channel, the following heat and momentum analogy is proposed (Fig. 3b, line 3):

$$\text{Nu} = 2.187 \cdot \text{Re}^{-0.356} \cdot \text{Pr}^{0.4} \tag{9}$$

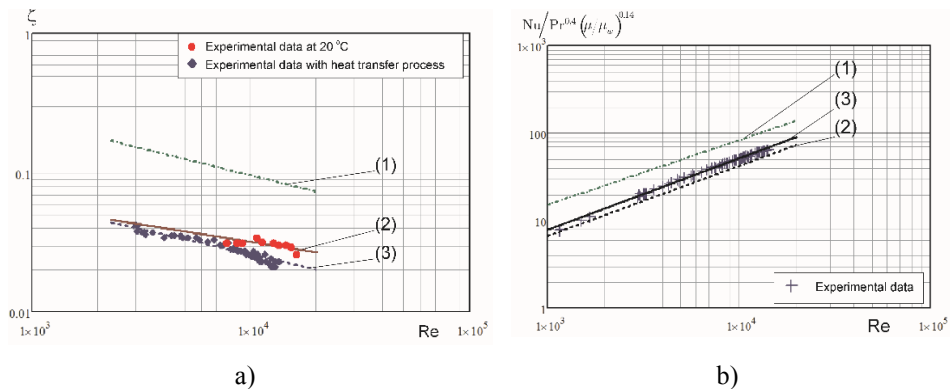

Figure 3. Measurements of friction factor (a) and heat transfer coefficients (b) in the outer pillow-plate channel: (1) – data for the large-scale pillow-plate channel investigated by Piper et al. (2016); (2) – data for tubes according to Eqs. (6),(8); (3) – predicted values according to Eqs. (7),(9)

Values calculated according to Eqs. (7),(9) differ from experimental data by less than $\pm 10\%$ and are valid in the range of Reynolds numbers between 2,000 and 20,000, what corresponds to fully developed turbulent flow in the PPHE channels. The analysis of the obtained experimental data revealed that the friction factor in the small-scale outer PPHE channel is 70 % lower than in the large-scale channel investigated by Piper et al. (2016), while the heat transfer coefficient is 40 % lower. It demonstrates a significant

influence of the channel geometry on thermal and hydraulic behaviour of the PPHE unit. The experimental results for friction factor were obtained both for the isothermal case and for varied temperature. For the isothermal case, they are in good agreement with the Blasius equation for tubes (Eq.(6)), whereas for varied temperature, a deviation is visible, and at high Reynolds numbers, about 20 % lower friction factor is obtained (Fig. 3a). This decrease could be caused by the change of the dry air temperature and pressure along the pillow plate. For a certain conclusion, further investigations are necessary. The heat transfer coefficients in small-scale PPHE outer channel (Eq. (9)) are 17 % higher than in tubes (Eq. (8)).

4. Conclusions

The experimental data for small-scale PPHE were analysed using the developed software. The correlations for friction factor and heat transfer in PPHEs channels were obtained and validated, with the deviation from experimental results within $\pm 10\%$. They are reliable for fully developed turbulent flow with the Reynolds numbers varying from 2,000 to 20,000. More detailed investigations of heat transfer processes in outer PPHE channel are needed. Nevertheless, the obtained low friction factor together with the high heat transfer coefficients for the studied geometrical pillow-plate parameters appear promising and allow to consider this equipment type interesting for implementation in process industries.

Abstract

This work focuses on the prediction of research and motor octane numbers of gasolines throughout multivariate statistical analysis, which may significantly increase the celerity of the quality control process. The aim of this work is to compare the performance of two different multivariate models, based on partial least squares regression and artificial neural networks. The results show that both models predict octane numbers with accuracy, presenting coefficients of determination above 0.95 for the calibration data set. For the test data set, partial least squares model is more accurate, which might indicate the existence of linear correlations between spectral data and octane numbers. The statistical parameters also show that the research octane number prediction is more accurate than the motor octane number.

Keywords: near infrared spectroscopy, partial least squares, artificial neural networks, octane numbers

1. Introduction

Due to the advances in technology, petroleum industry is facing one of the most transformative periods in its history. New energy sources are arising, especially in developed countries and now, more than ever, it is imperative to be more energy-cost-efficient, doing it right at first time and making products expeditiously available.

Petroleum products, namely gasolines, should meet several specifications, being conventional analytical techniques for their analysis very time consuming. Conversely, spectroscopic techniques are fast, and their implementation on products characterization, in combination with multivariate statistical models such as partial least squares (PLS) and artificial neural networks (ANN), represent powerful tools for industrial quality control and process monitoring. Research (RON) and motor (MON) octane numbers are two of the main parameters used for quality control of gasoline,

showing a significant impact on engine performance. Therefore, they were chosen for this case study.

Although petrochemical industry is a mature industry with much knowledge and improvement accumulated since its foundation, process improvements and safety enhancements are still possible, and spectroscopic methods such as near infrared (NIR) spectroscopy are tools that can be helpful.

1.1. NIR spectroscopy

Near infrared spectroscopy is a fast and non-destructive (vibrational spectroscopy based) technique for studying many multi-constituent chemical systems, namely for gasoline. It covers the wavelength range adjacent to the mid-infrared and extends up to the visible region (4000 to 12500 cm^{-1}). The adsorption bands presented in NIR spectra occur mainly due to the vibration of three functional groups, i.e., -CH, -NH and -OH (Reich 2005). Figure 1 depicts the NIR spectrum of a gasoline considered for the case study as well as the relative peak positions for prominent near infrared absorptions.

Figure 1. NIR spectrum of a gasoline.

The main advantages of NIR are little or no sample preparation, real-time data, and its immunity to thermal noise caused by internal electronic components. NIR instrumentation is simple to operate and no chemicals are used or generated (Andrade 2007). On the other hand, the presence of overtones makes NIR spectral data complex and not directly interpretable. Thus, it requires chemometric techniques to extract meaningful information from the spectra. In this work, two different multivariate calibration methods, PLS and ANN, were tested with the aim of comparing the predictive capacity for the determination of the octane numbers of gasoline.

1.2. Multivariate calibration analysis

The data obtained via spectroscopic analysis is a type of data that often presents the number of variables much higher than the number of objects and the variables are highly correlated. Thus, this type of data requires multivariate calibration.

PLS is one of the most frequently used methods for quantitative NIR analysis (Varmuza *et al.*, 2008). PLS is a multivariate linear regression method that finds the directions of greatest variability by comparing both spectral and target property information with the new axes, named PLS components. They represent the best correlation with the target property values, which are previously measured by conventional techniques.

ANN are learning methods that work in a way analogous to the neurons in the brain. The variables are presented to an input layer and processed by one or more intermediate layers, producing one or more outputs (Miller *et al.*, 2010). This method is particularly useful when there is no knowledge about the mathematical structure of the model.

2. Methodology

2.1. Experimental procedures

2.1.1. Standard method for RON and MON determination

Research and motor octane numbers provide a measure of the knock characteristics of motor fuels in automotive engines under mild and severe conditions of operation, respectively. The standard methods EN ISO 5164 and EN ISO 5163 were used for RON and MON determination, respectively.

2.1.2. Spectroscopic experiments

The NIR spectra were recorded with a NR800 Fourier Transformed Near-Infrared Analyzer equipped with a NIR fiber-optic probe, an interferometer, an InGaAs detector, and a halogen lamp as beam source. The FT-NIR spectrometer has a spectral range of 11000 to 4000 cm^{-1} with a resolution of 4 cm^{-1} . The software SPECTLAND 2 was used for the recording of NIR spectra.

2.2. Model calibration

The PLS and ANN models for the prediction of RON and MON of gasoline were developed using 70 samples of two different kinds of gasoline, covering a spectral range of 4500 – 9500 cm^{-1} . The data included RON values ranging from 91.7 to 99.8 and MON values ranging from 83.2 to 89.0.

The data was divided into three different groups: training, validation and test data sets. The training dataset was used for calibration, the validation data set was used to find the optimum dimensionality of the multivariate model, avoiding overfitting, and the test dataset was used to evaluate the models' performance when applied to a new dataset. This splitting is crucial for models with application in process control because the developed model must be valid not only for the overall dataset, but also for new samples. The approach used in this study considered that the three subsets had data points of the all range of the output data. The data division and the PLS regressions were performed in Microsoft® Excel using Visual Basic for Applications (VBA). The ANN models were developed in MATLAB® software.

The performance of the developed models was evaluated through the calculation and analysis of two statistical parameters, the coefficient of determination (R^2) and the root mean squared error-observations standard deviation ratio (RSR), which are presented in Table 1. A practical way of evaluating the developed models is to assign them a qualitative classification. Therefore, a qualitative classification was attributed as

follows: Very Good - If RSR is lower than 0.5; Good – If RSR is lower than 0.6; Satisfactory – If RSR is lower than 0.7

Table 1. Statistical parameters for model evaluation

Parameter	Expression	Definition
R^2	$R^2 = \frac{\sum_{i=1}^n (y_i - \bar{y})^2 - \sum_{i=1}^n (y_i - \hat{y}_i)^2}{\sum_{i=1}^n (y_i - \bar{y})^2}$	Variability of the model results compared with the observed data. High values of R^2 indicate small errors in variances.
RSR	$RSR = \frac{\sqrt{\sum_{i=1}^n (y_i - \hat{y}_i)^2}}{\sqrt{\sum_{i=1}^n (y_i - \bar{y})^2}}$	RSR is the ratio between root mean squared error-observations and the standard deviation of the measured data and is a valuable parameter once it integrates the benefits of error index statistics and a normalization factor.

Note: y_i = output value; \hat{y}_i = model output; \bar{y} = average of the output variable; n = number of predictions

3. Results and discussion

Figure 2 shows the NIR spectra of three gasoline samples with RON numbers of 91.7, 96.6, and 99.8. Due to structural similarities, the spectral features of the three samples are very similar, and there are only slight differences in some regions of the spectrum. These differences are the basis for the multivariate analysis to build models with capability to predict the properties in study. The full wavenumber range shown in Figure 2 was used for calibration.

Figure 2. NIR spectra of three gasoline samples with different research octane numbers.

Tables 2 and 3 present the performance results of the developed models for RON and MON determination, respectively. Both methods present very good results for the training and validation data sets. For the test data set, PLS model is more accurate, which might indicate the existence of linear correlations between spectral data and octane numbers. In most cases, the ANN models are more suitable for situations with

nonlinear correlations (Geladi *et al.* 2017). Furthermore, the statistical parameters values show that the models, both PLS and ANN, predict RON with better accuracy than MON.

Table 2. Models' performance results for RON determination

	PLS			ANN		
	RSR	R ²	Classification	RSR	R ²	Classification
Training	0.120	0.986	Very Good	0.186	0.966	Very Good
Validation	0.372	0.862	Very Good	0.260	0.932	Very Good
Test	0.276	0.924	Very Good	0.335	0.888	Very Good

Table 3. Models' performance results for MON determination

	PLS			ANN		
	RSR	R ²	Classification	RSR	R ²	Classification
Training	0.093	0.991	Very Good	0.167	0.972	Very Good
Validation	0.315	0.901	Very Good	0.204	0.958	Very Good
Test	0.431	0.814	Very Good	0.514	0.736	Good

Figures 3 and 4 show the research and motor octane numbers predicted by the model plotted against the values determined by the standard method.

Figure 3. RON predicted by the developed model versus RON determined by the standard method: a) PLS; b) ANN.

Figure 4. MON predicted by the developed model versus MON determined by the standard method: a) PLS; b) ANN.

4. Conclusions

Research and motor octane numbers have been successfully predicted from NIR spectra of gasolines via partial least squares and artificial neural network models without sample conditioning and data pre-processing. The values obtained for the statistical parameters R^2 and RSR indicate good agreement for both RON and MON prediction, which means that both methodologies can be implemented as a rapid and convenient alternative to the standard experimental method. PLS regression was slightly more accurate than ANN on predicting new samples.

Abstract

With regard to pollution produced in urban areas, low-cost sensors offer the possibility to collect temporal and spatial data and they have a great potential to change the way to monitor the exposure of the population to the atmospheric pollution. However, one of the challenges associated with data coming from this kind of sensors is to try to make them more significant by combining sensors in network. In this work a dispersion model is used to test the distribution of dust (10 μm) measured by individual points of the network. The monitoring area considered is within a seaside town in southern Italy. The monitoring network is made of three sensors placed in points sensitive for the anthropic activity. We have applied an interpolation model to determine the areas of greatest pollution concentration within the monitored area. The model simulated the pollution movements at the level of the individual monitoring points taking into account the weather conditions.

Keywords: air quality, forecast models, monitoring, pollution, particulate matter.

1. Introduction

In urban agglomerations, it is increasingly usual to find in the atmosphere pollutants able to cause damage to human health. Pollutants are defined as any substance causing the alteration of air composition. They are continuously produced by human activities and therefore are localized mainly in metropolitan areas. Small particulates are among the substances responsible of direct damages to human health with particular reference to particulates with size less than 10 μm , PM 10, and less than 2.5 μm , PM 2.5. The main particulate sources are the road traffic, industrial plants and building heating. Accurate measurements of the concentrations of these pollutants are important not only from an environmental point of view, but also for economic reasons, since a part of taxation may be dependent on the emission values (Salehi et al., 2015; Steffens, 2009). Jerrett et al. (2005) reviewed some models for assessing into city environment exposure including: (i) proximity-based models, (ii) interpolation models, (iii) land use regression models, (iv) line dispersion models, (v) integrated emission-meteorological models, and (vi) hybrid models. These latter combine personal or household exposure monitoring with one of the previous methods. Unfortunately, the development of air quality monitoring networks is hindered by the high costs and large dimensions of nodes (monitoring stations) that make impossible to install them in all the critical locations (such as densely populated urban centers). Consequently, the reduced number of data makes the forecasting models more generic for large areas, losing the details of air pollution distribution on the land. Recent advances of tunable all solid state laser sensors and

Lidar technique (Light Detection and Ranging) opened new perspectives in the monitoring and 3D-analysis of atmospheric pollution dynamics. In fact, 3D mappings of concentrations of pollutants have been obtained, allowing a direct access to the physical and chemical dynamics of air pollution (Frejafon et al. 1998). Besides the detection, these species have to be tracked in their movement towards neighboring areas by the use of dispersion models (Steffens, 2009). Low-cost sensors offer the ability to collect highly resolved temporal and spatial data and they have a great potential to revolutionize the way to monitor the exposure of the population to the atmospheric pollution (Tianxing Caia et al., 2014). In this work a dispersion model of pollutions was proposed in order to validate the results obtained with a monitoring of 10 μm particulates in a seaside town of South Italy (Salerno). The monitoring network composed by three sensory systems is located in some relevant points for anthropic activity (Barnard et al., 2001). The first objective is to examine the monitoring area in terms of PM 10 concentration in order to obtain the areas exposed to higher concentrations and to find the sources of pollution. The second objective is to understand the combined effects of distributed and concentrated sources.

2. Materials and Methods

2.1. Monitoring stations

The monitoring stations are composed by sensors for the detection of fine particles at low concentrations (PM 10). They are combined with temperature, humidity, pressure and wind direction sensors in order to better support the elaboration of pollution dispersion model. In particular, fine powders sensors are based on the use of a laser source that crosses an air stream sampling the outside atmosphere. The air stream is conveyed by to the measuring chamber by suction system of the external air. When a particle in this stream crosses the laser beam, scatters this light with a pattern in which intensity and direction distribution depend on the particle size.

2.2. Sensor Networks

The sites interested by installation of the monitoring station have been selected in areas that are heavily affected by human activity. In particular, the three selected points are (as shown in Figure 1): Teatro Verdi (1), Duomo (2), Portanova (3). They are chosen in pedestrian areas just to assess the population's exposure to PM10. The software R was used with the statistical model, called Kriging is a method of interpolation for which the interpolated values are modeled by a Gaussian process governed by prior covariances, as opposed to a piecewise-polynomial spline chosen to optimize smoothness of the fitted values, in order to evaluate the distributions of dusts in the selected periods.

Figure 1: Installed monitoring network.

2.3. Model description

In this work, the Operational Street Pollution Model (OSPM) was used in order to test the possibility to successfully apply it in single monitored streets (J. Silver et al. 2013). Briefly, the main components of the OSPM are summarized as follows. For the pollutant PM 10, the concentrations are modeled as:

$$C = C_{bg} + Q_{trf} (C_{dir}^* + C_{rec}^*) \quad (1)$$

where:

- C is the concentration at the receptor point ($\mu\text{g m}^{-3}$);
- C_{bg} is the background concentration ($\mu\text{g m}^{-3}$);
- Q_{trf} are the emissions from traffic per street length ($\mu\text{g m}^{-1} \text{s}^{-1}$);
- C^* is a function determining the persistence of pollutant including the effect of meteorology, traffic speed and volume and street geometry (units: s m^{-2}). It is composed of a direct, C_{dir}^* , and a recirculation, C_{rec}^* , component.

The concentrations of PM 10 mainly includes the pollutants emitted by vehicles and combustion processes (industrial or house-heating combustion emissions). In the C^* function the C_{dir}^* term is calculated assuming a Gaussian plume, while a box model is used to calculate the contribution from the recirculation vortex (C_{rec}^*). In particular, the recirculation vortex only forms under certain conditions, governed by the wind speed and direction, as well as the canyon geometry. Meteorological parameters as the wind speed and direction are used to determine the size of the recirculation zone. The wind direction and speed are considered in the following way. On the windward side, C^* includes only the recirculating component (possibly with a contribution from the direct component, depending on the length of the recirculation zone) while on the leeward side C^* is the sum of the direct and recirculating components. Both sides account for the urban background. The function C^* includes also the contribution from the turbulence produced by the vehicular traffic, which depends on the speed and the intensity the traffic, as well as from the frontal area of the vehicles. Meandering of the wind direction is also accounted for in C^* , as the wind direction is not expected to remain constant during the 24 h time steps.

2.4. Model inputs

The number of cars, vans, trucks and buses (for km^2) were available for three points for each hour of all days. We also considered the proportion of cold starts and the mean travel speeds at each hour of the day. Vehicle emission factors and vehicle fleet composition are based on the European COPERT IV emission model (EEA, 2009). The temperature, humidity and pressure are considered into the model in order to evaluate the pollution dispersion. In particular, these parameters are included into the model using data from the previous year referred to the monitored area (Salerno). The estimated horizontal dispersion coefficient in an urban environment takes into account the turbulent effects of the highest temperature.

3. Results

Below we report the experimental results related to the anthropic activities in the monitored area. The monitoring campaign lasted two months overall. Some of these results are reported below. In particular, the reported results refer to the most useful days with the sensor networks mentioned above. As shown in Figure 2a (corresponding to a day of the weekend) most of the PM 10 mass would seem to come from the south-

east of the city centre. In Figure 2b (corresponding to a midweek working day) no PM 10 accumulation is found in any part of the monitored territory.

The maximum-recorded concentration is equal to $38 \mu\text{g m}^{-3}$. Compared to a midweek day, it is clear that the intense anthropic activity of the weekend connected to traffic and tourist arrivals increases the average concentration across the analyzed zone. In particular, the maximum concentration in the midweek day is 73% lower than in the weekend. These results demonstrated the good feasibility of OSPM model used in other works (Silver et al., 2013) to compare air quality in shorter periods (weeks). In general, the emissions from buildings must be considered but in the specific case for the particular conformation of the monitored area the effect of point sources of emissions was marginal. From the obtained results the higher contribution of pollution is due to a greater number of vehicles circulation demonstrating a marginal effect of domestic heating.

In Figure 3 a, b, c a concentration profiles of PM 10 in three selected points is shown. Concentrations of PM 10 are recorded every 2 minutes in a time frame from 11 a.m. to 11 p.m. The three graphs show a concentration decrease of particulates during the night period, a peak corresponding to the beginning of the anthropic activities. A reduction of PM 10 concentration is recorded during the morning working hours and subsequently a progressive increase due to the vehicular traffic is registered at the end of the working hours. More in detail, in Figure 3 a in addition to the maximum peak we also note a higher concentration of the PM 10 probably due to the urban orography of the monitored point.

In Figure 3 d, e, f, the daily average values of PM 10 concentration levels measured in the three station points is compared with the OSPM predicted values. The model is able to predict concentration trends of PM 10 in all three monitoring points. In particular, in Duomo monitoring station (Figure 3 d) the model is able to predict all the experimental points while in Portanova monitoring station (Figure 3 e) the lack of correspondence between the model and the experimental data is limited to some days. Probably the reason is a variation between the ratio of the distributed and the concentrated sources.

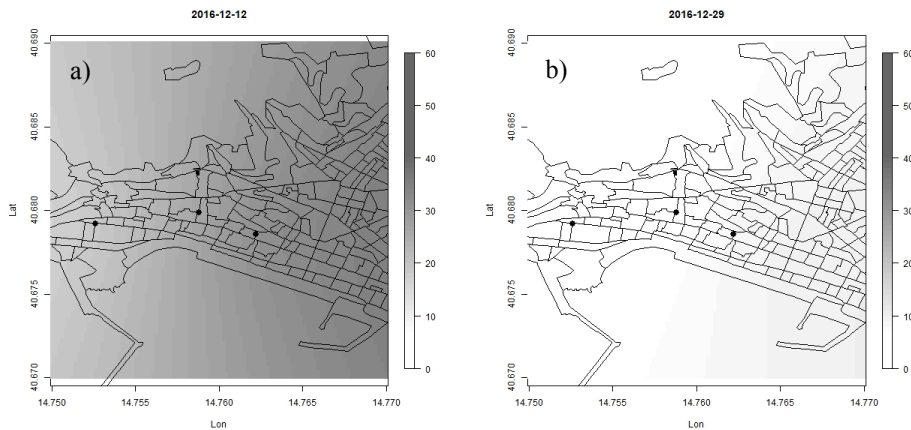

Figure 2: PM 10 concentrations in a weekend (a) and weekday (b).

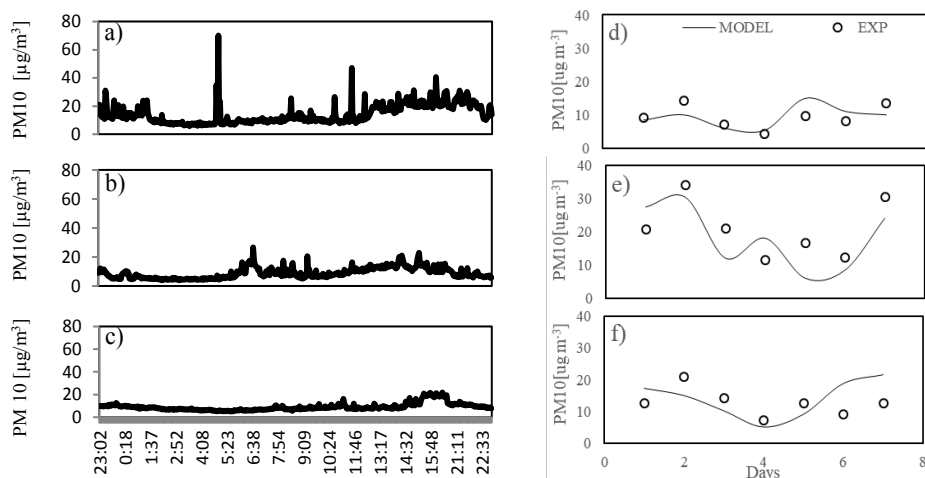

Figure 3: PM 10 concentration profile in Duomo (a), Portanova (b) and Teatro Verdi (c) recorded on Sunday 18th of December. Comparison of experimental and modelled results of PM 10 concentrations in Duomo (d), Portanova (e) and Teatro Verdi (f) monitoring stations.

4. Conclusions

A statistic model was used in order to compare the traffic effects on PM 10 concentration between mid-week and weekend days. In particular, the average concentration is higher in weekends, as expected, due to an increase in anthropic activities. The point of greatest concentration is almost always the Portanova monitoring station. A methodology is proposed to employ OSPM for the prediction of PM 10 concentrations in the town of Salerno. Applying the dispersion model to the experimental data, we can see how the model is able to predict the trend based on the hypotheses carried out mainly in the case of Duomo and Portanova monitoring stations but less in the case of Teatro Verdi station. The reason is probably due a variation of the ratio between distributed and concentrated sources of pollutants.

The successful application of the methodology is confirmed by the fairly good comparison between calculated results with measurements.

In the future in order to further improve the model it would be necessary to increase the number of monitored points and to have more data in the history.

Abstract

An empirical mathematical model to describe the xylan depolymerisation in a pilot-scale pretreatment continuous tubular reactor (PCTR) is presented. The proposed model involves depolymerization kinetics and mass flow dynamics. Although the reactor was modelling as a set of reactors in series, typical impulse response delays, kinetic behaviours and disturbances in the initial concentration of xylans were successfully simulated with low computational cost. Tracer injection method and experimental runs using corn stover at different PCTR operational conditions were used for experimental validation. Additionally, the accuracy of the proposed model and the classic modelling method were compared.

Keywords: Residence time distribution, continuous reactor, pretreatment, parameters estimation, autohydrolysis.

1. Introduction

Pretreatment is one of the most important steps in the biorefining of lignocellulosic biomass (LCB) to bioethanol and high value-added products. Among pretreatments, autohydrolysis followed by a sudden decompression (steam explosion) is gaining importance at industrial scale due to its high hemicelluloses release yield and increments in cellulose availability with low environmental impacts and acceptable CAPEX and OPEX. Previous studies indicate that hemicellulose depolymerization is due to autohydrolysis reaction (induced by water, organic acids and temperature witch the biomass is subjected before the decompression); while the sudden depressurization has a minimum contribution (Rodríguez et al., 2017).

Xylan is the main component in the hemicelluloses of different LCB sources, such as wheat straw, cane bagasse, corn stover, and agave bagasse. Besides increasing the bioethanol production yields, others different high added-value products can be also obtained from LCB xylan release. The simplest xylan autohydrolysis description is the set of simultaneous reactions described by Eq. (1), where XyP are polymeric xylan,

XOOS are short xylooligosaccharide chains, *Xy* is xylose and *DXy* are degraded xylans. k_1 , k_2 and k_3 are reaction rate constants of pseudo first order kinetics with Arrhenius temperature dependence. Therefore, temperature and residence time can be employed as control variables in order to produce maximum amounts of oligosaccharides and monomers as well as minimum degradation compounds. Temperature and residence time dependence of xylan depolymerization by autohydrolysis have been widely reported in batch reactors at laboratory scales. However transport phenomena (e.g. mass flows) also influence the kinetics in continuous reactors.

Analysing tubular reactor as a set of subsystems is a common technique for modelling the flows patters. According to Fogler (1999), experimental measurement of residence time distribution (RTD) using tracer injection and exit age density function ($E(t)$) provide valuable information to improve continuous reactor modelling. Mean residence time (t_m), variance (σ^2) and the number of tanks in series needed to describe the RTD (n) can be calculated from experimental results.

However, previous analysis of isothermal autohydrolysis kinetics in experimental runs in a pilot-scale PCTR showed that effects of biomass rheological characteristics (e.g. elasticity, flowability, viscosity and density) and mechanical reactor components must be taken into consideration on reaction models. Both items produce non ideal flows inside the reactor and therefore they influence in the particles age.

In this work an empirical mathematical model of xylan depolymerization in a 5 kg/h PCTR is proposed that may serve as the basis for designing control strategies.

2. Pretreatment continuous tubular reactor description

LCB is exposed to 3 pretreatments in the PCTR: extrusion, autohydrolysis and steam explosion (See Figure 1). Extrusion is carried out in the feeding section, where biomass is placed in the reactor body by a 4:2 extruder. Autohydrolysis is carried out while the LCB is transported along the reactor by a speed controlled screw conveyor. Water and thermal energy required for the reaction are provide by a steam supply. At the end, two globe valves open asynchronously producing steam explosion and consequently biomass output.

Figure 1: Pretreatment continuous tubular reactor (PCTR) diagram.

3. Experimental and simulated data

3.1. Experimental runs

Biomass pretreatment was carried out in the PCTR at 150 psi (180 °C approx.). Measured wet corn stover was manually fed in the hopper extruder. The extruder motor speed (Motor-02) remained constant throughout the experiment. The tested screw conveyor speeds (CS) were 100, 75, 50 and 33% of the nominal motor speed. The reactor operating conditions were constants for at least 2 hr in order to achieve the mechanical and chemical steady state (SS). After the system reached the SS a synthetic polymer tracer was fed in the PCTR. Valves opening frequency was fixed every minute and the biomass collection each 2 minutes.

3.2. Xylan depolymerization modelling

The effects of the PCTR on the biomass composition are synergy of individual contributions of extrusion, autohydrolysis and steam explosion phenomena. However, Rodriguez et al. (2017) showed that sudden changes of pressure from 150 psi to atmospheric pressure do not contribute significantly in the xylans depolymerization. Therefore, in this work xylan depolymerization yields were described using autohydrolysis variables. The autohydrolysis reaction was modelled as a first order reaction based on the reaction scheme of Eq. (1). The PCTR was approximated to a set of reactors in series with variable volume. Each screw conveyor vane was considered as a subreactor (r), so that the PCTR was modelled as 14 subreactors. Concentration of xylan in each subreactor ($[XyP]_r$) can be calculated from Eq. (2) and (3):

$$\frac{d[XyP]_r}{dt} = \frac{F_{r-1}}{m_r} [XyP]_{r-1} - \frac{F_r}{m_r} [XyP]_r - k[XyP]_r - \frac{[XyP]_r}{m_r} \frac{dm_r}{dt} \quad (2)$$

$$\frac{dm_r}{dt} = F_{r-1} - F_r \quad (3)$$

Where m_r is the mass in each subreactor, F_{r-1} and F_r are the input and output mass flow in the subreactor, respectively. Reaction rate constant (k) was estimated from experimental data using Particle Swarm Optimization (PSO) method (Rodríguez, 2014).

3.3. Mass flow modelling

Rheological characteristics of the biomass and mechanical components of the PCTR as well as operational conditions are important factors influencing biomass flows. Jaramillo (2017) developed an empirical model described by Eqs. (4) to (7) to estimate the biomass flow based on switched systems theory. In this model, the reactor was divided in 2 sections. The first part involves the extrusion step (Eq. (1) and (2)) where F_0 is the biomass extruder output, which depends on flow rate input (U), extruder fill delay (K_1) and biomass type dependent constants that describe the behaviour of the flow after a change in the motor speed (θ_1 to θ_4). In the second part, the model considers the reactor body as a set of subreactors in series with delay (δ_2). θ_5 and θ_6 are sampling period constants.

$$x_E(k+1) = \theta_1 x_E(k) - \theta_2 x_E(k-1) + \theta_3 U(k) - \theta_4 U(k-1) \quad (4)$$

$$F_0(k) = K_1(k)x_E(k) \quad (5)$$

$$x_r(k+1) = \theta_5 x_{nr}(k) + \theta_6 x_{(n-1)r}(k - \delta_2) \quad (6)$$

$$F_r(k) = x_r(k) \quad (7)$$

In this work, the proposed model incorporates Eqs. (2) and (7) in order to accurately describe the xylan depolymerization rate with low computational cost. Additionally, simulations using number of reactors (n) calculated from moments of RTD curves (Eq. (8)) at constant t_m and biomass flow (F_r) were analysed for comparative purposes. These assumptions are referred in the text as RTD-t.

$$n = \frac{t_m^2}{\sigma^2} \quad (8)$$

4. Results

4.1. Experimental and simulated RTD's curves

Figure 2 shows normalized concentration of tracer at four CS. As shown in the “RTD 100% curve” (screw conveyor is working at 100% of its nominal speed), the impulse responses are at least 16 min delayed and the spread across the reactor is more than 9 min. Delay time increased indirectly proportional to the CS in a non-linear way. The four experimental RTD's curves were used to estimate parameters of Eq. (4) to (6) by PSO and then, mass flows from Eq. (7). Simulation of “RTD 100%” using the proposed model is depicted in the continuous line (curve 14) of Figure 3. Response delay and the mass dispersion were satisfactorily approximated.

A total of 115 subreactors in series are required when Eq. (2) under RTD-t assumptions is applied to describe dispersive effects of the biomass inside the reactor. Simulations of “RTD 100%” using 14 and 115 subreactors with RTD-t characteristics are shown in the dotted (14 RTD-t) and dashed (115 RTD-t) lines in Figure 3, respectively. 115 subreactors in series describe in a correct manner the RTD curve. Actually the mean square error is 25 % less than the simulation of the proposed model. However, as shown in Eq. (1), xylan depolymerization reactions must be described for four equations in each subreactor, thus computational cost increases significantly when 115 subreactors are used. Therefore, using Eq. (7) for mass flow estimation we can save the computational cost up to 87% without significantly increasing the error in the estimation of t_m and σ^2 values.

4.2. Experimental depolymerization data

Experimental fraction of unreacted xylan from pretreated corn stover at 100, 50% and 33% of CS are shown in Figure 4 with black circles. Vertical semicontinuous lines show the time when changes were made in the CS set point.

Figure 2: Tracer RTD curves at four screw conveyor speeds (CS).

Figure 3: Experimental data and simulation of RTD using reactor in series technique.

Figure 4: Experimental data and simulation of xylan depolymerization.

Two SS can be identified in the time interval of 60 to 150 min and 215 and 250 min, that corresponding to the operation of the screw conveyor at 100 and 50% of its nominal speed, respectively. Results show that t_m increases proportionally when the CS decrease to 50% and the reaction yield increase from 53 to 70%.

4.3. PCTR simulations

Black line represents the simulation of Eq. (2) using Eq. (7) to estimate the mass flow in Figs. 4 and 5. Dotted and dashed lines are the simulation of 14 and 115 reactors under RTD-t conditions. Experimental data were fitted to the proposed model in order to estimate k by PSO method, whose value is 0.055/min. As shown in fig 4, the proposed model describes the behaviours of the autohydrolysis reaction in the stationary states as well as during the transient states due to CS decreasing. Simulations under RTD-t assumptions with the CS working at 100% could be acceptable, however the simulation

error increase by decreasing the CS to 50%. The estimated value of k from RTD-t conditions is 0.0475/min. Region 1 and 2 (R1 and R2) of Figure 5 show that RTD-t simulation only converges with the proposed model when the CS is 100%.

4.4. Simulation of initial concentration changes

Figure 5 shows the simulation of impulse responses to changes in the initial concentration of xylan in the biomass at two CS (100 and 50%). The proportion of xylan in the hemicelluloses chains decreased from 100 to 50% in the region bounded by vertical dotted lines. The magnitude of the impulse response at 100% of the CS was equal in the 3 cases. However, the proposed model really involved the responses delay observed on the RTD curves (Figure 3). Also, the ability of the proposed model to describe the response delay was more evident when the CS was at 50%, since the SS was reached 10 minutes after that the simulation with 115 subreactors.

Figure 5: Simulation of xylan depolymerization with disturbances.

5. Conclusions

Results show that biomass transfer phenomena should not be omitted in the pretreatment process modelling, especially impulse response delay. The PCTR can be described by 14 subreactors in series using an accurate model to describe the mass flow rates, as the selected model does. Experimental residence time distribution and xylan depolymerization behaviours were successfully simulated from the proposed model and estimated autohydrolysis kinetic parameters. This model can be used as an important tool to control the of xylan depolymerization cascade reactions inside the PCTR with low computational cost.

Abstract

The increasing demand of residential consumption and the integration of renewable energy sources have motivated researchers to develop grid simulations for testing energy management strategies. Agent-based modelling is one such methodology with the capability of mimicking the emergent and complex behaviour of grids over time. Thus, we have utilized this concept to model and predict the energy consumption of a house. Results from the simulation indicate the proposed approach closely mimics the fine-grained energy data obtained from the residential unit in India. This model possesses the flexibility to be extended to estimate the electricity demand of different localities in India and, in step, to understand the behaviour of the agent with the integration of low carbon technology.

Keywords: agent-based simulation, energy demand modeling, domestic sector, residential consumption.

1. Introduction

Domestic Sector in India accounts for 22% of the current electrical consumption which has increased from 80 TWh in 2000 to 186 TWh in 2012 (Rawal et al., 2014). It is predicted that the energy consumption in the domestic sector will increase by more than eight times by 2050. In order to manage the unsustainable energy demand, we need to focus on energy efficient management strategies and integration of Renewable Energy Sources (RES). Applications like demand side management (DSM), battery integration and micro grid with self-sustaining capabilities can help in efficiently utilizing the increased generation from RES for household energy consumption (Palensky et al., 2011). In order to plan and invest in better residential grid management strategies, it is essential to develop models of electricity consumption in the residential sector.

One of the approaches to model the behaviour of grid is by considering any of house, distribution sub-station, generator, humans, etc. as an agent, called agent-based modelling (Phelan and Scholl, 2004). It has the capability to model emergent behaviour of interactions by changing agent's behaviour and characteristics with time. This property of ABM can efficiently model the behaviour of a complex socio-technical system arising in biological, economic, engineering and social sciences (Alexrod et al., 1997). ABM approaches rely on the statistical data collected through audits for both model development and validation of residential consumption. Our work deals with collection of appliance level data from an Indian household and using the same to

develop fine-grained model of the residential grids. Results from our study show the distinct behaviour of Indian household over weekdays and weekends by modelling each major power consuming appliance. The behaviour of each appliance is validated with actual data and the errors in modelling are presented.

The paper is organized as follows: Section 2 summarizes the techniques used for modeling residential grids. Section 3 deals with agent based models in residential grids. A case study to validate our method is presented in Section 4. The article ends with a few concluding remarks.

2. Models for Residential Grids

Top-down and bottom-up are two distinct approaches used for modelling residential grids. Top down models “treats the residential sector as an energy sink and does not distinguish energy consumption due to individual end-uses”. In contrast, bottom up approaches extrapolates the residential consumption of individual sectors to estimate the energy demand of the whole residential grid. If the construction of any house is increased to 10% of the units, it will be difficult for the top-down approach to show its consequences in terms of increased demand as the vintage distribution of the housing stock would be changed significantly. Also, the reliance on historical data is a major drawback for these models as they have no capability of extrapolating discontinuous advances in technology, whereas, bottom up modelling takes into account the details of climate properties, indoor temperatures, occupancy schedules, equipment use etc. Although the simulation techniques become complex with this intricate level of modelling, yet the errors are highly minimized as compared to top-down approach (Swan and Ugursal, 2009).

Top down models are depended on statistical data and economic theory. A model for residential energy use in New Zealand uses this top-down approach (Saha and Stephenson, 1980). It describes the energy use at the national level for four types of fuels (electricity, oil, gas, and “others”). This study separately analyses the consumption due to end uses like space heating, domestic hot water, cooking which is then aggregated to obtain the annual energy consumption. This model predicts the consumption over 1960s and 1970s very well but since it does not take into account the shifts in home insulation levels, there is a mismatch between the actual and predicted results towards the end of 1970s. Their approach cannot estimate the city or further more segregated levels of consumption.

In contrast, the bottom-up approach identifies the contribution of each end-use towards the aggregate energy consumption value. It takes into account the electricity consumption at a much more ground level and then aggregates the total consumption to obtain the annual electricity consumption for the domestic sector. A case study in Chongqing (Yang et al., 2015) uses a bottom up model. Here, the residential household appliances are hourly monitored for a week. Based on this data certain rules are created to estimate the hourly energy consumption, running time, usage frequency and power of household appliances. The results are validated by the actual energy consumption value of residential building of a university in Chongqing. A deviation of 22.4% was established between the residential model and its true values. This study lacked the granularity of appliance level consumption in terms of time and power which can be addressed by monitoring the consumption at higher frequencies (in terms of minutes or

seconds). One of the bottom-up approaches which have recently been used to incorporate the emergent behavior of residential grids is agent based modelling.

3. Agent Based Models

Agent-Based Modelling and Simulation (ABMS) has been extensively used to study electricity systems integrated in an economic, technical and social context. In particular the dynamics of smart grid transitions require appropriate modelling approaches to understand such a complex model. The main focus of these modelling approaches lies in dealing with concepts related to demand response, distributed generation, intermediaries and their interactions with prosumers (active electricity consumers- who consume as well as produce electricity) as well as local markets and their integration in centralized markets. These approaches allow simulating in detail the behaviour of particular agents and observing an emergent development on system level by letting agents decide individually, cooperatively or competitively. Despite being a promising approach to increase the flexibility of modelling electricity systems, the reviewed literature struggles with well-known challenges of agent-based models concerning model description, calibration, verification, validation, and publication. However, studying smart grids with ABMS models is young and, therefore, a limited field of research and much work needs to be done in this field (Ringler et al., 2016).

A case study of London simulates the residential electricity and heat demands in urban areas using agent based approach (Bustos-Turu et al., 2016). It considers the humans living in these areas as agents. The data is calculated from seven boroughs in London covering an area of 175 km². Here, each borough or zone is simulated separately to understand the differences by taking into account factors like urban layout, land-use, socio demographic characteristics, energy infrastructure access, conversion technologies and user behaviour which affect the electricity profiles. The difference in statistical data and model was found to be 14.9% on an average. This study does not take into account the appliance level data or electricity consumption of individual buildings of each borough considered.

In this paper, we propose an agent based model to estimate the power consumption trend of a house and validate the same using information obtained from our NILM algorithm (Patel et al., 2016). Electricity data is collected at 1 Hz frequency from an Indian household and application of NILM algorithm (on this data) provides the electricity consumption profile (function of time) of various appliances. This information is used to model individual appliances in agent based simulation. The simulation studies takes into account factors like weather variations, the working status of the members of the household, the appliances present in their home, their consumption pattern and usage frequency that influences the residential energy consumption based on a local survey.

4. Case Study

The agent in our study is a house whose attributes are the appliances it contains. House consists of the following major power consuming appliances: refrigerator, television, washing machine, water purifier, dishwasher, air conditioner and rice cooker. All these appliances have distinct power consumption pattern. In our approach we model each appliance by splitting the consumption pattern based on their statistical characteristics. Each interval of the consumption pattern that has same statistical properties across

multiple runs is considered as a region. For example, appliances with motor element have an initial spike region before consumption settles to form a steady state region. In our study, this peak and the following steady part are modelled as two distinct regions.

Table 1: Refrigerator model parameters

Regions	Power ($\mu \pm \sigma$) (W)	Slope	Intercept	Duration ($\mu \pm \sigma$)(s)
Peak region	740.73 \pm 370.15	-	-	2 \pm 0
Slope region	139.40 \pm 4.63	-0.01	147.43	1238 \pm 30
Off region	1.84 \pm 0.52	-	-	3423 \pm 238

Each region is modelled by extracting following characteristics from the training data: mean power (P), slope (m) and intercept (c) of the region, variance (σ^2) of the fluctuations observed in the region and the duration of the region. Let us consider refrigerator as an example. As shown in Fig.1a the refrigerator (manufacturer-Whirlpool) has three regions: the peak region, the slope region and the OFF region. This pattern is repeated throughout the day. The refrigerator's pattern is modelled using the data of 15 patterns. We used 15 such patterns to train the parameters for each region. The parameters obtained from the training data are shown in Table 1. Five patterns are used as test data to calculate the error in our model. All other appliances like dishwasher, rice cooker, television, air conditioner, washing machine and water purifier are modelled in a similar manner. Every region in their power pattern is modelled separately. We validate our results by calculating the Percentage Error (PE) between our model and the test data.

$$PE = \frac{1}{n} \sum_{k=1}^n \frac{|P[k] - \hat{P}[k]|}{\max(P[k])} \quad (1)$$

Here, $P[k]$ is the actual power consumption and $\hat{P}[k]$ is the estimated consumption of an appliance at instant k . The results of our analysis are presented in Table 2.

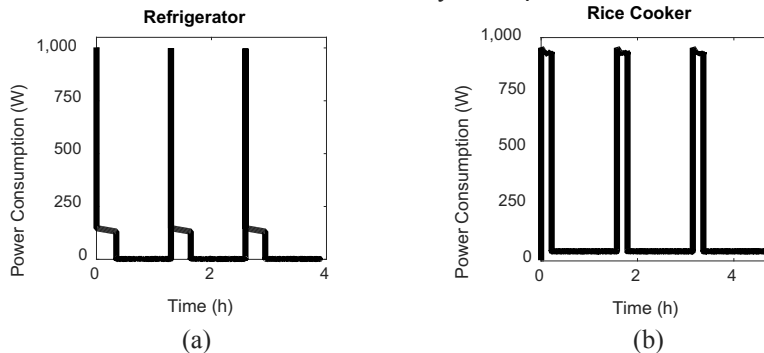

Fig. 1a : Behaviour of Refrigerator cycles; 1b: Behaviour of Rice Cooker cycles

Based on the survey of the usage time and frequency of each appliance we build a probabilistic model of the house. The rules for the agent are determined from the survey data obtained from the house being modelled. For example, refrigerator operates throughout the day so its pattern is repeated continuously, a TV operates approximately between 12pm-3pm on a weekend, we define a rule in which the model randomly chooses a turn on time between 12pm-12:30pm and also a duration of 2 $\frac{1}{2}$ -3hours

between which the TV is on. Similarly all other rules are laid down for each appliance. In this way house agent is modelled by integrating the region based model of each appliance with survey data containing information about time and its usage to estimate the consumption of the major appliances in the house. The consumption of entire house is obtained by aggregating the consumption of each appliance.

The behaviour across weekdays and weekends show a distinct pattern. Fig. 2a and Fig.2b shows the average consumption over a period of twenty days for the house during weekdays and weekends.

Table 2: MAPE of appliances

Sl. No.	Appliances	Regions of Appliances	Training Error (%)	Test Error (%)
1	TV	Region 1(on)	7.15	7.38
2	Rice Cooker	Region 1(Slope)	0.05	0.06
		Region 2(Steady State)	0.30	0.31
		Region 3(Fan Area)	0.52	0.56
3	Washing Machine	Region 1(rinse: on)	3.50	4.30
		Region 2(rinse: off)	5.70	6.40
		Region 3(heat: on)	0.38	0.49
		Region 4(heat: off)	0.30	0.45
4	AC	Region 1(temp 20°C: on)	0.83	0.97
		Region 2(temp 20°C : off)	9.70	10.00
		Region 1(temp 25°C : on)	1.72	1.80
		Region 2(temp 25°C : off)	9.03	9.31
5	Water Purifier	Region 1(Peak)	0.36	1.43
		Region 2(Slope)	0.01	2.83
		Region 3(Steady State)	2.85	2.94
6	Dish Washer	Region 1(65°C Wash-heat)	0.71	0.79
		Region 2(65°C Wash-rinse)	3.87	5.10
		Region 3(Intermediate-heat)	0.70	0.73
		Region 4(Intermediate-rinse)	2.95	5.00
		Region 5(Hot-heat)	0.78	0.85
		Region 6(Hot-rinse)	6.04	6.46

Fig. 2a: Average Weekday Consumption; 2b: Average Weekend Consumption

It is visible from Fig. 2a that there is minimum consumption for weekdays around 10am-3pm where usually the working members are not at home. The highest peak occurs between 3pm-4pm which indicates the dishwasher is being operated regularly. The behaviour of AC is visible during the early morning and late night period. The other appliances like washing machine are usually operated four to five times a week in the morning period. The weekend afternoons show the operation of TV in Fig.2b.

5. Conclusions

In this work, an agent based simulation model is developed to estimate the electricity consumption in the residential sector. The model is tested to mimic the power consumption trend of a house based in Gandhinagar; and the results are compared with the appliance level data obtained from the house which is expected to increase the accuracy of our predictions. This work also takes into account an almost exact user behaviour to arrive at the results which show that the behaviour of the house can actually be reproduced by understanding the consumption pattern and usage frequency.

Since this model takes into account the individual appliance level data, it ensures granularity but also consumes time. Future work will be to develop a model using ABM to mimic a residential colony. Also if we are able to collect the actual data containing details about base and peak loads of consumption throughout the day, it would help us in estimating the total power consumption of the house with minimal errors. This approach can then be validated to estimate the power consumption variation in places having a completely different weather conditions, user behaviour and socio economic factors which will then help to model the Indian domestic sector. We can then model our grid with the integration of renewable resources in order to look for ways to curb the increasing power demand.

Department of Chemical and Process Engineering, University of Surrey, Guildford GU2 7XH, UK

h.arellano-garcia@surrey.ac.uk

Abstract

Modern renewable energy sources have a great disadvantage of being intermittent. Harvesting solar energy directly using photovoltaic panels is one of the most promising renewable energy technologies. While this allows electricity generation during daytime when the sky is clear, at night there is no production at all and it is greatly diminished in cloudy or rainy conditions. Recently a concept of all-weather solar cells was proposed by Q. Tang et al. (*Angew. Chem. Int. Ed.* 55(17) (2016) 5243-5246) in which a solar panel was covered with a layer of graphene. This allows collecting energy from falling raindrops containing dissolved salts through charging and discharging of an electrical double layer at the water-graphene interface, which acts as a pseudocapacitor. Although this setup allows harvesting both direct solar radiation and some of the kinetic energy of falling rain drops, the output is low for realistic salt concentrations while the graphene layer diminishes the solar-to-electric conversion rate.

In this work, we propose a different approach to the same problem. Instead of relying on a sufficient concentration of salts in rain water, we propose to convert the mechanical energy delivered by drop impacts directly into electrical energy by supporting a thin-layer solar panel with an array of piezo crystals. The advantage of this setup is that the solar-to-electric performance of such a panel is not affected by the added piezoelectric support. However, only a fraction of the kinetic energy of the falling rain drops can be converted due to the energy dissipation within the material of the thin-layer panel. We have conducted detailed modelling of kinetic energy harvesting process from the drop impact and spreading to the dissipation of mechanical strain through the panel to the generation of piezoelectric potential. The results illustrate the viability of this concept, but they are still to be confirmed experimentally and require an economic feasibility analysis to be performed.

Keywords: renewable energy, rain energy, all-weather panels, piezoelectric energy harvester

1. Introduction

The development of cheap, efficient and reliable ways of harvesting energy from renewable sources is key to the solution of a number of global challenges such as providing power to an estimated 1.2 billion people (World Energy Outlook, 2016) who currently live without access to electricity, and combating climate change by substituting fossil fuels used for power generation. Renewable energy generation from all sources has been growing at a staggering rate of over 14% over the last 10 years,

however its share is still low relative to fossil fuels. Among the renewable sources, wind and solar generation are developing most rapidly. The former benefits from relatively high energy density of wind so large amounts of energy can be harvested from a relatively small area. The main disadvantage of wind power though is that the efficiency of generation increases with increasing turbine size, so substantial capital investment is required for efficient generation, which may be a limiting factor in poor or sparsely populated areas. On the other hand, the efficiency of harvesting solar energy using photovoltaic (PV) cells (which is the main type of solar panels) is independent of scale making it a more flexible and affordable (at least at small-to-medium scale) energy source. Moreover, the efficiency of the PV cells has increased dramatically over the last two decades with commercial panels achieving over 22% efficiency in commercially available panels and up to 46% efficiency in experimental solar cells. The main issue with the solar energy is its variability and intermittency due to the diurnal and annual cycles as well as the effects of cloud cover, snow, fog or dust. In fact, the solar energy is nearly zero 65-70% of the hours of the year.

There is, however, a largely overlooked renewable source available throughout at least 2/3 of land on Earth. This resource is rain. We already make use of hydroelectric power which utilises the potential energy of precipitation collected in a reservoir located at high altitude versus a lower reservoir. However, the enormous amounts of kinetic energy carried by raindrops as they fall to the ground are simply dissipated into the environment. Capturing this kinetic energy as the raindrops approach the ground would provide an additional contribution without affecting the output of hydroelectric generation. Combining raindrop kinetic energy harvesting with PV generation is also expected to reduce somewhat the intermittency of electricity generation since raindrop energy would partially compensate for the diminished solar irradiation in rainy conditions.

The amount of energy in question is indeed non-negligible. It has been estimated that in a country like Malaysia the annual average kinetic energy of rainfall is around 0.4 kWh/m²/day compared with ~5 kWh/m²/day of solar irradiance (Chua et al., 2016). This prompted a number of investigations into the possibility of harvesting this energy (Chua et al., 2016; Ilyas and Swingler, 2015; Wong et al., 2015; Zheng et al., 2014). The main approaches described in the literature include various applications of the piezoelectric effect to convert the mechanical strain caused by falling drops or collected rainwater (Guigon et al., 2008; Wong et al., 2015) as well as collecting the electrostatic energy of raindrops (Zheng et al., 2014) and using an electrochemical method relying on the effect of charging-discharging of the electrical double layer when a raindrop containing NaCl moves along a graphene-coated surface (Tang et al., 2016; Zhang et al., 2016). Despite the apparent simplicity of the latter approach the amount of energy generated is strongly dependent on the concentration of the salt, and it is low even for unrealistically high concentrations of NaCl (~3 orders of magnitude higher than the natural levels).

The use of the piezoelectric effect, on the other hand, is seen as a viable method of converting the kinetic energy of raindrops into mechanical deformations and vibrations of a piezoelectric material, which are in turn converted into electric potential. Piezoelectric energy harvesting (PEH) technologies have been widely used to convert vibrations and motions from any movements to electricity. Low cost of fabrication, simple structure and ease of application make them an affordable solution for many situations (Kumar et al., 2015; Wong et al., 2015). Although the concept of combined solar and piezoelectric energy harvesting has been around for some time, the existing contributions have not

offered a thorough computational framework instead limiting themselves to experimental measurements, quantitative estimations of energy output or partial modelling of the complex process of energy conversion inside such hybrid devices.

The aim of this study is to offer the first comprehensive modelling approach considering all the steps in detail: from the impact and spreading of raindrops on the surface of the panel, deformation and ensuing vibrations of the panel due to the pressure exerted by the spreading drop, and the electric potential ensuing from the ensuing compression of the piezoelectric crystals. This new model will then be used in an optimisation framework to design all-weather panels with maximum overall performance.

2. Modelling methodology

Falling raindrops are affected by drag and gravitational forces. For simplicity, in the following we assume that there is no side wind so that both forces act along the vertical axis. Provided the drop is not overly large (i.e., up to 5 mm in diameter), drag eventually equilibrates the gravitational pull due to the transfer of momentum from the drop to the surrounding air through eddies, and the drop reaches a terminal velocity, which determines its kinetic energy when it hits the ground. For drops ranging from 0.5 mm to 4 mm in diameter their terminal velocities lie between 2.06 m/s and 8.83 m/s. On the other hand, larger drops tend to flatten, become unstable and break up into smaller near-spherical ones (Ilyas and Swingler, 2015). Since heavy rain would naturally generate more energy, we focus here on the larger raindrops 4 millimeters in diameter with the terminal velocity at 8.83 m/s. This is a realistic value for the average drop diameter during a typical tropical thunderstorm.

Fig. 1. Geometry of the hybrid solar-piezo panel

The solar panel-piezoelectric crystals assembly considered in this work is shown in Fig. 1. The panel is assumed to be horizontal with raindrops falling strictly vertically. The panel is supported by a square array of piezo crystals represented by small cubes underneath the solar panel. Note that the impact probability is uniform throughout the surface of the all-weather panel.

Before the piezoelectric response of the hybrid panel to raindrop impacts can be simulated the impact itself and the subsequent spreading of the drop over the panel surface must be well understood quantitatively. We simulated this process using the volume of fluid (VOF) method in ANSYS 15 software by assuming the panel to be completely rigid. The fact that fluid-solid interaction was ignored is not expected to introduce a significant error in the simulations since the panel deformation as a result of the impact is negligible compared to the size of the drop. Additionally, any changes in air pressure, temperature and density were also ignored. A surface tension of 0.072 M/m and the contact angle of 70 degrees have been adopted (Manzello and Yang, 2002).

As a result of these simulations the time-dependent distribution of pressure over the affected area of the panel was obtained for the given raindrop size (see Fig. 2). The impact centre experiences the highest pressures in the initial moments after the impact, after

which the drop quickly spreads with the bulk of it forming an expanding ring which exerts an ever diminishing pressure on the affected area of the panel. The whole process takes not more than about 3 ms and the drop spreads over an area in excess of 3 cm in diameter.

Fig. 2. Pressure distribution resulting from the impact of a 4mm diameter drop

The pressure distributions in Fig. 2 were approximated using analytical expressions and used as an input in coupled structural mechanics and piezoelectric simulations performed in COMSOL Multiphysics v. 5.2 (<https://www.comsol.com/>). The solar panel material was taken to be polycrystalline Si, due to its widespread use and superior performance (Zheng et al., 2015), with the thickness of 1 mm.

Similarly, Polyvinylidene Fluoride (PVDF) has been adopted as the piezoelectric material owing to its widespread use in PEH technologies (Ilyas and Swingler, 2015; Wong et al., 2015; Guigon et al., 2008). PVDF has a number of advantageous properties such as high flexibility, low density, non-toxicity, low-cost, sensitivity to mechanical strain and high optical transparency. In addition, under otherwise equal conditions, PVDF generates higher voltage and power in comparison with other piezoelectric materials.

In order to achieve realistic results for the strain and oscillations of the solar panel as a result of raindrop impacts, the panel dimension was taken to be significantly higher than the spread drop, i.e. 60 mm \times 60 mm. This model panel was supported from the bottom by nine cubic PVDF crystals with the edge length of 3 mm located 20 mm apart (centre to centre distance). The bottom faces of the cubic piezo crystals were assumed to be fixed to a substrate and therefore immobile. Finally, the location of the impact was varied to study the effect of stress wave attenuation on the harvested electrical energy.

3. Results

A drop impact causes a stress wave to spread from the point of contact throughout the panel. As it reaches the PVDF crystals, their top surfaces begin to oscillate together with the panel causing the crystals to expand and contract alternately. Typical simulation results from COMSOL Multiphysics corresponding to the drop impact at the midpoint between four piezo crystals of the array are illustrated in Fig. 3 showing a) the pressure distribution from spreading drop over the panel surface at $t = 1$ ms, b) voltage distribution throughout the piezo crystals at 0.4 ms, c) surface total displacement at 1

ms, and d) surface stress at 0.2 ms. These distributions demonstrate the complexity of the interplay between the external stimulation from fallen drop, the structural mechanics of the panel-piezocrystals assembly and the piezoelectric energy generation.

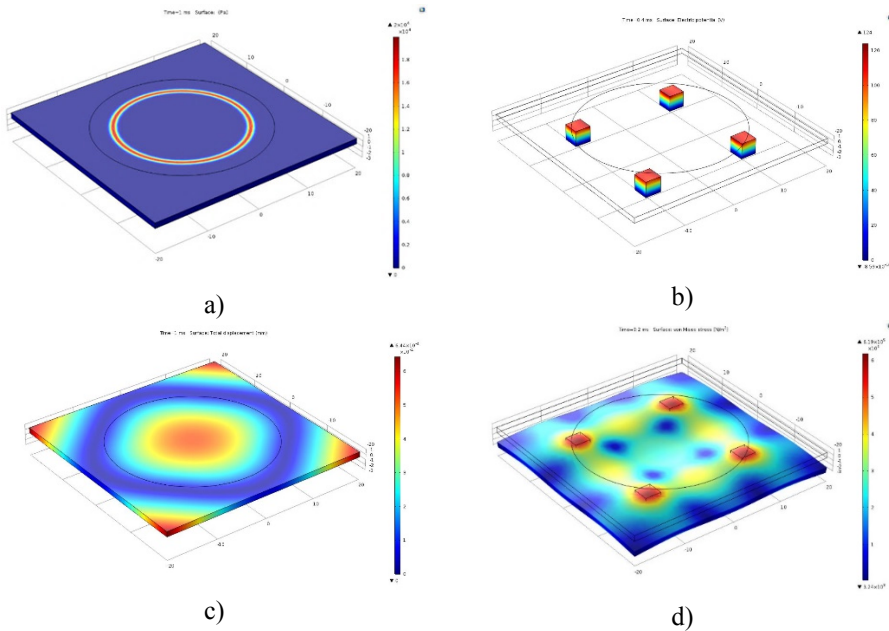

Figure 3. Distributions of a) pressure at 1ms, b) voltage at 0.4 ms, c) surface displacement at 1 ms, and d) stress at 0.2 ms.

As mentioned above, a raindrop hits any point on the panel with the same probability. However, different impact locations lead to different variations of the generated voltage depending on the propagation of the ensuing deformations in the panel (Fig. 4).

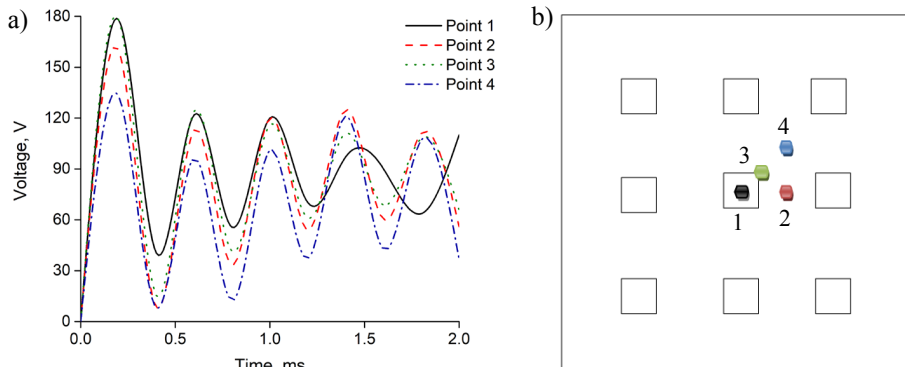

Figure 4. Open-circuit voltage generated by the all-weather panel (a) corresponding to drop impacts at different locations relative to the piezoelectric crystals (b).

Fig. 4a displays the simulated voltages corresponding to four impact points shown in Fig. 4b. Note that, if the size of the panel is sufficiently large, the triangle formed by

these four points represents the smallest tessellation unit for the square arrangement of the piezoelectric crystals. Therefore simulations of impacts within this triangle are representative of the whole panel. For the given sizes and relative distances between the PVDF crystals, there is no significant difference between voltages produced by impacts at different locations. Note that the electric potentials shown are open-circuit, and further work is being undertaken to extend the simulation to include an interfacing circuit and a load to obtain power characteristics.

4. Conclusions

Combining the capabilities of power generation from solar irradiation and kinetic energy of raindrops appears to be an appealing concept capable of enhancing the electricity production while also reducing its intermittency. This work offers a novel configuration of a hybrid all-weather panel consisting of a solar cell resting on an array of piezoelectric crystals. In rainy conditions, drop impacts cause transient vibrations of the panel that lead to the generation of piezoelectricity owing to the contraction-expansion of the piezoelectric elements. In order to achieve maximum efficiency of this setup in both modes of operation, a thorough modelling framework has been proposed that allows for the detailed simulation of raindrop impacts through CFD to be coupled with the structural mechanics and piezoelectric models to yield accurate distributions of pressure, stress, strain and power. The present model is key to accurate model-based optimisation of all-weather panels to yield maximum performance.

A thorough economic analysis must also be performed in order to ascertain the economic feasibility of combined solar-rain energy generation. It is clear, however, that hybrid solar panel designs like the one considered here, would be most efficient in areas with large amounts of both sunshine and rainfall, such as the tropical and equatorial zones.

Abstract

In order to carry out investigations of one of the most advantageous direct reduction processes, the fluidized bed reactors, computational tools need to be utilized. One such tool is the Computational Fluid Dynamics - Discrete Element Method (CFD-DEM) method. In this work, two of the most common types of models that represent the reactions between solid particles and fluids are implemented into the CFD-DEM library. Levenspiel (1999) describes these models as the Shrinking Particle Model (SPM), where the solid particle reacts with the fluid and changes its size, and the Unreacted Shrinking Core Model (USCM), where after reacting a product layer is formed around the layer that impedes the reaction rate. The SPM is used to verify communication between the CFD and DEM sides, whereas the USCM is used to represent the reduction of iron-ore.

The USCM is validated with a case that considers only a single iron-ore particle that reacts with a gas mixture of CO and N₂. The results are then compared with available experimental data that uses the ISO 4695 conditions at 950 °C and 50 Nl/min. We investigate possible parameters that influence the reduction process such as the particle porosity and pore diameter. Also, the reaction parameters such as the frequency factor, activation energy and the equilibrium constants are investigated by comparing the fractional reduction rates of simulations with experiments. These outcomes give us insight about the total reduction process.

Keywords: CFD-DEM, iron-ore modelling, particle shrinkage, unreacted core model, chemical-reaction kinetics

1. Introduction

The research on the reduction of iron ore has received much attention in the past few decades as a result of the increasing cost and low availability of raw materials. The reduction of gaseous emissions and the search for low-cost alternatives to traditional routes has also boosted the investigations for reduction processes (Plaul et al., 2009).

Currently the dominating process for the iron-ore reduction is the blast furnace (BF) technology. These furnaces consist of a moving bed reactor with a counter-current flow of the solid reactants against a reducing gas. Not only are the energy costs relatively high for these blast furnaces the pollution problems can also be quite severe. The iron-ore fines that enter the BF need to go through a pelletizing and sintering process. In other cases, such as the smelting reduction (SR) processes that use the fluidized bed technologies the iron-ore fines can directly be charged into the reduction process making it highly advantageous. Such fluidized bed reactors are used in the pre-reduction stage of the FINEX[®] process (Habermann et al., 2000). The FINEX[®] process, which was jointly developed by POSCO (Korea) and Primetals Technologies (Austria), produces

hot metal in the same quality as traditional blast furnaces. The iron-ores that are charged into the process go through fluidized bed reactors where they are heated and reduced to Direct Reduced Iron (DRI). The DRI is then charged into the melter gasifier where the final reduction and melting as well as the production of reducing gas by gasification of coal with oxygen takes place (Schenk, 2011).

To improve these processes computational tools such as the CFD-DEM method, which uses the coupling of CFD for the continuous fluid phase (i.e. the reduction gas) and DEM for the discrete particles such as iron-ore and coal, can be utilized. In this work, we are using the CFD-DEM coupling approach based on the open source software packages OpenFOAM and LIGGGHTS (Goniva et al., 2012). The Eulerian field follows a continuum approach and volume-averaged continuity equations are used to describe the behavior of the flow. The discrete particles are described by Newton's equations of motion. More information about the CFD-DEM system can be found in the works of Zhou et al. (2010). In this case, the DEM provides an easy way to evaluate the per-particle chemistry such as the shrink/growth of particles due to reactions. Other tools such as the Two-Fluid Model (TFM), can also be used. However, this model lacks the proper representation of particle size description and the related physical phenomena. Another method that can be thought of would be the hybrid Lagrangian-Eulerian model that combines the Lagrangian Discrete Phase Model (DPM) and a coarse-grained TFM such as in the works of Schneiderbauer et al. (2016).

2. Reaction Kinetics

A general type of non-catalytic reaction may be represented by

where gas A is reacting with solid particle B to produce a gaseous product C and a solid product D . For gasification processes, one might consider v_D as zero. For modelling the general reactions two of the most common types is the Shrinking Particle Model (SPM) and the Unreacted Shrinking Core Model (USCM). In the SPM, the particle reacts with the gas and shrinks whilst the product gas diffuses to ambient fluid, such as the gasification of coal. However, in the USCM a product layer is formed around the core as the reaction proceeds, which eventually impedes the reactant gas as it has to diffuse through this newly formed layer.

The main reactions for the direct reduction of iron with a gaseous reductant, CO/H_2 , can be expressed in three reaction steps as

In the topochemical reduction of iron oxide, firstly the reducing gas is transported through the gas film onto the particle surface. Afterwards, the gas diffuses through the porous iron layer where it partially reacts with wustite at the wustite/iron interface producing iron and a gaseous product. The rest gas diffuses through the wustite layer until the wustite/magnetite interface and a portion of the gas reacts with magnetite producing wustite and a gaseous

Figure 1: Resistance network diagram that illustrates the resistance of an iron-ore pellet that goes through in the reduction process.

product. The balance gas diffuses through the magnetite layer onto the magnetite/hematite interface. Chemical reaction of the leftover gas occurs at the hematite core and produces magnetite and a gaseous product. Eventually, the gaseous product diffuses outwards through the pores of the pellet (Tsay et al., 1976).

Each step poses a resistance to the completion of the chemical reaction. Therefore, a resistance network can be constructed as illustrated in Figure 1. If one of these steps is so slow that the others become insignificant, this step is considered to be the rate-controlling or rate-limiting step. The combined solution of this network leads to the chemical reaction rates, which are used to determine the mass source terms and can be calculated as

$$\begin{aligned} \dot{Y}_w = & \left([(A_1 + B_1)(A_2 + B_2 + B_3 + F) + A_2(B_2 + B_3 + F)](x_0 - x_{CO,3}^{eq}) \right. \\ & - [A_2(B_3 + F)](x_0 - x_{CO,1}^{eq}) \\ & \left. - [(A_1 + B_1)(B_3 + F)](x_0 - x_{CO,2}^{eq}) \right) \frac{1}{W}, \end{aligned} \quad (5)$$

$$\begin{aligned} \dot{Y}_m = & \left([(A_1 + B_1 + B_2)(A_3 + B_3 + F) + A_3(B_3 + F)](x_0 - x_{CO,2}^{eq}) \right. \\ & - [B_2(A_3 + B_3 + F) + A_3(B_3 + F)](x_0 - x_{CO,1}^{eq}) \\ & \left. - [(A_1 + B_1)(B_3 + F)](x_0 - x_{CO,3}^{eq}) \right) \frac{1}{W}, \end{aligned} \quad (6)$$

$$\begin{aligned} \dot{Y}_h = & \left([A_3(A_2 + B_2 + B_3 + F) + (A_2 + B_2)(B_3 + F)](x_0 - x_{CO,1}^{eq}) \right. \\ & - [A_3(B_2 + B_3 + F) + B_2(B_3 + F)](x_0 - x_{CO,2}^{eq}) \\ & \left. - [A_2(B_3 + F)](x_0 - x_{CO,3}^{eq}) \right) \frac{1}{W}, \end{aligned} \quad (7)$$

in which the term A_j represents the chemical reaction resistance term that is determined by

$$A_j = \frac{1}{(1 - f_j)^{\frac{2}{3}}} \frac{1}{k_j \left(1 - \frac{1}{Keq_j} \right)}. \quad (8)$$

The k_j is the reaction rate constant for layer j and is determined with the Arrhenius Equation of $k_j = k_0 \exp(-E_a/(RT))$, where k_0 is the frequency factor, E_a is the activation energy. The values for the frequency factor and activation energy for the reduction reaction can be found in the works of Negri et al. (1995), Tang et al. (2012) and Valipour (2009). R is the universal gas constant and T is the temperature. f_j represents the local fractional reduction rate that is determined with

$$f_j = 1 - \left(\frac{r_j}{r_{particle}} \right)^3. \quad (9)$$

Keq_j represents the reaction equilibrium constant. A wide range of correlations for the equilibrium constant is available in literature, however in this work we are using the correlation proposed by Valipour (2009). The diffusivity resistance term B_j can be calculated for the inner layers of magnetite and wustite as

$$B_j = \frac{(1 - f_{j+1})^{\frac{1}{3}} - (1 - f_j)^{\frac{1}{3}}}{(1 - f_{j+1})^{\frac{1}{3}} (1 - f_j)^{\frac{1}{3}}} \frac{r_g}{D_j^{eff}}, \quad (10)$$

and for the iron shell as

$$B_j = \frac{1 - (1 - f_j)^{\frac{1}{3}}}{(1 - f_j)^{\frac{1}{3}}} \frac{r_g}{D_j^{eff}}, \quad (11)$$

in which D_j^{eff} represents the effective diffusion coefficient of the relative layer. This is the combination of binary molecular diffusion, calculated with the Fuller-Schettler-Giddings correlation (Fuller et al., 1966), and the Knudsen pore diffusion. The term F in the chemical reaction rate equations represents the resistance generated by the gas mass transfer to the particle surface that can be determined by the Sherwood and Reynolds numbers as it can be found in the works of Valipour (2009) and Nouri et al. (2011).

3. Results and Discussions

Figure 2: Schematic representation of the lab experimental setup used in the investigation of reduction processes for various iron-oxide ores (Martina Hanel, 2014).

ert gas and a total inlet velocity of 0.011 m/s has been used. The initial particle is taken as the limonitic-ore, which is more porous than hematite. Therefore, we set the initial porosity as 15% and calculated the other layer porosities accordingly using the correlation proposed by Tsay et al. (1976). The tortuosity in this case is taken as 3. The mean pore diameter is not exactly defined with the experiments therefore we have carried out investigations for a range of pore diameters varying from $4e - 5$ to $4e - 7$ m, which is illustrated in Figure 3, in which the overall fractional reduction from the simulations are compared with the available experimental data for limonitic- and hematitic-ores. The simulation is run for 7500 seconds, with a CFD time step of 1 and DEM time step of 0.01 resulting in a computational run time on two-cores of approximately 1 hour.

It can be seen in Figure 3 that the simulation results get really close to the experimental outcomes, especially for the pore diameter of $4 - 5 \mu\text{m}$. Even though the simulation reduces the iron-ore faster than the experiment, they both reduce 80% of ore almost at the same amount of time. Evidently, as the pore diameter gets smaller, the reduction speed gets slower. This effect is to be expected since the diffusion gets slower which makes the diffusion resistance higher thereby reducing the reaction speed. Another parameter that we looked at was the initial porosity value of the particle. Experimentally the particles were said to have a porosity of 15%, however we have carried out investigations in order to see the effects of increasing and decreasing the porosity had on the overall reduction. This effect is illustrated in Figure 4. It is clear that decreasing the porosity

We have taken the experimental work from the Dissertation of Martina Hanel (2014) as a basis to validate our simulation results. In the experimental setup a vertical reduction aggregate with an inner diameter of 75 mm has been used. The setup is schematically represented in Figure 2 as it was used in the lab. In the test case, first N_2 was blasted into the aggregate with a volumetric flow of 50 NI/min for 60 minutes. The temperature was then increased to 950 °C and the gas composition was changed to 60% N_2 and 40% CO , with the relative flow rates being 30 NI/min to 20 NI/min.

For the numerical simulation, the convective and diffusive terms are discretized using a central differencing scheme. The pressure-velocity coupling is achieved through a PIMPLE (PISO + SIMPLE) algorithm as in OpenFoam (2011). A computational domain has been built that represents the aggregate, where a single iron ore particle was placed into the middle of the volume. First step of N_2 blasting was neglected, as it is an in-

reduces the reduction rate. This is also an effect of diffusion term, since the particle becomes denser the resistances are higher. The values for separate resistance terms are plotted as a function of time in Figure 5. According to the works of Kawasaki et al. (1962), Bonalde et al. (2005) and Melchiori and Canu (2014), if the USCM is used at the beginning of the reaction the chemical reaction resistances are dominant, whereas afterwards the diffusion resistances become the rate limiting step. If we take a closer look at the first 300 seconds of Figure 5, we can also realize that the resistance due to chemical reaction kinetics is higher than the diffusion resistances, but in overall development the diffusion resistances are dominant.

Figure 3: The overall reduction rate of experiments for limonitic- and hematitic-ores compared with the reduction rate of numerical simulations using various pore diameters.

4. Conclusion and Outlook

Through literature research, available models that represent the solid-fluid chemical reactions have been determined and implemented into the CFDEM coupling library, which can be used to investigate the reduction of iron-ores inside the fluidized bed reactors. Simulations have been carried out that investigate the different properties affecting the reduction process. The outcomes of these simulations are then compared with available experimental work. With the current comparison, it can be seen that the implemented mathematical model provides reasonable results for the reaction resistance terms and also the general reduction rate is in an acceptable agreement with experimental data. However, improvements are necessary in order to minimize the deviation between the experimental and simulation results. These deviations might be due to the solid properties and the effect that ongoing reaction has on it, such as the porosity values and each layers molar densities are definitive reduction effecting points that one should consider. Further investigations will cover other methods of calculating porosity and also using a time dependent pore diameter, in order to achieve results with less deviation.

Figure 4: The overall reduction rate for different particle porosities, compared with the experiments.

Figure 5: The reaction resistance terms A_j , B_j and F that define the chemical reaction rate dependent on time, on the left side (a) is the total development of the resistance values, on the right side (b) the first 300 seconds of the development of resistances confirming that the chemical reaction resistance is higher.

Abstract

The photo-enhanced Fenton process has proved to be an effective alternative to conventional treatment processes that have shown to be unable to remove Contaminants of Emerging Concern (CECs). A great experimental effort and several modelling approaches have been proposed. Despite of this, the major challenge still remains the identification of an approximately unified, causally established coupling between the general photo-Fenton system and the decontamination of the arbitrarily chosen organic compounds. In the present work, Direct Computer Mapping based Programmable Structures was applied for modelling and simulation based analysis of the experimental results of photo-enhanced decomposition of the paracetamol (PCT). A design of experiments was performed in a 15-L pilot plant, consisting of an annular photo-reactor. A simplified first principles model (FPM), based on the well-known Fenton and photo-Fenton kinetics, and on our suggested idea of consecutive breakage steps, depending on the number of carbon atoms in the molecule to be decomposed, was proposed. This model allowed the fast, approximate combination of the simplified photo-Fenton core with the simplified decomposition reactions of the actual target.

Keywords: photo-Fenton, paracetamol, design of experiments, first principles model, programmable structures

1. Introduction

The photo-Fenton process is an Advanced Oxidation Process (a group of processes based on the formation of highly reactive free radicals, mainly HO[•]) that represents an extension of the Fenton process. By using a UV-VIS light source at wavelengths > 300 nm, it increases the production of HO[•] radicals by Fe³⁺ initiated photolysis of water that leads to a strong increase of the degradation rate of organic pollutants. In the last years, the photo-Fenton process has received a notable attention since it has proved to be an effective alternative to conventional treatment processes for the removal of the Contaminants of Emerging Concern (CECs). CECs are a group of chemicals that may be included in future environmental regulations depending on the results of the investigations on their effects on human health and the environment. Despite the great experimental effort and regardless to the available first principles (Ortiz de la Plata et al., 2010), empirical/heuristic (Pérez-Moya et al., 2008) and data analysis based (Shokry

et al., 2015) solutions, the model based support to develop photo-enhanced Fenton process for the effective decomposition of CECs is still facing the major challenge of finding an approximately unified, causally established coupling between the general photo-Fenton system and the decontamination of the arbitrarily chosen, and quite different organic compounds.

Direct Computer Mapping (DCM; Csukas et al., 2013) based Programmable Structures (Varga and Csukas, 2017a, 2017b; Varga et al., 2017) was applied for modelling and simulation based analysis of the experimental system. The non-conventional computational methodology allows the easy generation of various model structures from the description of a network and from two general functional meta-prototypes. The main feature of this technique consists of building the process model from unified, state (describing the actual state of the process) and transitions (describing the actual transformations, transportations and rules) building elements, executing the local programs, described by the respective prototype elements.

In the present work, DCM is coupled with a design of experiments technique, based on the selection of paracetamol ($C_8H_9NO_2$) as model pollutant. Paracetamol was selected because it is one of the most widely used antipyretics and analgesics. The aim was to propose a novel modelling approach of medium complexity that can be able to find a causally interpretable and generalizable solution for the possible single and multiple targets.

2. Experimental: Design of Experiments

Fenton and photo-Fenton assays (dark and irradiated conditions, respectively) were performed in batch mode with recirculation (recycling flow rate = 12 L min^{-1}), under optimal pH (2.8) and at a temperature of $25 \text{ }^\circ\text{C} \pm 2^\circ\text{C}$. The 15-L pilot plant consists of a 9-L glass reservoir tank and a 6-L glass annular photo-reactor with an irradiated volume of 1.5 L. The latter is equipped with an Actinic BL TL-DK 36 W/10 ISL lamp (UVA-UVB).

The performed experimental design was obtained by changing the initial concentration of H_2O_2 ($C_{H_2O_2}^0$) between half and two times (94.5 and 378 mg L^{-1} respectively) the stoichiometric dose (189 mg L^{-1}) to achieve total mineralization. The initial concentrations of Fe^{2+} ($C_{Fe^{2+}}^0$) were 5, 7.5 and 10 mg L^{-1} , being the latter the maximum legal value in wastewaters in Spain. The initial value of PCT concentration (C_{PCT}^0) was the same (40 mg L^{-1}) in each case, because, although higher than that found in wastewaters and surface waters, it allowed simplifying the monitoring of the contaminant and Total Organic Carbon (TOC) concentrations along the treatment span. Measurements of PCT, TOC, H_2O_2 , and iron species (Fe^{2+} , Fe^{3+} , Fe^{10T}) concentrations were performed using a HPLC Agilent 1200 series with UV-DAD, a Shimadzu VCHS/CSN TOC analyser and a Hitachi U-2001 UV-VIS spectrophotometer, respectively. Especially, PCT measurement method is the one described by Yamal-Turbay et al. (2012). For H_2O_2 and iron species measurement, the spectrophotometric technique described by Nogueira et al. (2005) and the 1, 10-phenanthroline method following ISO 6332:1998 were adopted, respectively. Also, a set of blind experiments (disregarding one or more components from amongst PCT, Fe^{2+} , H_2O_2 and light, alternatively) were also performed to filter the experimental errors, as well as for the better understanding of production and elimination of free radicals in the core model.

3. Modelling and Simulation: Programmable Structures

The Programmable Structure of the process model was generated from the transition based declaration of the (optionally four compartments) process network and from one state and one transition defining meta-prototypes, automatically. The locally executable actual program prototypes, extended by the case specific declarative (Prolog) programs were prepared in the editable GraphML format, as the extension of the automatically generated structure. Having declared the parameters and initial values of actual state and transition elements, the dynamic databases of the declarative model were generated and executed by the general purpose kernel program. Considering the experimental setup, a four compartments loop model was generated, supporting the future scaling up. To avoid the infeasible fast startup, we initialized the model by a perfectly mixed condition, except for H₂O₂ that was added during a period of 5 s, mixed with the recycling.

In the first modeling and simulation trials we started from the elementary kinetic model, suggested by Conte et al. (2012) for the degradation of 2,4-dichlorophenoxyacetic acid (2,4-D). Especially, the 2,4-D specific equations were removed and the remaining 10 Fenton/photo-Fenton related reactions were tested with the knowledge of the set of kinetic parameters collected by Namgoo et al. (2002). This set of elementary transitions was extended by the model reaction of photochemical HO[•] radical production, based on Cabrera Reina et al. (2012), as well as by the consideration of the H₂O dissociation at the controlled pH = 2.8. This initial model seemed to be extremely stiff, as well as very sensitive to the applied kinetic parameters. In addition, a rough estimation of some missing and infeasible parameters was needed.

Turning to the decomposition of the target compound, a detailed qualitative knowledge of the PCT decomposition pathways is available (Villota et al., 2017). However, the comprehensive identification of the respective kinetic model would need enormous efforts with uncertain success. Conversely, the key issue was to find a causally interpretable, but generalizable solution of medium complexity, considering the possible set of single and multiple targets. Accordingly, a simplified first principles model (FPM) has been developed, consisting of three parts, as follows:

1) Simplified free radical production was described by i) oxidization of Fe²⁺ by H₂O₂, generating Fe³⁺ and HO[•], ii) reduction of Fe³⁺ by H₂O₂, resulting in Fe²⁺ and HO₂[•], iii) in case of the additional photo-catalytic process, the reaction of Fe³⁺ with H₂O, producing Fe²⁺ and HO[•] free radicals and H⁺ ion, as well as iv) H₂O dissociation equilibrium, according to the controlled pH (2.8).

2) For the approximate description of the degradation kinetics of target molecule, the hypothesis of a consecutive breakage of the target into fragments and of the produced fragments into smaller fragments, was done. We assumed the approximately identical, halved carbon content of fragments, implemented in the series of kinetic equations with a temperature dependent, target specific parameter k (approximately the same for each steps), as follows:

$$M_i + R \rightarrow 2M_{i+1} \quad \frac{dc_i}{dt} = k \cdot (2 \cdot c_{i-1} \cdot c_R - c_i \cdot c_R) \quad i = 1, 2, \dots, N; \quad c_0 \equiv 0$$

where $i=1$ refers to the targeted compound (M_1) with a non-zero initial concentration of c_1^0 . N refers to the number of consecutive breakage steps that can be estimated from the number of carbon atoms in the molecule to be decomposed (i.e. $N=4$). The possible

reactants R are the pool of the free radicals (mainly $R = \text{HO}^\bullet$ as well as optionally HO_2^\bullet), and H_2O_2 itself.

3) Finally, the third part of the model consists of a simplified elimination scheme of free radicals, producing directly H_2O and O_2 , which competes with the useful consumption of the free radicals.

4. Results and discussion

The behavior of Fenton and photo-Fenton system can be analyzed taking into account the PCT and TOC conversion values that can be obtained for the various studied experimental conditions.

The paracetamol total remediation was achieved under all investigated conditions within a maximum time of 900 s and a minimum time of 150 s. Particularly, by doubling the value of $C_{\text{Fe}^{2+}}^0$, a 67% and a 75% increase of the process performance, in terms of PCT total remediation time, was achieved in case of dark and irradiated conditions, respectively.

Regarding TOC conversion (e.g. the mineralization level), the use of radiation improved the TOC conversion of about 34% and 77% when the lowest and the highest values of $C_{\text{H}_2\text{O}_2}^0$ and $C_{\text{Fe}^{2+}}^0$ were set, respectively. Finally, a 19% and a 33% enhancement of the TOC conversion was obtained by increasing $C_{\text{Fe}^{2+}}^0$ from 5 to 7.5 and from 5 to 10 mg L^{-1} , respectively.

Blank experiments without PCT helped to check the simplified free radical production and elimination model. Blank experiments with PCT, but without Fe^{2+} showed a decrease of H_2O_2 with no TOC decrease, which suggested a H_2O_2 initiated first breakage of PCT. This is in accordance with the very fast decrease of H_2O_2 in all experiments.

In the case of PCT, radical HO^\bullet proved to be the major decomposing agent. The decontamination was modelled by three breakage steps, in line with the number of carbon atoms (i.e. 8). Considering the fast initial decomposition of H_2O_2 , as well as the results of the blank experiments (with PCT and without Fe^{2+}) we assumed also a possible slower direct reaction of PCT with H_2O_2 producing C_4 fragments.

Some of the experimental values are compared with the results of the simulations in Figure 1. a), b), and c) for TOC, PCT and H_2O_2 respectively. This figure illustrates the cases of the worst (lowest initial concentrations of the catalyst and the oxidant, under dark conditions) and the best (highest initial concentrations of the catalyst and the oxidant, under irradiated conditions) performance. Particularly, in the worst case, a mineralization level of 30% was attained and PCT total remediation was obtained after 900 s. Conversely, the best performance was characterized by a 70% of TOC conversion and by a total PCT remediation after 150 s. Concerning H_2O_2 , the total consumption of the oxidant was observed for the irradiated case, while a decreasing small concentration was shown under dark conditions.

The model, developed from a representative part of experiments, predicted the results of the remaining set of experiments (including the "worst" and "best" performing extreme cases). As an error measure, we calculated Normalized Root Mean Square Error values as follows:

$$NRMSE = \frac{\sqrt{\frac{\sum_{i=1}^n (X_i^{measured} - X_i^{simulated})^2}{n}}}{\max(X^{measured}) - \min(X^{measured})}$$

NRSME for simulated data were 23% for PCT, 23% for TOC, and 27% for H₂O₂.

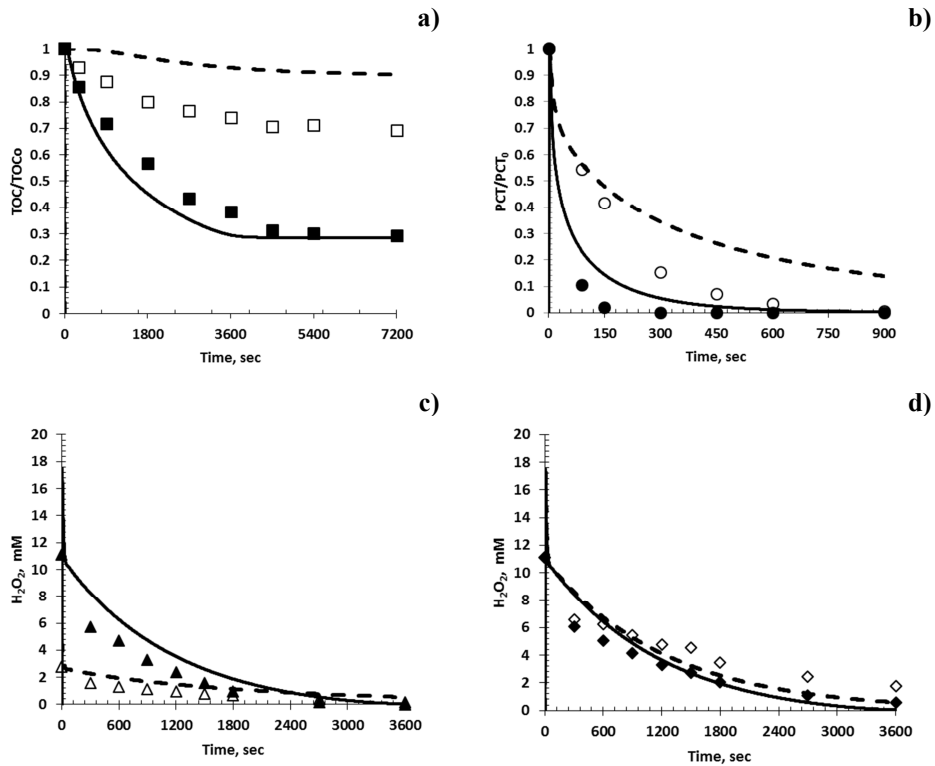

Figure 1. a), b) and c) show the experimental concentrations of TOC (\square), PCT (\circ), and H₂O₂ (Δ) versus predicted concentrations (--- , ---), in case of using $C_{PCT}^0=40 \text{ mg L}^{-1}$, $C_{Fe^{2+}}^0=5.00 \text{ mg L}^{-1}$ and $C_{H_2O_2}^0=94.50 \text{ mg L}^{-1}$ under dark conditions ($\square, \circ, \Delta, \text{---}$) and in case of using $C_{PCT}^0=40 \text{ mg L}^{-1}$, $C_{Fe^{2+}}^0=10.00 \text{ mg L}^{-1}$ and $C_{H_2O_2}^0=378.00 \text{ mg L}^{-1}$ under irradiated conditions ($\blacksquare, \bullet, \blacktriangle, \text{---}$). Fig. 1 d), shows the experimental (\diamond) versus predicted concentrations (--- , ---) of H₂O₂ for $C_{PCT}^0=0 \text{ mg L}^{-1}$, $C_{Fe^{2+}}^0=10.00 \text{ mg L}^{-1}$ and $C_{H_2O_2}^0=378.00 \text{ mg L}^{-1}$ under dark ($\diamond, \text{---}$) and irradiated conditions ($\blacklozenge, \text{---}$). TOC and PCT are normalized concentrations while H₂O₂ is a molar concentration (mM=mmol/L). In order to appreciate the different trends between the various investigated case studies, Figure 1. b) is plotted for the first 900 sec (maximum time at which the total removal of PCT occurs) while Figure 1. b) and c) are represented for the first 3600 sec (time at which the H₂O₂ is almost totally consumed).

5. Conclusions

First of all, it was concluded that it may be impossible to develop a detailed, but general first principles kinetic model, considering the possible reactions of the free radicals, as well as the alternative decomposition pathways for the various actual compounds to be decomposed. Also, the most detailed elementary reactions of the free radicals in the

photo-Fenton core may not be independent from actual targets. Consequently, they cannot be identified correctly, without the intimately coupled actual decomposition reactions. Another issue is that the kinetics of the detailed mechanism involving free radicals is stiff, and accordingly it is very sensitive for the individual parameters. To avoid "being penny wise and pound foolish", we tried to find a causally right, but simplified model of medium complexity, which makes the fast combination of the simplified photo-Fenton core with the simplified decomposition reactions of the actual target possible. The suggested simplified first principles model consists of three major parts i) a photo-enhanced Fenton core, ii) a simplified decomposition scheme of the organic target compounds (actually PCT) and iii) a simplified elimination scheme of free radicals. The photo-enhanced Fenton process produces more radicals, however it is accompanied by an increased H_2O_2 consumption. Considering the spontaneous elimination of the radicals, instead of a higher initial H_2O_2 concentration, the stepwise fed-batch supply of additional amounts seems to be an advantageous strategy to decrease the decontamination. Considering the applied novel methodology, Direct Computer Mapping based Programmable Structures showed the following advantages: i) it helped the easy generation and configuration of various model structures from the description of a network and from two functional meta-prototypes, ii) it supported the easy and local modification of the locally executable declarative programs associated with the state and transition prototypes, and iii) it allowed the switching on/off as well as the easy monitoring of the elementary processes through the transition based model representation. The application of the methodology is to be tried and refined for other target compounds in further work.

Abstract

In this paper, the objective was to develop surrogate models for a flotation process. A CFD model taking into account several complex phenomena involved in the flotation was first developed and simulated using COMSOL Multiphysics software. The approach of high dimension adaptive hierarchical polynomial interpolation was then used to develop simple surrogate models. The results show that the resulting models are accurate and fast to integrate compared to the original CFD ones. Their incorporation within an optimization algorithm to improve the flotation performances will be straightforward.

Keywords: Flotation processes, CFD simulation, Surrogate models, Hierarchical polynomial interpolation

1. Introduction

Flotation is a separation technique based on differences in the hydrophobicity of the surfaces of the particles to be separated. It is a kinetic process involving three phases, i.e. solid (fine particles), liquid (water) and gas (air). Its principle is based on the capture of particles (e.g. gangue minerals) suspended in a pulp to be treated, by means of floating collectors (air bubbles). If the particles brought into contact with the bubbles are captured by the latter, they rise to the surface of the flotation cell where these agglomerates are retained in foam which is then evacuated from the cell (Blazy, 1970). Flotation is considered to be the best available process for recovering fine ores. However, despite its widespread, especially in the recovery of phosphates, the flotation processes are still not well understood and the design and mastering of their operations still pose problems mainly due to the complexity of the phenomena involved. Understanding these phenomena is therefore of utmost importance in order to better model the processes and correctly predict the performances for their better optimization. In this work, a 3D transient CFD model was developed and solved under COMSOL Multiphysics modeling software. It takes into account several complex phenomena involved in the flotation process. However, taking into consideration all the mechanisms in the CFD model is computationally intensive. This makes the approach nonviable for repeated computational techniques such as iterative optimization algorithms or Monte Carlo sampling methods. Simple and accurate surrogate models are therefore necessary. The objective of this paper is to develop a flotation process surrogate model that relies on an efficient interpolation procedure that estimates the quantity of interest using a sampled data set. Each sample typically corresponds to an instance of the solution of the

CFD model. The approach of adaptive hierarchical polynomial interpolation will be particularly outlined.

2. Process model

Many research contributions have been recently devoted to CFD simulation of flotation processes with an emphasis on specific phenomena (Koh and Schwarz, 2008; Liu and Schwarz, 2009; Schwarz et al, 2016; Sarhan et al, 2017ab). The process model developed here is inspired from these contributions and involves three phases, i.e. liquid (continuous phase), particles (dispersed solid phase) and bubbles (dispersed gas phase). It is an Eulerian model that takes into account several complex phenomena involved in the flotation process. The governing equations consist of mass and momentum balance equations, turbulent kinetic energy and its dissipation rate. They have similar structure and are given as follows (for the lack of space, neither the $k - \varepsilon$ turbulence equations nor the initial and boundary conditions are presented):

- Mass balance equations:

$$\frac{\partial}{\partial t}(\rho_i \alpha_i) + \nabla(\rho_i \alpha_i U_i) = S_i \quad i = g, l, s \quad (1)$$

- Momentum balance equations:

$$\frac{\partial}{\partial t}(\rho_l \alpha_l U_l) + \nabla(\rho_l \alpha_l U_l U_l) = -\nabla p + \nabla \tau_l + \rho_l \alpha_l g + F_{lg} + F_{ls} \quad (2)$$

$$\frac{\partial}{\partial t}(\rho_g \alpha_g U_g) + \nabla(\rho_g \alpha_g U_g U_g) = -\nabla p + \nabla \tau_g + \rho_g \alpha_g g - F_{lg} \quad (3)$$

$$\frac{\partial}{\partial t}(\rho_s \alpha_s U_s) + \nabla(\rho_s \alpha_s U_s U_s) = -\nabla p + \nabla \tau_s + \rho_s \alpha_s g - F_{ls} \quad (4)$$

- The volume fractions should sum up to 1 as:

$$\alpha_l + \alpha_g + \alpha_s = 1 \quad (5)$$

where ρ_i , α_i , U_i , S_i and τ_i are density, volume fraction, velocity vector, mass source term (e.g. a source of air) and Reynolds stress tensor of phase i respectively. p is the pressure and g the specific gravity. F_{lg} and F_{ls} represent the interphase forces between liquid and gas phases, and liquid and solid phases respectively. All other forces including body, lift and virtual forces are neglected.

It is noteworthy that the resulting process model is quite complex and computationally intensive. Simple and accurate surrogate models will therefore be developed in §4. The next section will focus on the definition of the surrogate model problem.

3. Problem definition

One of the most relevant phenomena that influence the forces involved in equations (2-4), is the bubble-particle collision phenomenon. It is mainly controlled by the following mechanisms: (i) interception, (ii) inertia, (iii) gravitation, (iv) turbulence, and (v) Brownian diffusion.

The problem considered in this work dealt with the analysis of the bubble-particle collision phenomenon through the determination of the collision probabilities. More specifically, the influence of three parameters, i.e. bubble diameter, particle diameter and particle density, on the probabilities was investigated.

The model equations (1-5) were thus implemented and solved within COMSOL Multiphysics software (Rabhi et al, 2017). The computed collision probabilities were then compared to the literature results and showed that the model is quite accurate. The latter can therefore be used in optimization of the process performances. However, the computation time is so costly that the use of the model equations (1-5) within an optimization algorithm would not be an easy task and should be avoided. Simple and accurate alternatives are therefore needed. The next section is devoted to the development of surrogate models that will enable to compute the bubble-particle collision probability \mathbf{P}_c as a function of the aforementioned parameters, i.e. bubble diameter, \mathbf{d}_B , particle diameter, \mathbf{d}_p and particle density, ρ_p .

4. Development of surrogate models

The surrogate models developed are based on the approach of high dimension hierarchical polynomial interpolation (Chkifa et al 2014). We let $R = (r_j)_{j \geq 0}$ be a sequence of mutually distinct abscissas in $[-1, 1]$. We denote by $R_k := (r_0, \dots, r_{k-1})$ the subset of R formed by the first k abscissas of R and for a continuous function f in $\mathcal{C}([-1, 1])$, we denote $I_{k-1}[f]$ the polynomial of degree at most $k-1$ interpolating f at the k points $(r_0, f(r_0)), \dots, (r_{k-1}, f(r_{k-1}))$. We introduce the increment (or update) notation $\Delta_0[f] = I_0[f] \equiv f(r_0)$ and $\Delta_j[f] = I_j[f] - I_{j-1}[f]$ for $j \geq 1$. In view of the interpolation definition, $\Delta_j[f]$ is a polynomial of degree at most j , equal to 0 at r_0, \dots, r_{j-1} and equal to $f(r_j) - I_{j-1}[f](r_j)$ at r_j . Therefore, $\Delta_0[f] = f(r_0)h_0$ and $\Delta_j[f] = (f(r_j) - I_{j-1}[f](r_j)) h_j$ for $j \geq 1$ where $(h_j)_{j \geq 0}$ is the family of the so-called Newton polynomials defined here over $[-1, 1]$ by $h_0 \equiv 1$ and for $j \geq 1$ by

$$h_j(t) = \frac{\omega_j(t)}{\omega_j(r_j)}, \quad \omega_k(t) := (t - r_0) \dots (t - r_{j-1}) \quad (6)$$

The polynomials $I_k[f]$ can thus be computed using the hierarchical procedure

$$I_k[f] = \sum_{j=0}^k \Delta_j[f] = \sum_{j=0}^k c_j h_j \quad (7)$$

where the coefficients c_j are computed according to the recursion $c_0(f) := f(r_0)$ and

$$c_j(f) := f(r_j) - \sum_{i=0}^{j-1} c_i h_i(r_j) \quad (8)$$

This hierarchical procedure can be generalized to high dimensions using a technical tensor construction. We let $d \geq 1$ be an integer, $U := [-1, 1]^d$ the hypercube in dimension d and denote by $\mathcal{C}(U)$ the space of scalar valued d -variate continuous functions over U . We again let $R = (r_j)_{j \geq 0}$ be a sequence of mutually distinct abscissas in $[-1, 1]$. The goal is to build approximations to $f \in \mathcal{C}(U)$ using the interpolation of f at well-chosen nodes picked in the predefined grid $R^d \subset U$. The hierarchical feature of the scheme entails a certain structure on the nodes which we shall make clear. We let \mathbb{N}^d the set of multi-indices in dimension d . For $n := (n_1, \dots, n_d) \in \mathbb{N}^d$, we denote by y^n the d -variate monomial, i.e.

$$y^n := y_1^{n_1} \cdot y_2^{n_2} \cdot \dots \cdot y_d^{n_d} \quad (9)$$

and introduce the tensor product operator notation Δ_n by

$$\Delta_n := \Delta_{n_1} \otimes \dots \otimes \Delta_{n_d} \quad (10)$$

The definition of Δ_n uses standard of tensorization, see (Chkifa et al 2014). In other words, for a continuous function $f \in \mathcal{C}(U)$ we use the recursion

$$\Delta_n[f] = \Delta_{n_1} [t \rightarrow \Delta_{(n_2, \dots, n_d)}[f(t, \dots, \cdot)]] \quad (11)$$

We note however that we will not rely on (11). We recall that for $k \in \mathbb{N}$, $\Delta_k[\cdot]$ belongs to \mathbb{P}_k the space of univariate polynomials of degree at most k . We define over \mathbb{N}^d the order \leq by $m := (m_1, \dots, m_d) \leq n := (n_1, \dots, n_d)$ if and only if $m_1 \leq n_1, \dots, m_d \leq n_d$ and introduce for $n \in \mathbb{N}^d$ the rectangular block notation $\mathcal{B}_n := \{m \in \mathbb{N}^d : m \leq n\}$. Since every $\Delta_{n_j}[\cdot]$ belongs to \mathbb{P}_{n_j} , then $\Delta_n[f]$ belongs to $\mathbb{P}_{\mathcal{B}_n} := \text{span}\{y^m : m \in \mathcal{B}_n\}$ the space of d -variate polynomials of degree at most n_j in variable y_j for $j = 1, \dots, d$. For a set of multi-indices $\Lambda \subset \mathbb{N}^d$, we introduce the notation $\mathcal{J}_\Lambda[f]$ by

$$\mathcal{J}_\Lambda[f] = \sum_{n \in \Lambda} \Delta_n[f] \quad (12)$$

The d -variate polynomial $\mathcal{J}_\Lambda[f]$ is a sum of polynomials each belonging to $\mathbb{P}_{\mathcal{B}_n}$. We say that $\Lambda \subset \mathbb{N}^d$ is downward closed if and only if

$$n \in \Lambda \Rightarrow \mathcal{B}_n \subset \Lambda \quad (13)$$

This notion is central in the present framework. It implies in particular that if Λ is downward closed then $\mathcal{J}_\Lambda[f]$ belongs to

$$\mathbb{P}_\Lambda := \text{span}\{y^n : n \in \Lambda\} \quad (14)$$

In fact, in this case it is easy to verify, see (Chkifa et al 2014), that $\mathcal{J}_\Lambda[f]$ interpolates f at the node of the sparse high dimensional grid

$$\Gamma_\Lambda := \{r_n := (r_{n_1}, \dots, r_{n_d}) : n \in \Lambda\} \quad (15)$$

We observe that there exists a one-to-one correspondence between downward closed sets Λ , the polynomial spaces \mathbb{P}_Λ and the high dimensional grids Γ_Λ . In particular, the introduced scheme is hierarchical. Given $\Lambda \subset \mathbb{N}^d$ downward closed and $n \in \mathbb{N}^d$ such that $\Lambda' = \Lambda \cup \{n\}$ is also downward closed and having $\mathcal{J}_\Lambda[f]$ computed, we only need a single extra evaluation $f(r_n)$ to compute $\mathcal{J}_{\Lambda'}[f]$. The computation of $\mathcal{J}_{\Lambda'}[f]$ can be performed using a Newton like formula as in the one dimension setting. Indeed,

$$\mathcal{J}_{\Lambda'}[f] = \mathcal{J}_\Lambda[f] + \Delta_n[f] = \mathcal{J}_\Lambda[f] + (f(r_n) - \mathcal{J}_\Lambda[f](r_n)) h_n \quad (16)$$

where now $(h_n := \otimes_{j=1}^d h_{n_j})_{n \in \mathbb{N}^d}$ is the family of d -variate polynomials indexed in \mathbb{N}^d and obtained by tensor product from the family of univariate Newton polynomials $(h_k)_{k \in \mathbb{N}}$, i.e. $h_n(y) = h_{n_1}(y_1) \cdot h_{n_2}(y_2) \dots h_{n_d}(y_d)$. As mentioned earlier, we do not need to compute $\Delta_n[f]$ using the tensor product in (10) but we rely on this recursive formula. The hierarchical nature of the procedure can naturally be coupled with an adaptive strategy where the downward closed sets are enriched adaptively by adding one index n at a time according to a given criterion.

For example, we consider the following algorithm :

Algorithm: Adaptive hierarchical polynomial interpolation

Input: Integer $d \geq 1$, function $f \in \mathcal{C}(U)$ and a solver giving f for any query $y \in U$.

Parameter: N the total number of interpolation points, also the size of the set Λ .

Initialization: $i = 1, \Lambda := \{(0, \dots, 0)\}$ and $J_\Lambda[f] = c_0 \mathbf{1}$, with $c_0 = f(r_0, \dots, r_0)$.

Loop: while $i < N$:

- compute $\mathcal{N}(\Lambda) := \{n \notin \Lambda: \Lambda \cup \{n\} \text{ downward closed}\}$.
- for each $n \in \mathcal{N}(\Lambda)$, compute $f(r_n)$, $J_\Lambda[f](r_n)$ and $c_n := f(r_n) - J_\Lambda[f](r_n)$.
- find $n \in \mathcal{N}(\Lambda)$ with the largest update $\Delta_n[f] = c_n h_n$, in norm $|c_n| \sup_{y \in U} |h_n(y)|$.
- update $\Lambda \rightarrow \Lambda \cup \{n\}$ and $J_\Lambda[f] \rightarrow J_\Lambda[f] + c_n h_n$.
- update $i \rightarrow i + 1$.

Output: Downward closed set $\Lambda \subset \mathbb{N}^d$ of cardinality N and associated polynomial approximation $J_\Lambda[f] = \sum_{n \in \Lambda} c_n h_n$.

The stability and numerical behavior of this algorithm is studied in (Chkifa et al, 2014). The importance of the sequence R is in particular stressed. In our numerical experiment, we use the so-called \mathfrak{R} -Leja sequence (Chkifa et al, 2014) for which the stability was demonstrated.

5. Results and discussion

In the case study considered here, the parameters d_B , d_p and ρ_p vary in the intervals $[a_1 = 0.1, b_1 = 10]$ mm, $[a_2 = 40, b_2 = 125]$ μm and $[a_3 = 2000, b_3 = 10^4]$ kg/m³ respectively. They are then transformed into three variables y_1 , y_2 and y_3 defined in the unit interval $[-1, 1]$. The following affined function defined as: $\psi_{a,b}: x \mapsto \frac{a-b}{2}x + \frac{a+b}{2}$ allows to map linearly the unit interval $[-1, 1]$ to the intervals $[a_i, b_i]$, $i = 1, 2, 3$. The surrogate model for the prediction of the bubble-particle collision probability P_c is then defined over $[-1, 1]^3$ as:

$$P_c(y_1, y_2, y_3) = f(\psi_{a_1, b_1}(y_1), \psi_{a_2, b_2}(y_2), \psi_{a_3, b_3}(y_3)) \quad (17)$$

The algorithm described above was implemented using Python and allowed to compute the polynomials of the surrogate models. The main results are presented in figures 1 and 2. Figure 1 shows the variations of the collision probability P_c as a function of the bubble diameter for a fixed value of the particle diameter and for two different values of the particle density. Moreover, the figure compares the results obtained by CFD simulations (+ and \times) and by surrogate models computations (– – and – –).

It can be seen that as expected the probability decreases with the bubble diameter (Schwarz et al, 2016) and is lower when the particle density decreases for the same particle diameter. Furthermore, the resulting surrogate model predicts the computed CFD results with high accuracy which is exhibited in Figure 2 where the prediction absolute error, decreases with N the number of collocations points (also the dimension of the polynomial space where the surrogate is considered). Finally, we highlight one of the most important features of the surrogate models, i.e. their negligible CPU time compared to the CFD model computational load. For a fixed particle density ρ_p corresponding to phosphates particles, we could run a global optimization algorithm on the two decision parameters d_B and d_p . The evaluation of the probability of collision from the polynomial surrogate model permits to avoid the time consuming evaluations through CFD computations.

Figure 1 : Bubble-particle collision probability P_c vs bubble diameter d_b for $d_p=121\ \mu\text{m}$ and $N=650$.

Figure 2 : Prediction absolute error vs N , the size of Δ .

6. Conclusion

The method of high dimension adaptive hierarchical polynomial interpolation developed in this work has proven to be a powerful approach in surrogate models building for complex processes and/or computationally intensive CFD models. The approach favors a sparsity based reconstruction which is particularly emphasized since this explains the sparsity of effects observed for the mechanisms pertaining the bubble-particle collision phenomenon. The results obtained are very interesting and encouraging; they show that the surrogate models developed are very accurate with negligible CPU time. Further works will focus on the use of the resulting surrogate models in optimal design and operation of the whole flotation process.

From Process Graph to Process Simulation with Proper Model Documentation

Arne Tobias Elve^{a,*} and Heinz A Preisig^a

^a*Norwegian University of Science and Technology, Department of Chemical Engineering, Trondheim, Norway*
arne.t.elve@ntnu.no

Abstract

This paper presents a new modelling framework called the *Process Modeller Suite*, which combines ontologies and graph-based modelling to do automatic code generation for models. The process models are represented by a process graph where the graph components capture system knowledge in the ontology in a systematic manner. The result is a software tool that promotes correct model formulation, interoperability between different modelling environment and reusability of the models and also generates a proper model documentation.

Keywords: Model Documentation, Graph-based Modelling, Automatic Code Generation, Customised Modelling

1. Background

Generating process models is a key activity When maintaining a process model, complete and up-to-date documentation is needed. This model documentation must outline the model structures, attributes, assumptions and constraints. Furthermore, up-to-date documentation for the process model is crucial for the maintenance, further development, system quality and communication with domain experts (Shafiee et al., 2017). Our objective is to construct a generic modelling framework that produces executable model code for essentially any targeted language with the models being synthesised from the ontology (Preisig and Elve, 2016) and also provide proper model documentation.

The modelling framework builds on the principles of a generic approach to modelling, with the objectives of generating consistent models (Preisig, 2010), produce complete models, using a canonical representation and include parser and compiler for the output language. We meet these objectives by synthesising knowledge captured in the ontology into modelling objects that are consecutively generated in a graph-based modelling environment. The modelling objects distribute the knowledge, captured by the ontology, over to the model by constituting the nodes and arcs in the directed graph. This graph captures the structure of the model and represents the topology. The nodes of the directed graph represent the capacitive elements, and the arcs, the communication elements. The model knowledge from the ontology in combination with the topology represented by the directed graph is used to generate executable Python-code automatically.

This approach to modelling is inspired by (Fedorova et al., 2015) and MOSAICmodeling (Kraus et al., 2014) which use templates for model generation. However, we separate from the template approach since we use an ontology to build our modelling objects. Hence we are conceptually closer to (Brandt et al., 2008), (Koo et al., 2017) and (Heitzig et al., 2014) since we use knowledge based systems for the generation models.

2. The Modelling Framework

We are developing a new modelling framework called the *ProcessModellerSuite* implementing modelling language, described in (Elve and Preisig, 2017), to a graph-based modelling environment. An illustration of the different components in the ProcessModellerSuite is provided in fig. 1.

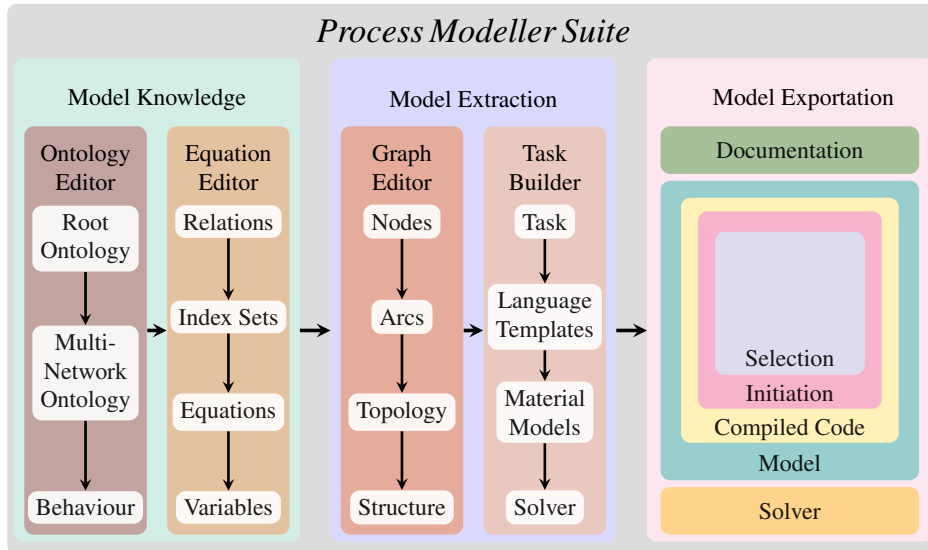

Figure 1: Illustration of the workflow for generating models. The user provides input to the different boxes which combined generate the model with full model documentation. The white boxes inside editors indicate what parts of the model are provided into the editors.

The framework is divided into three segments, following a sequential model implementation. In the first segment, we generate the model knowledge capturing what the model represents and the mathematical representation. The first editor constructs the ontology, which is the foundation for the rest of the modelling. We define an ontology to be the naming and definition of “things”, properties and relations that exist for a particular domain. The ontology captures all the model knowledge and provides the vocabulary that is used later when formulating the process models explaining the behaviour of these things. We start off by defining a root ontology describing basic terms and opening for definition into the graph-based modelling environment by defining the basic model components for a graph being nodes and arcs. The root ontology is then successively refined by adding properties specific to modelling domains, determining the behaviour of the produced model. In the equation editor, we define the relations for these “things” we are modelling. The relations describe how “things” are related, and adds the context to the graph by specific index sets adding the relations to specific sets model components in the graph. The equations capture the relations and are stored into variables, which are integrated as the mathematical description of the behaviour in the ontology.

In the next segment, we extract information based on the generated model knowledge and merge the knowledge to form a model. The central design tool in this software is the graph editor, which allows for a hierarchical representation of the model in the form of a topology. The topology has two components, the nodes representing capacities, and the arcs representing interactions that characterise these capacities, collectively the nodes and the arcs represent the structure of the model. Having the fundamental structure, we start preparing for the output generation. This

preparation happens in the task builder where the application is selected, and solver and solver properties are provided and linked up to any material models. The model is written out in the correct calculation sequence to the desired output format using specific language templates that translates the equations from the equation editor to the output language.

Based on the user input from the different editor, the software will produce a process model with attached documentation and solver. The model consists of an interface where the modeller can do selections of equations to be a part of the model, an initiation procedure for the state and constants variables and compiled model code, written out in executable form in the output language. The model is wrapped the specific task selected for the model. The model documentation is written out to pdf-file, containing all the important information for the model.

2.1. Equations

Equations are the relations of the ontology, and a set of equations describe how things are related. An equation is a recipe describing how to calculate a variable based on other variables and operators. Other equations can again describe these variables and so on. Together this forms a tree of altering equations and variables. Our model formulation is state-based with the state describing how “things” from the ontology behaves. In the equation tree, the state of the system is at the top, and the latent variables are below. Figure 2 illustrates an example of a small equation tree, where the yellow rectangles are equations and the circles are variables. A is the state variable, which is transmitted down the equation tree. Based on other constants defined in the leaves (B, C), the time (t) and the initial state value (A^o) we integrate a new state value at next time step and so on. D is the variable holding an equation used in the integration. This equation tree is automatically assembled and used by the framework to determine what equations from the ontology will be a part of the final model. By assembling the equation tree and checking for closure, the framework guarantee that the model can be computed.

Figure 2: Illustration of equation tree.

3. A process graph for a mixing tank

To help us explain the concepts we present a case study of the construction of a dynamic model for a mixing tank in the *Process Modeller Suite*. The physical outline of the modelled mixing tank is illustrated in fig. 3. The tank consists of a liquid phase and a gas phase open to the surroundings. A stirrer ensure that the liquid phase is properly mixed. The liquid phase has a stirrer, which means that we can assume lumped behaviour. There are two feeds into the tank and one outlet. One of the inlets is an acidic solution, and the other inlet is basic. All of the inflows and outflows have a valve with adjustable opening. The valves for the inlets will be set to a fixed position, while the valve for the outlet is used to control the liquid level in the tank. In this model, we do not consider any interactions between the liquid and the gas phase to be of importance. The presence of gas phase implies that we can assume constant pressure in the tank equal to the surrounding pressure, but we do not assume any mass transfer and such. We, therefore, do not have to include the gas phase in the model.

Figure 3: Illustration of the mixing tank.

Figure 4: Skeleton of the topology of the mixing tank.

We initiate the modelling by generating a skeleton representing the different parts and their interactions, as illustrated in fig. 4. The grey circles represent capacities, and the small black circles represent the valves that manipulate the flows. The bars represent interfaces between the physical system and the control system, where properties can be transacted between two networks. The solid black arrows are physical flows while the black dashed arrows represent the transaction of the properties between different networks. In this skeleton, we have only considered the liquid phase and the control to be a part of the model. The steel construction of the tank itself and the effects of the surround gas phase is considered to be constant throughout the simulations and are captured as constants into the model.

Having the skeleton of the topology, we can start assigning the different model components with properties from the ontology. First, we define that there are two different networks in the model, a control network and a liquid network. Hence we use two different layers of the ontology for the description of model components. In addition we have an interface between the two networks, which is a transaction network. For the inlets into the tank, we define them to have constant compositions and pressures, which means that we can assign them as reservoirs. We label the two inlets with “A” for acidic and “B” for basic. The flow between the inlets and the tank is defined to be unidirectional volumetric mass transfer. In the tank, we can assume uniform property distributions due to the stirrer, but we neglect the work the stirrer provide to the liquid. The composition of the tank will change throughout the simulation, so we select the state to be the amount of moles of the different components, and we label this node with “L”. For the control network, we measure the level within the tank. This measurement is compared to a set-point within the control system, and we calculate a control input that will steer the level in the tank closer to the set-point based on a feedback loop. The controller input is transacted back to the physical network and then used to update the valve position of the outflow from the tank. In the outlet, we assume constant pressure and denote the outlet with “D”. The full topology of the mixing tank is illustrated in fig. 5.

3.1. Species propagation and reaction network selection

Having constructed the process graph it is time to populate it. We have implemented the rule that chemical species can be injected into mass reservoirs. From the reservoirs, the species propagate throughout the graph. New a species can appear in a node if a chemical reaction is defined and all the reactants are present in the node. A species library with reaction networks is defined. For the example of the mixing tank, we start off by injecting water denoted by “w” and acid, denoted by “a”, into “A” and water and a base, “b”, into “B”. From the inlets, the species propagate into “L” which is a dynamic node. The *Process Modeller Suite* then suggests reaction networks relevant to the current species. If more than one alternative reaction network, the user has to select what networks that should be used in the current model. For the mixing tank, we select a reaction network with buffer effects in a set of new species, “c”, which then appears in “L” and propagates further. The propagation of the species is illustrated in fig. 6. Due to the unidirectional flow from the inlets, the species from the tank does not propagate back into the inlets. If we used modelled the flow as bi-directional flow, the species would also propagate back to the reservoirs. The process graph is generated and stored in a JSON-file.

Figure 5: Illustration of the topology of the mixing tank with networks.

Figure 6: Species propagation. The small circles are species that propagates through the process graph.

4. Generating the model

Having established the process graph, we can start selecting the application. In principle, the process graph can be implemented into any application. Presently we have implemented a dynamic simulator environment in Python, but we are planning to design other applications for optimisation and process design and adding more languages. For the simulation of the mixing tank, we select to use Runge-Kutta as integrator and let the simulation run for 100 seconds.

4.1. Manual equation selections and initialisation

The task builder knows based on the process graph what states need to be calculated. It then starts rendering an equation tree similar to the equation tree illustrated in fig. 2. Based on the assumptions made when constructing the process graph, the model factory can eliminate a lot of equation alternatives. For example in the case of our mixing tank, we only have uniform conditions in the tank. We can, therefore, eliminate all equations written for distributed conditions. In some cases, the user has to select what equations will have to be used. An example from our mixing tank is what kind of controller will be used to calculate the controller output:

$$u(t) = K_p e(t)$$

$$u(t) = K_p e(t) + K_i \int_{t_0}^t e(t) dt + K_d \frac{de(t)}{dt}$$

Both the alternatives calculate the same property with the same units. The difference is that the first equation is based on a P-controller, and the second equation is the control equation for a PID-controller. For the mixing tank example, it was sufficient to use a P-controller.

After the selection, the states and the constants need to be given initial conditions and values. For the mixing tank example, we need to set compositions of species and pressure in the inlets. For the flows into the tank, we need to set valve openings and the cross-sectional area for the pipes. For the tank, we have to give pressure, the amount of moles of each of the species and the geometry of the tank. For the control system we to give a set-point for the level. The outflow requires a cross-sectional area, and the outlet needs pressure. Also, we can select the variables we want to be logged into a log file. For the mixing tank, we want to log the pH in the outflow.

4.2. Model documentation

The generation of the model documentation follow a similar approach to the generation of the executable code as described in (Elve and Preisig, 2017), the difference is that now the output language is L^AT_EX which again is compiled to generate a PDF-file. All documentation produced by the *Process Modeller Suite* is initiated with a presentation of the ontology used for generating the model including the domains and the properties that are part of this ontology and a user-defined description of the ontology. In addition, does all documentation includes a description of the mathematical operators that are implemented in the targeted language. The specific model documentation for the dynamic model of the mixing tank is initiated with the topology of the model, similar to the topology presented in fig. 5. This includes a description of all the nodes and arcs summarising the properties selected from the ontology, list of the variables calculated for that node, and initial state values, and specific constants for that model component. We also include a description of the reactions that are part of the model, with properties, and the species propagation. For the variables, we use templates describing how the output format of that variable is in the output format. This template includes physical units and index sets describing where in the topology the variable is used. The equations are written out also using templates for the representation of the equation with the variables and operators in the output language and the equation tree describing the closure of the model. The simulator environment is also described by a description code of the simulator including the solver and the solver properties. The documentation for the mixing tank includes full description of 5 nodes, 5 arcs, 46 variables (with constants) and 13 equations.

4.3. Simulation results of the mixing tank

We initiated the mixing tank with three different initial conditions and ran three simulations. In the first simulation, we defined the initial composition of the tank to have pH = 10 and then closing the valve from the basic reservoir, meaning that we only have inflow from the acidic reservoir. For the second simulation we set the initial composition of the tank equivalent to a pH = 4 and then closed the valve from the acidic reservoir and opened the valve from the basic reservoir. Then only adding base to the tank. The last simulation we set the initial composition of the tank to have a pH of 4 and then add equal amounts of from both A and B. Figure 7 illustrates how the pH changes during the simulations for the three different cases.

Figure 7: Simulation results. The lines plots the pH in the tank over the simulation time.

5. Conclusions

Proper model documentation is essential for maintainance, reusability and further development of process models. We are currently developing a new modelling framework called the *Process Modeller Suite*, that aids the modeller securely through the modelling and then automatically generates code with proper model documentation. This automatic code and documentation generation is made possible by employing a structure modelling methodology based on ontologies, which defines the vocabulary for expressing the process models in the context of a process graph representing the topology of the model. This process graph expresses the distribution of the properties from the ontology, and from there it is quite easy to generate code and documentation automatically. The *Process Modeller Suite* was applied in a case study of the generation of a dynamic model of a mixing tank where we generated a process graph and then wrapped the graph into a simulation environment. The generated code was well documented and produced a dynamic simulation, automatically.

Graph-Based Modelling with Distributed Systems

Heinz A Preisig^a and Arne Tobias Elve^a

^a*Norwegian University of Science and Technology, Dept of Chem Eng, 7491 Trondheim, Norway*
Heinz.Preisig@chemeng.ntnu.no

Abstract

The importance of explicitly discussing the effects of assumptions when modelling is being put on the stage. Starting with a completely distributed system asking for simplifications puts the assumptions right in top of the table. Every assumption on transfer rates, capacity effects and what is considered and what not comes very visible with visual modelling starting with distributed systems.

Keywords: Ontology, computer-aided modelling, multi-scale modelling, modelling framework

1. Background

Visual modelling allows the person generating the model, we call this person "the modeller", to be creative, to experiment with the fundamental structures of physical systems containing chemical and biological systems, which together form what we call a "process". We use the term "model" for a mathematical description of a process. On the basis, we insist on a "mechanistic" description, a model based on the conservation principles of physics, thus a "white-box" model in contrast to an empirical or black box model. Though the latter is not quite that hard, as there are nearly always some black-box or grey-box components in a mechanistic description, which also most commonly can be seen as crude mechanistic models. This reflects the fact that one often lacks in parts a precise description and one has to compromise for semi-empirical descriptions.

Given the task to model a system, one has to go through a number of steps. 1) Break the process down into sub-processes. This is done recursively yielding the basic spacial domains, the primitive systems, for which one has a basic description. 2) The conservation principles applied to the primitive systems provide the mathematical behaviour of the dynamics. 3) The interactions between the different subsystems are to be identified next and for each a mathematical description must be provided in terms of the conserved quantities being transferred. 4) Chemical or biological species are introduced expanding the mass conservation into species mass balances, which incorporate production rates representing the conversion of materials. 5) The remainder is to "close" the equation set by adding material models and geometrical relations together as well as auxiliary relations and definitions. 6) Control is plugged in via measurements and manipulating transfers.

We have worked on this problem for some time with the objective to provide a modelling suite, that constructs complex models based on an ontology. As part of the suite, the equation/variable bipartite graph is constructed on the background of the ontology. Given an ontology, the "modeller" has no direct contact with the mathematical model. Instead, the model is designed using a graphical interface supporting the construction of a hierarchical directed graph representing the topology of the process and the control system. This *ModelComposer* uses a ontology-derived automaton imposing the structural construction rules and the objects defined in the equation/variable system. Compilation to code and splicing into software components is to be done automatically. Different target languages and solver environments are supported. Whilst one obviously cannot cover

all existing simulation environments, the software is structured to make it easy to implement and connect to a new one in a short time. The ontology-based approach eliminates equation/variable-based modelling errors. It also leads to a centralised code for the basic models. The remainder is a book-keeping problem, which is handled by the *ModelComposer* and the application factory.

On the project's history: whilst it started with flow sheeting activities, the first project work was done on life support systems (Makela et al., 1988; Preisig et al., 1989, 1990) which after several iterations yielded a commercial product aiming at a generic chemical engineering domain (Westerweele, 2003; Westerweele and Laurens, 2008). The concepts were extended since then considering time-scale assumptions (Preisig and Westerweele, 2003; Preisig, 2004, 2008) and multi-network representation (Preisig and Elve, 2016), which is strongly linked to a Framework 7 EC project (Karoliuss et al., 2016, 2017). The project was related to other similar projects in Preisig (2010).

The overall objective is to enable the modeller to interact with the software on a more conceptual level, namely on the level of defining the structure of the model, whilst another person can provide the description of the various involved mechanisms and models. Thus the separation is essential. The latter results in defining a set of ontologies that can be linked together, where the term "ontology" is here used as a representation of the structure of the knowledge associated with a particular subject domain augmented with a precise mathematical representation of the modelled phenomenon (Elve and Preisig, 2017; Preisig and Elve, 2016).

Whilst the earlier papers dealt mostly with lumped systems, here we extend to networks of distributed systems and add the multi-scale aspect by enabling the computation of material properties from lower-scale models, such as what is usually referred to as meso-scale or the molecular scale.

2. Multi-networks for multi-scale systems

2.1. Concepts forming the ontology

To reach the current level of constructing the ontology is the result of an evolutionary process. It leads to the construction of a program set that allows us to define a very minimal basic ontology, which captures all the structural elements on which the lower-triangular equation system is constructed. The ontology is also used to define the graphical elements for the graphics driven model composer as well as the automaton controlling its interface. Finally the ontology supplemented with the equations and variable supergraph, facilitates the basics for the compilation into an executable task/application.

The key elements in the ontology are **structure**, which acknowledges the view that all systems can be represented as a directed graph rather independent of their nature: *physical systems* are networks of capacities and connecting transfers for the extensive quantities mass, energy and momentum, whilst *control* has dynamic and static blocks with signals connecting them. Or in *economical systems* it is money that flows from account to account.

Graphs may be typified or more detailed by adding classifying attributes such as liquid, solid and gas. With the nodes representing the material/mass capacities and the arcs the transfers of extensive quantities. Since transfer can be due to different mechanisms, such as heat conduction, radiation or mechanical work, arcs are equipped with corresponding attributes.

Capacities may be of different nature, like distributed or lumped. Transfer between neighbouring capacities occurs through the common interface, for which equilibria and flux conditions apply.

An abstraction can be achieved by defining communicating networks, where the interfaces are special trans-network graph components representing behaviours of phase boundaries or measurements/manipulation. Tokens generalise what is present in the graph, in physical systems the conserved quantities, in control information. This allows the concept to be expanded in almost all scientific and associated domains.

In earlier publications we reported the compact representation of lumped systems (Preisig, 2010). The conservation principles then read $\underline{\Phi} = \underline{\mathbf{F}} \underline{\Phi}$. For distributed systems we start with the integral balance:

$$\int_V \frac{\partial \underline{\Phi}}{\partial t} dV = - \int_S \underline{\hat{\Phi}}^T \underline{\mathbf{n}} dS \quad \left\{ \begin{array}{l} \underline{\Phi} \text{ density extensive quantity} \\ \underline{\hat{\Phi}} \text{ flux extensive quantity} \\ S \text{ surface} \\ \underline{\mathbf{n}} \text{ normal direction} \end{array} \right.$$

$$= - \int_V \frac{\partial}{\partial \underline{\mathbf{r}}} \underline{\hat{\Phi}} dV \quad \text{Gauss theorem}$$

$$\underline{\Phi} = - \sum_i \int_{S_i} \underline{\hat{\Phi}}_i^T \underline{\mathbf{n}}_i dS_i := - \sum_i \hat{\Phi}_i$$

which for a network of distributed systems also takes the form $\underline{\Phi} = \underline{\mathbf{F}} \underline{\Phi}$. With the "internals" obviously being the the integral of the left-hand-side of the partial differential equation representing the behaviour of the respective distributed system. Namely $\int_V \frac{\partial}{\partial \underline{\mathbf{r}}} \underline{\hat{\Phi}} dV$. The flows between distributed systems will in general be of distributed nature – the flux is a function of the position on the surface. In some cases though, a one or two dimensional distributed system is appropriate for the description of the physical system. Flows that cross the systems boundary orthogonal to the distribution direction, are uniform over the surface.

2.2. An example: tubular heat exchanger

The example was used to demonstrate model reduction in the frequency domain (Ma, 1993; Ma and Preisig, 1994a). The hot and the cold flows are modelled as 1-D systems and so is the wall but in orthogonal direction. The hot fluid transfers heat to the wall, whilst the cold receives heat from the wall.

Figure 1: Topology heat exchanger

the isotropic linear heat transfer law : $\frac{\partial}{\partial \underline{\mathbf{r}}} \underline{\hat{\Phi}} := -k^q \frac{\partial T}{\partial \underline{\mathbf{r}}}$ which when substituted results in Fourier's heat diffusion equation.

The network equations then write:

$$\dot{H}_C = - \int_{V_C} \frac{\partial}{\partial \underline{\mathbf{r}}_C} \underline{\hat{\Phi}}_C dV_C = \hat{Q}_C + \hat{H}_{D|C} - \hat{H}_{C|E}$$

$$\dot{H}_H = - \int_{V_H} \frac{\partial}{\partial \underline{\mathbf{r}}_H} \underline{\hat{\Phi}}_H dV_H = -\hat{Q}_H + \hat{H}_{F|H} - \hat{H}_{H|G}$$

$$\dot{H}_W = - \int_{V_W} \frac{\partial}{\partial \underline{\mathbf{r}}_W} \underline{\hat{\Phi}}_W dV_W = \hat{Q}_H - \hat{Q}_C$$

Whilst the above network representation looks simple, the reader should be aware that the solu-

These heat flows are orthogonal to the fluid flow and thus the convective energy flow. For simplicity reasons, we assume constant mass flow and properties. The partial differential equations describing the fluids and the wall may be derived through the shell-balance mechanism. For the fluids the flow of enthalpy density $\hat{H} := \hat{m} c_p T$ which is to be normed by the volume to form the density. The term $\frac{\partial}{\partial \underline{\mathbf{r}}} \underline{\hat{\Phi}} := \hat{m} c_p V^{-1} \frac{\partial T}{\partial \underline{\mathbf{r}}}$ with \hat{m} the mass flow, c_p the specific heat capacity, thus the heat capacity per kg and K, V , the volume, T the temperature and $\underline{\mathbf{r}}$ the spatial coordinates. For the wall the simplest version is

The connections in the liquid streams are mass flows, whilst the ones to the wall are heat flows. One thus can split the network into two, namely a mass flow network and a heat flow network.

$$\underline{\dot{H}} = \underline{\mathbf{F}}^m \underline{\hat{H}} + \underline{\mathbf{F}}^q \underline{\hat{Q}}$$

tion of these three coupled partial differential equations is by no means trivial. They can be solved readily in the Laplace domain, given the assumptions (Ma, 1993), which can also be taken as the starting point for a model reduction, which is of particular interest for control applications (Ma and Preisig, 1994b; Preisig and Ma, 1995). In the time domain, this calls for numerical solutions, thus approximations are being made. With networks of control volumes being our core approach, we have a brief look on how such approximation institute themselves shown as topologies.

2.3. Approximations

The division into control volumes is in computational fluid dynamics referred to as gridding or meshing, which implies to superimpose a mesh of lines extending into intersecting surfaces thereby defining a block of non-overlapping control volumes. Whilst the gridding results in an exact representation of the space, the interactions are subject to approximations, as during the integration process one only gets information about each control volume as a whole, whilst for the transfer, the conditions at the common boundary should be known. The subject cannot be discussed in detail, but what comes out clearly in a topology representation is the question on how the interfaces are being defined. Gridding methods using block gridding for example require procedures to match the grids at the surface, either by design or by interpolations.

We give two simple approximations below and demonstrate that we can use the graphical representation to visualise different approximations.

Figure 2: Topology lumped heat exchanger

If one approximates the distributed behaviour by a series of lumped systems, thus "slices" the heat exchanger. One defines a network of lumps and connections. One thus can split the network again into two, namely a mass flow network and a heat flow network.

$$\begin{aligned}\dot{\mathbf{H}} &= \underline{\mathbf{F}}^m \hat{\mathbf{H}} + \underline{\mathbf{F}}^q \hat{\mathbf{q}} \\ &= \underline{\mathbf{F}}^m_i \hat{\mathbf{H}}_i + \underline{\mathbf{F}}^m_e \hat{\mathbf{H}}_e + \underline{\mathbf{F}}^q_i \hat{\mathbf{q}}_i\end{aligned}$$

where the index i indicates the internal flows, whilst the e labels the external flows. An alternative would be to eliminate all capacitive elements in the wall by adding a time-scale assumption, namely that the heat transfer in the wall is instantaneous compared to the rest of the plant's dynamics of interest (Preisig,

2004). This results in the well-known overall-heat transfer model for the heat transfer between the two fluid bodies. The approximation with two lumps in the wall is a very interesting one as it requires the same number of parameters as its simpler non-capacity model, namely the three transfer coefficients film, wall, film. In contrast though, it does not neglect the capacity effect of the wall and thus is definitely a much better choice.

2.4. Dynamic splitting

The typical process model can be split into two dynamic regions, a fast one for the momentum distribution, as the pressure wave moves at the speed of sound, and the mass / energy transport, which is order of magnitudes slower. This time-scale separation is applicable for most processes but certainly excluding the description of explosions, detonations or any other process, where "things" happen at speed of sound.

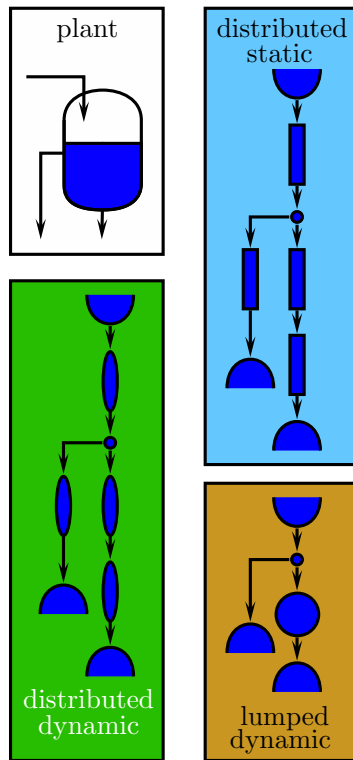

Figure 3: Topology lumped heat exchanger

A typical process that exhibits this behaviour is a tank with inlets and outlets. We show a tank with one inlet on the top and one on the side and another one on the bottom. The first model we generate is a distributed one - the green box. The liquid is fed on the top from a reservoir through a pipe, which we do not model. If included it would be a one-dimensional-along-the-pipe distributed system. The fluid above the side outlet though is modelled as a distributed system and the one below the outlet as well. The two outlet pipes are modelled as one-dimensional-along-the-pipe distributed system. In order to compute the pressure distribution in the plant, which we require to compute the outlets' volumetric flows, a stationary assumption is made about all parts yielding the model in the blue box on the right upper corner.

For the mass transfer we require the volumetric flow in the pipes, thus the pressures at the point of the side outlet, the bottom of the tank and the two receiving reservoirs. The representation of the fluid in the tank is also simplified. It is assumed to be ideally mixed and that the fluid body above the location of the side outlet is negligibly small which for an overflow is the most common assumption made even though that fluid level is a direct function of the outflow rate as constituted by what is often referred to as the weir equation.

3. Mechanics

Considering the mechanics of nature, modelling using distributed systems is the most natural approach, at least for macroscopic systems where the particular nature of matter is not of relevance. Since the world is not uniform, and process need to operate between two domains of systems that are not in equilibrium, distributed systems is the first thing to consider. Coupling occurs through the joint interfaces, the boundaries, which also are distributed. For the formulation of the model, one requires the description of the coupling between the adjacent distributed system, which in each point of the surface are equilibrium conditions with respect to the generalised forces, also called the effort variables, which are the conjugates to the potentials driving the flow of volume by pressure difference, mass through diffusion by a difference in the chemical potential, and conductive heat transfer through a temperature difference, to mention the most common transfers describing industrial processes. The second condition derives from the statement that the boundary has no capacity thus cannot accumulate extensive quantity. (Note - charge can be seen as an exception.) This implies that the flow of extensive quantity into the boundary must come out again, thus making the influx identical to the outflux.

Establishing the model based on distributed systems is thus rather straightforward. At this point one can start to implement a set of assumptions. Probably the first one is to assume that the pressure propagation is very fast, in comparison with the rest of the plant it is so fast, that it can be

assumed to be instantaneous thus of event dynamic nature. The second set of assumption may then be about mixing dynamics, thus time-scale separation between mixing and other dynamic effects, like reactions. The latter may or may not be a good assumption and mixing-controlled selectivity is not necessarily an exception (Bourne, 2003).

Many assumptions are implicitly applied by "modellers". One of the most common ones are heat transfer modelled by and "overall heat-transfer". They assume not only fast heat transfer in the complete assembly of the transfer system, which is of distributed nature but also as a consequence eliminates and thus ignores the capacity effects of the transfer system itself. The latter may be rather significant if one thinks of the construction of a vessel, for example.

4. Conclusions

Process modelling should start with distributed systems, and then assumptions should be applied. The model itself does not necessarily have to be established in algebraic form, but visual modelling offers a powerful tool to discuss and derive simple models from distributed and complicated ones. This makes it visible on where assumptions are made about the relative size of the capacities, relative transfer rates, relative time constants, distribution effects and neglecting parts of the system completely, besides the nature of the environment, which always drives the overall process.

Abstract

Chemical looping reforming (CLR) processes offer textbook examples for challenges in chemical engineering with respect to transport limitations. Phenomena that potentially need to be considered in a rigorous reactor model include (i) diffusion in solids and nanometer-scale pores, (ii) heat and mass transfer between suspended particles and the ambient gas, (iii) meso-scale phenomena such as clustering, as well as (iv) large-scale phenomena such as particle and gas-phase dispersion in the reactor's axial direction. Here we summarize key scientific advances made in the "NanoSim" project, which established a computational platform that enables modelling a large range of these phenomena. Specifically, we show that already at the particle scale significant uncertainties are introduced when modelling chemical reactors in very detail. This is due to the nature of gas-particle flow, i.e., the spontaneous formation of heterogeneities (i.e., so-called meso-scale structures) that impact flow, species transport and reactions. The key finding is that these heterogeneities must be accounted for in typical CLR applications to correctly predict reaction rates in an industrial-scale reactor.

Keywords: fluidized bed, computational fluid dynamics, multi-scale model, chemical looping reforming, process intensification

1. Introduction

1.1. Context of the Present Models with Chemical Looping Technology

Chemical looping (CL) technology often uses dual fluidized beds (FBs) to circulate oxygen-carrier (OC) particles. The OC particles provide oxygen for the (partial) combustion of a fuel. In CL reforming (CLR), the focus is on the production of syngas, e.g., via partial oxidation of methane on catalytically-active OC particles. Nanostructuring such OC particles offers a potential to greatly increase their reactivity, mainly by increasing the surface area. In our present contribution we focus on FB technology applied to CLR.

Understanding the flow and conversion of particles in FB reactors offers another potential, namely for the intensification of CL processes. However, considering all relevant phenomena in FBs typically requires a “zoo” of models and software tools. The present study employs a multi-scale modelling approach (see Figure 1, panel a) involving scales spanning from the atomistic to the reactor level. Our ultimate aim is to quantify the process intensification benefit when using nano-structured OC particles for syngas production.

1.2. Scope and Overview of Scales

As an example for an important chemical looping reforming reaction, the partial oxidation of CH_4 over an iron oxide is considered. Specifically, we will focus on equipment-scale simulations (i.e., level 2 in Figure 1) that account for all relevant phenomena on the scales below (i.e., scales 3 to 6). With respect to the latter, reaction rates for (i) a nano-structured, and (ii) a standard OC materials were determined via atomistic modelling. An intra-particle diffusion model is used to account for particle-scale diffusion resistances. On modeling level 2, a filtered Two Fluid Model-based approach (fTFM; see Section 2 for details) is used to model the reactor. The fTFM accounts for the effect of nano-sized grains by a larger reaction rate (see Eqns. 2 and 3, as well as accompanying text). In the context of an fTFM, filtering refers to the spatial averaging of results from more detailed flow simulations. In addition to classical transport mechanisms (i.e., convection and diffusion), fTFMs account for transport limitations imposed by meso-scale structures (i.e., fluctuations of the local particle concentration; see Figure 1, panel b, for an illustration).

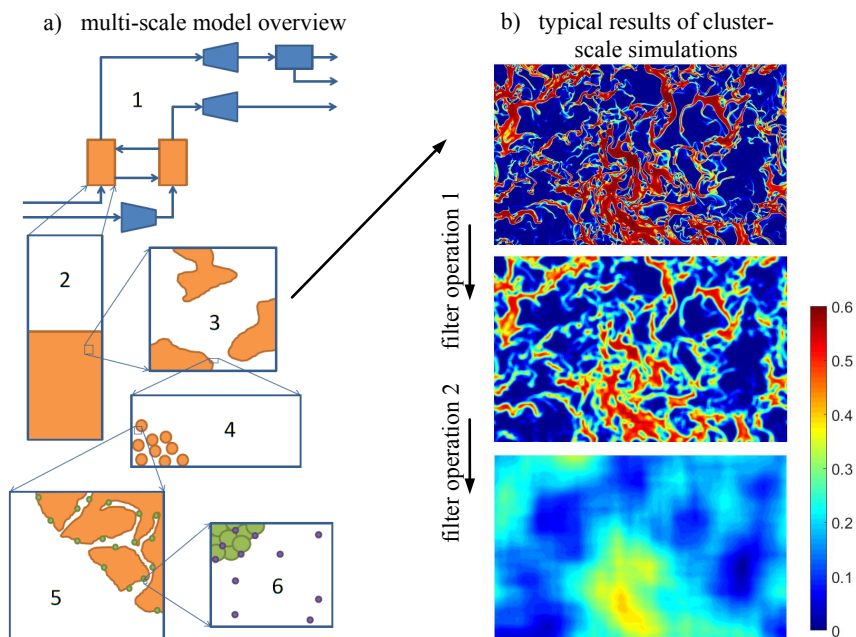

Figure 1. Overview of the multi-scale models (panel a; 1: system scale, 2: equipment scale, 3: cluster scale, 4: particle scale, 5: intra-particle pore scale, 6: atomistic scale), as well as a typical result of a cluster scale simulation (panel b; the colorbar illustrates the particle volume fraction).

2. Comprehensive Fluidized Bed Reactor Model

The reactor simulations were completed using the fTFM approach (Igci *et al.*, 2008) with closures derived from computationally expensive resolved simulations. These closures were developed by us, including verification and validation, during the past three years within the “NanoSim” project (<http://www.sintef.no/projectweb/nanosim>). The fTFM approach allows for the use of much larger computational cells than would normally be required. Therefore, this approach can be used to describe industrial-scale reactors with high accuracy and at moderate computational cost. The two most important fTFM closures were included in the present fTFM simulations: drag (similar to Igci *et al.*, 2008), and the effective reaction rate (Cloete, Cloete, Radl and Amini, 2017). The latter is expressed via the factor η_{meso} , see Section 2.2.

2.1. Case Description

Simulations were completed in a simple cylindrical geometry, 1 m in diameter and 5 m in height. The geometry was meshed with structured hexahedral elements using the cut-cell method. A mesh resolution of 6 cm (typical for industrial-scale CFD simulations) was used, leading to approximately 20,000 cells. A mass flow inlet was specified feeding pure methane at various flow rates. Partial slip wall boundary conditions were employed (Johnson and Jackson, 1987) with a specular coefficient of 0.1. A pressure outlet was used with a backflow solids volume fraction of 0.1 to ensure that the entire geometry contains particles (thus, the simulated geometry can be seen as a representative element of a larger system). The porous oxygen carrier particles were assumed to have a density of 4,000 kg/m³ and a particle size of 100 μ m. An operating pressure of 20 bar was selected with the gas density and viscosity/diffusivity determined via the ideal gas law and kinetic theory of gases, respectively. fTFM Simulations were carried out using ANSYS FLUENT (significantly extended by user-defined functions), with 2nd order spatial, and 1st order temporal discretization.

2.2. Reaction and Closure for the Reaction Rate

Partial oxidation of methane over an iron-based oxygen carrier was simulated in the present study. This CLR reaction can be described with:

Atomistic modelling (using the tool “REMARC”) was used to determine intrinsic reaction kinetics for this reaction for (i) a porous OC particle consisting of nano-size grains (10 nm in diameter), and (ii) a regular OC particle consisting of “standard” 1 μ m grains. The local (effective) reaction rate was modeled based on the local particle volume fraction α_s , the methane and iron oxide concentrations (i.e., C_{CH_4} , $C_{Fe_3O_4}$), the effectiveness factors η_{pore} and η_{meso} , as well as a temperature-dependent reaction rate constant k (E_A was fixed to 1.32 $\cdot 10^5$ J/mol):

$$R = \alpha_s k C_{CH_4} C_{Fe_3O_4} \eta_{pore} \eta_{meso} \quad (2)$$

$$k = A \exp\left[-E_A / (RT)\right] \quad (3)$$

In the above rate law, the pre-exponential factors for the nano-sized and standard grains are $A_{nano} = 1.17 \cdot 10^5$ cm³/mol/s and $A_{standard} = 2.23 \cdot 10^4$ cm³/mol/s. An intra-particle diffusion model (Yang, Cloete and Amini, 2016) is employed to consider intra-particle transport limitations, i.e., to calculate η_{pore} .

3. Key Results and Discussion

Simulations were carried out using a range of gas feed rates (i.e., 0.2-3 kg/s) for both OC materials. Simulations were run for at least 60 s, while collecting the outlet methane flow rate (in order to calculate methane slip) and the overall solids holdup in the geometry (to calculate the mass of OC in the system). These measures were averaged over the last 30 s of simulation time (i.e., after reaching a steady-state). For the ease of comparison, the reactor temperature and the Fe_3O_4 mass fraction were fixed at 900 °C and 0.15, respectively. Key results are shown in Figure 2, as well as Figure 3.

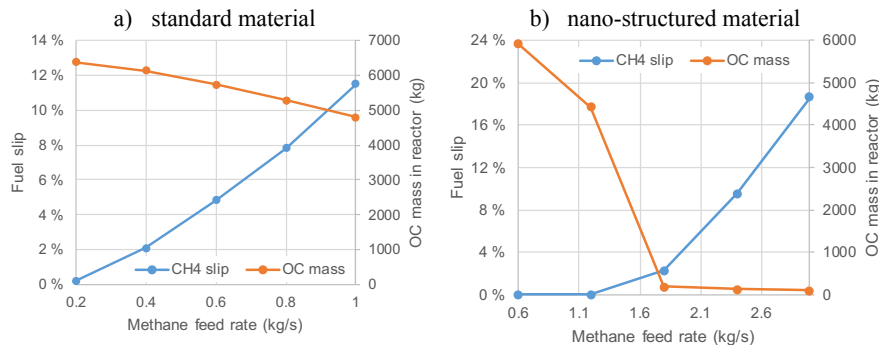

Figure 2: Reactor performance with the standard (panel a) and nano-structured (panel b) OCs (fuel slip is defined as one minus methane conversion, and illustrates reactor performance).

Clearly, the nano-structured oxygen carrier (10 nm grains) allows for much higher gas throughputs and lower oxygen carrier loadings than the standard (1 μm grains) oxygen carrier. From the results in Figure 2, it can be estimated that 99% methane conversion (i.e., 1% fuel slip) can be achieved with a flow rate of 0.3 kg/s and 6100 kg for the standard oxygen carrier. In contrast, the nano-structured oxygen carrier allowed for a flow rate of 1.4 kg/s (i.e., 4.7 times higher!) with only 2500 kg of OC required for the same methane conversion. It is also interesting to note that there is a sharp reduction of oxygen carrier loading for fuel flow rates of 1.8 kg/s and above. This is the result of the average solids loading becoming too low for dense solids clusters to form in the reactor. As a result, individual particles are easily swept upwards by the gas, whereas particle clusters forming at lower CH_4 feed rates (i.e., lower gas speed) can be retained in the reactor.

The superior performance of the nano-structured OC may be expected given that it has a 50 times faster intrinsic reaction rate constant than the standard OC. However, the increased reactivity is compensated to some degree by intra-particle and meso-scale transport limitations in the fluidized bed reactor: (i) intra-particle mass transfer limitations (expressed by η_{pore}) are often negligible for the small particles employed in typical FB applications. This is even the case for the highly reactive nano-structured OC particles (effectiveness factor 0.97). (ii) As shown in Figure 3 (panels iii) the mass transfer resistance imposed by the meso-scale phenomena (i.e., clustering) can be very large, resulting in effectiveness factors (defined as the ratio of the observed reaction rate to that without clustering) as low as 0.05. Clearly, not accounting for clustering on the reaction rate would lead to unrealistic predictions of the methane conversion rate, and ultimately an incorrect sizing of the reactor.

Despite the large meso-scale mass transfer limitations, the nano-structured oxygen carrier still enables a large degree of process intensification: In this case, a 5 m tall reactor achieving 99% methane conversion of a feed of 1000 MW_{th} methane would need to be 8.2 m in diameter with the standard OC, but only 3.8 m in diameter with the nano-structured OC (reactor volume reduction of -79%). The OC requirements for these two cases would be 407 tons and 36 tons (i.e., -91%), respectively, leading to respective pressure drops of 0.76 bar and 0.31 bar. Even though the nano-structured OC will be significantly more expensive to produce than the standard OC, these large process intensification benefits are likely to result in significant overall cost savings.

Figure 3: Snapshots of the instantaneous distribution of solids volume fraction (panels i, range 0-0.6), methane mole fraction (panels ii, range 0-0.2), as well as the meso-scale effectiveness factor (panels iii, range 0-1) for standard and nano-structured oxygen carrier particles (panel a and b, respectively); the colors indicate the range from low (blue) to high (red); 0.6 kg/s methane feed).

4. Conclusions

Our present contribution focused on a fully mechanistic description of an FB reactor as an alternative to simplified models often used on the system level (i.e., in the context of flow sheeting models). The presented hierarchy of models is especially interesting for the development of new processes (e.g., process intensification studies) and new materials. Furthermore, “virtual testing” of materials, as well as data generation to support simplified device models (e.g., 1D and compartment models, see (Morgado *et al.*, 2017)) is possible with the developed simulation platform.

The focus of our efforts was on establishing a new generation of closure models that account for both particle-scale (i.e., how fluid flow around individual particles affects

heat and mass transfer, see Municchi and Radl, 2017) and meso-scale phenomena (i.e., clustering and bubble formation in fluidized beds; see, e.g., Radl and Sundaresan, 2014). We have highlighted here one selected result, i.e., the importance of accounting for the meso-scale effectiveness factor when calculating effective reaction rates. The development of such meso-scale closures is of current interest, and was greatly accelerated by novel data filtering tools developed by us (Municchi, Goniva and Radl, 2016). While a rigorous experimental validation was not done in the present study, we speculate that these closures enable significantly more reliable simulations of reactive fluidized beds at industrial scale.

Finally, one should not forget about phenomena on other scales: (i) per-particle variations of drag, heat and transfer coefficients (Municchi and Radl, 2017), (ii) intra-particle (i.e., pore scale) transport, or (iii) diffusion through the metal (oxide) product layer on a sub-pore scale may play a decisive role in other types of reactors. The open-source multi-physics simulator “COSI” developed by us integrates the tools ParScale, CFDEM® (Hager *et al.*, 2014), and LIGGGHTS® (for download see <https://github.com/CFDEMproject>). COSI enables direct simulation of the above mentioned phenomena for small systems made up by $O(10^5)$ individual particles.

Abstract

The carbon capture technology is the new concept for cleaner energy production in the Czech Republic. In order to comply with sustainability requirements, this paper summarizes the analysis of carbonate loop technology (CaO looping) from environmental aspect by the Life Cycle Assessment (LCA) method by two main methodologies CML and ReCiPe. Two general scenarios were considered for evaluation – 250MWe Czech power unit based on brown coal combustion without (Scenario 1) and with carbonate loop (Scenario 2). Scenario 2 is further divided in three sub-scenarios with different source of energy for carbonate loop operation. LCA study was performed in different evaluation stages of characterization level, normalization level and pareto analyses of identifying the most significant environmental categories. Results are showing the significant reduction in scenario 2 in environmental categories of acidification, ozone formation and global warming potential. On the other hand, scenario 1 results in better values for abiotic depletion levels. Sub-scenarios of scenario 2 are showing, that the most optimistic is scenario 2.3 manifesting utilization of steam from carbonation process as the energy source. The most pessimistic is scenario 2.1 focusing on combustion of brown coal and no further utilization of energy from carbonation process. Environmental impacts are connected with the processes of brown coal mining and processing and with the subsequent thermal energy production. Thus, suggested scenarios are focused on the elimination of the impacts connected with mentioned processes even though brown coal is the primary source of energy in the energy mix of the Czech Republic.

Keywords: Life Cycle Assessment, carbon dioxide capture, carbonate loop.

1. Introduction

Life Cycle Assessment (LCA) is a suitable tool to assess CCS technologies in order to achieve sustainable goals in socio-economic and environmental pillars (Carvalho et al., 2014). LCA studies require understanding material and energetic inputs and outputs in order to create comprehensive model. LCA results are essential to point out the bottleneck of the technologies in order to diminish and minimize environmental impacts. The majority of the LCA studies were already performed specifically for post-

combustion capture using monoethanolamine (MEA) as a sorbent. Considering the other solvents, the CaO looping is one of the main research current focuses. Further research in CaO looping was made by Perejón et al. (2016). The main focus was on the possibility of integrating CaO looping in pre-combustion systems in order to reduce the energy demand. In the field of LCA and CaO looping, the comparative assessment of CaO looping and amine-based absorption was performed and discussed by Clarens et al. (2016). The study is confirming the assumption that the CaO looping is a viable alternative to amine based systems and it presents a 73% reduction in the climate change category. Based on the previous studies it is possible to confirm that LCA analyses for CO₂ capture technologies are in a rapid progress. CaO looping systems seem to be currently new area in the research of LCA and CO₂ capture technology. In this paper we will show, that it is necessary to analyze the final model by two considered LCA methods. The present paper aims to contribute with the following aspects:

- Two different LCA methods are applied in the study (CML and ReCiPe), leading to more robust conclusions and comparisons;
- Several different environmental impact categories are assessed, which provides a detailed assessment of the whole system.
- The LCA assessment will be performed in various scenarios at different LCA decision levels (characterization, normalization and identification of most contributing potential environmental impacts);

The recent studies, model development and its implementation were performed for the real case study of the brown coal power unit in the Czech Republic.

2. Methods

In order to build up and evaluate the LCA model of the case study, it is necessary to follow the methodological steps according to ISO 14044 (ISO, 2006), which specifies requirements for LCA. The LCA methodology consists of four steps, which include: 1) definition of the goal and scope of the LCA; 2) the life cycle inventory analysis (LCI); 3) the life cycle impact assessment (LCIA); 4) the life cycle interpretation and reporting. The goal of the study is to build a model to assess the environmental impact of capturing CO₂ by CaO looping process in a connection with an existent Czech power unit, of gross capacity 250 MWe, which is based on brown coal as source of energy. To define correctly the LCA model and to compare the results a functional unit, compatible for considered scenarios, should be defined. In this case, the functional unit is the nominal power output 250MWe, which is the same for all scenarios. Boundaries of the system considerate the power plant and carbonate loop chain from raw materials extraction through power generation to the final emissions treatment and CO₂ capture. Boundaries are excluding CO₂ transportation and final storage. Therefore, this approach is considered as “cradle to gate”. The phase of LCI involves the compilation and quantification of input and output flows for the system under the considered boundary (ISO, 2006). The aim of this step is to collect all the data required to develop LCA model. Data for the Czech power unit was collected from its annual operations’ report (Štefanica, et al., 2016). LCIA aims to understand and evaluate the magnitude and significance of the potential environmental impacts of a system. This phase is divided into 4 steps. The first two steps are classification and characterization, where impact potentials are calculated based on the LCI results. The next steps are normalization and pareto analyses. Normalization provides a basis for comparing different scenarios

according to regional (European) standardization of environmental impact categories. In order to define the most significant impact categories, pareto analyses was performed. The step of characterization and interpretation is based on evaluation of the computed environmental impacts and results. Results are characterized as potential environmental impact. Also, the final conclusions, limitations or recommendations are involved in the interpretation phase. According to ISO 14044 (ISO, 2006), normalization, in the context of LCA, is an optional step of Life Cycle Impact Assessment (LCIA) which allows to express results after the characterization step using a common reference impact. The normalization factors is showing the total impact occurring in a reference region for a certain impact category (e.g. climate change, eutrophication, etc.) in a reference year (Benini et al., 2014). The results of the normalized impact categories are further assessed by Pareto analyses in order to identify the most relevant impact categories. Pareto's rule, or the 80/20 rule, states that 20% of the all impact categories is causing 80 percent of environmental impacts (Carvalho et al., 2014).

3. Considered Scenarios

Two basic scenarios are considered for LCA evaluation. Scenario 1 represents the Czech power unit (PU) with the nominal power output 250MWe, in which the primary fuel is brown coal. This scenario represents the real power unit characterized by operational data (Štefanica, et al., 2016). Scenario 2 represents the modelled carbonate loop connected to the real power unit. Under scenario 2, three more sub-scenarios are considered:

Scenario 2.1 - Assessment of PU + CaO loop, where CaCO₃ is heated by combustion of lignite and thermal energy from the carbonation process is not used.

Scenario 2.2 - Assessment of PU+ CaO loop, where CaCO₃ is heated by combustion of natural gas and thermal energy from the carbonation process is not used.

Scenario 2.3 - Assessment of PU+ CaO loop, CaCO₃ heated by combustion of lignite + thermal energy from carbonation process is used in a steam form for CaO loop heating.

The high temperature carbonate loop is based on two crucial reactions of carbonation and calcination process. Carbonation process represents chemisorption of CO₂ on CaO, which is operating in the presence of high temperatures between 450-750 °C and is an exothermic reaction. Regeneration of the sorbent is performed by heating up on temperatures, which are exceeding the heat stability limit of actual carbonate (800-900 °C) where the thermic decomposition of produced carbonates is raised. The reaction is the calcination which is an endothermic reaction. Sulphates are not decomposed by these temperatures, thus it is necessary to separate them and substitute by a new sorbent. SO₂ is also reacting in a carbonation process with metal oxides and provides desulphurization of flue gases. The advantage of the carbonate looping is the high capacity sorption of CaO sorbent for CO₂. This process takes place usually in fluidized bed reactors, the carbonator and the calciner. The reactors are providing intensive circulation of materials and heat which contributes to high CO₂ capture from flue gases. Another advantage is the parallel desulphurization of flue gases. CaO looping system connected to the power unit is illustrated in the Figure 1.

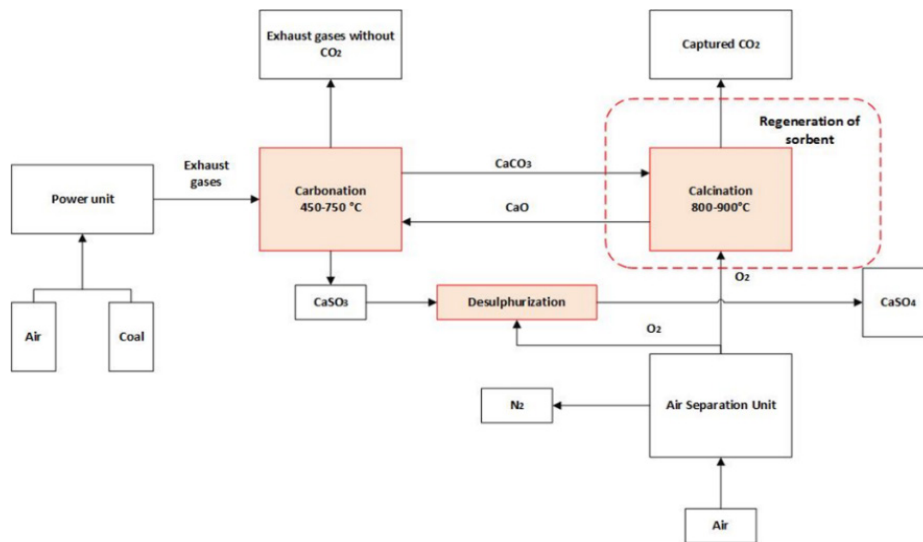

Figure 1 Scheme of CaO looping system with power unit connection

4. Results and discussion

The following table (Table 1) is summarizing normalized values for both methods ReCiPe and CML. The comparison of each scenario is showing for both methods the same result. However, values for both methods in the same scenario differs significantly (Table 1), because of different normalization coefficients for each LCA method. Scenario 1 has the highest contribution to the sum of environmental impacts, while scenario 2.3 is showing the lowest environmental impacts. Table 2 is providing a detailed look for comparison of scenario 1 and 2.3. The most significant is the depletion of climate change (CC) environmental category from $1.65\text{E}+05$ in scenario 1 to $1.94\text{E}+00$ in scenario 2.3. Moreover, another depletion occurs in categories such as fossils depletion (FD), terrestrial acidification (TA) and particulate matter formation (PMF). The depletion of TA is the consequence of utilization of carbonate loop as desulphurization unit. Moreover, TA potential depletion is caused by utilization of steam as the source of energy for CaO loop. Therefore, there is no need for additional combustion of brown coal or natural gas for heating. Particulate matter is the sum of all solid or liquid particles suspended in air and can cause several health issues. In a case of power unit, high concentration of SO_2 and CO_2 in the air increases PMF impact category. Pareto analyses shows that FD and CC contribute in 80% to the sum of all environmental impacts. Although, carbonate loop is assuming to capture 90% - 99% of CO_2 from exhaust gases, it still contributes to CC environmental impact due to combustion of lignite for thermal energy production in power unit but also for the carbonate loop operation. Another minor contribution is coming from CO_2 emissions, which were released to air through chimney. However, utilization of the energy is increasing, because of the carbonate loop operation energy requirements. Carbonate loop demands the energy for heating of fresh calcium carbonate from outdoor-air temperature to calcination temperature, which is 950°C . For 250 MWe nominal power, utilization of 240 t/h of brown coal is required in the current state of the Czech Republic

energy mix. If the primary source of energy for carbonate loop heating would be changed to natural gas (scenario 2.2), results will show slightly lower values (Table 1) in comparison with scenario 2.1. However, the best option would be to decrease FD by utilization of waste heat in the form of steam for carbonate loop heating (scenario 2.3). It would lead to the environmental credit for the whole system.

Table 1 Sum of environmental categories normalized values for CML and ReCiPe methods

Methods	Scenario 1	Scenario 2.1	Scenario 2.2	Scenario 2.3
CML	1.65E-06	9.59E-08	7.74E-08	6.09E-08
ReCiPe	7.34E+02	4.65E+01	3.73E+01	2.97E+01

Table 2 Normalized values for significant environmental category for Scenario 1 and Scenario 2.3

	Scenario 1	Scenario 2.3
FD	3.67E+04	2.32E+01
CC	1.65E+05	1.94E+00
TA	1.58E+04	1.20E+00
PMF	3.15E+03	1.06E+00
POF	1.29E+03	4.95E-01

5. Conclusions

Technology of CaO loop has potentially high importance in lowering the level of CO₂ in flue gases produced by brown coal combustion in the Czech Republic. LCA is a tool which provides environmental results and can lead to the further steps or scenarios towards the innovation. By LCA we could compare not only basic concepts of power unit with and without capture unit, but also different scenarios within carbonate loop implementation. The scenarios were mainly focused on the source of energy for the carbonate loop because it determines the main environmental problem in the frame of Czech energy mix. The results from the used LCA analyses based on two major methodologies ReCiPe and CML are showing significantly lower environmental harm in the scenarios with implemented carbonate loop. It is namely, depletion of climate change and terrestrial acidification. Carbonate loop technology contributes to depletion of CO₂ levels but also contributes as a desulphurization unit in depletion of SO₂ levels from flue gases. But in the whole life cycle of the power unit with carbonate loop, brown coal production and combustion creates the most significant problem. That is why the choice of the other energy source for CaO loop supply of heating, as is natural gas, could be the potential possibility for the environmental cost reduction. Another potential can be seen in the effective utilization of the steam from the waste heat which also could contribute to the overall environmental impacts reduction. The CaO loop technology is seen as a relatively cheap and environmentally very promising technology for the region of the Czech Republic. In the future, further analysis of the transportation infrastructure and final CO₂ storage from life cycle view has to be done. The complication is occurring with the pilot concepts of extensive infrastructure and potential storage sites which are currently investigated from geological and geomorphological conditions and their suitability in the Czech Republic.

Abstract

In a mean value thermodynamic model of an internal combustion engine, operational parameters such as volumetric efficiency have a significant effect on the thermal performance of the engine, for example the combustion process inside the cylinder depends on the air-fuel ratio, large amounts of air are introduced to the combustion chamber require and consequently more fuel it is needed, which traduces in a higher output engine torque and electrical power. The air-fuel flow in the admission line has an appreciable inertia due to the turbocharged operation, but the intake manifold, the admission valves and the throttle act as an obstruction for the air-natural gas. Considering everything considered before, this paper proposes a model for the volumetric efficiency on the 2 MW Jenbacher Gas Engine, which is the capacity of the engine to fill the available geometric volume of the engine with a new charge of the air-fuel mix. A thermodynamic model was introduced to study the ratio between the real volume of air drawn off the cylinder, concerning the theoretical geometric volume of the cylinder based on a typical day of operation of the thermal power plant. Finally, to show the impact of the volumetric efficiency on the model results, a regression as a function of the intake manifold temperature and pressure, the volumetric gas flow and the engine revolutions was proposed. This allows to estimate the engine volumetric efficiency with a quadratic accumulated error ranging from 5.65 (when the volumetric efficiency model depends only on the air-gas mixture pressure) to 1.94 (when the model was correlated as a function of the pressure and temperature of the inlet manifold, motor angular speed, and the volumetric natural gas flow). The study gives evidence about a successful simulation of a Natural Gas Engine thermodynamic model built in Matlab due to the similarity found between the simulated results and the experimental data obtained from the data acquisition software installed on the equipment, obtaining in most cases a good accuracy to predict the effective efficiency and the electric power under different operation conditions.

Keywords: computer-aided simulation, volumetric efficiency, thermodynamic model, gas engine.

1. Introduction

Energy Sustainability (ES) in power generation systems has become a priority issue in the international research agenda (Omer, 2008), due to its close relationship with climate change, the rational use of energy and the fast increasing energy demand (Lima et al., 2017, Morales-Acevedo, 2014). The operational efficiency of systems and processes is one of the main ways to promote energy sustainability and eventually reduce greenhouse gas emissions, highlighting thermal generation engines as an alternative solution of distributed generation (DG) outstanding to the crisis energy (Jain et al., 2017). DG is defined by the IEEE as generation of energy through facilities smaller than the central generation, when interconnection with the network is provided, and supplying power to other facilities (Ackermann and Andersson, 2001).

The generation of electric power from the Internal Combustion Engines (ICE) has played a leading role in DG, to obtain lower operating costs and energy consumption (Dunia and Qin, 1998). This objective implies an effort to obtain higher performance in the machine improving volumetric and effective efficiency. For these parameters there are mathematical models intended for different applications.

Ahmed et al. (2013, 2011, 2010) has worked on the subject. Those works showed that the parameters that allow studying the performance of an engine, which is difficult or impossible to measure, such as the volumetric efficiency, can be estimated using observers. Another approach for estimating volumetric efficiency is the use of linear regressions (De Nicolao et al., 1996), which through multiple linear combinations of different variables, obtains statistical expressions that describe the behavior of the variable.

The previous developed search shows the importance that has an operative parameter such as volumetric efficiency at time of diagnosis the performance of an internal combustion engine. Taking into account the aforementioned, the main objective of this paper is to offer a comparative study of the simulated results of some thermodynamic models for the volumetric efficiency of the 2 MW Jenbacher Gas Engine as function real operation condition for 31 days, which can be used for control and observation of the engine.

2. Methodology and Experimental Set Up

In order to identify and generate an easy and reliable expression for the volumetric efficiency, as first step was needed to study the engine performance during normal and abnormal operation, and also must be known in general the engine parts, type of fuel and the operational regime. Second, a thermodynamic analysis of the different variables that participates in the behaviour of the volumetric efficiency was developed and finally a statistical expression was proposed.

As for subsequent control and observation of the engine, it is important to rely on a precise model to describe it; it is possible to obtain tuned equations using the real-time sensors values. The studied J612 Jenbacher gas engine offers high levels of fuel consumption due to a combustion technology according to the world quality standards. The engine reaches 2004 kW of electrical output at 1,500 rpm, under a thermal efficiency (i.e., a fuel to power efficiency) of 42.9%. Figure 1a shows the industrial plant and Figure 1b the schematic diagram of the air admission system to the engine

including the turbocharger, which is used to obtain more power output with the same size of the engine. As seen before, it is important to estimate the volumetric efficiency. To obtain a reliable estimator for this variable, the mathematical equations that describe the dynamic behavior of admission air system are needed.

Figure 1. J612 Jenbacher gas engine a) Industrial plant, b) Schematic diagram.

The pressure (P_{int}) and temperature (T_{int}) in the intake manifold were considered constant due to engine control unit, allowing to calculate the inlet air mass to the cylinder (\dot{m}_{ap}) as Eq. (1).

$$\dot{m}_{ap} = \frac{\omega_e V_d \eta_v P_{int}}{120 R_{air} T_{int}}, \quad (1)$$

Where ω_e is the engine angular speed in rpm, V_d is the displacement volume in the cylinders (m^3), \dot{m}_{ap} is the air mass flow that enters the cylinders in kg/s , P_{int} is the intake manifold pressure in kPa, T_{int} is the intake manifold temperature in K, R_{air} is the ideal gas constant for air in $kPa m^3/kg K$, and η_v is the volumetric efficiency (dimensionless). In addition, the fuel mass flow is computed as function of the air mass flow as Eq. (2).

$$\lambda = \frac{1}{\alpha_s} \frac{\dot{m}_{ap}}{\dot{m}_f}, \quad (2)$$

Where λ is the air/fuel ratio, and α_s is the stoichiometric coefficient with a value of 17.2 for the natural gas. Finally, the volumetric gas flow measurement should be corrected with the gas density to obtain the mass flow under the Eq. (3).

$$\dot{m}_f = \frac{P_f V_f}{R_f T_f} \quad (3)$$

With (2) and (3), the volumetric efficiency can be calculated according to Eq. (4).

$$\eta_v = \frac{\lambda \alpha_s \dot{m}_f 120 R_{air} T_{int}}{\omega_e V_d P_{int}} \quad (4)$$

Finally, four linear regressions were proposed using the volumetric efficiency equation (Eq. (4)) and the real data operation condition for 31 days (T_{int} , \dot{m}_f , ω_e , P_{int} and λ are the

real data operation condition used), allowing to estimate the quadratic accumulated error for each model suggested as a function of the intake manifold temperature and pressure, the volumetric gas flow and the engine revolutions. The linear least squares approach fitting in Matlab® was used to determine the parameters of the statistical models.

3. Results and Discussion

From the operational database of the engine, the resulting fitted models were used to predict the volumetric efficiency values as shown in Table 1, with the respective sum of squared residuals (SSR).

Table 1. Proposed linear models for the volumetric efficiency

Proposed linear models	SSR = $\sum e^2$
Eff Vol1(T_{int}) = $-0.37212 + 0.0029436 \times T_{int}$	5.6507
Eff Vol2(P_{int}, T_{int}) = $0.055047 + 3.5993 \times 10^{-5} \times P_{int} + 0.0016411 \times T_{int}$	5.5829
Eff Vol3($P_{int}, T_{int}, \omega_e$) = $0.51079 + 5.5385 \times 10^{-5} \times P_{int} - 0.0009234 \times T_{int} + 0.0002695 \times \omega_e$	4.5892
Eff Vol4($P_{int}, T_{int}, \omega_e, \dot{V}_f$) = $0.24354 - 0.001371 \times P_{int} + 0.00035484 \times T_{int} + 0.00013084 \times \omega_e + 5.1829 \times \dot{V}_f$	1.9497

The best regression is the fourth one, reaching an SSR of 1.9497, which can be explained due to the fact that the volumetric gas fuel was considered in the model. The remaining regressions have a good performance, but due to limitations in their capability of prediction when the gas flow change, they presented a high SSR. The variables were separately simulated for 6 hours to have a full understanding of the accuracy of each model. Figure 2 shows the case of the first model. In it, the intake manifold temperature does not have a severe impact on the behavior of the volumetric efficiency. Also, the Figure 2 shows that at 0.025 hours of operation, 330 K were obtained for the intake manifold temperature, 1482 kW for the electric power and 0.441 for the volumetric efficiency. This behavior implies a relative error of 28.21 % comparing to the response obtained with the fourth model as shown in Figure 3, which means that this regression does not take into account some effect of other influencing variables on the engine operation and could be improved.

Analyzing the behavior of the volumetric efficiency for all the proposed models as shown in Figure 3, it is important to highlight that the third regression although has an abnormal behavior in the first operation hours, with the lower SSR in comparison with the first and second regressions.

An abnormal behavior in the third regression of the volumetric efficiency, which does not consider the effects of the gas volume, is presented in Figure 3. A relative error during the first 0.03 hours of operation of 62.29 % was obtained compared to the fourth model, revealing the importance of the gas flow variable. For the case of the other models that do not consider the gas flow, the linear combination effect of their variables does not generate a big impact on the volumetric efficiency estimation. This situation could be justified by the values of the relative errors of 4.32 % and 1.819 % for the first and second regression, respectively. These results were obtained from the values of 0.588, for the first regression, and 0.604 for the second, at 0.025 hours, as shown on Figure 3. Then, a good behavior in the volumetric efficiency, due to the correct lineal interaction, is observed, as shown in Figure 4.

Figure 2. Respond of the volumetric efficiency using the first model.

Figure 3. Comparative responds of the volumetric efficiency models.

Figure 4. Respond of the volumetric efficiency using the fourth model.

4. Conclusions

Based on the simulated results obtained from the different model proposed for the volumetric efficiency of the natural gas generation engine, we conclude that both the angular speed of the engine and its volumetric fuel flow have an important impact on the volumetric efficiency of the engine, moreover the volumetric flow of fuel, as observed in the Table. 1 in term of the sum of squared residuals obtained respect to real data. Also, the effects of the temperature and the pressure of the intake manifold should not be despised, since they directly define variables associated with the volumetric efficiency, such as the density of the new charge of the combustion chamber. Finally, as expected, a proportional linear relation between the power generated by the gas engine and the volumetric efficiency was identified. Since this parameter indicates that the load was renewed inside the cylinders, directly affecting its performance, results that confirm the correct behavior of the proposed modeling and simulation.

Abstract

This paper investigates the data-driven MultiVariate Dynamic Modelling (MVDM) and MultiStep-Ahead Prediction (MSAP) of nonlinear systems based on the Ordinary Kriging (OK) metamodel. The OK is used to build a set of Nonlinear Autoregressive models with Exogenous inputs (NAREX), able to approximate the system future outputs as a function of previous inputs and outputs considering a specific delay. Then, these OK-based dynamic models are used in a recursive interactive interpolations scheme to predict the process outputs over several time steps. The capabilities of the OK-based dynamic models are compared to other leading techniques, via their application to benchmark cases. The application results reveal the OK promising and competitive capabilities for MVDM of nonlinear systems, in terms of prediction accuracy and prediction time horizon.

Keywords: Multivariate dynamic modelling, Multistep-ahead prediction, Complex Nonlinear processes, Surrogate Models, Ordinary Kriging, ANNs, Gaussian models.

1. Introduction

In the process system engineering area, a considerable attention has been directed to the use of Ordinary Kriging metamodels, due to their potential capabilities for approximating complex highly nonlinear systems. These capabilities stem from the OK ability to combine global modelling through estimating a general trend of the system, and local modelling through its correlation function. However, almost all the OK usages and developments are concentrated in the approximation and modelling of “static” systems. So few works (Hernandez and Gallivan 2008; Boukouvala et al. 2011) have explored the OK capabilities in dynamic modelling and simulation, where the OK has been used to describe the dynamic system future outputs as a function of the current inputs and outputs. However, these works assumed simplified Markovian dynamic processes with no delayed behaviour. Besides, they have considered significantly simple dynamic profiles of the control inputs. Additionally, they have assumed the habitual availability of a First Principle Model (FPM) that can be combined with a proper design of computer experiments techniques, in order to generate optimal training datasets. However, in real engineering applications, only input-output data signals measured from the process may be available. Moreover, the comparison of these methods with the other existing state of the art proposals is not sufficiently illustrated.

This work presents a generic and robust data-driven method for the MultiVariate Dynamic Modelling (MVDM) and MultiStep-Ahead Prediction (MSAP) based on the OK metamodels. The method is aimed at approximating general real-world nonlinear dynamic processes, providing dynamic models able to predict the process future outputs for any change in the inputs, over relatively large time horizons, and also to accommodate delayed behaviours of the processes. The proposed method trains a set of OK metamodels to approximate the system future outputs -over a constant time step- as a function of previous inputs and outputs. The fitted OK-based dynamic models are then used in a recursive interactive interpolation scheme to predict the system outputs over several time steps. Within the proposed MVDM approach, the OK capabilities are compared to other pioneer techniques as Artificial Neural Networks (ANNs) and Gaussian Process (GP) models, through their application to benchmark case studies. The results show the OK promising capabilities for the MVDM of nonlinear systems.

2. Compared modelling techniques (data-based models)

2.1. Ordinary Kriging (OK)

Given a set of input-output training data $[x_i, y_i]$, $i=1,2,\dots,n$, $x \in R^k$, $y \in R$, the OK assumes a predictor $\hat{y}(x) = \mu + Z(x)$ that is composed by a constant term μ , and a deviation $Z(x)$ from that term. The deviation $Z(x)$ is considered as a stochastic Gaussian process with expected zero value, $E(Z(x))=0$, and a covariance between two points x_i , x_j as $cov(Z(x_i), Z(x_j)) = \sigma^2 R(x_i, x_j)$, being σ^2 the process variance, $R(x_i, x_j) = \exp(-\sum_{l=1}^k \theta_l |x_{i,l} - x_{j,l}|^{p_l}) + \delta_{ij} \lambda$, a correlation function, δ_{ij} the Kronecker delta and λ a regularization constant. The parameters $[\mu, \sigma^2, \theta_l, p_l, \lambda]$ are estimated via maximizing the likelihood function of the observed data $[Y]_{n \times 1}$. Then, the OK final predictor is obtained as $\hat{y}(x^*) = \mu + r^T R^{-1}(Y - 1\mu)$, where x^* is a new interpolating point, and r is the $n \times 1$ vector of correlations $R(x_i, x^*)$ between the n training data and the new point x^* . For this work, a specific Matlab implementation of this OK formulation has been used.

The OK is considered as a specific form of the general class of the GP models. Although of the quite similarity between them, still each one attracting different audiences.

2.2. Gaussian Process (GP) models

Within a Bayesian modelling framework, and assuming an unknown relation $y(x) = f(x) + \varepsilon$, where $\varepsilon \sim \mathcal{N}(0, v_o)$ is a white noise, the GP approach places a Gaussian prior probability distribution over the space of the observed unknown function (Rasmussen, 2006). This prior is considered as a collection of random functions having a joint zero-mean multivariate Gaussian distribution; $y_1, \dots, y_i \dots y_n \sim \mathcal{N}(0, \mathcal{R})$, being $\mathcal{R}(y_i, y_j) = v e^{-\sum_{l=1}^k \varpi_l |x_{i,l} - x_{j,l}|^2} + \delta_{i,j} v_o$ the covariance between the observed functions, $\varpi_l, l = 1, 2, \dots, k$ the set of hyper-parameters of the covariance function, and v a parameter controlling the covariance magnitude. The GP model provides the predictive distribution of \hat{y} corresponding to a new input point x^* as $\hat{y}(x^*) = r(x^*)^T \mathcal{R}^{-1} Y$. The function “fitrgp” included in the Matlab statistical toolbox is used in this work to construct GP models.

2.3. Artificial Neural Networks (ANNs)

ANNs are efficient data-driven modelling tools widely used for nonlinear systems dynamic modelling and identification, due to their universal approximation capabilities

and flexible structure that allow to capture complex nonlinear behaviors. Feed-forward multi-layer perceptron ANNs type is frequently used in engineering applications (Nagy, 2007). In this work, the Matlab ANNs toolbox and the function “*feedforwardnet*” have been used to create a feed forward ANNs; the number of neurons and layers, and the training algorithm (“*trainbr*”- Levenberg-Marquardt optimization method) were selected to balance simplicity and accuracy.

3. Multivariate dynamic modelling and multistep-ahead prediction

Considering a dynamic system or process having the inputs $U(t) \in R^{D_u}$ and the outputs $Y(t) \in R^{D_y}$, which are assumed to be either measured from a real process or simulated using a complex FPM over discrete and equal time steps $T_0, T_1, T_2, \dots, T_j, \dots, T_{q-1}, T_q$. Then, $U(t) = [U_{T_0}, U_{T_1}, \dots, U_{T_j}, \dots, U_{T_q}]$ and $Y(t) = [Y_{T_0}, Y_{T_1}, \dots, Y_{T_j}, \dots, Y_{T_q}]$, and the sampling time step is $\Delta t = (T_j - T_{j-1})$. Using this input-output training signal/data, the OK is employed to construct a set of D_y NAREX models (Eq.(1)) where each model f_i approximates the future value of one process output $\hat{y}_i(t + 1)$ as a function of the process previous inputs and outputs $[Y_{T_j}, U_{T_j}]$, considering a specific delay L .

$$\hat{y}_i(t + 1) = f_i [\hat{Y}(t), \dots, \hat{Y}(t - L), U(t), \dots, U(t - L)], i = 1, 2 \dots D_y \quad (1)$$

Once the set of the OK-based dynamic models – one step-ahead models- are trained, it will be possible to emulate or predict the dynamic evolution of the system outputs over larger time domain through the MSAP. This is accomplished via recursive interactive interpolation, where the initial conditions of the outputs $Y_{T_0}^v$, and the new inputs scenario $U^v(t) = [U_{T_0}^v, U_{T_1}^v \dots U_{T_j}^v, \dots, U_{T_{w-1}}^v, U_{T_w}^v]$ are given (the superscript v refers to “validation”). Considering zero lag ($L=0$) dynamic models (for simplicity of illustration), the recursive interpolation starts using the known interpolation inputs $[Y_{T_0}^v, U_{T_0}^v]$ to predict the values of the outputs at next time step $\hat{Y}_{T_1}^v$. The predicted output values $\hat{Y}_{T_1}^v$ are fed back to the models together with the new control values, representing the new interpolation inputs $[\hat{Y}_{T_1}^v, U_{T_1}^v]$ for the new time step prediction, in order to estimate the values of the outputs $\hat{Y}_{T_2}^v$, and so on until the last time step, in which the interpolation inputs $[\hat{Y}_{T_{w-1}}^v, U_{T_{w-1}}^v]$ are used to predict the outputs $\hat{Y}_{T_w}^v$. Hence, an accuracy measure (e.g. Normalized Root Mean Square Error (NRMSE)) can be calculated by comparing the real and the estimated values of the output signal. During the recursive interactive interpolation, each dynamic model f_i contributes with its prediction \hat{y}_i^v to compose the outputs $\hat{Y}_{T_j}^v = [\hat{y}_1^v, \hat{y}_2^v, \dots, \hat{y}_i^v, \dots, \hat{y}_D^v]$, which at the same time, represent the inputs for the dynamic models in the next step, so each model exploits the information provided by the other dynamic models in the previous time step.

4. Applications

4.1. Continuous Stirred Tank Reactor (CSTR)

A benchmark model (Eqs.(2)) for a CSTR (Bequette, 1998) is used to evaluate the proposed method, and to compare different metamodels types. The model describes the evolution of the reactant concentration C_A ($kgmol/m^3$) and the reactor temperature T_r (K), which are affected by the three control variables: the inlet feed concentrations C_F , the inlet feed temperature T_F and the water jacket temperature T_{jck} . The model parameters can be found also in the Matlab system identification toolbox. In this study, the values of C_F and T_F are kept constants ($10 kgmol/m^3$, and $298.15 K$), while the water

jacket temperature can be manipulated within the range $250\text{ K} \leq T_{jck} \leq 310\text{ K}$. The model is just considered here as the process plant, from which input-output data are measured (i.e. simulated), considering a sampling period of 1 hour. The goal is to construct a set of multivariate dynamic models (Eqs.(3)).

$$\left. \begin{aligned} \dot{C}_A &= -\frac{F}{V}(C_F - C_A) + k_0 \exp\left(-\frac{E}{R T_r}\right)C_A \\ \dot{T}_r &= -\frac{F}{V}(T_F - T_r) - \frac{H}{C_p Rho} k_0 \exp\left(-\frac{E}{R T_r}\right)C_A - U A \frac{(T_r - T_{jck})}{C_p Rho V} \end{aligned} \right\} \quad (2)$$

A random training signal of the process input-output variables $[T_{jck}(t), C_A(t), T_r(t)]$ is generated. Thus, a piecewise-constant signal of the input $T_{jck}(t)$ is synthesized (Figure 1-(a)) by random changes of its amplitude values within the allowable control limits (each step change holds for several (20) sampling periods, in order to capture the whole dynamic behavior of the outputs in response to each step change).

$$\left. \begin{aligned} \hat{C}_A(t+1) &= f_1 [C_A(t), \dots, C_A(t-L), T_r(t), \dots, T_r(t-L), T_{jck}(t), \dots, T_{jck}(t-L)] \\ \hat{T}_r(t+1) &= f_2 [C_A(t), \dots, C_A(t-L), T_r(t), \dots, T_r(t-L), T_{jck}(t), \dots, T_{jck}(t-L)] \end{aligned} \right\} \quad (3)$$

Figure 1. Random training signal (CSTR).

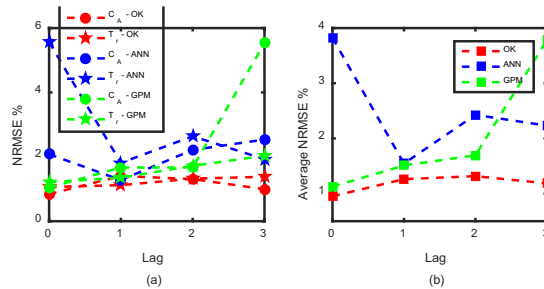

Figure 2. NRMSE of the dynamic models prediction (CSTR).

The input signal is simulated by the process model (Eqs.(2)) in order to obtain the corresponding outputs (Figure 1-(b, c)). Gaussian noise is added to each output (C_A and T_r) with a zero mean and a standard of deviation of 0.00075% of their variation range. This input-output random signal is used to train the dynamic models (Eqs.(3)) based on the OK, GP and ANNs considering different model orders/lags ($L=0, 1, 2, 3$). In order to validate the fitted dynamic models, a random validation signal is generated (Figure 3) as previously mentioned. The dynamic models are harnessed to predict the reactant concentration C_A and the reactor temperature T_r over 500 time steps, corresponding to the validation input signal (Figure 3-(a)) through the recursive interactive interpolation

fashion (section 2). Figure 2-(a,b) shows the prediction accuracy of the output signals in terms of the NRMSE for each metamodel type (OK, ANNs, GP) with the different lags. Figure 3-(b, c) shows the prediction of C_A and T_r using the best dynamic models (with lag achieving the lowest NRMSE, see Table 1).

Figure 3. Random validation signal (CSTR), and the multivariate dynamic model predictions.

4.2. Fed-batch Fermentation reactor

This case considers a common nonlinear model (Eqs.(4)) of a yeast fermentation fed-batch reactor (Galvanin et al., 2007). In the model, C_m is the biomass concentration (g/L), C_s is the substrate concentration (g/L), $U1$ is the dilution factor (h^{-1}), and $U2$ is substrate concentration in the feed (g/L). Besides, some operating limits should be considered. The process variables are measured each 15 minutes along the batch run of 40 hr.

$$\left. \begin{aligned} \dot{C}_m &= (r - U1 - 0.05)C_m \\ \dot{C}_s &= -\frac{r C_m}{0.55} + U1(U2 - C_s), \quad r = \frac{0.31 C_s}{0.18 + C_s} \\ 1 \leq C_m(0) \leq 20, C_s(0) &= 0.01, 0.05 \leq U1 \leq 0.15, 15 \leq U2 \leq 30 \end{aligned} \right\} \text{* MERGEFORMAT} \quad (4)$$

In order to construct a set of multivariate dynamic models ((Eqs.(5)), the same procedure is applied here also: a random signal of the process inputs and outputs [$U1(t)$, $U2(t)$, $C_m(t)$, $C_s(t)$] is generated (Figure 4) and used to train the dynamic models based on the different metamodels and lags L .

$$\left. \begin{aligned} \widehat{C}_m(t+1) &= f_1[C_m(t), \dots, C_m(t-L), C_s(t), \dots, C_s(t-L), U1(t), \dots, U1(t-L), U2(t), \dots, U2(t-L)] \\ \widehat{C}_s(t+1) &= f_2[C_m(t), \dots, C_m(t-L), C_s(t), \dots, C_s(t-L), U1(t), \dots, U1(t-L), U2(t), \dots, U2(t-L)] \end{aligned} \right\} \quad (5)$$

Figure 4. Random training signal (fed-batch).

Figure 5. Random validation signal (fed-batch).

Similarly, a random validation signal (Figure 5) is used to assess the dynamic models, which are harnessed to emulate the biomass and substrate concentrations over 160 time steps (Figure 5-(b,c)).

Table 1. NRMSE (%) of the best dynamic models for both application cases.

	Lag	Case 1: CSTR			Lag	Case2: fed-batch		
		\widehat{C}_A	\widehat{T}_r	Average		\widehat{C}_m	\widehat{C}_s	Average
OK	0	0.8	1.1	0.95	2	5.8	5.8	5.80
GP	0	1.0	1.2	1.10	3	6.9	5.7	6.30
ANNs	1	1.3	1.8	1.55	2	8.3	10.6	9.45

5. Conclusions

The paper presents a robust and generic method for the data-driven MVDM and MSAP based on metamodels, which has not been investigated before. The method employs metamodels to construct a set of NAREX models, which are then used in a recursive interactive interpolation scheme, in order to predict the process outputs over several time steps. The method is applied to two multi-input/multi-output nonlinear dynamic processes showing promising capabilities: high prediction accuracy, large prediction time horizon, high flexibility to simulate complex dynamic profiles of the inputs and ability to model the delayed behaviour of the system. The method is also able to model both continuous and batch processes, although the later shows extra challenges (higher NRMSE), due to the higher nonlinearity often inherent to these processes. Within the proposed MVDM and MSAP method, the OK is compared with other leading techniques as ANNs and GP models: the OK shows better characterises in dynamic modelling, not only in terms of higher prediction accuracy, but more importantly, easier and more flexible tuning of parameters. The work also opens several novel application areas for the OK models, as model predictive control, dynamic soft sensing (Shokry et al., 2017(b)) and monitoring studies (Shokry et al., 2017(a)).

Abstract

In this work, we propose mechanistic models for water quality and hydrological management in freshwater and saline lakes within a dynamic optimisation framework. We formulate management problems as optimal control problems for two case studies corresponding to water bodies located in Buenos Aires Province, Argentina. The hydrological model is used to address flooding and salinity issues in salt lakes. The water quality model allows dealing with eutrophication problems in freshwater reservoirs. The proposed optimization models provide decision-making tools to plan management actions for different objectives and under different scenarios, as well as to evaluate their effects.

Keywords: Dynamic Optimisation, Lake Management, Hydrological Mathematical Model, Eutrophication

1. Introduction

During the last decades, much work has been devoted to modelling of water bodies with different objectives and approaches. The identification of meteorological, hydrological and ecological components and driving forces behind problems as eutrophication, floods and salinisation in water bodies is the first step to develop useful tools for decision-making in the management of lakes and reservoirs. Barjas Blanco et al. (2010) and Uysal et al. (2016) proposed hydrological models for flood management in freshwater reservoirs for short-term operations. Estrada et al. (2011) formulated a mechanistic model within a dynamic optimization framework to control algal blooms in water bodies. Di Maggio et al. (2015) proposed the integrated management of lakes and artificial wetlands through the application of dynamic optimization strategies. A recent review on main ecological simulation models was carried out by Anagnostou et al. (2017), focusing on the understanding of eutrophication processes. However, these authors do not address hydrological and ecological models formulated within an optimization approach.

In this work, we formulate optimal control problems to plan management strategies in lakes and reservoirs, based on ecohydrological models represented by differential

algebraic equation systems that include mass balances, evaporation, kinetic equations, etc. In the first case, the objective is to avoid flooding of a nearby village and tourist facilities and to keep salinity at appropriate levels for fish reproduction within a salt lake. In a second case study, we address control of algal blooms in a reservoir that provides drinking water to two cities, by considering reduction of external nutrient charge to the water body (control variable: fraction of nutrient rich water stream that is diverted through an artificial wetland) and fish removal strategies (control variable: fish removal rate). Dynamic optimization problems are formulated within a control vector parameterization framework in gPROMS (PSEnterprise, 2017). Numerical results provide control variables profiles to plan restoration actions and their ecological and hydrologic effects.

2. Model description

2.1 Hydrological Model

In the hydrological model for a salt lake, the dynamic water mass balance is as follows:

$$\frac{dm}{dt} = \left[Q_{pp}(t) \left(\frac{V}{h} \right) + Q_{river}(t) + Q_{gw} - Evap(t) \left(\frac{V}{h} \right) \right] \delta_w / 1000 \quad (1)$$

where m is total mass in the lake (kg); δ_w , is water density (kg. m⁻³), which is assumed constant; V corresponds to lake volume and h is average depth. Q_{pp} (L.day⁻¹.m⁻²) corresponds to precipitations, Q_{river} (L.day⁻¹) is tributary river flowrate, Q_{gw} (L.day⁻¹) is groundwater flowrate and $Evap$ (L.day⁻¹.m⁻²) corresponds to evaporation per unit area in the lake. Bathymetric information is used to assess lake volume at the beginning of the integration horizon. Evaporation is calculated taking into account energy and momentum balances (Penman 1948):

$$Evap = \frac{10}{\lambda v} [W Rn(t) + (1 - W) F_{wind} (T_{vap0} - T_{vap})] \quad (2)$$

where W is a weighting factor of the radiation effects on evaporation; $Rn(t)$ is net radiation (ly.d⁻¹), F_{wind} is a wind function that expresses wind effects as available energy to evaporate water (km.d⁻¹) and $(T_{vap0} - T_{vap})$ is a vapour saturation deficit. Additional algebraic equations include latent heat of vaporization for water and forcing functions, represented by Fourier series, including tributary and groundwater flowrate, air temperature, relative humidity, solar radiation, mean wind rate and related meteorological variables. As salt concentration in both groundwater and the tributary is negligible, we assume that salt mass is constant within the lake. Therefore, salt concentration (C_s) is calculated as:

$$\frac{dC_s}{dt} = - \frac{C_s}{V} \left[Q_{pp}(t) \left(\frac{V}{h} \right) + Q_{river}(t) + Q_{gw} - Evap(t) \left(\frac{V}{h} \right) \right] \delta_w / (\delta \cdot 1000) \quad (3)$$

Furthermore, we include a water mass balance for an artificial reservoir of fixed area, located upstream of the tributary, to which a fraction of the tributary can be diverted for lake management purposes:

$$\frac{dhm}{dt} = [Q_{pp}(t) + Q_{out}(t)/A - Evap(t)] / 1000 \quad (4)$$

where hm is water column height, Q_{pp} corresponds to rainfall over the reservoir, Q_{out} is the diverted fraction flowrate. The model has 3 differential and 23 algebraic equations.

2.2 Water Quality Model

A water quality model for a freshwater reservoir has been previously proposed (Estrada et al., 2009; 2011). Based on experimental evidence from a monitoring program that is being carried out by our group since 2013, the model has been extended to include piscivorous fish dynamics due to the control that this predator exerts on the lower trophic level (zooplanktivorous fish). The extended model includes mass balances for the main components of the trophic chain of the Reservoir, represented by:

nutrients \rightarrow phytoplankton (Diatoms, Chlorophytes, Cyanobacteria) \rightarrow zooplankton (Copepoda and Cladocera) \rightarrow zooplanktivorous fish (three sizes of *Odontesthes bonariensis*) \rightarrow piscivorous fish (two sizes of *Oligosarcus jenynsii*).

Algebraic equations stand for forcing functions profiles, such as solar radiation, temperature, tributaries inflows and their associated nutrient concentrations, as well as the generation/consumption rates for each ecological state variable. The model takes into account concentration gradients along the water column through two horizontal layers; horizontally averaged concentrations, constant water density and constant lake transversal area are assumed. The entire model has 42 differential and 110 algebraic equations.

2.3 Dynamic Optimisation Model

We formulate management problems for water bodies as optimal control problems subject to the differential algebraic equation (DAE) systems described in the preceding sections. In the first case, the goal is to keep salt concentration in the lake (C_s) around a desired value of 23 kg.m^{-3} within a wet climate scenario, considering the flowrate fraction of the tributary that is diverted (Q_{out}) as the control variable. In the second case, the inclusion of the main variables controlling the phytoplankton growth in the freshwater reservoir model, allows the formulation control problems to evaluate optimal restoration strategies. Table 1 shows both problems formulation.

Table 1. Optimal control problems for hydrological management (Case 1) and eutrophication control (Case 2)

Case 1	Case 2
Control Variable	Control Variables
Fraction of tributary diverted to an artificial water reservoir for salinity control with ecological/commercial purposes and to avoid flood	Fraction of tributary stream diverted to an artificial wetland for nutrient removal Removal rate for each of three zooplanktivorous fish size classes ($m = S1, S2, S3$)
$\min Z = \int_0^{t_f} (C_s(t) - 23)^2 dt$ s.t.	$\min Z = 0.7 \int_0^{t_f} (C_{phyto}(t) - 0.2)^2 dt + 0.3 \int_0^{t_f} (C_p(t) - 0.02)^2 dt$ s.t.
DAE Hydrological Model	DAE Water Quality Model
$C_s(0) = C_s^0, V(0) = V^0$	$C(0) = C^0$
$C_s^L \leq C_s \leq C_s^U$	$C^L \leq C \leq C^U$
$V^L \leq V \leq V^U$	$0 \leq F_{wetland} \leq 0.5 F_{El\ Divisorio}$
$Q_{river} = Q_{in} + Q_{out}$	$S_i R^L \leq S_{m,removal} \leq S_i R^U$
	$r_{im} = R_{im,pred} - R_{im,bm} - R_{im,recruit} + R_{im,spaw} - S_{m,removal}$

We include two restoration methodologies: 1) the reduction of external loading of nutrients to achieve bottom-up control of algae blooms (Di Maggio et al. 2015), and 2) a top-down control strategy, based on the food chain manipulation (Jeppesen, 2012; Estrada et al., 2011). This technique consists in the removal of the zooplanktivorous fish biomass to increase the grazing pressure of zooplankton over the phytoplankton community. Both control problems (Case 1 and 2) were implemented within a control vector parameterization framework in gPROMS (gPROMS, PSEnterprise, 2017).

3. Results and Discussion

3.1. Case 1. Salinity and flood control in Chasicó Lake

In this case, we address salinity and flood control in Chasicó Lake, a salt lake located in Argentina (38°38' S; 63°03' W). This water body belongs to an endorheic basin and has one tributary (Chasicó River). The lake has undergone salinity variations ranging from 17 to 100 g.L⁻¹, during the last fifty years (Lara, 2006). The hydrologic regime of this basin is closely related to climatic conditions, with decadal dry and humid cycles. Floods and droughts have brought devastating consequences in the regional economy, damaging productive fields, sports fishing of silverside (*Odontesthes bonariensis*) and touristic activities (Kopprio et al., 2014). The hydrological model has been calibrated and validated with collected salinity data throughout the last ten years (Siniscalchi et al., 2017). Chasicó Lake groundwater flowrate is estimated as 24% of the local rainfall. Figure 1 shows Chasicó River and the diverted stream (Q_{out}) flowrate profiles for two control interval lengths, 30 and 15 days, with a time horizon of two years within an extended a wet period. Similar results are obtained for either length of the control interval, keeping salinity and volume lake, around the proposed objective for salinity (23 kg.m⁻³) and volume (480 Hm³), as can be seen in Fig. 2a. The accumulated water volume diversion is 63.4 Hm³ during the period, taking into account evaporation and rainfall within the artificial reservoir (Fig. 2b).

3.2. Case 2. Eutrophication control in Paso de las Piedras Reservoir

In this case study, we focus on the restoration of Paso de las Piedras Reservoir, a eutrophic freshwater reservoir, located in Argentina (38° 22'S;61°12'W) that supplies drinking water to more than 450,000 inhabitants of two cities and for industrial purposes at a petrochemical complex nearby. It has two tributaries that run through an important agricultural area in the country, with a drainage basin area of 1620 km². The lake has a surface area of 36 km², while its mean depth is 8.2 m and its retention time is 4 years. The eutrophic characteristic of the reservoir is mainly caused by the external discharge of nutrients (mainly phosphorus and nitrogen). This fact causes recurrent algal blooms, which produce several problems in the potabilization process, affecting humans and in the natural ecosystem. The high concentration of cyanobacteria within the blooms raises concerns on the potential production of cyanotoxins, harmful for human and animal health. Optimal preliminary profiles for the restoration strategies are obtained based on the extended water quality model calibrated with data from 2015. Tributary diversion to an artificial wetland for nutrient removal is at its upper bound throughout the entire time horizon. Figures 3 (a) and (b) show fish biomass and removal rate profiles for a two-year horizon for size S1 (0-100 mm) and Size S2 (100-200 mm) of the zooplanktivorous fish *O. bonariensis*, respectively. Gut content studies (data not shown) show that zooplankters copepoda and cladocera (which in turn graze on phytoplankton) are the

main items in *O. bonariensis* diet, supporting the biomanipulation strategy. Preliminary numerical results indicate a substantial increase in zooplankton biomass after fish removal (Figure 4 (a)) and subsequent decrease in phytoplankton biomass (Figure 4 (b)). The inclusion of mass balances for a predator of *O. bonariensis* (two sizes of *O. jenynsii*) provides more realistic insights on restoration actions.

Figure 1: Chasicó River flowrate without control (dotted line) and River diversion (Q_{out}). Interval controls for river diversion: 15 and 30 days

Figure 2. (a) Optimal salinity profiles with control intervals of 15 and 30 days and without control (S/C); (b) Water column height and volume profile in artificial reservoir with management actions

Figure 3. Zooplanktivorous fish sizes S1 (a) and S2 (b) concentration profiles before and after fish removal (left axis) and optimal removal rate (right axis)

Figure 4. Total phytoplankton (a) and zooplankton (b) concentration profiles before and after fish removal and diversion of tributary to an artificial wetland

4. Conclusions

In this work, we propose detailed mechanistic models of lakes and reservoirs as constraints for optimal control problems to provide useful tools in planning water bodies management and exploring the associated effects. In Case 1, we study a salt lake. Numerical results show the optimal profile for the tributary fraction that should be diverted to an artificial water reservoir to avoid flood events and keep salt concentration at the physiological optimum for a high-commercial value fish. In Case 2, we address algae bloom control in a freshwater reservoir. Numerical results show the need for tributary diversion to an artificial wetland for nutrient removal, as well as zooplanktivorous fish removal, to keep phytoplankton concentration under eutrophication limits.

Abstract

In recent years, plasma etching process has been considered important because it is one of the most critical processes in semiconductor manufacturing. Numerous research results have been presented in relation to the plasma etch processes, especially plasma parameters control. Although the above results are expected to bring about positive effects in various fields, they do not consider the variability of the system. In this paper, we performed the recursive model estimation of which the model structure is ARX considering the time delay. The recursive algorithm contains the Kalman filter interpretation to the model parameters. We have confirmed that the system model updated in real-time by our recursive model estimation algorithm continuously calculates the model parameters that predict the output variable precisely. Through these results, we expect the better performance of MPC control using the recursive model estimation

Keywords: Online System Identification, Recursive Normalized Model Estimation, Plasma Parameter Control, Real Time Control

1. Introduction

Due to Moore's law, the higher quality control is demanded in the semiconductor industry as well as the semiconductor manufacturing process has also been regarded as a very important issue because of the development of AI. There have been many studies about the plasma etch process the most important processes in the semiconductor manufacturing process in various forms. Also, our research group has presented a paper about successful multivariable plasma parameters control in real-time using optical emission spectroscopy (OES).

Though previous studies have shown good results, it is difficult to apply them directly to the current semiconductor manufacturing environment for a variety of reasons. One of the reasons is that the monitoring of the plasma parameters must be done in real-time because of the high sensitivity of the plasma. In addition, online model estimation is indispensable because of the characteristics of the plasma parameters control process, in which the system model changes not only in different batches but also in the same batch. This is even more essential in the case of using model predictive control (MPC)

the default control technique in current semiconductor manufacturing process because of the high model dependency of MPC. The last important reason is that no other studies using online parameter estimation in plasma parameters control process normalized their variables though the normalized variables have a large impact on system control and the performance.

In this paper, we performed the recursive normalized model estimation, a form of online system identification, for realizing the plasma parameter system. We utilized an OES based single input single output (SISO) plasma parameter controller. OES, a non-invasive tool and the default plasma monitoring sensor for every plasma reactor, has the advantages of less impact on the system than other invasive sensors such as hairpin probe and no concern about installation.

This paper is organized as follows. In Section 2, the monitoring of the plasma parameter through OES is explained briefly. In Section 3, the theoretical backgrounds of recursive model estimation including the normalized model estimation are explained. In Section 4, the results of the recursive normalized model estimation are illustrated

2. Plasma Parameter Estimation by OES

It is important to control plasma parameters in plasma etch processes such as electron density, electron temperature and so on. As mentioned in section 1, many studies and literature about the control of plasma parameters have been presented and our research group have also published the study of the control of plasma parameters monitored by OES. Optical fiber attached on the chamber viewport measures the plasma emission. An emission intensity from p^{th} state to k^{th} state is described as

$$\Phi_{pk} = n_0 n_e \int_{E_{thr}}^{\infty} \sigma_{pk}(E) \left(\frac{2E}{m_e} \right)^{\frac{1}{2}} f(E) dE \quad (1)$$

where n_0 is the number density of ground state atoms, n_e is the electron density, $\sigma_{pk}(E)$ is the excitation cross section from level p into level k as a function of electron energy E , $f(E)$ is the electron energy distribution function (EEDF), m_e is the electron mass.

In order to compute the plasma parameters by OES, we utilized the ratio of several emission lines based on the separate line-ratio techniques that is only a function of the electron density (J. B. Boffard et al., 2004).

We used a capacitively coupled plasma reactor illustrated in Figure 1. It carries 300mm wafer and is powered by three radio frequency (RF) generators. The gap between top and bottom electrodes is 25 mm. For the definition of plasma system, the input variable is 60 MHz RF power and the output variable is electron density measured through Eq. (1) with OES.

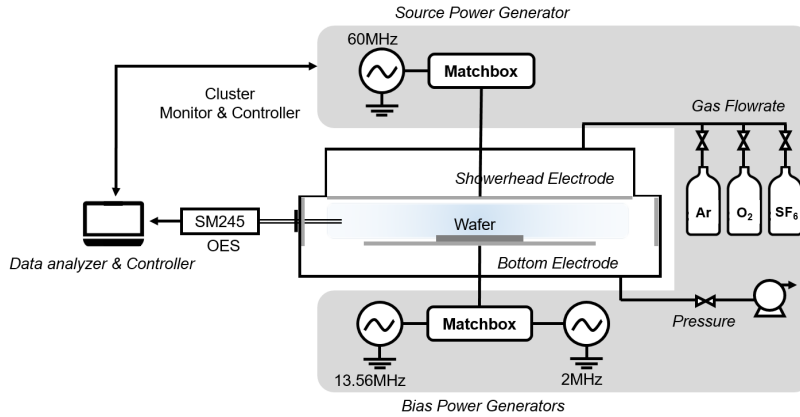

Figure 1. Schematic of capacitively coupled plasma reactor and plasma sensors used in this study.

3. Recursive Model Estimation

3.1 Recursive model estimation algorithm with forgetting factor

As mentioned earlier, online model estimation is essential when controlling a sensitive system such as a plasma related system. It is even more so for MPC controller which has high model dependency. Recursive model estimation is one form of the online model estimation algorithms. It uses the estimated model parameter,

$$\hat{\theta}_t = \underset{\theta}{\operatorname{argmin}} \sum_{k=1}^t \beta(t, k) [y(k) - \varphi^T(k)\theta], \quad (2)$$

which minimizes the weighted error criterion where $y(k)$ is the measured output, $\varphi(k)$ is the regression vector, θ is the present model parameter and $\beta(t, k)$ is the weighting sequence which has the following property:

$$\beta(t, k) = \lambda(t)\beta(t-1, k), \quad 0 \leq k \leq t-1$$

$$\beta(t, t) = 1 \quad (3)$$

where $\lambda(t)$ is the forgetting factor the value of which is recommended to be from 0.98 to 0.995. Solving Eq. (2), we have

$$\hat{\theta}_t = \hat{\theta}_{t-1} + \bar{R}^{-1}(t)\varphi(t)[y(t) - \varphi^T(t)\hat{\theta}_{t-1}] \quad (4.a)$$

$$\bar{R}(t) = \lambda(t)\bar{R}(t-1) + \varphi(t)\varphi^T(t) \quad (4.b)$$

where

$$\bar{R}(t) = \sum_{k=1}^t \beta(t, k) \varphi(k)\varphi^T(k). \quad (5)$$

3.2 Recursive model estimation algorithm with Kalman filter interpretation

The other methodology is not using the forgetting factor but utilizing the Kalman filter interpretation. That is,

$$\begin{aligned}\theta(t+1) &= \theta(t) + w(t) \\ y(t) &= \varphi^T(t)\theta(t) + v(t)\end{aligned}\quad (6)$$

with $Ew(t)w^T(t) = R_1(t)$, and $E v(t)v^T(t) = R_2(t)$. Then the expectation and covariance of $\hat{\theta}_t$ as

$$\hat{\theta}_t = \hat{\theta}_{t-1} + L(t)[y(t) - \varphi^T(t)\hat{\theta}_{t-1}] \quad (7.a)$$

$$L(t) = \frac{P(t-1)\varphi(t)}{R_2(t) + \varphi^T(t)P(t-1)\varphi(t)} \quad (7.b)$$

$$P(t) = P(t-1) - \frac{P(t-1)\varphi(t)\varphi^T(t)P(t-1)}{R_2(t) + \varphi^T(t)P(t-1)\varphi(t)} + R_1(t). \quad (7.c)$$

The initial parameter covariance matrix and the process noise covariance should be set by engineers. Engineers set these based on the system condition and experience.

3.3 Normalization of the system for robustness

The sizes of matrix $R_1(t)$ and $R_2(t)$ inflict on $\hat{\theta}_{t-1}$. Normally, the difference between the sizes of variables of plasma parameters control system is large enough. Therefore, normalization is essential for more accurate recursive model estimation. The normalization can also affect MPC design, so that when designing a controller, the normalization should be considered. In our study, all variables were gathered through normalization process, and the model parameters calculated through normalized Eq. (6)~(7) are parameters of the normalized system.

4. Results and Discussion

The performance of the recursive model estimation algorithm with Kalman filter interpretation was evaluated by the control results data that was previously performed. The control results had been done by MPC controller performing a setpoint tracking test of electron density.

The system input (manipulated variable for MPC) is 60 MHz RF power and system output (controlled variable for MPC) is electron density which is measured in real-time by OES and Eq. (1).

The chosen model structure is a linear, time-varying, discrete-time autoregressive exogenous model (ARX),

$$A(z)y(k) = B(z)u(k) + e(k), \quad (8)$$

where

$$A(z) = a_1 + a_2z^{-1} + \dots \quad (9.a)$$

$$B(z) = b_1 + b_2z^{-1} + \dots \quad (9.b)$$

where a_1 is always 1, b_1 is always 0, $u(k)$ is the input variable, 60MHz RF power, $y(k)$ is the output variable, electron density, $e(k)$ is a zero-mean, white noise with variance σ^2 and $A(k, z)$ and $B(k, z)$ are model parameters which are calculated in real-time based on Eq. (7). The model parameters are calculated in real-time based on Eq. (2) ~ (5).

Figure 2. The model parameters, $A(k, z)$ and $B(k, z)$, composing the ARX model structure.

Figure 2 shows the recursive model estimation results. The recursive model estimator needs the initial parameter values, A_0 and B_0 , which can be set from the original model structure which had been performed at the setpoint tracking control test. The initial parameter covariance and the process noise covariance in Eq. (7.c), R_1 , were set previously and R_2 was set as 1. It shows some changes in various time which means that the model estimation could develop the performance when it is applied to adaptive MPC.

In figure 3, the comparison of the estimated electron density calculated by the recursive model estimator and the measured electron density are illustrated.

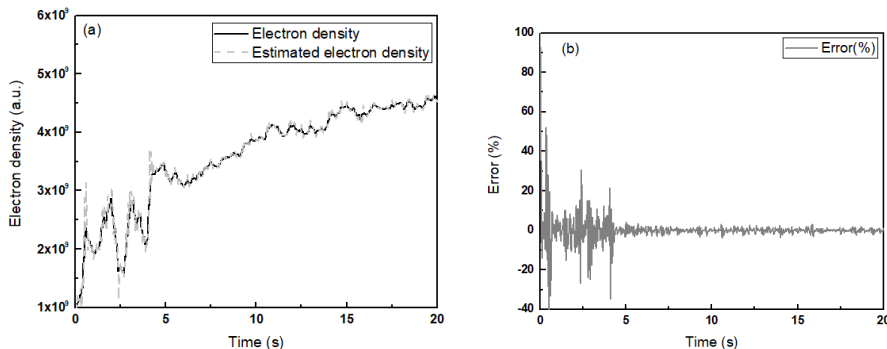

Figure 3. (a) The measured electron density and the estimated electron density calculated by the recursive model estimator and (b) error percentage.

As shown in figure 3, the estimated electron density suits well to the measured electron density. The error percentage is within 2% after 4.6s. These guarantee that the recursive model estimator conducted the estimation successfully and it has the potential of better performance in control strategy.

5. Conclusions

We conducted the recursive model estimation of the plasma parameter system of which the final goal is to get the best control results. Because the plasma parameter control system has very sensitive characteristics which means the model might be changed and the better MPC requires the better fitted model. The recursive model estimation simulation of ARX model structure shows successful performance which has only 2% error between the estimated electron density and the measured electron density. We hope that these results will contribute to maximize the performance of plasma parameter control process.

6. Future Work

In this study, the normalization of the system and the recursive model estimator and the experimental results using them are omitted. Our future studies will contain the results of the normalized estimation experiment. Also, the optimization problem of the initial parameter covariance and the process noise covariance is also well worth considering.

Model transformations and integration for process plant simulation, optimization and visualization

Manuel Rodriguez^a, Ismael Diaz^a

^a *Universidad Politecnica de Madrid, Dpt. Of Chemical Engineering, C/ Jose Gutierrez Abascal 2, 28006 Madrid, ES*

manuel.rodriguez@upm.es

Abstract

Industry is in constant evolution. Nowadays we are in what is called the fourth industrial revolution (called Industry 4.0 or connected industry). Its target is to make more efficient and flexible plants, reduce times and costs of projects and products lifecycle. It is an integrated engineering approach where different software tools are interconnected during the whole lifetime of the project, reducing inconsistencies and developing times.

To have a central neutral model of a process plant that is available during the whole lifecycle of the system (process + product) and that can be transformed automatically to specific models suited for different applications.

To achieve this goal we use a Model Based Systems Engineering approach, starting from the model requirements and covering the whole lifecycle of the project. This central model is specified using the Systems Modelling Language (SysML). This language is a profile of the Unified Modelling Language (UML developed by the Object Management Group) that is neutral and domain free. The developed model is partially generated in SysML and partially constructed using existing specific models. Having a single central model guarantees the consistency and allows for traceability at any stage of the lifecycle.

First, we present the architecture developed to implement this system. After, we create a SysML model of a process plant (the production of ethylbenzene) starting with the requirements. This model includes the behavioural (block definition and activity diagrams) and structural (internal and block definition diagrams) aspects of the model. Once the model is created automatic transformations (bidirectional) from it to some applications are performed. The applications are:

- Process design . Transformation to a steady state model used (specifically an Aspen Plus model) in a process simulation environment(Previous work presented in other conferences).
- Risk assessment. Transformation to a functional model to perform risk analysis (HAZOP).
- Process optimization . Automatic generation of the objective and constraints. We use Melody to integrate the SysML with the optimization model. In this

case Matlab is being used for the optimization (Previous work presented in other conferences).

- Process visualization. Transformation from the 3D model to SysML. We use Syndeia to achieve the integration. The 3D models are done using PTCreo.

In this work we will put more focus on the development of the 3D modelling integration in the proposed architecture.

This work shows the potential of having models at design time, central and consistent and coherent models. Industry trends look for models that generate virtual plants that can be “operated” and that allow to discover design mistakes at early design phases. Thus providing, when constructed, more robust, consistent and efficient plants. Model development effort is reduced and data exchange between different applications is facilitated keeping a central and consistent model.

Property Prediction of Pharmaceuticals for Designing of Downstream Separation Processes

Getachew S. Molla^a, Lukasz Ruszczynski^a, Jens Abildskov^a, Gürkan Sin^a

^a*Technical University of Denmark, 2800 Kgs. Lyngby, DK*

gsmo@kt.dtu.dk

Abstract

Downstream processing of pharmaceuticals is often a complex and expensive process section in pharmaceutical industry. The separation and purification cost of small to medium-sized active pharmaceutical ingredients (APIs) can be up to 70-90% of the total production cost. Designing a downstream processing includes selection, arrangement and rigorous evaluation of various unit operations such as crystallization and extraction. Solvent screening and selection is a critical step in designing such unit operations. The solubility of APIs is a major property for solvent screening and selection. Solubility can either be determined experimentally or by using predictive thermodynamic models. However, experimental solvent screening is most often expensive and laborious, or sometimes simply not possible due to the lack of sufficient amount of an API. Moreover, designing some unit operations; for example, crystallization further requires solubility property of an API as a function of temperature, solvent composition and pH for cooling, antisolvent and reactive crystallization, respectively, or any combination thereof.

In this work, different predictive thermodynamic models such as COSMO-SAC, COSMO-RS, NRTL-SAC and UNIFAC were applied for solubility prediction of a large molecular weight steroid-like structure antibiotic. The predicted solubility data were compared with experimental solubility data in a set of various solvents representative of wide solvent properties. Therefore, a model which gives more accurate solubility prediction can be selected. For this specific case study, the root mean square errors (RMSEs) of COSMO-SAC, UNIFAC, COSMO-RS and NRTL-SAC are 54.3%, 51.8%, 34.3% and 4.8%, respectively. NRTL-SAC was selected as a property prediction tool for solvent screening and selection as well as for further designing and optimization of crystallization unit operation. Moreover, global sensitivity and uncertainty analyses of the predictive thermodynamic model parameters were performed in order to identify sources of uncertainty and evaluate their influence.

Abstract

Efficient heat recuperation is of primary concern in resolving the problem of optimal energy usage. To achieve best results it requires the use of efficient compact heat exchangers among which Plate Heat Exchanger (PHE) is one of the most promising types. Its flexibility allows finding economically viable solutions in different processes of heat utilisation. But the fouling formation on surfaces of plates can lead to energy losses, additional power consumption and the costs of cleaning. This practical operational problem is a significant challenge in the progression towards sustainable development.

The traditional two approaches to account for fouling in heat exchanger design are (1) to increase heat transfer surface by employing fixed fouling thermal resistance or (2) by introducing margin for heat transfer surface area. However the reliable data on fouling factors for different streams in PHEs are limited and both approaches can lead to significant errors in estimation of required heat transfer area in PHE, the increase of which can lead to lower flow velocities and higher fouling tendencies. The method of PHE based on the mathematical model accounting for local process parameters distribution along heat transfer surface is proposed. It is incorporating earlier developed fouling model (Arsenyeva et al., 2013). It requires the data of fouling monitoring for any heat exchanger working with considered streams to identify model parameters. Having these data the method can be used for design of new PHEs or for retrofitting the existing PHEs on considered enterprise for optimal performance.

The applicability of the method is demonstrated with a case study for PHE working in food industry application. The PHE (290 plates) with heat transfer area 259.2 m² was initially designed to heat glucose solution by another stream of glucose solution coming with 140 °C. The heavy fouling was observed, which required cleaning after one week of operation due to drop in heat transfer load and increase in pressure drop up to 1 bar. The redesigning of PHE with the proposed method has shown the possibility to decrease

heat transfer area to 137.7m² (155 plates) of the PHE by rearranging plates with different corrugation geometry and reducing their number on the same frame. The monitoring of PHE performance during one year of operation have shown that the same drop in heat transfer load and increase in pressure drop was observed only after a month of operation, the cleaning during that period was not required. It has reduced the capital cost of PHE, operating cost for cleaning and prolonged the service life time of rubber gaskets. The case study demonstrated the ability of the proposed method of PHE design to optimise the PHE performance with proper selection of PHE plates and complete use of available pressure drop to mitigate fouling formation.

carla.pinheiro@tecnico.ulisboa.pt

Abstract

The present work focuses on one of the more promising new post-combustion technologies using calcium-based materials, known as the “Ca-looping cycle” process, which endeavors to scrub CO₂ from flue gases and syngases by using natural lime-based sorbents and which appears to potentially offer limited CO₂ capture costs. So, the major driving force is to improve overall efficiency, reduce the cost, and minimize adverse environmental impacts of post-combustion Ca-looping cycle CO₂ capture, as compared to more conventional technologies (e.g., amine-based solvent scrubbing). There is a large energy penalty with amine scrubbing, the closest to market technology.

The main objective of this work is to develop a first principles model to simulate different natural sorbents looping cycle performance in a fixed bed reactor laboratory scale system.

A rigorous non-linear dynamic model of the looping cycle process was developed in gPROMS, based on the multiscale concept. The multiscale modeling is an emerging technique, where the characteristic length for each phenomena that occurs is taken into consideration, leading to a set of submodels with different scale lengths. These submodels when coupled together allow the simulation of a macrosystem (Hangos and Cameron, 2001). After the identification of the characteristic dimensions involved in the models, the first step is the development of a single particle model, which takes into account the energy and material transport, undergoing reactions (carbonation and calcination) and structural changes inside the particle. The material and heat transport inside the particle take into account the structural changes. Detailed models of single particle undergoing cycles of calcination and carbonation are developed. An improved decay approach is introduced in the model for those sorbents exhibiting carbonation decay with the number of cycles. The experimental characterization of the samples gave vital information on the physicochemical changes occurring during testing that need to be described in the model in the carbonation decay function. The conversion decay does not only depend on the number of cycles, but also on the conditions of the previous cycles, temperature, pressure, gas phase composition and characteristics of the material used for the carbonation. Model parameters are estimated from experimental results obtained for different sorbents tested (Santos et al., 2012)(Pinheiro et al., 2016). Several simulations for different sorbents and operating conditions were performed and the

model was validated with experimental data obtained in a fixed bed reactor. It was also important to ensure that the model is numerically stable within a large range of values.

Good modelling practice for process engineering: pitfalls and requirements to develop fit for purpose models

Ingmar Nopens^a

^a*Ghent University, BIOMATH – Department of data analysis and mathematical modelling, Coupure Links 653, 9000 Gent, BE*

ingmar.nopens@ugent.be

Abstract

Many process industries are yearning for more detailed process knowledge mainly envisioning process optimization, both in terms of operation and design. Most processes are complex in nature (physical-chemical and kinetic processes involving multiple phases and in a heterogeneous environment due to process scale) and cannot be optimized using experimentation only. The last decades have proven that mathematical models are powerful tools to achieve this goal. However, many physical-based modelling frameworks of different levels of complexity are at hand and many pitfalls exist in the model building process. It is therefore crucial that Good Modelling Practice (GMP) is applied in any modelling study in order to get the most out of models, i.e. ensuring they are reliable and have a sufficient predictive power. This is crucial to convince people that models are a necessity for any process optimization and worth investing in. Consecutive steps in a model building exercise according to GMP are: objective definition, state of the art, experimental data collection (including optimal experimental design-OED), framework definition, parameter estimation and model selection and model validation.

Within GMP, the goal or objective is probably the most important decision as it significantly impacts the subsequent steps such as the framework choice and data collection. In many cases the objective is process optimization, either at unit process level (operational and design) or at process train level (mostly operational). In any case, a model for optimization should have a sufficient predictive power if one wants to use it in decision making, which means it should be validated up to a certain accuracy level (defined in the objective). The latter is not yet common practice for a variety of reasons: insufficient data quality and/or quantity, lack of availability of tools to verify calibration quality, model overparameterisation, insufficient model complexity. In most cases, this leads to uncertainties in inputs and parameters that result in model output uncertainty. One should therefore strive for this as part of the modelling exercise and be self-critical about the real usefulness of a model rather than being pleased by calling a model prediction “quite good”.

The uncertainties mentioned are mostly related to insufficient process knowledge. In order to increase process knowledge, one needs to move to more complex models that aim to describe processes in more detail (e.g. CFD, PBM, DEM). This comes at a significant cost as it requires significantly higher computational effort as well as more tedious data collection. Probably the latter is even most often the problem and is a clear

point of attention. Another issue is the fact that many model analysis tools such as sensitivity analysis, global optimization, uncertainty analysis and optimal experimental design require a vast number of model simulations which become hard or even impossible when model structures are too complex. The avenue to go here is to translate the obtained knowledge at the complex model scale to models at intermediate complexity scale such as compartmental models (CM). Those models should be less uncertain given the extra knowledge they contain which will reflect in less need for calibration and, hence, a higher predictive power yielding better decisions for operational optimization. When it comes to design optimization, the developed complex models are now a good reference to evaluate where improvement is possible. However, using these models is also not straightforward as they are computationally intensive and there is a myriad of options to alter a design. There is clearly a need for a sound methodology that could also be based on CMs. Alternatively, we need to investigate scale-up vs numbering up and think out of the box.

In this contribution I would like to touch on some of these aspects by means of examples.

Abstract

Recently, we developed an approach for the efficient simulation of packed bed adsorbers accounting for equilibrium models with any kind of implicit adsorption isotherm. Application was demonstrated for stoichiometric ion exchange with constant solution normality (Fechtner and Kienle, 2017) and later on for the ideal adsorbed solution theory (Fechtner and Kienle, 2018). In this paper, the extension to stoichiometric ion exchange with variable solution normality and its application to salt gradient elution is presented. Further, the approach is also extended to the steric mass action law, which is frequently applied to protein separation.

Keywords: Adsorption, Differential algebraic systems, Stoichiometric ion exchange, Steric mass action law, Protein separation

1. Introduction

Mathematical modeling of spatially distributed packed bed adsorbers leads to systems of partial differential equations. An important class of models assume thermodynamic equilibrium between the fluid and the solid phase (Rhee et al., 1986, 1989). Besides explicit isotherms also implicit formulations are quite common to describe the adsorption equilibrium. Typical examples are stoichiometric ion exchange (Tondeur, 1969; Helfferich and Klein, 1970) and the ideal as well as real adsorbed solution theory approaches (Ruthven, 1984). These are computationally much more difficult to treat due to the implicit phase equilibrium. Usually some challenging implicit analytical or numerical differentiation of the equilibrium relations is required to calculate the capacity matrix of the model equations (Kaczmarski and Antos, 1999; Landa et al., 2013). Recently, we developed an approach for the efficient simulation of packed bed adsorbers with implicit adsorption isotherms (Fechtner

parameter	value	description
L [m]	5.0	column length
N_z [-]	1000	number of grid points
v [$\frac{m}{s}$]	1.0	interstitial velocity
ε [-]	0.5	void fraction
q_{tot} [$\frac{mol}{T}$]	2.0	exchanger capacity
K_{13} [-]	8.0	equilibrium constant
K_{23} [-]	1.905	equilibrium constant

v_2 [-]	1	stoichiometric factor
v_3 [-]	1	stoichiometric factor

Table 1: Parameters of the step gradient example.

and Kienle, 2017). The resulting system of partial differential and algebraic implicit equations is reformulated such that explicit differentiation of the isotherm is avoided. Using the method of lines (Schiesser, 1991), the resulting differential algebraic equations (DAE) can be solved simultaneously using standard software. Application was demonstrated for stoichiometric ion exchange with constant solution normality. In this paper, the extension to systems with variable solution normality is presented. This extension allows to consider a large variety of additional processes like salt gradient elution and / or protein separation (Carta and Jungbauer, 2010). In the present paper, application to step gradient elution (Karkov et al., 2013) with stoichiometric ion exchange and linear gradient elution (Gallant et al., 1995) with steric mass action law (Brooks and Cramer, 1992) for protein separation is demonstrated.

2. Modeling

2.1. Adsorber dynamics

In this paper focus is on the equilibrium dispersive model to describe the dynamics of a fixed bed adsorber (Guiochon and Lin, 2003). All dispersive effects that cause band broadening are lumped together in a single parameter, namely the apparent dispersion coefficient D_a . The model exploits a set of simplifying assumptions that are justified for many different applications (Guiochon et al., 2006). This set includes isothermal operation, thermodynamic equilibrium between solid and fluid phase, a constant mobile phase velocity u as well as a constant void fraction ε . Thus, the adsorber dynamics accounting for N adsorbable components with fluid phase concentration \mathbf{c} and solid phase concentration \mathbf{q} , respectively, are described by the following system of N partial differential equations (PDEs)

$$F \frac{\partial \mathbf{q}(\mathbf{c})}{\partial t} + \frac{\partial \mathbf{c}}{\partial t} + u \frac{\partial \mathbf{c}}{\partial z} = D_a \frac{\partial^2 \mathbf{c}}{\partial z^2}, \quad \mathbf{c}, \mathbf{q} \in \mathbb{R}^N, \quad (1)$$

with time t and spatial coordinate z . Parameter $F = \frac{1-\varepsilon}{\varepsilon}$ denotes the volumetric phase ratio. For constant solution normality only $N - 1$ equations are required. In contrast to this for variable solution normality an additional material balance has to be taken into account. For the solution of Eq. (1), further N boundary conditions $\mathbf{c}(z = 0, t) = \mathbf{c}_{feed}(t)$ and initial conditions $\mathbf{c}(z, t = 0) = \mathbf{c}_{init}(z)$ as well as the adsorption isotherm model represented by $\mathbf{q}(\mathbf{c})$ are required.

2.2. Mass action laws

In ion exchange chromatography, the stoichiometric ion exchange is a classical problem formulation, which has been treated first by Tondeur (1969) and Helfferich and Klein (1970). The corresponding mass action law

$$K_{iN} = \left(\frac{q_i}{c_i} \right)^{v_i} \left(\frac{c_N}{q_N} \right)^{v_N} = const, \quad \forall i \in \{1, \dots, N-1\}, \quad (2)$$

Figure 1: Chromatographic cycle with constant solution normality $c_{tot} = 1 \frac{mol}{l}$.

is also valid for formulation with variable solution since the N -th algebraic relation is defined by the constant exchanger capacity

$$q_{tot} = \sum_{i=1}^N \frac{q_i}{\nu_i} = const. \quad (3)$$

and does not require a constant solution normality. Parameters K are the equilibrium constants of the ideal mass action law, and the ν variables denote the reciprocal valences of the ionic species.

Protein separation can also be realized through ion exchange chromatography (Carta and Jungbauer, 2010). In this case, the equilibrium relation can be expressed by the steric mass action (SMA) law (Brooks and Cramer, 1992), which can be summarized by the following algebraic equations

$$K_{iN} = \left(\frac{q_i}{c_i}\right)^{\mu_i} \left(\frac{c_N}{q_N}\right)^{\mu_N} = const, \quad \forall i \in \{1, \dots, N-1\}, \quad (4)$$

$$q_{tot} = \sum_{i=1}^N \frac{1 + p_i \mu_i}{\mu_i} q_i = const. \quad (5)$$

Eq. (4) has the same structure as (2), but therein the $\mu \in \mathbb{R}_+$ denote the reciprocals of characteristic charges of the proteins with μ_N being typically the only ionic charge related to the salt. For classical SMA, $\mu_N = 1$ is assumed. The feature of the SMA is given by the steric factors p_i that account for the steric hindrance of the proteins. This hindrance is based on the assumption that large adsorbed proteins block a certain amount of the active surface of the ion exchanger. Accordingly, for the salt, $p_N = 0$ applies.

3. Simulation

Since the adsorber dynamics are based on the equilibrium dispersive model, and the algebraic equations (2,3) as well as (4,5) can be easily rewritten into the form

$$\mathbf{0} = \mathbf{f}(\mathbf{q}, \mathbf{c}), \quad (6)$$

the methodology presented in Fechtner and Kienle (2017) can be also applied here. In particular, we introduce the joint capacity

$$\mathbf{v} = \mathbf{c} + F\mathbf{q}, \quad (7)$$

to avoid explicit differentiation of the adsorption isotherms. For simplicity, axial dispersion is neglected here in a first step. This allows us to rewrite the PDAE system (1,6) into the general form

$$\mathbf{0} = \frac{\partial \mathbf{v}}{\partial t} + u \frac{\partial \mathbf{c}}{\partial z}, \quad \mathbf{c}, \mathbf{v} \in \mathbb{R}^N \quad (8)$$

$$\mathbf{0} = \mathbf{f}(\mathbf{q} = \frac{\mathbf{v} - \mathbf{c}}{F}, \mathbf{c}). \quad (9)$$

Figure 2: Hodograph for chromatographic cycle with $c_{tot} = 1 \frac{mol}{l}$ including numerical concentration profile (green and orange).

A corresponding DAE system is obtained from (8,9) by applying the method of lines (Schuesser, 1991). Resulting ODEs from (8) and the AEs (9) can be solved simultaneously for \mathbf{v} and \mathbf{c} using standard DAE numerics such as DASSL (Brenan et al., 1989), LIMEX (Deuffhard et al., 1987), or ODE15s (The MathWorks, 2016). In the present paper the latter is used. For demonstration purposes, simple spatial discretization is realized through first order backward differences on an equidistant grid. However, application of more advanced discretization techniques (LeVeque, 1992) is straight forward. Step gradient as well as linear gradient elution use typically piecewise initial conditions based on an equilibrated column. Hence, consistent initial conditions for the initialization of the DAE numerics can be easily obtained offline by solving (9) once for given $\mathbf{c}_{init}(z)$. Compared to the approach in Fechtner and Kienle (2017), a PDE corresponding to an arbitrary component 'i' in (8) can be replaced by the PDE for the total solution normality $c_{tot} = \sum_{i=1}^N \frac{c_i}{v_i}$, which can be easily derived using the adsorber dynamics (1) together with (3) or (5)

$$\frac{\partial c_{tot}}{\partial t} + u \frac{\partial c_{tot}}{\partial z} = \mathbf{0}. \quad (10)$$

For simulation purposes, either the total material balance (7) in combination with $N - 1$ component material balances or alternatively N component material balances can be used. Computational times are similar in both cases. Since Eq. (7) is linear, it also can be solved separately with an analytical approach, which is then used afterwards for the numerical solution of the remaining component material balances. However, effect of such an analytical approach on computational costs for the overall solution is small. Additionally, its implementation is much more involved. Therefore, simultaneous numerical solution of Eq. (1) is done in the remainder.

4. Applications

4.1. Step gradient elution

The first application is to step salt gradient elution with stoichiometric ion exchange. Focus is on the extension of the numerical approach to systems with variable solution normality. The associated additional degree of freedom allows to change one component in order to improve the ad-/desorption of the other components. For this purpose, a ternary example is considered where the component with the lowest affinity is used to specifically affect the adsorption of the other two components. Corresponding parameters can be found in Tab. 1. Two different chromatographic cycles are considered.

First, the column is equilibrated with $1 \frac{\text{mol}}{\text{l}}$ salt (c_3), i.e. $\mathbf{c}_{init} = [0, 0, 1]^T$. The feed composition is set to $\mathbf{c}_{feed} = [0.2, 0.8, 0.1]^T$ for the loading step and is maintained for 50 s. Afterwards, the feed is changed back to $\mathbf{c}_{feed} = [0, 0, 0.1]^T$ for the regeneration of the other two components. As a result, the solution normality $c_{tot} = \sum_{i=1}^N \frac{c_i}{v_i}$ with v_i according to Tab. 1 is kept constant during the complete cycle. Corresponding simulation results can be found in Fig. 1. The numerical solution in Fig. 1 is validated with theoretical prediction from equilibrium theory in Fig. 2 (Fechtner and Kienle, 2017; Mazzotti and Rajendran, 2013).

For the second chromatographic cycle, the initial condition of the column is $\mathbf{c}_{init} = [0, 0, 0.1]^T$, again, containing salt (c_3) only. The same feed $\mathbf{c}_{feed} = [0.2, 0.8, 0.1]^T$ as in the first cycle is

Figure 3: Chromatographic cycle with constant $0.1 \frac{\text{mol}}{\text{l}}$ salt but variable solution normality.

used also here for the loading step. After 50 s the feed is changed to $\mathbf{c}_{feed} = [0, 0, 0.1]^T$ for the regeneration keeping the salt concentration c_3 constant but not the total solution normality. Simulation results can be seen in Fig. 3.

Comparing Figures 1 and 3, the following can be observed. The first chromatographic cycle consists of four transition in total, two shocks during the loading step and two rarefaction waves during the regeneration, which is in agreement with Fig. 2. The second chromatographic cycle, however, consists of six transitions in total. Here, the loading step consists of a contact discontinuity and two shocks, while the regeneration consists of a contact discontinuity followed by a shock and afterwards a rarefaction wave. The following can be deduced from these observations. The variable solution normality in the second chromatographic cycle increases the number of transitions. In particular it allows for two contact discontinuities at 5 s and 55 s in Fig. 3 with a change of the solution normality c_{tot} . This was already deduced from Eq. (10). Furthermore, the variable solution normality also changes the type of one of the transitions in the regeneration step from rarefaction wave (first cycle at 60 s) to a shock (second cycle at 105 s). A more detailed theoretical investigation revealed a selectivity reversal, which is not present for constant solution normality as in the first example (see Fig 2 without reversed direction on neither blue nor red curves). The last fact is supported by Fig. 2, which shows clearly no selectivity reversal. Finally, the first cycle is much shorter with approximately 80 s compared to the second cycle with approximately 250 s. The reason is obviously the significantly different regeneration behavior. In the first cycle the regeneration uses an increased salt concentration by the factor of ten, while the salt concentration is kept constant for the second cycle. The example demonstrates, how the present approach can be used to study systematically the effect of step salt gradients on separation performance. Furthermore, it could also be used to optimize the separation, which however is beyond the scope of the present paper.

4.2. Linear gradient elution

The second application is concerned with linear gradient elution with steric mass action law. It demonstrates the applicability of the numerical approach to feed conditions that are not piecewise constant. A quaternary example, which is taken from Gallant et al. (1995) with parameters in Tab. 2, is considered. The objective of this example is the separation of three proteins. For this purpose, a column is equilibrated with 30 mM of the salt (NaCl). A feed is injected containing 30 mM sodium and 0.2 mM of each protein (chymotrypsinogen A, cytochrome c, lysozyme) for 254.47 s. The feed is then changed to contain sodium only. In addition to the 30 mM NaCl, a linear gradient of $0.19649 \frac{mM}{s}$ further increases its feed concentration over time. The separation result is shown in Fig. 4. Comparison with Fig. 1b in Gallant et al. (1995) shows good agreement of our simulation results and verifies the extension of the presented numerical approach to protein separation based on the steric mass action law.

Figure 4: Protein separation with linear salt gradient $0.19649 \frac{mM}{s}$.

5. Conclusion

In this paper, the numerical approach for implicit adsorption isotherms presented in Fechtner and Kienle (2017) was successfully extended to applications with variable solution normality and vari-

able feed conditions. Again, the system of partial differential and algebraic implicit equations is reformulated such that explicit differentiation of the isotherm is avoided. Using the method of lines, the resulting DAEs can be solved simultaneously using standard software. In particular, the applicability to step and linear gradient elution, which are standard process operations for bio separations, were demonstrated. Further, some additional features of Riemann experiments with variable solution normality were observed, namely the occurrence of contact discontinuities and the associated existence of selectivity reversals. A detailed discussion with equilibrium theory was beyond the scope of the present paper and will be the subject of future work.

Virtual splitting of shared resource networks for price-based coordination with portfolio tariffs

Simon Wenzel^{a,*}, Lukas Samuel Maxeiner^a and Sebastian Engell^a

Abstract

In the process industries, the optimal allocation of shared resources among physically coupled units or plants is key to an efficient operation of the overall site. If the units or plants have a certain degree of autonomy or it is desired to preserve confidentiality of the detailed operation and performance of the plants, price-based coordination can be employed where an independent system operator (ISO) iteratively adjusts transfer prices for the shared resources until the demand and the supply match, i. e., the shared resource networks are balanced. In this contribution, a modified subgradient price update scheme is presented, which can be used for systems that are connected to external resources, e. g., via pipelines, so that certain amounts of these resources can be exchanged at prices that are fixed in portfolio tariffs. The approach virtually splits the shared resource networks to account for the different price regimes in the available tariff. The principle is illustrated in a simulation study of a production site with three production plants that are connected to an external distribution grid.

Keywords: Demand-side response; Price-based coordination; Lagrangian decomposition; Resource allocation; Resource efficiency; Energy tariffs

1. Introduction

Increasing the efficiency and sustainability in the process industries is not only beneficial with respect to plant economics, but also necessary to fulfill environmental regulations from the government (Sirola and Edgar, 2012). One important handle is the time-varying optimal allocation of shared resources such as electricity, steam at different pressure levels, heating gas, or intermediates in a system. Distributed price-based optimization techniques based on Lagrangian relaxation or ADMM (Boyd, 2010) can be used to determine the optimal allocation of shared resources in systems of systems that consist of physically coupled subsystems, while preserving a certain level of autonomy and confidentiality (Wenzel et al., 2016). Large production sites in the process industries that consist of many production plants—possibly belonging to different business units or companies are examples of such systems of systems (Engell and Sonntag, 2016). In addition to the side-wide networks, there are usually connections to external (smart) grids (Samad and Kiliccote, 2012) as illustrated in Figure 1, through which resources can be bought or sold. This can be managed by grid tariffs that range from simple to highly sophisticated constructs (Braithwait, 2010) (e.g., see Figure 2). Especially, when there is shortage or surplus of the shared resources in the networks, price-based coordination algorithms lead to transfer prices that can exceed or be below the market prices of the external resources by far. Thus, it is beneficial for the site to buy or sell certain amounts of resources externally to cope with such shortage or surplus.

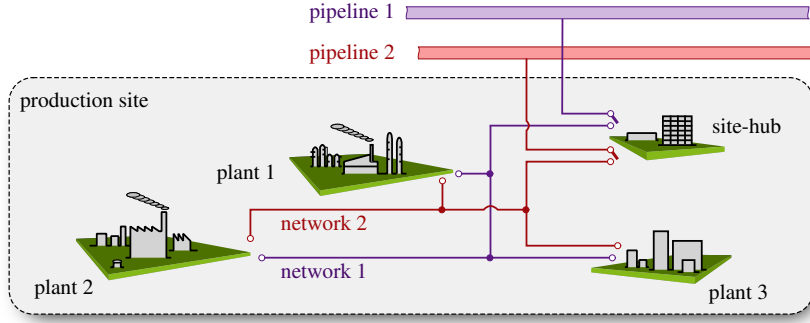

Figure 1: Site-wide optimization problem with external pipeline connections.

In this contribution, we study such a situation and propose a price-based coordination scheme that is aware of the portfolio tariffs for the external pipeline systems or grids. The networks for the shared resources on site are virtually split according to the contract structure and the coordinating entity on site can decide to buy or sell certain amounts of shared resources. We illustrate the principle of the coordinator update by a simulation study using three production plants that are internally connected by two networks on site and externally connected to two pipelines for which a portfolio tariff with three different price regimes has been negotiated. The rest of the paper is structured as follows: First, the site-wide optimization problem is stated. Then the modeling of the virtual networks for the price-based coordination in the presence of portfolio tariffs is introduced. A tariff-aware coordinator update is proposed and tested in a simulation study and finally a brief outlook on future research is given.

2. Problem description

The topology of an industrial production site that consists of (partially) autonomous subsystems (plants) that are physically connected by networks for shared resources is depicted in Figure 1. The internal networks are connected to the pipelines via the site hub. The site-hub manages a surplus of demand or supply of a particular resource by buying or selling resources. This resource allocation in the presence of different price regimes can be formulated as an optimization problem. It is assumed that the site-hub can acquire limited amounts of shared resources at different rates. A possible tariff structure that reflects the amounts and prices that are available from the pipeline is shown in Figure 2. The optimization problem of the site can be formulated as follows

$$\max_{\mathbf{u}_i, \mathbf{r}_i, \forall i} \sum_{i=1}^n \mathbf{p}_{i,\text{prod.}}^\top \mathbf{y}_i - \mathbb{1}^{(1 \times m)} (\mathbf{P} \circ \mathbf{R}_P) \mathbb{1}^{(s \times 1)}, \quad (1a)$$

$$\text{s. t. } \sum_{i=1}^n \mathbf{r}_i - \mathbf{R}_P \mathbb{1}^{(s \times 1)} = \mathbf{0}, \quad \mathbf{R}_P \in \mathcal{R}_P, \quad (1b)$$

$$\mathcal{F}_i(\mathbf{u}_i, \mathbf{r}_i) := \{\mathbf{u}_i, \mathbf{r}_i | \mathbf{y}_i = \mathbf{f}_i(\mathbf{u}_i), \mathbf{r}_i = \mathbf{g}_i(\mathbf{u}_i, \mathbf{y}_i), \mathbf{u}_i \in \mathcal{U}_i\}, \forall i, \quad (1c)$$

where it is assumed that the site strives for a maximization of the sum of the individual objectives (here, product sales $\mathbf{p}_{i,\text{prod.}}^\top \mathbf{y}_i$) under the consideration of the additional costs or benefits that are caused by interfacing the pipelines with the constrained resource amounts given in \mathbf{R}_P . We denote $\mathbf{A} \circ \mathbf{B}$ as the Hadamard product (element-wise multiplication) and $\mathbb{1}^{(s \times 1)}$ as a column vector with s identity entries. The matrix $\mathbf{P} \in \mathbb{R}^{(m \times s)}$ contains the individual prices for m resources and s price regimes in the tariff (cf. Figure 2) and $\mathbf{R}_P \in \mathbb{R}^{(m \times s)}$ is the amount of resources that is exchanged with the pipelines for each resource at each price. The overall costs

Figure 2: Portfolio tariff with different price regimes.

or benefits are then computed as $\mathbf{P} \circ \mathbf{R}_p$. The constraints are on the one hand the network balance Eq. (1b), which should be closed at any time and on the other hand the individual constraint sets \mathcal{F}_i for each subsystem $i = 1, 2, \dots, n$ that result from technical limitations. In the site-wide formulation, the contribution of the subsystem i to the network balance is given by a vector $\mathbf{r}_i \in \mathbb{R}^{(m \times 1)}$ that indicates the demand or supply, which is computed based on a tariff-independent model and where positive numbers indicate demands and negative numbers supplies. If the optimization problem is decomposed by Lagrangian relaxation to set up a price-based coordination algorithm (Bertsekas and Tsitsiklis, 1997), a single vector of Lagrange multipliers with a single multiplier for each resource is not sufficient, since the site-hub can buy and sell resources at different rates depending on the amount that is taken from or sent to the pipelines. This leads to the following modeling approach.

3. Virtual splitting of the networks on the subsystem level

A standard Lagrangian relaxation of the problem stated in Eq. (1) can be written as the following optimization problem that needs to be solved by each subsystem i

$$\max_{\mathbf{u}_i, \mathbf{r}_i} \mathbf{p}_{i,\text{prod}}^\top \mathbf{y}_i - \boldsymbol{\lambda}^\top \mathbf{r}_i, \quad (2a)$$

$$\text{s. t. } \mathcal{F}_i(\mathbf{u}_i, \mathbf{r}_i), \quad (2b)$$

where $\boldsymbol{\lambda}$ is the vector of Lagrange multipliers, which can be interpreted as the vector of prices that are associated with the demand or supply of the shared resources given by \mathbf{r}_i that depends on the degrees of freedom \mathbf{u}_i . To account for different price regimes in the portfolio contract, the constraints of the individual systems have to be extended. To model the different price regimes in a tariff, the networks can be split into *virtual networks*, i. e., each of the m resource networks is split into s virtual networks of the same resource. Here, without the loss of generality, we assume that for each resource s price regimes exist. This results in the following formulation ($r_{i,j,l} \in \mathbb{R}$)

$$\mathbf{r}_i = \begin{pmatrix} r_{i,1} \\ \vdots \\ r_{i,m} \end{pmatrix} = \begin{pmatrix} \sum_{l=1}^s r_{i,1,l} \\ \vdots \\ \sum_{l=1}^s r_{i,m,l} \end{pmatrix} = \mathbf{R}_i \mathbf{1}^{(s \times 1)} = \begin{pmatrix} r_{i,1,1} & \cdots & r_{i,1,s} \\ \vdots & \ddots & \vdots \\ r_{i,m,1} & \cdots & r_{i,m,s} \end{pmatrix} \mathbf{1}^{(s \times 1)}. \quad (3)$$

The optimization problems for each subsystem are changed such that for each resource j only one virtual network is allowed to be active. This is realized by a constraint adaptation, announced by the site-coordinator. The reasoning behind this is as follows: If the internal price of a shared resource exceeds the next higher external price (pipeline price in the tariff), the coordinator buys an amount of resource from the pipeline and allocates it to the internal shared resource network. From this point in time on, the subsystems that demanded shared resources receive an allocated amount of resource for the particular network. Afterwards, the

amount they received is fixed and the cost is stored at the rate of the pipeline price. The next virtual network is activated for the next price coordination round. The reformulation involves the following constraint adaptation, where the resources from the preceding price regimes ($t_j - 1$, with \mathbf{t} as a vector storing the index of active price regimes $(1, 2, \dots, s)$ for each resource j) are frozen and the succeeding virtual networks, i. e., for $t_j < l$, are set to zero

$$r_{i,j,l} \in \mathcal{R}_{i,j,l}^{(\mathbf{t})}, \quad \mathcal{R}_{i,j,l}^{(\mathbf{t})} = \begin{cases} \mathbb{R} & t_j = l \\ 0 & l > t_j, \\ \hat{r}_{i,j,l} & \text{else} \end{cases} \quad (4)$$

where $\hat{r}_{i,j,l}$ is the amount of the resource that has been bought during the last price regime by the coordinator and that has been assigned proportionally to the demanded amount of every subsystem. Further, the modeling involves the matrix $\mathbf{F}^{(\mathbf{t})}$, $f_{j,l} \in [0, 1]$, which activates the respective virtual networks. The optimization problems for the subsystems are changed to

$$\begin{aligned} \max_{\mathbf{u}_i, \mathbf{R}_i, \forall i} \quad & \mathbf{p}_{i,\text{prod}}^\top \mathbf{y}_i - \mathbf{1}^{(1 \times m)} (\mathbf{\Lambda} \circ \mathbf{R}_i) \mathbf{1}^{(s \times 1)} & (5a) \\ \text{s. t.} \quad & \left. \begin{aligned} & \mathcal{F}_i(\mathbf{u}_i, \mathbf{r}_i), \\ & \mathbf{r}_i - \mathbf{R}_i \mathbf{F}^{(\mathbf{t})} \mathbf{1}^{(s \times 1)} = \mathbf{0} \\ & r_{i,j,l} \in \mathcal{R}_{i,j,l}^{(\mathbf{t})}, \forall j, l \end{aligned} \right\} \text{individual constraints,} & (5b) \end{aligned}$$

where the manipulated variables of the subsystem are the vector \mathbf{u}_i and the matrix \mathbf{R}_i . The vector of Lagrange multipliers $\boldsymbol{\lambda}$ is extended to the matrix of prices $\mathbf{\Lambda} \in \mathbb{R}^{(m \times s)}$.

4. Proposed coordination scheme

The proposed update scheme is formulated for buying resources only. The formulation for selling resources to external resources can be formulated analogously. The proposed coordination scheme receives the planned amounts of consumed and produced shared resources from the subsystems as input (see Algorithm 1). After a convergence check, the network balance is evaluated and it is checked whether the Euclidean norm of the balance is below a threshold ε . The coordinator evaluates whether one of the internal prices exceeds the next higher pipeline price that is offered to buy additional quantities of resources. If the coordinator decides to buy additional resources at the pipeline price, the subsystems are queried again for the exact pipeline price, since $\boldsymbol{\Lambda}_{j,t_j}$ can be higher than the pipeline price \mathbf{P}_{j,t_j} , before the bought amount is assigned to the subsystems. The assigned quantities are calculated based on the demands of the receiving plants only, i. e., a producing plant is not assigned any resource. If the internal price is lower than the next higher price in the tariff, a normal subgradient update is performed. Whenever the coordinator buys an amount for a specific network, the virtual networks that are linked to the lower-priced tariff regimes are “frozen”, i. e., the Lagrange multipliers in $\mathbf{\Lambda}$ and the received quantities $r_{i,j,l}$ are fixed (see constraint in (4)).

5. Case study

The optimization problem is given in Eq. (5). The manipulated variables of each plant are limited to lie between 0 and 1 (lower and upper bound on the load). The numerical values for

```

the tariff are given in Figure 2. The model equations for the three plants are:

$$\mathbf{f}_1(\mathbf{u}_1) = \begin{bmatrix} 32u_{1,1}^2 + 8u_{1,1} \\ 24u_{1,2}^2 + 3u_{1,2} \end{bmatrix}, \mathbf{g}_1(\mathbf{u}_1) = \begin{bmatrix} 60u_{1,1} + 20 \\ 40u_{1,2} + 35 \end{bmatrix}, \mathbf{p}_{1,prod.} = \begin{bmatrix} 5.4 \\ 2.1 \end{bmatrix}, \quad (6a)$$

$$\mathbf{f}_2(\mathbf{u}_2) = \begin{bmatrix} 35u_{2,1}^2 + 15u_{2,1} \\ 37u_{2,2}^2 + 10u_{2,2} \end{bmatrix}, \mathbf{g}_2(\mathbf{u}_2) = \begin{bmatrix} 50u_{2,1} + 10 \\ 45u_{2,2} + 2 \end{bmatrix}, \mathbf{p}_{2,prod.} = \begin{bmatrix} 1.5 \\ 2.6 \end{bmatrix}, \quad (6b)$$

$$\mathbf{f}_3(\mathbf{u}_3) = \begin{bmatrix} 25u_{3,1} + 15 \\ 30u_{3,2}^2 + 8 \end{bmatrix}, \mathbf{g}_3(\mathbf{u}_3) = \begin{bmatrix} -25u_{3,1} - 15 \\ -20u_{3,2} + 20 \end{bmatrix}, \mathbf{p}_{3,prod.} = \begin{bmatrix} 1.5 \\ 3.2 \end{bmatrix}. \quad (6c)$$

The results of the simulation study using Algorithm 1 with $s_{i,j=i} = 0.7, s_{i,j \neq i} = 0, s_{i,j} \in \mathbf{S}$ are shown in Figure 3 and Figure 4. It can be seen that when for a particular resource network the price-based coordination leads to a price that is higher than the next higher pipeline price (diamond symbols in Figure 3), the coordinator buys the necessary (less or equal to the available) amount from the pipeline for this price (see vertical bars in Figure 4). The network imbalance at these events is reduced until finally the network imbalance is below the threshold. Upon convergence of the algorithm the final cost a subsystem has to pay is the summation of the costs from each virtual network, i. e., the cost for a particular resource is determined from the amounts that are bought and received externally at different price regimes and the amount that is traded at the equilibrium price on site.

6. Conclusion and outlook

The problem of portfolio tariffs with different price regimes depending on the quantity of shared resource that is retrieved from the pipeline network has been studied and a price-based coordinator update that is aware of the tariff has been proposed. The simulation results show that the coordinator is able to react to the situation by buying optimal amounts of shared resources at fixed rates. The coordination strategy converges to a solution that is feasible for the two networks and that finds the equilibrium price by employing a subgradient-based update step for the investigated case study. The optimality of the found solution cannot be

Figure 3: Transfer prices against the number of iterations.

Figure 4: Network resource balance against the number of iterations.

ensured in general. However, the strength of the proposed approach is its transparency with respect to the different price regimes, i. e., each subsystem has consistent information how its overall cost function is computed. The advantage of price-based coordination is kept and thus, the individual cost functions remain private. Future research should be devoted to higher degrees of interactions between the different shared resource networks, which are usually coupled through the plant models, e. g., by a joint demand of steam and electricity.

Abstract

For distributed energy supply systems, reliability is important but still often neglected during design. We present a rigorous design approach which ensures the exact supply of all energy demands during the failure of one arbitrary component at any time. Since this $(n - 1)$ -reliable approach leads to high computational effort, we propose an alternative inexact approach with reduced computational effort. This so-called $(n - \max)$ -reliable approach also ensures sufficient energy supply but allows overproduction. An industrial real-world case study shows that both reliability approaches reduce both investment costs as well as total annualized costs significantly for a reliable design compared to current practical heuristics.

Keywords: Optimization, energy systems, synthesis problem, reliability, MILP

1. Introduction

For the design of distributed energy supply systems (DESS), mathematical optimization is a well suited tool (Frangopoulos et al., 2002). However, the resulting optimal design depends on many uncertainties. Uncertain input parameters, such as demand and price data, have been integrated into the optimal design using robust optimization approaches (e. g., based on Γ -robustness (Akbari et al., 2014) or strict robustness (Majewski et al., 2017)).

However, uncertainty also arises from the availability of energy components. Availability describes the probability that an item delivers its required function during a certain time period (Aguilar et al., 2008). Despite uncertain availability, DESS need to ensure high system reliability—the probability that a system is able to provide a required function. In practical applications, system reliability is often enhanced by installing additional units following rules of thumb (Aguilar et al., 2008). Such heuristics usually result in a sub-optimal design since the additional components are not part of the optimization. Thus, developing optimization approaches for reliability is an important task. In literature, the application of stochastic optimization approaches is popular to achieve reliable designs (e. g., Abdollahzadeh and Atashgar (2017); Andiappan and Ng (2016)). However, employing stochastic approaches cannot guarantee 100% security of energy supply since only probabilities are regarded in the optimization. To circumvent the dependence on probabilities, scenario-based approaches have been proposed (Caserta and Voß, 2015; Aguilar

et al., 2008). However, considering scenarios also cannot guarantee 100% reliable supply since selecting scenarios becomes crucial.

We present a rigorous approach which identifies 100% reliable designs for DESS: The so-called $(n-1)$ -reliable approach depends neither on the selection of failure scenarios nor on failure probabilities. The approach allows for failure of 1 arbitrary component at any time and thus ensures that all energy demands can still be covered exactly during failure of 1 component or maintenance. Since applying the $(n-1)$ -reliable approach increases the computational effort remarkably, we propose an inexact but computationally efficient approach: The $(n-max)$ -reliable approach ensures sufficient energy supply during the failure of 1 arbitrary component at any time while allowing overproduction.

2. Reliable design of distributed energy supply systems

Reliability of distributed energy supply systems (DESS) is crucial in practical applications to ensure security of energy supply and to enable maintenance of components. To illustrate our approach, we focus on reliable tri-generation systems covering heating, cooling, and electricity demands. In Section 2.1, we introduce the optimization problem for DESS without failure of components. In Section 2.2, two new reliability approaches are presented.

2.1. The nominal design model

The model of industrial DESS optimization is formulated as a mixed-integer linear program (MILP) (Voll et al., 2013). In the following, we call this model nominal. In the nominal model, no failure of components is taken into account; and thus, no reliability can be ensured. To optimize DESS, we choose the total annualized costs as objective function (Pintaric and Kravanja, 2006). Instead of the total annualized costs, any other objective function can be chosen since the proposed reliability approaches only affect the constraints, i. e., the energy balances:

$$\sum_{k \in K} \dot{V}_{kt} = \dot{E}_t \quad \forall t \in T. \quad (1)$$

Here, the supplied energy flow of component k is given by \dot{V}_{kt} ; K and T denote the set of all components k and all time steps t , respectively. \dot{E}_t represents the energy demand in time step t . In each time step t , the energy demand \dot{E}_t comprises the heating demand \dot{E}_t^h , cooling demand \dot{E}_t^c , and electricity demand \dot{E}_t^e . Here, the heating demand \dot{E}_t^h already includes the heating required for running absorption chillers AC , besides the heating demand of the considered industrial site $\dot{E}_t^{h,s}$:

$$\dot{E}_t^h = \dot{E}_t^{h,s} + \sum_{k \in AC} \dot{E}_{kt}^h. \quad (2)$$

2.2. An exact approach for $(n-1)$ -reliable design

The idea of the $(n-1)$ -reliable approach is adapted from electrical network planning where any component out of n components might fail at any time—but only 1 at the same time (Wiest et al., 2018). To obtain a reliable design based on this idea, we need additional energy balances to capture the potential failure of each component of the implemented system and the resulting lack in supply. Thus, every potentially failing component $k' \in K$ leads to a new set of energy balances:

$$\sum_{k \in K \setminus \{k'\}} \tilde{V}_{kt}^{k'} = \dot{E}_t \quad \forall t \in T \quad \forall k' \in K. \quad (3)$$

Here, we introduce new operation variables \tilde{V}_{kt}^k which specify the adapted output of component k in time step t if component k' fails. The new operation variables are determined such that the demands can still be covered exactly with the remaining components $K \setminus \{k'\}$. The number of additional constraints is proportional to the product of the number of time steps and potentially installed components which might result in high computational times. As a result, the $(n-1)$ -reliable approach might be unsuitable for large-scale design problems. Thus, as an alternative, we propose a computationally fast but inexact reliability approach.

2.3. $(n-max)$ -reliability: Optimal design ensuring sufficient energy supply

$(n-max)$ -reliability ensures sufficient energy supply during the failure of 1 arbitrary component at any time while allowing overproduction. If overproduction is allowed, only failure of the largest component has to be considered since a larger component can always replace a smaller component. Here, we focus on supplying heating demands \dot{E}_t^h and cooling demands \dot{E}_t^c since we assume that electricity demands can always be covered by the electricity grid. Instead of considering all occurring heating demands \dot{E}_t^h and cooling demands \dot{E}_t^c in each time step t , it is sufficient to consider only peak demands ($\dot{E}^{h,max}$ and $\dot{E}^{c,max}$, respectively). This is due to the fact that all inequalities including smaller demands are redundant if overproduction is allowed. As a result, we only obtain the additional inequalities

$$\sum_{k \in K^{h/c}} \dot{V}_k^N - \dot{V}_{K^{h/c}}^{max} \geq \dot{E}^{h/c,max} \quad (4)$$

where the set of all heating and all cooling components is given by K^h and by K^c , respectively. \dot{V}_k^N is the installed thermal power of component k and $\dot{V}_{K^{h/c}}^{max}$ represents the maximal deficit in energy (heating/cooling) supply for 1 failing component. The maximal heating and cooling deficit $\dot{V}_{K^{h/c}}^{max}$ is defined as the installed heating/cooling power of the largest component:

$$\dot{V}_{K^{h/c}}^{max} := \max \left\{ \dot{V}_k^N \mid k \in K^{h/c} \right\}. \quad (5)$$

The impact of a failing heating component on the cooling circuit is taken into account by considering the required heating of the absorption chillers AC in the heating demand \dot{E}_t^h (Eq. (2)).

Eq. (5) can be replaced by the following constraints in order to keep an MILP formulation:

$$\dot{V}_{K^h}^{max} \geq \dot{V}_k^N \quad \forall k \in K^h \quad (6)$$

$$\dot{V}_{K^c}^{max} \geq \dot{V}_k^N \quad \forall k \in K^c. \quad (7)$$

The number of additional constraints in Eq. (4), (6), and (7) depends on the number of potentially installed components $|K|$ but does not depend on the number of time steps $|T|$. Thus, the advantage of $(n-max)$ -reliability compared to $(n-1)$ -reliability is that the number of additional constraints is only proportional to the number of potentially installed components. Therefore, the expected increase in computational time is low compared to the nominal problem. Further details can be found in Hollermann et al. (2017).

3. Case Study

We consider a real-world example of an industrial park. The case study is based on a nominal design problem of a DESS published by Voll et al. (2013). All problems are implemented in GAMS 24.7.3 and solved with CPLEX 12.6.3.0 to machine accuracy on a computer with 64 GB RAM and 3.24 GHz employing 4 threads.

3.1. Description of the industrial real-world example

We consider an industrial park with time-varying heating, cooling, and electricity demands (Voll et al., 2013). Beside peak demands, we consider time-aggregated demands based on k -means aggregation with 5 time steps leading to a high accuracy for the full time series (Bahl et al., 2017). The cooling demands are supplied by two separated circuits (Site A and B) while the heating grid is connected. We assume that the industrial site is a “green field” with no existing components. However, the proposed approach can also be employed for the optimal retrofit of reliable DESS.

3.2. Reliable designs for the distributed energy supply system

To benchmark the approaches introduced in Section 2.2 and 2.3, we employ a rule of thumb for reliability from engineering practice: Based on the nominal optimal design, the largest component in each supply circuit is installed twice to ensure reliability of the DESS while allowing overproduction. We call this approach ($2 \times \max$)-reliability.

Computational times for calculating optimal solutions vary from less than 18 seconds for the calculation of the nominal, the ($2 \times \max$)-reliable, and the ($n - \max$)-reliable design up to 15 minutes for the calculation of the ($n - 1$)-reliable design.

The costs for the nominal problem without considering reliability aspects and the costs for the three reliability approaches are compared in Figure 1.

Figure 1: Total annualized costs TAC , operational costs $OPEX$, maintenance costs $MAINT$ and (annualized) investment costs $CAPEX^{(ann)}$ of the nominal problem (nom) and the reliability approaches

The total annualized costs for the ($2 \times \max$)-reliable design are the highest, 5.1% above the costs for the nominal design, whereas the total annualized costs for the ($n - \max$)-reliable design and the costs for the ($n - 1$)-reliable design are only 3.3% and 3.5% higher, respectively. The operational costs $OPEX$ are nearly identical for all approaches with only 2% variation around 5.20 Mio. €/y. Differences can be observed in the investment costs (Figure 1): The nominal design leads to 3.85 Mio. € investment costs; investment costs for the the ($2 \times \max$)-reliable design are 1.06 Mio. € higher which corresponds to an increase of 27.5%. In contrast, the ($n - \max$)-reliable design and the ($n - 1$)-reliable design involve only low additional investment costs compared to the nominal design, i. e., 0.77 Mio. € and 0.80 Mio. €, corresponding to an increase of 20.0% and 20.8%, respectively. Therefore, the ($n - \max$)-reliable approach and the ($n - 1$)-reliable approach save 35.4% and 32.5% of additional investment costs compared to the heuristic ($2 \times \max$)-reliable approach, respectively.

Figure 2: Installed components and their installed thermal capacities for each approach: components of nominal design (nom), of reliable designs ($2 \times max$), ($n - max$), and ($n - 1$) for each technology from left to right; B boiler, CHP combined heat and power engine, CC_A and CC_B compression chillers, and AC_A and AC_B absorption chillers installed on Site A and Site B, respectively

Despite high investment costs, the ($2 \times max$)-reliable design cannot cover the required demands exactly if one component fails and leads to overproduction of up to 55.5%. The ($n - max$)-reliable design comprises smaller and more components compared to the ($2 \times max$)-reliable design (Figure 2). But still, the ($n - max$)-reliable design might also lead to overproduction: If the smallest compression chiller on Site A (CC_A) fails, the minimal part load of the replacing compression chillers and absorption chillers (AC_A) is too high to cover the minimal cooling demand exactly. However, the resulting overproduction is only 83.7kW (= 13.8%) during one time step. This overproduction can be avoided by running 1 absorption chiller in part load with 17.6% of the nominal installed power instead of the allowed minimum of 20%. In emergencies, such a slight adaption or a slight overproduction for a short time will often be justifiable. For higher system flexibility, the ($n - 1$)-reliable design comprises even smaller and more absorption chillers on Site A. The results of the case study show that reliable design options can be identified at low additional costs with both proposed reliability approaches. However, there remains a trade-off between ($n - 1$)-reliability and ($n - max$)-reliability regarding solution quality and computational time.

4. Conclusions

In the design of distributed energy supply systems (DESS), reliability is crucial. We propose an exact approach to identify $(n - 1)$ -reliable designs for DESS. The approach does not require selection of scenarios or probabilities. Our approach ensures reliable energy supply during the failure of 1 arbitrary component at any time and thus also enables to maintain components at any time when no failure occurs simultaneously. However, the exact approach might involve high computational effort. For this reason, we propose an inexact but computationally efficient approach, called $(n - max)$ -reliability which ensures sufficient energy supply if 1 component fails but allows overproduction. An industrial real-world example shows that pragmatic heuristics from industry applications, such as installing redundant components by rules of thumb, lead to unnecessary high investment costs. Applying the proposed reliability approaches reduces the investment costs for a reliable design up to 35.4% compared to a pragmatic heuristic. The total annualized costs increase only by 3.5% compared to the original problem without considering reliability. Thus, our proposed reliability approaches identify reliable designs for distributed

energy supply systems at low additional costs. The exact $(n - 1)$ -reliable approach ensures reliability while $(n - \max)$ -reliability is easy to implement and identifies computationally efficiently an inexact but well-performing design.

Abstract

Given increasing urban population, environmental issues and limited natural resources, long-term planning of water supply systems driven by renewable energies is the only way towards affordable secure and sustainable water and energy future. In this context, daily surplus output from grid-connected rooftop photovoltaics (PVs) is a promising clean energy source to be considered in urban water-related energy mix. In this paper, we address the optimal strategic investment decisions of an urban desalination-based water supply system driven by grid electricity and surplus PVs output, considering real-time operational constraints. The model is formulated as a two-level mixed integer linear programming (MILP) problem. The real-time operational constraints associated with water production, storage and transfer are integrated with yearly planning constraints corresponding to desalination plants, storage tanks and pipeline capacities and locations. The optimal decisions are obtained such that the operation of the water supply system has the most compatibility with available renewable energy. The capabilities of the proposed model are tested through a case-study from north-western corridor of Perth, Western Australia.

Keywords: Desalination, rooftop photovoltaics, long-term planning, optimisation

1. Introduction

Urban areas are responsible for high level of water and energy consumptions as a result of being the centres of population and economic development. Supplying increasing urban water and energy demand given the diminishing natural resources and environmental concerns highlights the importance of an analytical long-term planning to address water security and clean energy.

In land-restricted cities located in arid regions, daily surplus output from residential grid-connected rooftop photovoltaics (PVs) is a clean energy source that can be potentially allocated to energy-intensive water supply technologies. This source of energy is the result of the mismatch between load and PV output during the day and due to its intermittency, is a limiting factor for connection of greater number of these systems to the existing electrical grid. Hence, using it for meeting the water-related electricity demand, not only aligns with the sustainable future water supply but can also enable higher level of PV installations in urban areas.

In our previous study (Vakilifard et al., 2017), we addressed the optimal operation of the urban desalination-based water supply system driven by grid electricity and surplus PV output such that it resulted in the highest compatibility with available renewable energy. In the current study, we extend the mathematical model to a long-term planning of such system and include more detailed modelling of some system components (such

as pipeline network) as well as detailed financial analysis of the water supply system. The model is formulated as a two-level mixed integer linear programming (MILP) problem combining yearly constraints of long-term planning of water supply system with real-time (hourly) operational constraints. Three tools of geographical information system (GIS), system advisor model (SAM) and Excel analysis are used to provide some of the main model parameters. Accordingly, while the discounted total cost of the water supply system is minimised, the model gives the optimal strategic investment decisions such as the capacities and locations of desalination plants, storage tanks and pipeline as well as optimal operational scheduling of the system including desalinated water production, storage and transfer, such that it has the most compatibility with available renewable energy. A case study from north-western corridor of Perth, Western Australia is then considered to show the application of the model.

2. Methodology

2.1. Problem statement

1. The temporal aspect of the problem is captured considering a planning horizon of 20 years (begins from 2017), two seasons of summer and winter and 24 time blocks representing hours of a day.
2. Four zones are considered in the case-study area using ArcGIS 10 and Excel tools. The zones boundaries were determined based on our previous study (Vakilifard et al., 2017). In each zone and time period, water demand is supplied by desalination-based water supply system. Considering the annual water demand and population growth rate, we used a simple unit loading method (Walski et al., 2003) to forecast water demand in each zone till the end of 20 years. We assumed the constant water demand during all hours of a day.
3. Total water demand is supplied by a decentralised seawater reverse osmosis (SWRO) water supply system composed of desalination plants, storage tanks and a pipeline network. For a given zone, a desalination plant design capacities are selected from 7 discrete values (from 20,000 to 140,000 m³/day) considering the plant factor of 0.85. Their potential locations were considered to be next to the ocean. For those zones equipped with a desalination plant, a storage tank can potentially be located in the relative population center to store extra produced water. The design capacities of storage tanks are chosen from 3 different values (5000, 10,000 and 20,000 m³).
4. Desalinated water can be transferred between any two adjacent zones. The maximum water that can be transferred is ascertained based on the capacity of the associated pipeline. In this study, we considered a modular design for pipeline network where the design capacity is standard for a flow of 80,654 m³/day. Additional capacity can be added to the infrastructure annually, as needed.
5. The capital costs and the average operational and maintenance (O&M) cost for different desalination plants capacities were estimated based on (Watson et al., 2003). The capital cost of storage tanks and average O&M cost of storing per unit of desalinated water were determined according to (T&ES, 2015). The capital cost per unit length of pipeline was estimated based on (Shahabi et al., 2017). The operational cost of transferring water was calculated based on the electricity cost of water pumping. All cost data have been adjusted to 2017 Australian dollars (\$).
6. Seasonal residential electricity demand and water-related electricity demand are met by electricity sources consisting of residential rooftop PVs output and grid electricity. The maximum grid electricity that can be transferred to each zone is limited by the

maximum capacity of the associated substations. Using SAM tool, the maximum possible PV output for each zone is determined based on Perth's weather file (from the solar resource library of the model) as well as PV installation density in each zone.

8. The grid electricity price follows the time of use (TOU) tariff structure for residential and business sectors. For surplus PV output usage, variable electricity charge is implemented based on the net feed in tariff (FiT). All electricity price data was taken from Synergy, the electricity retailer of Perth.

9. Discount factors for business and residential sectors are calculated based on the discount rates adopted from (WCWA, 2012) and (AEC, 2017), respectively.

Accordingly, the model gives the optimum solution for the following decision variables:

1. The design capacities of water supply system components as well as their locations on yearly basis

2. Real-time scheduling of desalinated water production, storage and transfer

Such that the most compatibility with available surplus PV output is achieved while the discounted total cost of the water supply system is minimised.

2.2. Mathematical formulation

In line with our previous study (Vakilifard et al., 2017), we formulated the problem as a two-level MILP model. The first level objective function concerns the minimisation of the discounted residential electricity cost during planning horizon (z1). The output of this stage is stored in an auxiliary parameter used in the second level of optimisation to calculate the surplus PV output in each time period that can be assigned to both electricity demand of households not equipped with PV systems as well as water supply system. The objective function at this level is discounted total cost of water supply system (z2) minimised over the planning horizon. The main model constraints are given by Eqs.(1)-(21) as follows:

$$z_1 : \text{Min} \sum_t DF_t^r \cdot \sum_s nd_s \cdot \left[Cfe_t^r + \sum_i \sum_b Ce_{t,s,b}^r \cdot P_{t,i,s,b}^r \right]$$

$$z_2 : \text{Min} \sum_t DF_t^{bi} \cdot \sum_s nd_s \cdot \left[Cfe_t^{bi} + \sum_i \sum_b Cr_t^{bi} \cdot RE_{t,i,s,b}^w + Ce_{t,s,b}^{bi} \cdot P_{t,i,s,b}^w + COM_t \cdot Q_{t,i,s,b} + Cs_t \cdot V_{t,i,s,b} \right]$$

$$+ \sum_t DF_t^{bi} \cdot \sum_i \left[\sum_c Cap_{t,c}^{DP} \cdot XW_{t,i,c} + \sum_m Cap_{t,m}^{STT} \cdot X_{t,i,m} \right]$$

$$+ \sum_t DF_t^{bi} \cdot \left[\sum_{(i,j) \in \{AL_{i,j} | i=j\}} Cap_{t,i}^{PI} \cdot np_{t,i} \cdot L_{i,j} \cdot convf_2 + \sum_{(i,j) \in \{AL_{i,j} | i \neq j\}} Cap_{t,i}^{PI} \cdot np_{t,i} \cdot L_{i,j} \cdot convf_2 \right]$$

$$\text{Residential energy balance (with PVs):} \quad P_{t,i,s,b}^r + RE_{t,i,s,b}^r = k_1 \cdot D_{t,i,s,b} \quad (1)$$

$$\text{Residential energy balance (without PVs):} \quad P_{t,i,s,b}^m + RE_{t,i,s,b}^m = (1 - k_1) \cdot D_{t,i,s,b} \quad (2)$$

$$\text{Water-related energy balance:} \quad P_{t,i,s,b}^w + RE_{t,i,s,b}^w = Q_{t,i,s,b} \cdot De^{DP} + \quad (3)$$

$$\sum_{j:(i,j) \in \{PL_{i,j} | i=j\}} WTC_{t,i,s,b} \cdot De_{i,j}^{PI} + \sum_{j:(i,j) \in \{PL_{i,j} | i \neq j\}} WT_{t,i,j,s,b} \cdot De_{i,j}^{PI}$$

$$\text{PV share constraints:} \quad RE_{t,i,s,b}^m + RE_{t,i,s,b}^w \leq \text{Surp}_{t,i,s,b}; RE_{t,i,s,b}^r \leq \text{MaxR}_{t,i,s,b} \quad (4),(5)$$

$$\text{Grid share constraint:} \quad P_{t,i,s,b}^r + P_{t,i,s,b}^m + P_{t,i,s,b}^w \leq \text{dur}_b \cdot \text{MaxPS}_{t,i} \quad (6)$$

$$\text{Water balance:} \quad WQ_{t,i,s,b} + WV_{t,i,s,b} + \sum_{j:(i,j) \in \{AL_{i,j} | i \neq j\}} WT_{t,j,i,s,b} = Dw_{t,i,s,b} \quad (7)$$

$$\text{Plant capacity:} \quad DQ_{t,i} = DQ_{t-1,i} + \sum_c AC_c \cdot XW_{t,i,c} \cdot ; \sum_c XW_{t,i,c} \leq 1 \quad (8),(9)$$

$$\text{Storage capacity:} \quad SN_{t,i} = SN_{t-1,i} + \sum_m ST_m \cdot X_{t,i,m} ; \sum_m X_{t,i,m} \leq \sum_c XW_{t,i,c} \quad (10),(11)$$

$$\text{Pipeline capacity within zone:} \quad DTW_{t,i} = DTW_{t-1,i} + MaxTW \cdot np_{t,i} \quad (12)$$

$$\text{Pipeline capacity between zones:} \quad DTWIJ_{t,i,j} = DTWIJ_{t-1,i,j} + MaxTW \cdot npIJ_{t,i,j} \quad (13)$$

$$\text{Max. water desalinated:} \quad \sum_s nd_s \cdot \sum_b Q_{t,i,s,b} \leq PF \cdot \sum_s DQ_{t,i} \cdot nd_s \quad (14)$$

$$\text{Total and Max. water pushed for storage:} \quad WTC_{t,i,s,b} = Q_{t,i,s,b} - WQ_{t,i,s,b} - \sum_{j:(i,j) \in \{AL_{i,j} | i \neq j\}} WT_{t,i,j,s,b} \quad (15)$$

$$WTC_{t,i,s,b} \leq convf_1 \cdot DTW_{t,i} \cdot dur_b \quad (16)$$

$$\text{Total and Max. water stored:} \quad V_{t,i,s,b} = V_{t,i,s,b-1} + WTC_{t,i,s,b} - WV_{t,i,s,b} \quad (17)$$

$$V_{t,i,s,b} \leq SN_{t,i} \quad (18)$$

$$\text{Max. water transferred between zones:} \quad WT_{t,i,j,s,b} \leq convf_1 \cdot DTWIJ_{t,i,j} \cdot dur_b \quad (19)$$

$$\text{Max. water distributed from the storage tank:} \quad WV_{t,i,s,b} \leq V_{t,i,s,b-1} \quad (20)$$

$$\text{Unused surplus energy:} \quad Surp_{t,i,s,b} - RE_{t,i,s,b}^m - RE_{t,i,s,b}^w \cong 0 \quad (21)$$

2.3. Results and discussion

The two-level MILP model consists of 117,960 constraints and 97,774 variables (including 1,006 binary variables). The model was run in GAMS 24.3.1 software and solved by CPLEX 12.6.

The optimal result gives the accumulated total cost of \$ 3,003,833,149 for investment and operation of the desalination-based water supply system. As shown in Figure 1, the optimal investment solution considers desalination plants in all zones in year one, which will be then expanded once in zone 2 and twice in zone 4 during the planning horizon. Except for zone 1, all other zones are equipped with storage tanks to store extra water produced. In zone 1, the whole water demand is met by desalinated water directly assigned from the desalination plant during the planning horizon.

The optimal operational scheduling (on hourly basis) of the system during summer, for a representative zone 3 and year 2023 is presented in Figure 2(A) and 2(B). As expected, the business TOU tariff is not the only affecting factor on the operational scheduling of the system but the availability of renewable energy also plays a significant role. Accordingly, despite the high electricity rate, the highest level of production and hence the water storage occurs during peak electricity period due to the availability of the surplus PV output that can be assigned to water-related electricity demand. The stored water is then used to satisfy the demand for later hours of the peak electricity pricing period when there is no availability of surplus PV output. This is in agreement with our previous study (Vakilifard et al., 2017) where similar operational behaviour was observed for the hybrid energy scenario, in which both grid electricity and PV output were considered to meet the demand.

For off-peak periods, the production of the desalinated water is limited to the water demand directly assigned from the desalination plant. It is also notable that the amount of water transfer obtained is negligible for all zones during the planning horizon. This is because of the fixed installation density assumed for all zones during the planning horizon as well as the necessity of using all surplus PV output. Consequently, in the

optimal solution all zones are equipped with a desalination plant and hence there is no need for water transfer. This limitation will be addressed in the future work.

3. Conclusion

In this paper, we addressed long-term planning of a desalination-based water supply system integrated with real-time operational constraints. The model has been formulated as a two-level MILP to give the optimal strategic investment decisions as well as real-time operational scheduling of the water supply system based on availability of the renewable energy and discounted total cost of the system over the planning horizon. The results of applying the model to an urban area located in the north-western corridor of Perth, shows a multi-stage construction and expansion planning as an optimal solution for long term sustainable demand supply.

Nomenclatures

Sets:

AL, PL = allowable zones for water transfer and where pumping is needed, respectively
c = discrete points of plant capacities

Parameters (cont'd):

Cr = renewable electricity cost (\$/kWh)
Cs = O&M cost of water storage (\$/m³)
D = residential energy demand (kWh)

i, j = zone	De = water-related electricity demand (kWh/m ³)
m = discrete points of storage tank capacities	DF = discount factor
t, s, b = planning horizon, season and time block, respectively	dur = duration of the time block (h)
Continuous variables:	Dw = residential water demand (m ³)
DQ = capacity of a plant (m ³ /day)	k_l = PV installation density (%)
$DTW, DTWIJ$ = capacity of pipeline (m ³ /day)	L = distance (m)
P = share of grid electricity (kWh)	$MaxPS$ = Max. substation capacity (kW)
Q = desalinated water produced (m ³)	$MaxR$ = Max. PV output (kWh)
RE = share of renewable energy (kWh)	$MaxTW$ = Max. pipeline capacity (m ³ /day)
SN = capacity of the storage tank (m ³)	nd = number of days (day)
V = existing water storage (m ³)	PF = plant factor
WQ = water distributed from a plant (m ³)	ST = size of storage tank with m element (m ³)
WT = desalinated water transferred (m ³)	$Surp$ = surplus PV output (kWh)
WTC = water pushed for storage (m ³)	Integer variables:
WV = stored water distribution (m ³)	$np, npIJ$ = capacity multiplier of pipeline
Parameters:	Binary variables:
AC = design capacity of plant with c element (m ³ /day)	X, XW = decisions for storage tank size and plant capacity, respectively
Cap = capital cost for plant and storage tank (\$) and for pipeline (\$/km)	Superscripts associated with:
Ce = variable grid electricity cost (\$/kWh)	bi = business sector (water supplier)
Cfe = fixed grid electricity cost (\$/day)	DP = plant
COM = plants O&M cost (\$/m ³)	PI = pipeline
$convf_1, convf_2$ = conversion factors, (day/h) and (km/m), respectively	r, rn = households with and without PVs, respectively
	STT = storage tank
	w = water

Leveraging the Power of Big Data Analytics for Process Scheduling under Uncertainty using a Stochastic Robust Optimization Approach

Chao Ning, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

This paper is concerned with the multipurpose batch process scheduling problem under uncertainty. A novel process scheduling model is developed using a data-driven stochastic robust optimization approach to hedge against uncertainty. Labeled multi-class uncertainty data collected in batch productions are modelled with machine learning methods including Dirichlet process mixture model and maximum likelihood estimation. A stochastic robust process scheduling modelling framework is further proposed based on the data-driven uncertainty model through a bi-level optimization structure. The outer optimization problem follows a two-stage stochastic programming approach to optimize the expected profit obtained from the scheduling horizon over different data classes; adaptive robust optimization is nested as the inner problem to ensure the robustness of the process schedule while maintaining computational tractability. A case study on batch process scheduling under processing time and product demand uncertainties is presented to demonstrate the effectiveness of the proposed scheduling framework.

Keywords: big data, scheduling, uncertainty, stochastic robust optimization

1. Introduction

In recent years, the area of batch process scheduling under uncertainty has attracted immense attention from both academia and industries (Wassick et al., 2012; Chu and You, 2015). Since deterministic schedule could become suboptimal or even infeasible with parameter variations, operators in batch plants need to account for various uncertainties when making a production schedule. Risk management of batch process scheduling was investigated using a stochastic programming approach (Bonfill, 2004). To immune against demand uncertainty, a multi-period scheduling model was developed based on a stochastic programming approach (Balasubramanian and Grossmann, 2004). Stochastic programming method focuses on the expected performance of a solution by leveraging the scenarios of uncertainty realization and their probability distribution (Birge and Louveaux, 2011). However, these scheduling model requires accurate information on the probability distribution, and the resulting optimization problem could become computationally challenging as the number of scenarios increases. As an alternative paradigm, robust optimization could effectively tackle process scheduling under uncertainty (Bertsimas et al., 2011). Recently, adaptive robust optimization (ARO) was employed for batch process scheduling in which some decisions can be made in a “wait-and-see” mode based upon uncertainty realizations (Shi and You, 2016). Nevertheless, robust scheduling models do not take advantage of available probability distribution information, and its solution usually suffers from the

conservatism issue. The state-of-the-art approaches for optimization under uncertainty leverage the synergy of different optimization methods to inherit their corresponding strengths and complement respective weaknesses (Yue and You, 2016). In this work, we propose a novel data-driven stochastic robust process scheduling model that makes the most of uncertainty data for batch operations.

2. Data-Driven Stochastic Robust Scheduling Model

We adopt a continuous-time process scheduling model as the deterministic scheduling model (Méndez et al., 2006), shown as follows:

$$\begin{aligned}
\max \quad & \text{Profit of selling products minus the purchasing and operating cost} & (1) \\
\text{s.t.} \quad & \text{Mass balance constraints} & (2) \\
& \text{Batch size constraints} & (3) \\
& \text{Inventory constraints} & (4) \\
& \text{Demand satisfaction constraints} & (5) \\
& \text{Processing time constraints} & (6)
\end{aligned}$$

which is formulated as a mixed-integer linear programming problem. Based on the deterministic model (1)-(6), we propose a two-stage data-driven stochastic robust scheduling model in its compact form, denoted as DDSRO, which is presented in (7). The first-stage decisions include task sequencing variables, whereas the second-stage decisions are continuous variables including timing of tasks, batch sizes, inventory levels. Notice that the second-stage decisions are made after the uncertainty is realized.

$$\begin{aligned}
\min_{\mathbf{x}} \quad & \mathbf{c}^T \mathbf{x} + \mathbb{E}_{s \in \Xi} \left[\max_{i \in \{1, \dots, m(s)\}} \max_{\mathbf{u} \in U_{s,i}} \min_{\mathbf{y}_s \in \Omega(\mathbf{x}, \mathbf{u})} \mathbf{b}^T \mathbf{y}_s \right] \\
\text{s.t.} \quad & \mathbf{A}\mathbf{x} \geq \mathbf{d}, \quad \mathbf{x} \in R_+^{n_1} \times Z^{n_2} & (7) \\
& U_{s,i} = \left\{ \mathbf{u} \mid \mathbf{u} = \boldsymbol{\mu}_{s,i} + \kappa_{s,i} \boldsymbol{\Psi}_{s,i}^{1/2} \boldsymbol{\Lambda}_{s,i} \mathbf{z}, \|\mathbf{z}\|_{\infty} \leq 1, \|\mathbf{z}\| \leq \Phi_{s,i} \right\} \\
& \Omega(\mathbf{x}, \mathbf{u}) = \left\{ \mathbf{y}_s \in R_+^{n_3} : \mathbf{W}\mathbf{y}_s \geq \mathbf{h} - \mathbf{T}\mathbf{x} - \mathbf{M}\mathbf{u} \right\}
\end{aligned}$$

where \mathbf{x} represents the task assignment decision, and \mathbf{y} includes other decisions, such as timing and batch size decisions. \mathbf{u} is the uncertainty vector. Notice that \mathbf{x} is made “here-and-now”, whereas \mathbf{y} is made in a “wait-and-see” manner. $\Xi = \{1, 2, \dots, C\}$ is the set of data classes, C is the total number of data classes, $m(s)$ is the total number of mixture components for data class s .

In the following, we build an uncertainty model. We consider the multi-class uncertainty data with labels $\left\{ \mathbf{u}^{(i)}, c^{(i)} \right\}_{i=1}^L$, where $\mathbf{u}^{(i)}$ is i th uncertainty data point, $c^{(i)}$ is its corresponding label, and L is the total number of uncertainty data. The uncertainty information on the probability of different data classes can be extracted from labeled uncertainty data by leveraging their label information. The occurrence probabilities of data classes are modeled with a multinoulli distribution. The probability of each data class can be calculated through maximum likelihood estimation, as given by Eq. (8),

$$p_s = \frac{\sum_i \mathbb{I}(c^{(i)} = s)}{L} \quad (8)$$

where p_s represents the occurrence probability of data class s , $c(i)$ is the label associated with the i th uncertainty data point, $c(i)=s$ indicates that the i th uncertainty data point is from data class s , and $\mathbb{I}(c^{(i)}=s)$ is an indicator function. The second part of the uncertainty modelling is the construction of data-driven uncertainty sets from uncertainty data in the same data class. Based on the extracted information from Dirichlet process mixture model, we construct a data-driven uncertainty set for data class s using both l_1 and l_∞ norms (Ning and You, 2017a), as presented in Eq. (9).

$$U_s = \bigcup_{i: \gamma_{s,i} \geq \gamma^*} U_{s,i} = \bigcup_{i=1}^{m(s)} \left\{ \mathbf{u} \mid \mathbf{u} = \boldsymbol{\mu}_{s,i} + \kappa_{s,i} \boldsymbol{\Psi}_{s,i}^{1/2} \Lambda_{s,i} \mathbf{z}, \|\mathbf{z}\|_\infty \leq 1, \|\mathbf{z}\|_1 \leq \Phi_{s,i} \right\} \quad (9)$$

where $\gamma_{s,i}$ is the weight of the i th component data class s ,

$$\gamma_{s,i} = \frac{\tau_{s,i}}{\tau_{s,i} + \nu_{s,i}} \prod_{j=1}^{i-1} \frac{\nu_{s,j}}{\tau_{s,j} + \nu_{s,j}}, \quad i = 1, \dots, M-1 \quad \text{and} \quad \gamma_{s,M} = 1 - \sum_{i=1}^{M-1} \gamma_{s,i} \quad (\text{Campbell and$$

How, 2015). The weight $\gamma_{s,i}$ indicates the probability of the corresponding mixture component. γ^* is a threshold value. Variational inference algorithm is employed for the Dirichlet process mixture model. $\tau_{s,i}$, $\nu_{s,i}$, $\boldsymbol{\mu}_{s,i}$, $\kappa_{s,i}$, $\boldsymbol{\Psi}_{s,i}$ are the inference results of the i th component using the variational inference algorithm. $\Lambda_{s,i}$ is a scaling factor, and $\Phi_{s,i}$ is an uncertainty budget. Other data-driven methods, such as kernel learning (Shang et al., 2017) and kernel smoothing (Ning and You, 2017b) techniques, can also be used to derive the data-driven uncertainty set for robust optimization.

3. An Industrial-Scale Application

Process scheduling plays a critical role in process systems engineering, and attracts immense attention. The case study is originated from an industrial multipurpose batch process in The Dow Chemical Company (Chu et al., 2013), and the network is shown in Figure 1. This multipurpose batch process has one preparation task, three reaction tasks, two packing tasks and two drumming tasks. The equipment units include one mixer, two reactors, one finishing system and one drumming line (Yue and You, 2013).

Figure 1. The state-task network of the multipurpose batch process.

In this case study, the processing times of all reaction tasks and demands of all final products are subject to uncertainty. The uncertainty sets are directly constructed from data via the variational inference algorithm. Due to different set points of temperature and pressure, the reaction tasks are performed under multiple operating modes. Therefore, class labels for batch processing time in this case study are various operating

modes. To demonstrate the superiority of the proposed approach, the deterministic optimization method and ARO with budgeted uncertainty set are also implemented for comparisons. In the deterministic scheduling model, the processing times and the demands are set to be their mean values of the corresponding uncertainty data. Without leveraging the label information, the ARO with budget based uncertainty set treats all these uncertainty data as a whole.

The computational experiments are implemented on a computer with an Intel (R) Core (TM) i7-6700 CPU @ 3.40 GHz and 32 GB RAM, and a Windows 10 64-bit operating system. The optimization models and the solution algorithm are coded in GAMS 24.7.3. Since both the master problem and the sub-problems are MILP problems, we solve them using CPLEX 12.6.3 with an optimality tolerance of 0. We set the relative optimality gap for the solution algorithm to be 0.1%.

Figure 2 shows the Gantt chart of the deterministic scheduling approach. Although this schedule generates a high profit, it becomes infeasible when processing times deviate from their nominal values. For example, when the processing time for Reaction 1 performed in Reactor 2 in the 3rd time slot becomes longer than the nominal value, there are some overlaps between Reaction 1 and Reaction 2 in the same equipment unit. However, it is impractical to perform these two reaction tasks in the same reactor simultaneously. Consequently, the scheduling result determined by the deterministic optimization approach becomes infeasible when the processing time varies.

Figure 2. Gantt chart determined by the deterministic scheduling model.

Figure 3 demonstrates the Gantt chart determined by the ARO with a budget based uncertainty set. Since this method hedges against the uncertainty in processing times, the time allocations for reaction tasks tend to be longer than those of the deterministic method. Therefore, the scheduling solution remains feasible when the processing times are subject to uncertainty. For the ARO with budgeted uncertainty set method, it ensures the robustness of the operation at the expense of optimality.

Figure 3. Gantt chart determined by the conventional ARO with budgeted uncertainty set.

The Gantt chart determined by the proposed approach is shown in Figure 4. As can be observed, one more Reaction 3 task is performed in the optimal solution determined by the DDSRO approach. Compared with the deterministic scheduling method, the ARO and the DDSRO approach perform more Reaction 2, Reaction 3, Packing 2 and Drumming 2 to manufacture sufficient amount of product 3 and product 4 for satisfying the demands. The deterministic scheduling method tends to manufacture relatively expensive products, i.e., products 1 and 2. However, it cannot fulfill the demands for other final products when their required amounts increase.

Figure 4. Gantt chart determined by the proposed approach.

In terms of computational time and results, we can see that the computational times of the ARO approach and the proposed scheduling approach are longer than that of the nominal deterministic method. Compared with ARO with budget based uncertainty set, the proposed approach is less conservative by generating more profits while ensuring that the schedule remain feasible under uncertain processing times and demands.

4. Conclusions

A novel data-driven stochastic robust scheduling model was proposed that explicitly accounted for the label information in the proposed multi-level optimization model. Probability distribution for data classes was learned from uncertainty data through maximum likelihood estimation. A group of Dirichlet process mixture models was used to construct uncertainty sets for each data class. The proposed robust process scheduling framework leveraged the advantages of two-stage stochastic programming approach and robust optimization, and at the same time exploited the value of big data. We presented an application on multipurpose batch process scheduling. The results showed that the proposed approach was advantageous over the conventional robust scheduling method in handling uncertainty with historical data, and was more computationally efficient.

Abstract

Liquid-liquid extraction has widespread use in industry, e.g., for separation of highly diluted components from fermentation broths. Feasibility and economic operation of the extraction processes depend critically on the selection of a suitable solvent. While the choice for an optimal solvent inherently depends on the overall process performance, common methods for solvent selection focus on much simpler performance indicators which can lead to suboptimal solutions. In order to improve solvent selection, we present a hierarchical approach with successive model refinement. The approach builds on the prediction of thermodynamic properties by COSMO-RS, avoiding the need for experimental data in early conceptual design phase. In the approach, advanced pinch-based shortcut models are combined with rigorous superstructure optimization to determine promising solvent candidates. The approach allows for an evaluation of several thousand potential solvents and identifies highly promising solvents based on the evaluation of process economics for an optimized process. The approach is illustrated for the extraction of γ -valerolactone from an aqueous feed stream.

Keywords: Optimization, Solvent, Screening, Extraction, Distillation

1. Introduction

Liquid-liquid extraction is one of the most promising techniques for the separation of components with similar molecular sizes, boiling and melting points (Skiborowski et al., 2013). Furthermore, the separation of azeotropic and highly diluted mixtures can effectively be addressed. Therefore, liquid-liquid extraction is of specific importance for the processing of bio-renewables, e.g., highly diluted aqueous streams such as fermentation broths. For liquid-liquid extraction, the solvent has a considerable impact on the economic and environmental performance of the final process. Thus, one of the first and usually most important steps in designing a liquid-liquid extraction process is selecting a suitable solvent. However, solvent selection is usually based on heuristic guidelines, expert knowledge and simplified process performance indicators such as distribution coefficients, as well as the selectivity and the capacity of the solvent (Gmehling and Schedemann, 2014). These simplified process performance indicators are usually combined to characterize the performance of solvents (Hampe, 1985). To identify solvents with the best performance indicators, computer-aided molecular design (CAMD) methods can automatically design solvent candidates (Harper et al., 1999).

However, the use of process performance indicators in CAMD implies a strong simplification of the separation performance which is usually maximized by a certain trade-off between different indicators. E.g., efficient extraction requires a high affinity of the solute to the solvent, whereas a low affinity helps to reduce the energy for solvent recovery by distillation (Papadopoulos and Linke, 2006).

To overcome heuristic weighting of multiple performance indicators, solvent candidates should be evaluated based on a performance evaluation on the process level, preferably taking into account process economics. In order to accomplish this and enable CAMD based on process performance, a variety of approaches have been proposed for integrated solvent and process design in the last fifteen years (for details see the excellent review by Austin et al. (2016)). For the design of liquid-liquid extraction processes especially the works of Kim and Diwekar (2002), Papadopoulos and Linke (2006), as well as Karunanithi et al. (2005) are of interest. These approaches are usually based on group-contribution models which need experimental data for parameterization. To avoid also the limitations of group-contribution based CAMD models, some of the present authors recently proposed a new method for an automated solvent screening for hybrid extraction–distillation processes (Scheffczyk et al., 2016). The approach builds on the prediction of thermodynamic properties by COSMO-RS, a semi-empirical model based on quantum mechanical (QM) calculations without substance-specific parameters. The predicted thermodynamic models enable an automated evaluation of the process performance based on thermodynamic sound pinch-based process models. While this approach already provides an efficient evaluation of the process performance on the basis of the required energy demand, this work expands the scope to integrate economics in the screening and add subsequent rigorous superstructure optimization of the hybrid process based on equilibrium-stage models in combination with sizing and costing equations. The resulting approach facilitates the efficient selection of a solvent for an extraction–distillation hybrid process with a hierarchical model refinement to manage the trade-off between detailed results and minimal effort.

2. Methodology

The methodology can be divided into four subsequent stages according to Figure 1. A thorough discussion of the first three stages is presented in the work of Scheffczyk et al. (2016). The following subsections provide a brief summary of these steps, with a focus of integrated economic aspects already in the target function for solvent performance in the rapid shortcut-based screening. Finally, a rigorous optimization of the process is performed for the most promising solvents from the preceding shortcut screening.

Figure 1: Schematic representation of hierarchical design approach

2.1. Generation of solvent candidates and property prediction (first stage)

In order to evaluate the process performance of different solvent candidates thermodynamic models for various properties are required. To overcome the need for

experimentally determined interaction parameters, recent solvent selection approaches propose the use of QM-based approaches, which are, however, computationally demanding (Struebing et al., 2013). In this work, COSMO-RS (Klamt et al., 2001) is used as a prediction tool. A large-scale database is employed which contains several thousand solvents. This database is evaluated with COSMO-RS, providing property predictions for pure components and mixtures. While the available database allows for a large-scale screening, the generation of new molecules is a potential extension that was already investigated by Scheffczyk et al. (2017). Thus, the presented framework could be extended towards integrated process and molecular design.

2.2. Process feasibility screening (second stage)

Prior to the evaluation of the process performance, the general feasibility of the process concept is evaluated for each solvent. At first, the existence of a miscibility gap between the solvent and the carrier is evaluated, based on binary liquid-liquid equilibrium (LLE) calculations. Furthermore, the existence of any azeotropes between solvent and solute is checked, based on vapour-liquid equilibrium (VLE) calculations. Additional constraints on thermodynamic properties may be employed to further limit the number of feasible solvent candidates. E.g., constraints on the boiling point of the solvent ensure liquid state of the solvent at ambient conditions (cf. Scheffczyk et al. (2016) for details).

2.3. Rapid shortcut-based screening (third stage)

All of the solvent candidates, which are feasible according to the previous step, are passed to the shortcut-based process screening. For an accurate evaluation of the process performance, the use of advanced pinch-based shortcut models allows for the consideration of non-ideal thermodynamics, which is a necessary prerequisite for the application to non-ideal systems such as those considered whenever dealing with liquid-liquid extraction processes. The evaluation of the minimal solvent demand in the extraction process is performed by the shortcut method of Redepinning et al. (2016), while the minimal energy demand for the solvent recovery is subsequently performed by the rectification body method (Bausa et al., 1998). Both are computationally highly efficient, allowing for the evaluation of more than thousand solvents within few hours of computational time (Scheffczyk et al., 2016). In the previous work of Scheffczyk et al. (2016), the optimal solvent choice was determined based on the minimal energy demand for solvent regeneration ($Q_{b,\min}$), being a good indicator of the operating costs, which usually dominate the overall separation process costs. However, preliminary results of the subsequent rigorous process evaluation indicated a significant effect of the solvent loss on the overall process costs depending on the specific solvent. Thereby, we adapted the target function for the screening by integrating solvent loss into the estimate for operating costs (C_{op}). Solvent loss in the raffinate phase was considered with a fixed price of the benchmark solvent, and the costs for fresh solvent were added to the utility costs for the distillation column. This adjustment reflects the actual costs more closely and results in a much better agreement with the subsequent economic optimization.

2.4. Rigorous optimization (fourth stage)

Despite the adaption of the target function for the shortcut-based screening, pinch-based process models only provide an estimate of the process costs since they are based on simplified models leading e.g. to sharp separation splits. The final cost of the process can only be calculated accurately with detailed models and especially a simultaneous process optimization, which considers the aggregation of all processing steps and closed recycle streams with finite purities. Therefore, the last step in the described approach

(Fig. 1) is the application of a rigorous process optimization based on detailed equilibrium-based superstructure models for the most promising solvent candidates. The optimization approach builds on the model description and the solution approaches described by Skiborowski et al. (2015).

The superstructure model of the hybrid extraction-distillation process is shown in Figure 2. Compared to the process structure for the shortcut-based screening, two additional heat exchangers are considered for preheating the feed to the distillation column and cooling the top product stream prior to the decanter, in order to get a more accurate estimation for the process cost. Furthermore, the recycle

Figure 2: Superstructure of the hybrid process

stream coming from the decanter considers the finite purities in the rigorous optimization. While this recycle can be negligible in some cases, it can result in drastic changes of the operation point of the whole process. The extraction column is operated in counter-current mode and the number of equilibrium stages in the extraction and the distillation column are degrees of freedom in the optimization. This superstructure model provides the trade-off calculation between operational and investment cost. Investment cost are estimated using the method of Guthrie (1969).

While the full process optimization has a significant number of benefits compared to the shortcut-based screening, the computational effort is much higher and the approach is not directly applicable to the large number of feasible solvents from the second step (Fig. 1). The proposed hierarchical combination therefore allows for screening the full solvent database and subsequent detailed investigation of the process performance for the most promising candidates only.

3. Case study – purification of γ -Valerolactone

The proposed approach is applied to the purification of the platform chemical γ -Valerolactone (GVL) from a fermentation broth. GVL is a bio-based platform chemical and a promising preliminary product in the synthesis of bio-based fuel or commodity chemicals (Alonso et al., 2013). This case study is also presented in the publication of Scheffczyk et al. (2016) where the first two stages of the approach have already been performed. This work therefore focuses on the changes of the results in step three due to the modified target function and the results of the rigorous process costs evaluation for an evaluation based on the process costs. A feed stream of 100 mol/s is considered that consists of 5 mol% GVL and 95 mol% water. All equipment is operated at a pressure of 1 atm, while the temperature for extraction and decantation is 25 °C. The desired purity for GVL is 99.99 mol% and water in the raffinate is limited to 0.001 mol%.

The process feasibility screening and the rapid shortcut-based screening is performed for a database with 4600 solvent candidates. The results for stage 1 and 2 are summarized in the article of Scheffczyk et al. (2016). From these candidates, we consider five solvents for further evaluation in the rigorous design optimization: n-Butylacetate as benchmark solvent, toluene as a common industrial solvent and three different furane molecules (furane (FUR); 2-methyl-furane (2MFUR); 3-methyl-furane

(3MFUR)). Furane molecules are among the best in the shortcut-based screening, both in terms of energy demand $Q_{b,\min}$ and estimated operating costs C_{op} . Further solvents, mainly diols, are found to be superior in terms of process energy demand but the chemical stability of these molecules stands to question. These molecules are thus excluded from further consideration.

Table 1 lists the ranking of the selected molecules in terms of the shortcut screening ranking with energy demand $Q_{b,\min}$ and the adapted target function integrating solvent cost C_{op} , as well as the results of the rigorous economic process optimization for each of the five solvent candidates. Additionally, the total annual cost (TAC) and operating cost (TOC) are listed along with the amount of fresh solvent S_{fresh} , the composition of the recycled solvent x_S and the energy demand in the reboiler of the distillation Q_b .

Table 1: Results of the cost optimization with fixed superstructure

Solvent	Ranking		$S_{fresh} /$ $\text{mol}\cdot\text{s}^{-1}$	$x_{S,GVL} /$ $\text{mol}\%$	$x_{S,W} /$ $\text{mol}\%$	$Q_b /$ MW	TOC / $\text{k}\text{€}\cdot\text{y}^{-1}$	TAC / $\text{k}\text{€}\cdot\text{y}^{-1}$
	$Q_{b,\min}$	C_{op}						
3MFUR	18	28	0.050	0.0001	1.03	0.49	262	340
2MFUR	30	37	0.044	0.0000	0.92	0.59	269	354
TOL	211	54	0.011	0.0014	0.53	1.03	346	465
FUR	11	219	0.165	0.0000	1.20	0.44	421	490
nBAC	161	380	0.090	0.0000	21.01	1.14	623	738

As indicated by the positions listed in Table 1 the ranking of all investigated solvents changes already on shortcut level depending on whether cost C_{op} or energy $Q_{b,\min}$ is used as target function. In particular, a switch occurs in the order of nBAC and TOL. For both molecules, a significant amount of solvent is lost in the raffinate stream, which indicates a strong influence of solvent loss on the overall process performance. This importance of solvent loss is further highlighted for FUR where costs for fresh solvent exceed the operating costs of the distillation column by almost a factor of three. Thus, solvent loss needs to be already considered on pinch-based process level by cost C_{op} .

Using cost C_{op} as target function, the ranking of the shortcut-based screening is in excellent agreement with economic optimization for the five considered solvents. Thus, the general concept of the presented approach allows for a reliable ranking of the solvents on pinch-based level and detailed evaluation of a few promising candidates. This final evaluation is still required to capture all effects on the process performance. E.g., the simultaneous optimization of the full process for nBAC reveals that the recycled solvent stream to the extraction column contains about 20 mol% water. This solvent dilution reduces the solvent make-up demand in closed recycle streams in comparison to sequential pinch-based evaluation. Such effects are successfully captured by the hierarchical design approach presented in this work.

4. Conclusion

The current article presents a systematic approach for an elaborate and efficient solvent selection based on advanced property prediction and hierarchical model refinement. For the investigated case study, more than 4600 solvent candidates are evaluated. The results of the revised screening and rigorous optimization demonstrate the capability of the approach to determine a cost-optimal solvent based on the overall process design. In particular, a process using the solvent 2- or 3-methylfurane can reduce the total annual cost by more than 50% compared to the benchmark solvent n-butylacetate. The results

also illustrate the importance of an appropriate target function for the screening of suitable solvents. The presented approach is highly flexible and computationally efficient and thus the application to other solvent-based separation processes and more complex process configurations will be subject to future work.

Abstract

The use of mass exchange networks is a strategy that allows the recovery and reuse of dangerous components from effluents of industry, reducing, or even avoiding, the pollution derived from the release of such components to the environment. The most common strategy for the synthesis of mass exchange networks involves the use of analogies to the pinch point method for heat exchange networks, and some approaches have been reported on the use of mathematical methods to solve the synthesis problem following a super-structure based on stages. Nevertheless, such super-structure requires deciding the proper number of stages. In this work, a superstructure is proposed to represent the synthesis of a mass exchange network for the recovery of copper in an etching process. The superstructure is developed following a state-task representation, using the concepts of transfer units for the design of the mass exchangers. This representation allows obtaining a wide search space, with no need of assuming additional parameters related to the formulation. The disjunctive mathematical model is developed and its MINLP equivalent is obtained through the convex hull strategy. The MINLP is then solved using the DICOPT solver of GAMS.

Keywords: mass exchange networks, state-task representation, mathematical programming

1. Introduction

Mass exchange networks are structures with many direct-contact mass transfer units, on which waste process streams (so-called rich streams) are treated to remove pollutants. This removal task is usually performed through external mass separation agents (so-called poor streams). The selection of which rich streams must exchange mass with which poor streams is one of the main challenges in the design of mass exchange networks. One of the first methodologies to synthesize mass exchange networks has been proposed by El-Halwagi and Manousiouthakis (1989), where the minimum capital cost is obtained through heuristics. The use of superstructures to represent the set of

possible configurations for the network has been widely developed in the last years. Chen and Hung (2005) proposed a synthesis methodology based on the design of heat exchange networks. On the other hand, Isafiade and Fraser (2008) used a superstructure based on intervals of composition. Liu et al. (2013) reported a superstructure for the synthesis of mass exchange networks, involving the recovery of multiple components. Isafiade and Short (2016) proposed the use of more rigorous cost functions to solve the synthesis problem of mass exchange networks. Ghazouani et al. (2017) proposed a superstructure for the simultaneous design of mass and heat exchange networks, with a simplified model, obtaining a MILP problem. Other design approaches have been also reported, based on graphical methods and the pinch point analysis (Gadalla, 2015).

Most of the previously mentioned works report the use of a stage-based superstructure. Nevertheless, an important parameter to choose when obtaining such a superstructure is the number of stages, whose proper value is unknown at the beginning of the solution, although some approaches have been reported to this end (Chen and Hung, 2005). An alternative way to propose the superstructure is through the development of a state-task-network based superstructure. In this approach, the tasks (physical or chemical transformations) and the states (properties for the streams) are defined, while the assignation of equipment is unknown. In this work, a state-task-network based superstructure is developed for a classic mass exchange network synthesis problem. The problem is modelled through general disjunctive programming, relaxed into a MINLP and solved with the software GAMS. The non-linear terms are involved mainly in the design equations for the mass transfer units.

2. Case study

The design of a mass exchange network for the removal of copper in an etching plant is studied (Chen and Hung, 2005). This problem involves the integration between two rich streams and two poor streams. Figure 1 shows a simplified representation of the network. Stream R_1 is a solution with ammonia, while stream R_2 comes from a washing stage. Both, R_1 and R_2 , have a high concentration of copper, so they must be treated to reach the environmental regulations with little affection to the process economy.

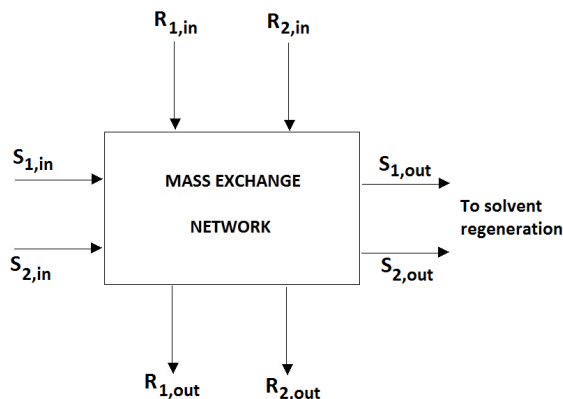

Figure 1. Simplified representation of the mass exchange network.

R_1 has a flowrate of 0.25 kg/s, with initial composition of copper of 0.13. On the other hand, flowrate for R_2 is 0.10, with initial composition of copper of 0.06. It is desired to reach compositions of 0.10 and 0.02 for streams R_1 and R_2 , respectively. To perform this task, there are two external mass separation agents, S_1 and S_2 , where S_1 has a unitary cost of 58,680 USD/kg·y, while the unitary cost of S_2 is 704,160 USD/kg·y (Papalexandri et al., 1994).

3. Superstructure and mathematical modelling

Figure 2 shows the superstructure representing the feasible combinations between streams and equipment. Such superstructure is based on a state-task-network representation. In Figure 2, the circles are units for mixing or separation of streams, which allows to split a single stream and treat its sub-streams in different equipment, or mixing to streams to be treated in a single equipment. Units 1 and 3 are trayed columns, while Units 2 and 4 are packed columns. Variables written in capital letters (Q_i , R_i , S_i and T_i) are mass flowrates, while variables in lowercase letters (x_i , y_i , z_i) are mass compositions. The superstructure is arranged in a way to allow parallel and serial arrangements, or combinations of both. Moreover, as abovementioned, this superstructure allows the split of the streams, which is one of the major advantages of this approach.

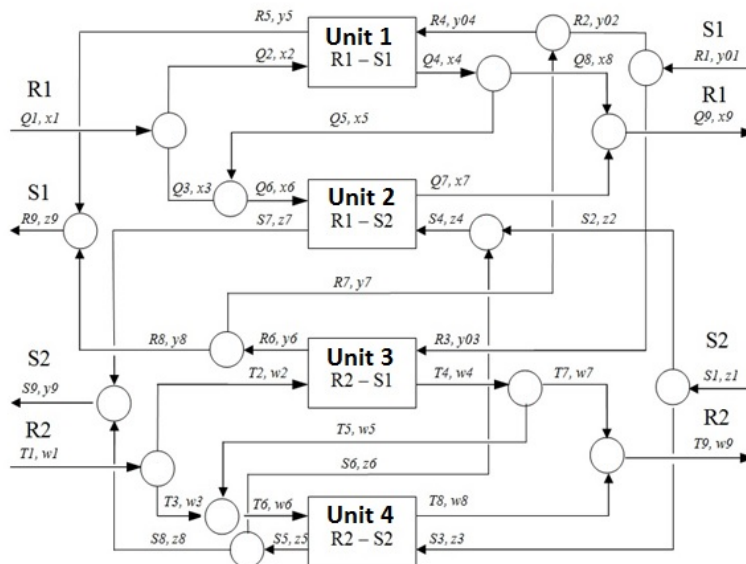

Figure 2. State-task-network based superstructure.

The mathematical model for the superstructure includes the mass balances in the nodes, the mass balances in the separation units, relationships for thermodynamic equilibrium, equations for dimensioning of the mass exchangers, disjunctions and logical

propositions, and equations for the calculation of total annual cost. The mass balances in the nodes are applied in each point where streams are mixed or split. The bilinear terms in these balances contribute to the non-convexity of the model. The mass balances in the separation units are applied for each component. The relationships for thermodynamic equilibrium are used to establish the feasibility for mass transfer in each exchange. Here, a minimum allowed difference in composition is used to ensure a finite number of stages in the trayed columns and/or a finite packing height in the packed columns. In the case of the dimensioning of the mass exchangers, the Kremser equation with the approximation of Chen has been used for the trayed columns. As aforementioned, for the packed columns, the concept of height of transfer unit is used. The logical propositions are established to allow independence between the mass exchangers, i.e., the selection of one unit does not affect the possibility of selection or not selection of a second unit. The objective function for the optimization is given by the minimization of the total annual cost, which is the sum of the annualized capital costs and the operational costs. For this network, the operational costs are given by the solvents. The disjunctions have been relaxed through the convex hull strategy, and the resulting MINLP model is solved using the DICOPT solver of GAMS.

4. Results

The MINLP model to be solved has 93 continuous variables, 4 binary variables and 148 equations. Figure 3 shows the resulting network. The numbers in the rectangles with dotted lines represent the quantity of mass transferred in each unit. The exchanges R1-S1 and R2-S2 have parallel arrangement, while the exchanges R2-S1 and R2-S2 have a serial arrangement. From Figure 3, it can be seen that the stream S1 is divided, so a fraction of S1 exchanges mass with R1, while the other fraction performs the exchange with R2. The total annual cost for the network is 50,855 USD/y, where 63% of the total annual cost is given by the operational costs.

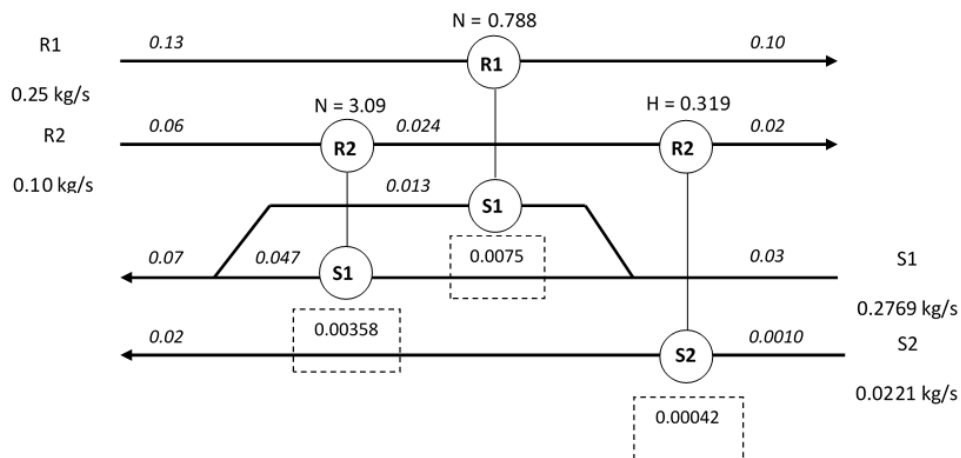

Figure 3. Optimal mass exchange network.

Table 1. Comparison of the results with a previous work.

	S1 (kg/s)	S2 (kg/s)	TAC (USD/y)
This work	0.2769	0.0221	50,855
Chen and Hung (2005)	0.276	0.023	52,300

The obtained solution has been compared with that reported by Chen and Hung (2005), this comparison is shown in Table 1. In terms of the use of solvent, the results for the base work are very similar to those obtained by the proposed alternative. Nevertheless, the total annual cost obtained through the method reported here is around 3% lower than that obtained by Chen and Hung (2005). Thus, the state-task-network based superstructure has allowed obtaining a similar solution to that previously reported for the same case study, with a lower total annual cost and making use of the possibility of split streams.

5. Conclusions

A state-task-network based superstructure has been proposed to solve the synthesis problem of a mass exchange network. This approach opens the possibility of split for a given stream to exchange mass with more than one stream. Moreover, the dimensioning of the columns is performed through semi-rigorous approaches, namely the Kremser equation and the high of transfer unit concept. This allows obtaining proper designs of the mass transfer equipment. The superstructure has been modelled through general disjunctive programming, and relaxed to a mixed-integer non-linear problem through the convex hull method. The proposed superstructure has been applied to a classic problem for the removal of copper in an etching facility. The relaxed problem has been solved using the software GAMS, with a proper selection of the initial values for the degrees of freedom, obtaining a solution similar to that reported in the literature. Moreover, the resulting network makes use of the split of one of the solvent streams to satisfy the requirement of one of the rich streams.

Abstract

Cryogenic processes are industrial processes of sub-ambient or low temperature, used for freezing or liquefaction of gas. The cryogenic condition is done by the refrigeration system with compressors and condensers consuming high operating costs of shaft work, and condenser duty, therefore mathematical programming; GAMS, is applied as a tool to optimize the energy efficiency of the refrigeration system. In this work, cryogenic carbon capture and LNG processes (Fazlollahi, 2015) was applied as a base case for improving energy efficiency by reducing shaft work and energy duty at compressors and condensers. The concept of energy-optimization model was from Non-Linear Programming model (NLP) (Colmenares and Seider, 1989). The base-case process was simulated by software Aspen plus V8.8. Representing economic change, scenarios of different operating costs were applied. Two energy-optimization models of simple and cascade refrigeration systems; under two scenarios of shaft-work cost dominance and condenser-duty cost dominance, were developed. Under shaft-work cost dominance, the simple-refrigeration model saved 72.68% and 56.12 % in shaft-work and condenser-duty costs, respectively, compared to the base case. Cascade-refrigeration model saved 48.53% and 64.77 % in shaft-work and condenser-duty costs, respectively. Under condenser-cost dominance, the simple refrigeration model saved 65.12 % and 57.73 % in shaft-work and condenser-duty costs, respectively. Cascade refrigeration model saved 8.12 % and 62.1 % in shaft-work and condenser-duty costs, respectively. As a result, cascade refrigeration model gave lower condenser-duty cost in both scenarios. However, the cascade refrigeration model had constraints to prevent negative temperature approach in condensers and constraints not to allow shaft work at compressors reach the lowest value. Simple refrigeration model gave a better design solution for only shaft-work reduction. However, cascade refrigeration model gave higher energy efficiency for both condenser-duty and shaft-work costs reductions.

Keywords: mathematical programming model, non-linear programming, cryogenic process, optimization.

1. Introduction

Low-temperature process is the process mainly dealing with refrigeration system. The problems of this process is high energy requirement from both shaft work and cold utility. Therefore, plant manager can save energy usage by several methods. Mathematical programming is an optimization method for improving the energy efficiency of refrigeration system. The energy optimization model by NLP (Colmenares and Seider, 1989) has its objective function of minimum shaft-work and cold-utility costs in

refrigeration system. The solution is the optimal cryogenic process design. In this research, cryogenic process and carbon capture process (Fazlollahi, 2015) were chosen as a base cases. Cryogenic carbon capture and liquefied natural gas (LNG) processes used integrated refrigeration systems. Natural gas is utilized as a refrigerant for process capturing carbon dioxide (CO_2) from flue gas of power plant. Heat exchanger network (HEN) in refrigeration system of the base case was simulated by ASPEN plus 8.8 program and optimized by GAMS software. Therefore, the objective of this research is to improve the process for saving shaft-work and cold-utility costs in the refrigeration system.

2. Simulation of Base-case Cryogenic Carbon Capture and LNG processes

Base-case cryogenic carbon capture and LNG processes have been simulated using commercial software Aspen plus V8.8. The fluid package of thermodynamics properties is Peng Robinson equation of state. The ambient conditions are assumed at 25°C (298.15 K) and 1 bar. Its process flow diagram is shown in Figure 1. According to simulation, it consumes 3,121.41 kW of shaft work and cold utility or 32,662.65 \$/hr. The energy load is high at loop 4; the biggest loop of refrigeration system. Therefore, loop 4 is focused for improvement.

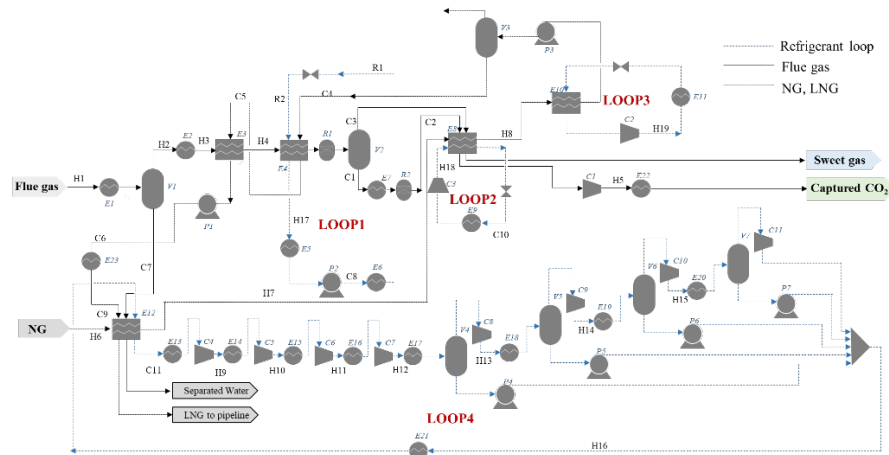

Figure.1 Process flow diagram of cryogenic carbon capture and LNG processes

3. Model and Equations

There are two models of refrigeration loop design in this research; simple and cascade refrigeration model. Both of model was non-linear programming model (NLP) set to minimize shaft-work and cold-utility costs under equality and inequality constraints. To formulate NLP model, these following definitions and equations must be defined.

i { i i is hot process stream }	TRI_k Inlet evaporator temperature refrigerant k
k { k k is cold process stream }	TRO_k Outlet evaporator temperature refrigerant k
W_k Shaft work of compressor	TRCO_k Inlet condenser temperature refrigerant k
J Interval	TRCDO_k Outlet condenser temperature refrigerant k
n Number of Interval	h_{BC_k} Enthalpy of refrigerant before compressor
$S_{i,k,J}$ Heat exchanged in stream	h_{AC_k} Enthalpy of refrigerant after compressor
$R_{i,J}$ Heat load in each interval J	PRI_k Refrigerant pressure entering to compressor

$D_{i,j}$ Heat of hot stream flowing between intervals	PRO_k Refrigerant pressure leaving from compressor
Q_k^c Heat condenser of refrigerant k	PR_k Compression ratio of compressor
Q_k^e Heat evaporator of refrigerant k	Le_k Latent heat of refrigerant at evaporator
CpR_k Heat capacity flow rate of refrigerant k	Lc_k Latent heat of refrigerant at condenser
FR_k Flow rate of refrigerant k	C_w Cost of work
	C_c Cost of condenser duty

The main objective function is Eq. (1)

$$\text{Minimize (WCT)} = \sum_{k=1}^n C_w W_k + \sum_{k=1}^n C_c Q_k^c \quad (1)$$

Calculation of condenser duty is

$$Q_k^c = FR_k(CpR_k(TRCDO_k - TRCO_k) + Lc_k) \quad (2)$$

and evaporator duty for simple refrigeration model is

$$Q_k^e = FR_k(CpR_k(TRI_k - TRO_k) + Le_k) \quad (3)$$

For cascade refrigeration model, evaporator equation is added with logical function which are divided into 4 stages of refrigeration.

$$\text{Stage 1: } Q_{ref1'}^e = -S('H_1', 'ref1', 'J_0') \quad (4)$$

Stage

$$2: Q_{ref2'}^e =$$

$$-S('H_1', 'ref2', 'J_1') +$$

$$\left[\text{bool_or} \left[\text{floor} \left(\frac{Q_{ref3'}^c + 1}{10} \right), \text{floor} \left(\frac{S('H_1', 'ref2', 'J_1') + 1}{10} \right) \right] \times Q_{ref3'}^c \right] +$$

$$\left[\text{bool_and} \left[\text{bool_not} \left(\text{floor} \left(\frac{Q_{ref3'}^c + 1}{10} \right), \text{floor} \left(\frac{Q_{ref2'}^c + 1}{10} \right) \right) \times Q_{ref4'}^c \right] \right] \quad (5)$$

Stage3:

$$Q_{ref3'}^e =$$

$$-S('H_1', 'ref3', 'J_2') + \left[\text{bool_or} \left(\text{floor} \left(\frac{10}{Q_{ref4'}^c + 10} \right), \text{floor} \left(\frac{Q_{ref3}^c + 1}{10} \right) \right) \times Q_{ref4'}^c \right]$$

$$\text{Stage 4: } Q_{ref4'}^e = -S('H_1', 'ref4', 'J_0'); \quad (6)$$

For outlet refrigerant temperature of evaporator and compressor, Eq (7) and (8) are applied.

$$\left(\frac{Q_k^e}{FR_k CpR_k} \right) + TRI_k = TRO_k \quad (7)$$

$$TRCO(k) = TRO(k) \left(1 + \frac{PRO_k^{k-1}}{PRI} - 1 \right) \quad \text{which } k = Cp/C_v \quad (8)$$

and η is an isentropic efficiency = 0.9

From energy balance of hot and cold stream I in interval J, Eq. (9) and (10) are represented, respectively.

$$D(I, J_n) - D(I, J_{n-1}) + \text{SUM}(K, S(I, K, J_n)) = R(I, J_n) \quad (9)$$

$$\text{SUM}(I, S(I, K, J_n)) = P(K, J_n) \quad (10)$$

Properties equations in this model which are enthalpy, latent heat and bubble point equation come from data simulation in aspen Hysys V.8.8. Moreover, logical function (Bool_not(x)) must be applied to the GAMS model in a part of outlet enthalpy calculation due to varied compression ratio. Constraints of positive-temperature-approach is for heat exchanger design and controlling temperature of hot and cold streams which are added to both models.

Shaft work (\$/kWh)	Cold utility1 (\$/kWh)	Cold utility 2 (\$/kWh)
0.08	1.8051	2.7341

Figure 2 Simple-refrigeration model

Table 1 Cost of shaft work and cold utilities

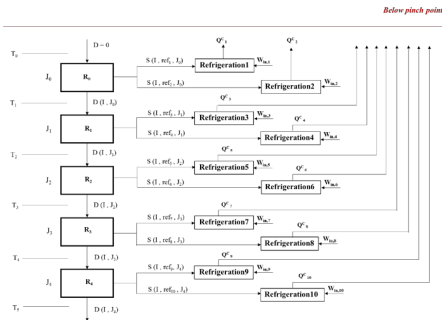

Figure 3 Simple refrigeration model

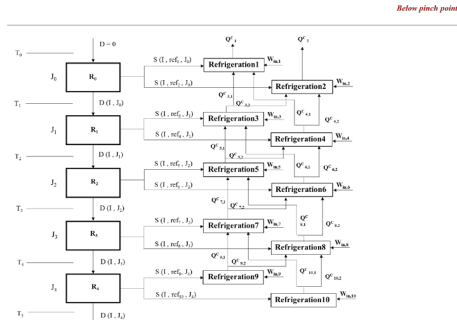

Figure 4 Cascade refrigeration model

4. Results and discussion

According to simulation result, the modification of refrigeration occurs at unit E12 due to the highest shaft work loaded. So E-12 unit which is one-stage refrigeration was improved. Model was achieved under these assumptions: (1) Constant heat capacity flow rate (2) EMAT(Exchanger minimum approach temperature) lower than 10 °C (3) Refrigerant pressure inlet of evaporator = 1 bar and vapor fraction = 0.1 (4) Layout and pressure drop costs are neglected. Variables in this program are $S_{I,K,J}$, $D_{I,J}$, FR_K , TRO_K and PR_K . These variables are varied until the lowest cost of shaft work and cost of utility are achieved. The optimal solutions are represented in two scenarios which are more significant on cold utility cost (scenario1) and more significant on shaft work (scenario2). Cost of shaft work was assumed as an electricity cost of Thailand. For cold utility, there are only 2 types which are listed in Table1. The optimal solutions from GAMS are validated by Aspen plus simulation before analyses the result.

4.1. Simple-refrigeration model

In scenario 1, cost of cold utility is higher than cost of shaft work. An optimal refrigeration system at scenario 1, as shown in Figure. 5a, is two-stage refrigeration which reduces cold

utility cost 57.73 % and shaft work 65.12 % comparing to the base case (3,121.41 kW of total shaft work and 32,662.65 \$/hr cost of cold utility), as shown in Table 2. The model selected process with high loaded compressors to design two-stage refrigeration. In scenario 2, cost of shaft work is higher than cost of cold utility about 5 times. Therefore, four-stage refrigeration was applied to design the optimal refrigeration system, as shown in Figure. 5b. The more stage of refrigeration system, the more shaft work reduction. The energy saving results of refrigeration system at scenario 2 are shown in Table 2.

Table 2 Simple refrigeration model results

Scenario 1		Scenario 2	
% Shaft work reduction	% Cost of cold utility reduction	% Shaft work reduction	% Cost of cold utility reduction
65.12	57.73	72.68	56.12

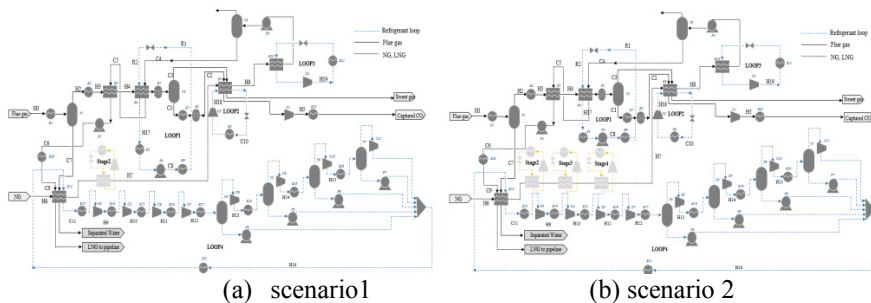

Figure. 5 Improved refrigeration systems using simple refrigeration model

However, simple refrigeration model still shows high amount of cold utility cost. Then, cascade refrigeration model was applied to improve process by optimizing both of condenser and shaft work, simultaneously.

4.2. Cascade-refrigeration model

Cascade-refrigeration model is another kind of refrigeration system used in this work. Heat from condenser at lower stage (n) is sent to a higher stage (n-1) in order to reduce condenser duty at very low temperature which consumes higher cost. All of definitions and equations are the same as simple-refrigeration model except equation of heat of evaporator listed in Eq. (4)-(6). Scenario 1 has cold-utility-cost dominance. The condenser in process was improved by changing temperature level of cold utility to higher one which consumes the lower price of utility. The result shows that cascade-refrigeration model can eliminate condenser operated at very low temperature by using higher-temperature-stage condenser. The improved refrigeration system is three-cascade-refrigeration system applied to the base case. However, shaft work of this case is saved only 8.2 % as shown in Table 3, due to small cost of shaft work in objective function. For scenario 2 which is shaft-work-cost dominance, this model is to minimize shaft work, significantly. By using cascade-refrigeration model, cold utility is reduced 64.77 %, as shown in Table 3, which is lower than one from simple-refrigeration system at scenario 2. Moreover, shaft work is decreased around 48.53 % higher than one from simple-refrigeration model. This model has more constraint equations of temperature controller. Therefore, the compression ratio was limited by positive temperature approach constraint (hot stream temperature must be higher than cold stream at least EMAT of 10 °C)

Table 3 Cascade refrigeration model results

Scenario 1		Scenario 2	
% Shaft work reduction	% Cost of cold utility reduction	% Shaft work reduction	% Cost of cold utility reduction
8.2	62.10	48.53	64.77

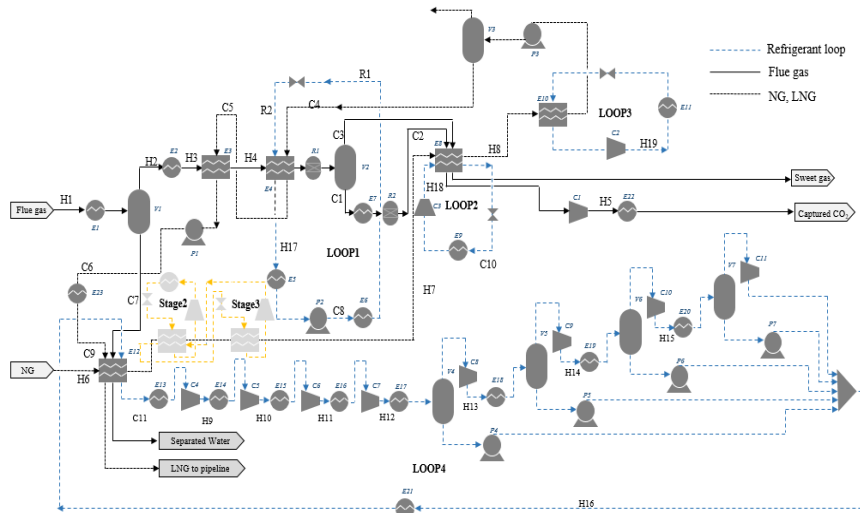

Figure. 6 Improved refrigeration system by cascade-refrigeration model at scenario 1 & 2

According to the result, cold-side condenser temperature at scenario 1 is increased from -67.21 to 35.73 °C having lower cold-utility cost than one at scenario 2 increased from -88.94 to 29.95 °C having higher cold-utility cost at scenario 2. Table 3 shows higher cold-utility-cost reduction at scenario 2 than one at scenario 1.

5. Conclusions

Mathematical programming method shows a potential improvement for the base-case process on energy efficiency. The best improved case for cryogenic carbon capture and liquefied natural gas (LNG) processes depends on requirement of process. For the lowest shaft-work consumption, simple-refrigeration model under both scenarios gives the best refrigeration system design. For the lowest condenser-duty cost, cascade-refrigeration model gives the best alternative design.

Abstract

We aim to suggest a methodology of a smart hybrid hydrogen supply network based on diverse alternative energy resources of hydrogen footprint constraint. To date, hydrogen production has been mostly dependent on fossil fuels. However, future hydrogen would be harnessed contingent on eco-friendly energy resources to support environmentally benign hydrogen economy. In this study, a smart hybrid hydrogen supply network is designed considering hydrogen production from solar energy, wind energy and wastewater and hydrogen distribution by using reinforcement learning. A mathematical model is divided into two phases. First phase is a stochastic programming under demand uncertainty, where multi objective functions are to minimize the total annual costs and environmental costs, respectively. Second phase is a heuristic optimization problem based on Q-learning which is one of the reinforcement learning algorithms. The suggested model is applied to Gyeongsang province in the Republic of Korea as a case study. Alternative energy resources are selected considering regional characteristics. We verify possibilities for construction of a smart future hydrogen supply network based on various feasible scenarios, where can propose the best hydrogen network to decision-makers.

Keywords: Smart hybrid hydrogen supply chain network, renewable energy resource, stochastic programming, reinforcement learning.

1. Introduction

Hydrogen production in industries has continuously increased and the role of hydrogen as a promising energy carrier has explicitly been highlighted. Research on hydrogen production, storage and distribution have been broadly studied and changes from fossil fuels to hydrogen energy based on hydrogen economy concept have been suggested (Marbán and Valdés-Solis 2007). To date, hydrogen production processes have mostly been dependent on fossil fuels such as natural gas and great amounts of hydrogen have been generally harnessed by steam methane reforming. Recently, eco-friendly hydrogen production methods using renewable resources have been studied and commercialized (Figure 1) (Nikolaidis and Poullikkas 2017). Even though hydrogen production from renewable resources has several drawbacks a financial point of view comparing to existing hydrogen production processes, hydrogen price is expected to converse toward a suitable price range through the technical advance and political support such as a subsidy. One of the biggest advantages of hydrogen is that hydrogen is able to be stored

as a fuel cell and converted into electricity. Therefore, the way to hydrogen storage would be one of the crucial components to construct a hydrogen economy. Lastly, proper distribution of hydrogen between various sink companies and source companies has to be designed. The idea of supply chain network has been applied to hydrogen transfer (Hwangbo, Lee et al. 2017). In spite of the evaluation of case studies, geometric barriers between a sink company and a source company has not been taken into account because, in the case of the consideration of those barriers, a number of variables and nonlinear equations would be generated and also it is almost impractical that all constraints are formulated within one mathematical model.

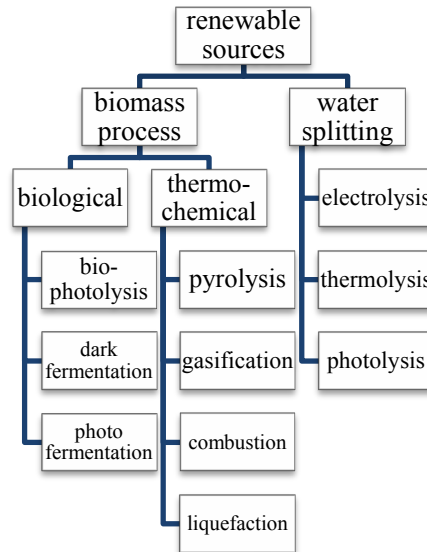

Figure 1. Hydrogen production methods utilizing renewable resources.

Therefore, this study proposes a methodology of the construction of a smart future hydrogen supply network dividing hydrogen production, storage and distribution into two phases. Hydrogen production and storage using alternative energy resources are conducted based on a stochastic programming under hydrogen demand uncertainty and smart distribution of hydrogen is performed by reinforcement learning. A case study of Gyeongsang province in the Republic of Korea was applied to the proposed methodology and the possibilities of this study were confirmed according to the results

2. Problem statement

The expected amounts of future hydrogen demands are illustrated showing different values depending on into various reports or papers. However, the common ground is that hydrogen demand will increase and the range of hydrogen utilization will be extended. Moreover, hydrogen world will go away from hydrogen production from fossil fuels, toward hydrogen production from renewable resources which hardly emit carbon emissions. Storage systems in this study are assumed to operate existing storage systems because the qualities of hydrogen from fossil fuels and renewable resources are usually identical.

2.1. Algorithm

Figure 2 depicts an algorithm of the proposed model. Firstly, hydrogen demands by region are calculated and a two-stage stochastic programming model considering hydrogen demand uncertainty is constructed. The type of objective function is able to be selected depending on a situation. Costs can be optimized by using a simple single objective function and environmental costs or risk as well as costs are able to be minimize by multi objective functions. In the case of multi objective optimization, ϵ -constraint method as a typical algorithm to solve multi objective problems is generally employed. Pareto analysis is performed based on Pareto sets of the above procedure and feasible scenarios are created. Regions for hydrogen production from renewable resources and a quantity of produced hydrogen are determined and capital and operating costs of needed facilities or processes are decided. In Phase B, smart distribution for hydrogen transfer is designed contingent on the results from Phase A. As aforementioned, the development of global environmental model considering all components in detail is normally impossible because there exist diverse sink and source companies in different regions and many barriers are located in between. Therefore, reinforcement learning is selected to find an optimal route without knowing an environmental model. This study uses Q-learning among several algorithms in reinforcement learning because four results from a value function at regions where are divided by a grid can be illustrated by Q-table. The optimal pathway from a source company to a sink company is suggested by following the maximum value among the results. Finally, a smart hydrogen supply network is developed by phases A and B.

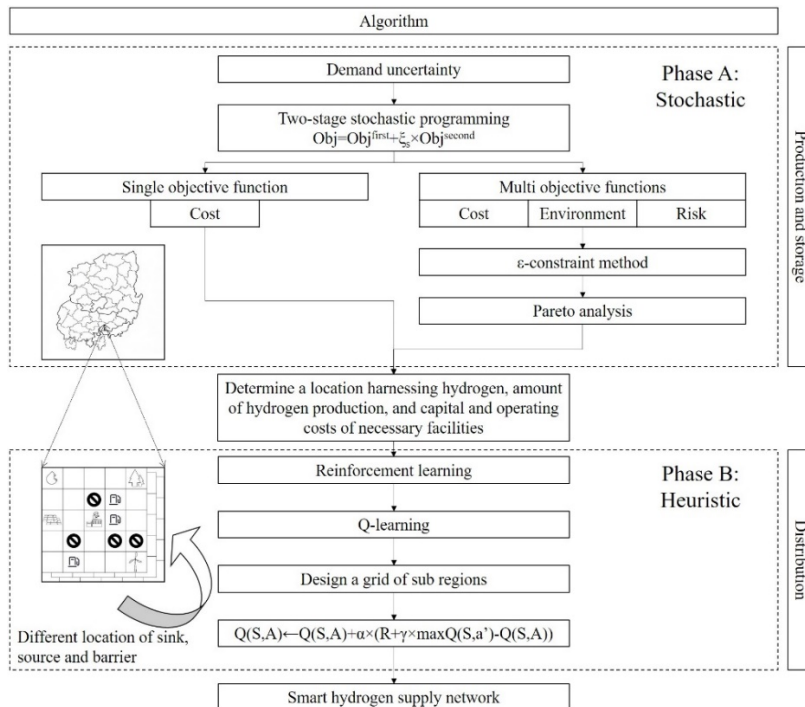

Figure 2. An algorithm of two-phase optimization problem for construction of smart hydrogen supply network.

3. Mathematical model

A stochastic programming used in phase A is a mixed-integer linear programming and multi objective functions concerning costs and environmental costs are formulated (Eq. (1)). Phase B is constructed by environment and agent. Sink, source and barrier in each region are encompassed in environment and agent performs the state and action forward the direction having the biggest reward value which is obtained by Q-learning. The reward value of a source company is assigned as a positive value on the other hand the reward value of barriers where are allocated in many places is designated as a negative value. The total 1,000 episodes are generated. Agent initially acts random exploration, as time goes by, agent finds an optimal route to a source company because Q-function is updated when an episode ends up (Eq. (2)).

Phase A :

$$\min Total_Cost = Cost^{First} + \sum_s \{ \zeta_s \times Cost_s^{Second} \} \quad \forall s \quad (1)$$

$$\min Downside_Risk = \sum_s \{ \zeta_s \times Index_s \} \quad \forall s$$

Phase B :

$$Q(S_t, A_t) \leftarrow Q(S_t, A_t) + \alpha \times \left\{ R_{t+1} + \gamma \times \max_{a'} Q(S_{t+1}, a') - Q(S_t, A_t) \right\} \quad (2)$$

The first stage total cost of the total costs in phase A $Cost^{First}$ is the term which is not affected by demand uncertainty and generally includes facility capital costs. The second stage total cost of the total costs in phase A $Cost_s^{Second}$ is the term which is directly affected by demand uncertainty and normally contains facility operating costs. The probability considering demand uncertainty ζ_s has in general the value that 1 is divided by the number of scenarios. Q-function $Q(S_t, A_t)$ is consistently updated according to the nearest state and action. Learning rate α is constant and assists that Q-function is converged. Reward R_{t+1} is able to be constant or formulated as a function. This study takes into account that a barrier has a negative value and a source company has a positive value. Discount factor γ presents the difference between Q-function values from the initial state to the final state based on the number of steps.

4. Results and discussion

A case study of Gyeongsang province of the Republic of Korea is simply applied to the proposed method. According to regional characteristics of Korea, renewable energy production using wind power and solar power are mainly conducted and a future renewable energy roadmap is expected to focus on those energy systems. Regions for large-scale wind and solar power systems where have been already installed or are anticipated to be built in the future are allocated in four and five places, respectively. And, industry complexes including a huge petrochemical industry are located in four regions. All regions underpin wastewater treatment plants where are able to produce

biogas. This study assumes that wind power and solar power are necessarily integrated into a smart hydrogen supply network. Results from multi objective problems in phase A by using a moderate epsilon value show that 13 regions among the total 42 regions construct and operate waste biogas production processes in order to harness hydrogen (Figure 3). The developed hydrogen supply network in this study covers above the half of the total hydrogen demand which were fulfilled by hydrogen production from fossil fuels. The total costs increase 19% otherwise the amounts of carbon emissions decrease 26% compared to the base case. A smart distribution by reinforcement learning for hydrogen transfer results from phase B. In the case of the previous hydrogen transfer model, a number of variables and nonlinear equations were created because a mathematical model was formulated by applying Euclidean distance calculation between a sink company and a source company, and it would result in infeasible solutions and the consideration of a barrier was rarely conducted (Figure 4(a)). However, in the case of Q-learning which does not request a mathematical model for the environment, an optimal route avoiding barriers is suggested.

Figure 3. A case study of Gyeongsang province in the Republic of Korea.

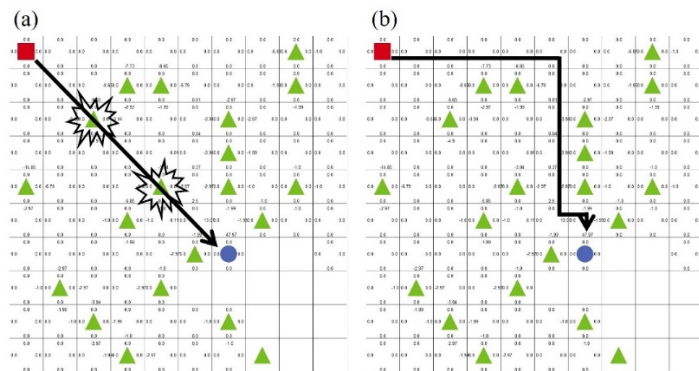

Figure 4. A result example from Q-learning; (a) existing pathway using Euclidean distance; (b) modified pathway using reinforcement learning; rectangle: source, circle: sink and triangle: barrier.

5. Conclusions

This study suggested a novel methodology for the development of a smart future hydrogen supply network. The proposed model was divided into two phases in order to separate hydrogen production/storage and distribution. We verified the reasonable smart distribution of hydrogen without the design of a specific mathematical model by employing reinforcement learning. We believe that the results from this study can propose the feasibilities of the efficient construction of a hydrogen economy or a hydrogen infrastructure.

Abstract

Pyrolysis of waste polymers looks attractive way for their transforming into valuable hydrocarbons. Due to the high number of reactions, the detailed kinetic modeling of the pyrolysis process is often not feasible. Hence the so-called lumping technique is often used to study these complex systems. In this study, the pyrolysis reactions were modeled in a two stage laboratory scale batch reactor using five component lumps. For pyrolysis the mixtures of real plastic waste were used. Kinetic parameters were identified and the model results were compared to the experimental results. It was found that the suggested model can properly describe the dynamic behavior of the reactor under semi batch conditions.

Keywords: discrete lumping, energy from waste, fuel production, kinetic identification, recycling

1. Introduction

Pyrolysis has growing interest in terms of waste recycling. Both biomass (Kim-orba et al., 2015) and petroleum based polymer waste can be transformed into valuable feedstocks for petrochemical sector and refinery. Pyrolysis is a versatile process with a wide product range that can be easily varied with reaction temperature and residence time (Onwudili et al., 2009).

Kinetic modeling of pyrolysis can be challenging due to the various composition of feedstocks and the high complexity of decomposition reactions. The complex network approach is a more sophisticated method to analyze the pyrolysis process. Given that sufficient a priori information is available, the detailed reaction network can be generated automatically; nevertheless the kinetic parameter identification requires some simplification in the model (e.g. the assumption that similar reactions have similar rate coefficients) (Zang et al., 2015). The incremental model identification (IMI) approach can also be applied when the model has a high number of parameters to be identified in case of that the main problem is decomposed into a sequence of subtasks easier to handle individually; for example determine the extent of each reaction in a tubular reactor first then identify the relevant kinetic parameters in each section (Bhatt and Visvanathan, 2015). However, to use this method, concentrations of all components need to be measured along reactor length.

Discrete lumping is a straightforward yet powerful method to analyze complex processes and identify reliable kinetic parameters for a specific process. There are

numbers of previous studies (e.g. Ding et al., 2012, Artetxe et al., 2014) dealing with discrete lumping methods, yet the majority of these solutions deal with batch reactors that are extensively used extensively in laboratory scale. Therefore the potential application of discrete lumping for semi batch processes has been investigated. The aim of our study is to identify the kinetic parameters of a lumped reaction network suitable for the thermal pyrolysis of real plastic waste.

2. Experimental setup

Plastic waste pyrolysis was carried out in a laboratory scale two-stage reactor at atmospheric pressure. 50 g of shredded and crashed real plastic waste was charged into the 1st reactor. To ensure inert atmosphere nitrogen was used. Temperature was maintained at 425/455/485 °C in the 1st reactor and at 395 °C in the 2nd reactor. The mixture of decomposed hydrocarbons obtained from 2nd reactor was driven through a water cooled tube-in-tube heat exchanger, where condensable was transformed into liquid phase. During the pyrolysis, samples of liquid products were collected at given intervals, and then were analyzed by gas chromatography. The volume of gaseous products was measured using a gas flow meter.

3. Reactor model

For kinetic studies, a reaction network was proposed consisting five lumps and nine first-order reactions (Figure 1). The model was developed using a discrete lumping approach. Plastic waste feedstock (P) decomposes into lighter pseudocomponents, namely heavier liquid (L+), lighter liquid (L-) and pyrolysis gas (G). These lumps were characterised based on the average carbon number of the compounds forming them (L+: 15-30, L-: 6-15, G: 0-6). The coke is formed during the decomposition of the feedstock and the L+/L- lumps as well. At the high temperature of the first reactor, P and C are considered to be quasi solid (immobile) and the other pseudocomponents as gaseous (mobile). The mass transfer between the two phases were regarded as instantaneous, in other words, L+, L- and G are only present in gas phase while P and C form the solid phase. Nitrogen from reactor flush was considered as a standalone component aside from pyrolysis gas.

The rate of the i^{th} reaction in the j^{th} reactor is described as a function of the mass concentration of the reactant (with the weight of the specific pseudocomponent divided by the volume of the appropriate phase) (Eq (1)). Reaction rate coefficients were assumed to have Arrhenius-type temperature dependencies (Eq (2)).

$$r_i^j = k_i(T^j) \cdot \frac{m_r^j}{V_p^j} \quad (1)$$

$$k_i = k_{0,i} \cdot \exp\left(-\frac{E_{a,i}}{R \cdot T^j}\right) \quad (2)$$

Component sources were calculated from reaction rates and the stoichiometric matrix of the reaction network (Eq (3)). In order to maintain the mass balance, reaction rates were multiplied by the volume of the phase in that the reaction takes place (Eq (4)).

$$\underline{R}^j = \underline{\nu} \cdot \underline{r}^{j'} \quad (3)$$

$$r_i^j = V_p^j \cdot r_i^j \quad (4)$$

Figure 1. Suggested reaction network consisting five component lumps and nine lumped reactions.

Both reactors were considered to be ideally mixed given the small volumes and low residence time. The change in mass of component c is the result of the difference between the inflow and outflow rates as well as its source from Eq (3):

$$\frac{dm_c^j}{dt} = m_c^{j,in} - m_c^{j,out} + R_c^j \quad (5)$$

For components P and C, flow rate calculation can be omitted because of immobility. In case of the 1st reactor, gaseous component inflow rates are equal to zero except for the nitrogen flush while the inlet of the 2nd reactor is equal to the outlet of the 1st vessel. Reactor outflow (Eq (6)) is a result of three independent phenomena:

- components are formed or depleted in the reactor;
- component mass is increased because of inflow;
- gas phase volume increases with the decrease of the solid phase.

$$m_{c,g}^{j,out} = \left(\sum_k \frac{R_k^j}{M_k} + \sum_k \frac{m_k^{j,in}}{M_k} + \frac{dn_g^j}{dt} \right) \cdot x_{c,g}^j \cdot \bar{M}_c \quad (6)$$

Assuming that the behavior of gaseous phase follows the ideal gas law, at constant pressure and temperature the molar mass of substance changes with the gas phase volume as described in Eq (7):

$$\frac{dn_g^j}{dt} = -\frac{p}{R \cdot T^j} \cdot \left[\frac{d}{dt} \left(\frac{m_p}{\rho_p} \right) + \frac{d}{dt} \left(\frac{m_c}{\rho_c} \right) \right] \quad (7)$$

The aim of our study is to determine the reaction kinetic parameters defined in Eq (2) to model and predict thermal degradation of polymer waste. The objective is to minimize the difference between measured and calculated weight fractions (Eq (8)), in that square error between measurement (m) and calculation (c) is summarized for three temperature (T) levels, five pseudocomponents ($comp$) and all measurement points (p) (one for P, C and G; four to six for L+ and L-):

$$f(x^n) = \sum_T \sum_{comp} \sum_p (w_m - w_c)^2 \quad (8)$$

Decision variables in Eq (8) are expressed in Eq (9-10) and include the pre-exponential factors and activation energies for each reaction, normalized between 0 and 1 for better convergence. Values of lower and upper bounds summarized in Table 2 were chosen as

a result of a set of preliminary studies regarding the values of rate coefficients at individual temperature levels.

$$\mathbf{x}^n = \left[\left(k_0^n \right)^T \quad \left(E_a^n \right)^T \right]^T \quad (9)$$

$$\mathbf{x}^{act} = \mathbf{x}^n \cdot (\mathbf{u}_b - L_b) + L_b \quad (10)$$

The dynamic model of the laboratory scale two-stage pyrolysis reactor was implemented and solved in MATLAB R2011b. The reactor model was solved using the variable-step, variable-order (VSVO) solver based on the numerical differentiation formulas called ode15s (Shampine and Reichelt, 1997). For solving the optimization problem, the NOMAD software package was used that implements the Mesh Adaptive Direct Search (MADS) algorithm and is a well suited solver for derivative-free optimization (Le Digabel, 2011). It also has a MATLAB interface available that can be called directly from the OPTI Toolbox (Currie and Wilson, 2012).

4. Results and discussion

Measured and calculated mass fractions are shown in Figure 2 as a function of time. In case of liquid and gas products (L+, L- and G) the mass fraction was calculated as a quotient of the amount that has left the 2nd reactor and the initial charge; while in case of P and C, the amounts inside the two reactors were taken into consideration. The resulting curves appear to indicate that the suggested reaction network can properly describe the concentration changes taking place during polymer waste pyrolysis. Curve fitting for both liquid fractions are mostly the same and is acceptable within reason. The model predicts the final mass of G and C accurately, while predicted remaining P amount is fairly high.

Figure 2. Pseudocomponent mass fractions at 455 °C – experimental (markers) and model (lines)

Table 1. Root-mean-square error (RMSE) between measured and calculated data

	P	L+	L-	G	C	Lump aggregated
425 °C	7.0 %	1.9 %	2.6 %	2.8 %	0.9 %	2.8 %
455 °C	9.4 %	3.8 %	6.9 %	1.1 %	1.9 %	5.6 %
485 °C	5.3 %	3.2 %	3.8 %	1.3 %	0.2 %	3.4 %
Temperature aggregated	7.4 %	2.9 %	4.5 %	1.9 %	1.2 %	4.0 %

To express the reliability of the identified kinetic parameters quantitatively, the root of mean square errors between measured data and model results for each lump and the complete data set were calculated and are listed in Table 1. Overall, the lowest values were obtained for 425 °C reactor temperature. The identified model gives reasonable estimation for G and C; on the other hand, it tends to overestimate the remaining amount of P at the end of the run. Estimated values of L+ and L- are in reasonable agreement with the measured data; however, as shown in Figure 2, the actual formation of these components is slightly slower at the beginning than predicted.

The identified kinetic parameters for the suggested reaction network as well as the values of reaction rate coefficients at 455 °C are listed in Table 2. It is visible that the rate coefficients for the first four reactions are significantly higher than for the latter five; this could indicate that the formation of products during polymer waste pyrolysis happens simultaneously rather than following a consecutive pattern. This is also supported by reaction networks suggested previously in literature (Ceamanos et al., 2002, Al-Salem and Lettieri, 2010).

Table 2. Lower and upper bounds, identified kinetic parameters and reaction rate coefficients for the specified reactions

Reaction	k_0 [s^{-1}]			E_a [$kJ\ mol^{-1}$]			k at 455 °C [s^{-1}]
	l_b	l_b	actual	l_b	u_b	actual	
P → L+	$1.00 \cdot 10^{16}$	$1.00 \cdot 10^{16}$	$1.23 \cdot 10^{16}$	10.0	500	268.37	$6.87 \cdot 10^{-4}$
P → L-	$1.00 \cdot 10^{19}$	$1.00 \cdot 10^{19}$	$7.62 \cdot 10^{19}$	10.0	500	319.40	$9.31 \cdot 10^{-4}$

P → C	$1.20 \cdot 10^{12}$	$1.20 \cdot 10^{12}$	$1.07 \cdot 10^{13}$	10.0	500	232.67	$2.18 \cdot 10^{-4}$
L+ → L-	$1.44 \cdot 10^{-2}$	$1.44 \cdot 10^{-2}$	$1.24 \cdot 10^{-1}$	17.3	864	229.71	$4.10 \cdot 10^{-18}$
L+ → G	$1.66 \cdot 10^{-1}$	$1.66 \cdot 10^{-1}$	1.18	14.4	720	386.17	$2.34 \cdot 10^{-28}$
L+ → C	$7.68 \cdot 10^{-4}$	$7.68 \cdot 10^{-4}$	$1.37 \cdot 10^{-3}$	14.4	720	215.74	$4.57 \cdot 10^{-19}$
L- → G	$6.40 \cdot 10^{-1}$	$6.40 \cdot 10^{-1}$	3.94	14.4	720	208.21	$4.56 \cdot 10^{-15}$
L- → C	1.15	1.15	6.95	17.3	864	393.89	$3.85 \cdot 10^{-28}$

5. Conclusions and future work

In this work, kinetic parameters of a lumped reaction system consisting five pseudocomponents and nine reactions were identified from experimental data obtained

in a laboratory scale two-stage semi batch reactor. In general, the proposed model can effectively describe the concentration changes in the system, while also fast and slow reaction routes can be distinguished; this fact might give room for further model reduction. Future work may consider the non-isothermal behaviour of the reactor, i.e. taking the heat-up period of measurements into consideration. The proposed method can be applied for catalytic pyrolysis as well, for instance the effect of different catalysts on individual reactions can be investigated.

Experimentally Driven Guaranteed Parameter Estimation: a Way to Speed up Model-Based Design of Experiments Techniques

Arun Pankajakshan,^a Marco Quaglio,^a Federico Galvanin^{a,*}

^a*Department of Chemical Engineering, University College London, London, WC1E 7JE, United Kingdom*

f.galvanin@ucl.ac.uk

Abstract

Parameter estimation in modelling reaction kinetics is affected by the prior knowledge on the domain of variability of model parameters which can be very limited at the beginning of model building activities. In conventional parameter estimation approaches a reasonably wide domain of variability for kinetic parameters is initially assumed, but this uncertainty on domain definition might deeply affect the efficiency of model-based experimental design techniques for model validation. In this work, we propose the use of binary classification techniques to define a feasible parametric region of parameter variability satisfying a set of user-defined model-based constraints. The proposed approach is illustrated in a case study of consecutive reactions in a plug flow reactor.

Keywords: Support vector machine, guaranteed parameter estimation, model-based design of experiments

1. Introduction

Mathematical models are an approximation of the real system, limited by the knowledge and understanding of the dynamics from experimental observations (Box, 1976). First-principles-based models have been used to represent nonlinear dynamic systems, but the major challenge involved with the use of such models is the precise estimation of large numbers of model parameters (Prasad and Vlachos, 2008). Modelling the kinetics of chemical reactions represents a typical example of such complex nonlinear systems. Recently, model-based design of experiments (MBD_{oE}) techniques have emerged as powerful tool for the rapid development and refinement of reaction kinetic models from flow data (Galvanin et al., 2016). However, in the conventional MBD_{oE} framework proposed in Asprey and Macchietto (2000), the model building procedure might become time-consuming and computationally expensive because the robustness of experimental design is critically affected by the presence of parametric uncertainty (Asprey and Macchietto, 2002). As an alternative method to the conventional MBD_{oE} using Fisher information matrix (FIM) Mukkula and Paulen (2017) used guaranteed parameter estimation (GPE) technique in the optimal design of dynamic experiments. In the optimal experiment design using GPE, the knowledge on measurement error is limited to error bounds. In comparison to MBD_{oE} using FIM, MBD_{oE} using GPE is computationally expensive. Both the methods assume an initial admissible parameter space containing the prior estimate and are critically affected by its definition. In the present work, we propose a computationally fast methodology to identify a feasible parametric space without any knowledge on measurement error and prior estimate. In

the proposed approach, bounds on a set of user defined characteristic variables are used to obtain the prior admissible parameter set. Characteristic variables are either derived from experimental observations or obtained from experimenter's intuition on the process. In this way, the experimenter's knowledge on the process can be exploited to obtain a robust prior parametric space before performing any experiments. The proposed methodology is implemented as a two-step binary classification procedure using support vector machine (SVM) and can be used with both FIM based and GPE based optimal design approaches. The method is applied to a simulated case study for the identification of the domain of variability of kinetic parameters in reaction systems.

2. Problem statement

We assume that a process model is described by a set of differential and algebraic equations (DAEs) in the form

$$\mathbf{f}(\dot{\mathbf{x}}(z, t), \mathbf{x}(z, t), \mathbf{u}(z, t), \mathbf{w}, \boldsymbol{\theta}, t, z) = 0 \quad (1)$$

$$\hat{\mathbf{y}}(z, t) = \mathbf{h}(\mathbf{x}(z, t), \mathbf{u}(z, t), \mathbf{w}, \boldsymbol{\theta}, t, z) \quad (2)$$

where $\mathbf{x}(z, t) \in \mathbf{R}^{N_x}$ is the time and space dependent vector of state variables (i.e. for example time and space dependent concentrations in a flow reactor), $\mathbf{u}(z, t) \in \mathbf{R}^{N_u}$ is the vector of control variables (manipulated inputs) whereas $\mathbf{w} \in \mathbf{R}^{N_w}$ represents the vector of constant controls, $\boldsymbol{\theta} \in \mathbf{R}^{N_\theta}$ is the set of unknown model parameters to be estimated within a continuous realisable set Θ which is unknown and to be identified in the present problem, $\mathbf{y}(z, t) \in \mathbf{R}^{N_y}$ is the set of response variables (i.e. state variables that are measured in the process) and $\hat{\mathbf{y}}(z, t)$ represents the corresponding values of response variables predicted by the model, t is the time and z is the axial domain.

3. Methodology

The procedure involved in the proposed approach is illustrated in Figure 1. First step in the proposed approach is the generation of model-based constraints using support vector machine (SVM) classifiers. The experimenter's intuition and understanding about the process is used to define a set of constraints. These constraints are defined by the expected limits of variability of a set of characteristic variables identified by the experimenter to provide a quantitative description of the process. In the second step, a region of parametric space satisfying these constraints (feasible parametric space) is identified using binary classification technique carried out with SVM. The two stage classification procedure is implemented as a standalone module in Python and can be easily integrated to the MBDoE module built in Python.

3.1. Generation of model-based constraints and classification criteria

The model-based constraints are defined by a set of characteristic variables $\boldsymbol{\psi}(\mathbf{u}, \mathbf{y}, \mathbf{w}, z, t) \in \mathbf{R}^{N_\psi}$ identified by the experimenter (these can be for example yield, conversion or concentrations) and correspond to the extreme model responses at given experimental conditions. For the generation of model-based constraints, the set $\boldsymbol{\Psi}$ is enforced on the model by using a set of functional relationships \mathbf{g} between $\boldsymbol{\Psi}$ and $\hat{\mathbf{y}}(z, t)$ at specific experimental conditions $\mathbf{u}(z, t)$ and \mathbf{w} in the form

$$\boldsymbol{\psi}(z, t) = \mathbf{g}(\hat{\mathbf{y}}(z, t), \mathbf{u}(z, t), \mathbf{w}). \quad (3)$$

It is assumed that the input from the experimenter is in the form of maximum expected variability range $\psi^- \leq \psi \leq \psi^+$, where ψ^- and ψ^+ respectively denotes the lower/upper bounds of the variable ψ .

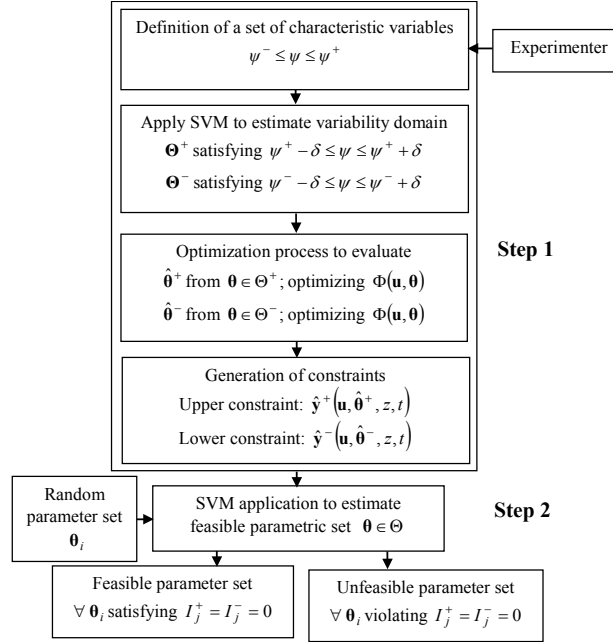

Figure 1. Proposed framework for the identification of feasible region of model parameters

Once the set Ψ is known, binary classification using SVM is applied to identify the parameter domains Θ^+ and Θ^- corresponding to a small variability range for upper limit ψ^+ defined as $(\psi^+ - \delta, \psi^+ + \delta)$ and that for lower limit ψ^- defined as $(\psi^- - \delta, \psi^- + \delta)$ respectively, where δ is a small number; Θ^+ and Θ^- are the parametric domains enclosing all set of parameters for which the predicted responses give ψ in the range $(\psi^+ - \delta, \psi^+ + \delta)$ and $(\psi^- - \delta, \psi^- + \delta)$ respectively. In the next procedure, an optimization problem is formulated within the domains Θ^+ and Θ^- to compute the desired set of parameter values $\hat{\theta}^+$ and $\hat{\theta}^-$ generating the upper and lower bounds for the model given by $\hat{y}^+(\mathbf{u}, \hat{\theta}^+, z, t)$ and $\hat{y}^-(\mathbf{u}, \hat{\theta}^-, z, t)$ respectively. The objective function $\Phi(\mathbf{u}, \theta)$ depends on the process and can be generally represented as

$$\hat{\theta}^+ = \arg \min_{\theta \in \Theta^+} \Phi(\mathbf{u}, \theta) \quad \text{and} \quad \hat{\theta}^- = \arg \min_{\theta \in \Theta^-} \Phi(\mathbf{u}, \theta) \quad (4)$$

In the second step of the proposed procedure, SVM is applied to estimate a feasible parametric domain Θ of model parameters from any random set such that the predicted responses for the feasible set of parameters are always constrained within the constraints generated in the first part. Mathematically this is formulated based on the following criteria

$$I_j^+ = \int_0^\tau \min(0, y_j^+(\mathbf{u}, \hat{\theta}^+, t) - \hat{y}_j(\mathbf{u}, \theta_i, t)) dt \quad i=1, \dots, N_s; \quad j=1, \dots, N_y \quad (5)$$

$$I_j^- = \int_0^\tau \min \left(0, \hat{y}_j(\mathbf{u}, \boldsymbol{\theta}_i, t) - y_j^-(\mathbf{u}, \hat{\boldsymbol{\theta}}^-, t) \right) dt \quad i=1, \dots, N_s; \quad j=1, \dots, N_y \quad (6)$$

where N_s and N_y denotes the number of random parameter sets and the number of model responses respectively, I_j^+ and I_j^- respectively denotes the integral of minimum deviation between model response for j -th response variable and the upper and lower constraint at any parameter set $\boldsymbol{\theta}_i$.

3.2. Application of support vector machine

SVM is capable of learning the decision function with appropriate training data to determine the optimum hyperplane that separates the given samples into feasible and unfeasible sets. In the present problem, the training set for SVM is represented as $(\boldsymbol{\theta}_i, Y_i)$, where $Y_i \in \{-1, 1\}$; -1 for feasible parameters and 1 for unfeasible parameters (binary classification). SVM classifier seeks to maximize the width of the largest margin separating the sample $\boldsymbol{\theta}_i$ into two classes and can be formulated as a convex optimization problem (Cortes and Vapnik, 1995):

$$L = \sum_{i=1}^n \alpha_i - \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n \alpha_i \alpha_j Y_i Y_j k(\boldsymbol{\theta}_i \cdot \boldsymbol{\theta}_j) \quad \text{s.t. } \boldsymbol{\Lambda} \geq 0 \text{ and } \boldsymbol{\Lambda}^T \mathbf{Y} = 0 \quad (7)$$

Where L is the Lagrangian form of the objective function, $\boldsymbol{\Lambda}^T = (\alpha_1, \dots, \alpha_n)$ is the n -dimensional vector of Lagrange multipliers, $\mathbf{Y}^T = (Y_1, \dots, Y_n)$ is the n -dimensional vector of labels which is either -1 or 1, k is the kernel function which is a measure of similarity between two samples $\boldsymbol{\theta}_i, \boldsymbol{\theta}_j$ to be classified. In the present study, the Gaussian radial basis function (RBF) kernel was selected over linear and polynomial kernels based on accuracy of classification of the training set. The two parameters C and γ of the RBF kernel were optimized using grid search cross validation scheme reported in Scholkopf and Smola (2002).

4. Case study

We demonstrate the proposed approach to identify the feasible region of reaction rate constants for a series of consecutive reactions in a plug flow reactor in the form: $A \xrightarrow{k_1} C \xrightarrow{k_2} D$. Assuming power law type kinetic model, the reaction system is described by the following set of DAEs:

$$\frac{-V_{in}}{A_c} \frac{dC_i}{dz} + \sum_{j=1}^{N_{rean}} \nu_{ij} r_j = 0 \quad i=1, \dots, N_{comp}; \quad j=1, \dots, N_{rean} \quad (8)$$

$$r_j = f(k_j, C_i) \quad ; \quad k_j = k_{0j} \cdot \exp(-Ea_j/R \cdot T) \quad i=1, \dots, N_{comp}; \quad j=1, \dots, N_{rean} \quad (9)$$

In Eq. (8), C_i is the concentration (mol/L) of the i -th component, r_j and ν_{ij} are respectively, the j -th reaction rate and the stoichiometric coefficient of the i -th species in the j -th reaction, V_{in} is the inlet volumetric flowrate of reactant A (ml/min), A_c is the reactor cross sectional area (here assumed 2 cm²), z is the axial coordinate along the

reactor length, l is the length of reactor channel (25 cm), u is the vector of control variable consisting of initial concentration of reactant A (1.5 mol/L), reaction temperature T (353 K) and the inlet volumetric flowrate of reactant A (5 ml/min), i.e. $\mathbf{u} = [1.5, 353, 5]$. In Eq. (9), the temperature dependency of reaction rate is described using Arrhenius law, where k_j denotes the reaction rate constant for the j -th reaction (min^{-1}), k_{0j} the frequency factor (min^{-1}) and Ea_j the activation energy (J/mol). The four model parameters $\boldsymbol{\theta} = [k_{01}, Ea_1, k_{02}, Ea_2]$ were normalised with respect to the set $\boldsymbol{\theta}^0 = [50, 10000, 80, 20000]$. The normalised parameters $\boldsymbol{\theta}^n$ defined as $\boldsymbol{\theta}^n = \boldsymbol{\theta}/\boldsymbol{\theta}^0$ were randomly varied from a uniform distribution with range (0, 2) and the corresponding values of parameters ($\boldsymbol{\theta}$) were used to compute the two reaction rate constants k_1 (min^{-1}) and k_2 (min^{-1}) which were actually used as the training set for the classifier. Thus the four model parameters were varied to obtain the corresponding rate constants which were used for the classification. The characteristic variables with suitable ranges provided by the experimenter are: (i). Conversion of reactant A: (80 – 100 %), (2). Yield of product C: (20 – 40 %), (3). Yield of product D: (60 – 80 %). In this work, constraints on yield of product C was used for generating the model-based constraints with $(\psi^+ - \delta, \psi^+ + \delta) = (38\%, 42\%)$ and $(\psi^- - \delta, \psi^- + \delta) = (18\%, 22\%)$. The time t_{\max} at which the intermediate product C reaches the maximum concentration, calculated as $t_{\max} = \ln(k_2/k_1)/(k_2 - k_1)$ (Fogler, 2006), was chosen to be the objective function $\Phi(\mathbf{u}, \boldsymbol{\theta})$ in Eq. (4). The parameter set $\hat{\boldsymbol{\theta}}^+$ (defining the upper bound of variability) was estimated from the domain Θ^+ by minimizing t_{\max} which corresponds to the fastest reaction (comparing the model responses for C for all $\boldsymbol{\theta}_i \in \Theta^+$). Similarly, $\hat{\boldsymbol{\theta}}^-$ was estimated from the domain Θ^- maximizing t_{\max} which corresponds to the slowest reaction for the formation of C.

5. Results

Following the procedure for the generation of model-based constraints explained in Section 3.1, the parameter sets corresponding to upper and lower constraints were estimated to be $\hat{\boldsymbol{\theta}}^+ = [2.52, 0.09]$ and $\hat{\boldsymbol{\theta}}^- = [0.17, 0.24]$ and corresponding constraints are given in Figure 2a. In the figure, the thick dashed line represents the upper constraint which is the concentration profile of product C at the parameter set $\hat{\boldsymbol{\theta}}^+ = [2.52, 0.09]$ calculated from Eq. (4). Similarly, the thick dotted line represents the lower constraint which is the concentration profile of C at the parameter set $\hat{\boldsymbol{\theta}}^- = [0.17, 0.24]$ calculated from Eq. (4). Due to small misclassification, it can be seen that some of the generated profiles violates the constraints. Figure 2b shows the feasible parametric space identified by the trained classifier for a random parametric domain of variability (0, 2). In the figure, the dotted white space shows the feasible parametric region and the plane area represents the unfeasible region. Each point within the feasible space (except the misclassified parameter sets shown in white circle) represents a feasible parameter set for which the concentration profile of product C is within the constraints (these profiles are shown in thin dotted lines in Figure 2a). The approach provides a narrow feasible parametric domain (the white area) for any random set of model parameters where the model identification techniques such as MBDoE for parameter estimation can be applied in a more robust and effective way. The whole procedure is computationally very fast and consumed a total CPU time of approximately 5 seconds on an Intel® Xenon® E5-1650, 3.5 GHz, RAM 32 GB.

Figure 2b. Feasibility region for parameters k_1 and k_2 (dotted white area) separated from the unfeasible region (plane area)

6. Conclusions

A general method is proposed in this paper to estimate the domain of variability of model parameters satisfying a set of model-based constraints whose definition can be obtained from user-defined information on the experimental system. Support vector machine (SVM) methods were used for both defining the set of constraints and for obtaining the feasibility region of model parameters. Results from the case study show how even limited preliminary information on conversion and yield can significantly reduce the expected uncertainty domain of model parameters. The method provides a narrow feasible region of model parameters where identifiability analysis can be targeted to obtain a reliable parametric uncertainty region in estimation problems. In the resultant narrow parametric space, MBDoE techniques can be effectively applied for the quick development and validation of deterministic process models.

Abstract

Dividing wall columns (DWC) are the industrial implementation of the Petlyuk configuration in a single shell. The optimal design of dividing wall columns is a multivariable, mixed-integer and non-linear problem with a non-convex optimization function presenting several local optima. The response surface method (RSM) associated with the steepest descent method offers a practical approach to optimize the DWC design. In the present study, a central composite design is carried out to obtain and validate the response surface for a DWC performing an aromatic ternary separation. The resulting aromatic DWC system presented a better optimal design compared with previous work and energy savings by 44% compared with a conventional two-column configuration (C2C) typically used for aromatic separation. The method is able to systematically solve the problem while minimizing simulation effort and optimizing the DWC design parameters.

Keywords: Dividing wall columns, Optimization, Response surface method, Distillation process.

1. Introduction

Distillation has been the most commonly used process for the separation of liquid mixtures and one of the most studied unit operations in the history of chemical engineering (Li et al., 2016). Despite its wide industrial application, distillation technology has drawbacks related to its high operational and implementing costs. In conventional two-column (C2C) sequences the natural presence of flow remixing in the columns sections results in energy inefficiency. This remixing is inherent in any separation involving the presence of a component with intermediate volatility at high concentrations (Hernández et al. 2006). An alternative configuration which is more energy efficient is a fully thermally coupled (FTC) configuration, called the Petlyuk configuration (Figure 1a). In this configuration, the vapor and liquid streams emerging from the first column (pre-fractionator) are directly coupled to the second column (main column). The Petlyuk configuration has higher thermal efficiency compared to the C2C configurations due to the decrease in the remixing effect, providing considerable energy savings, approximately 30% (Petlyuk, 2004).

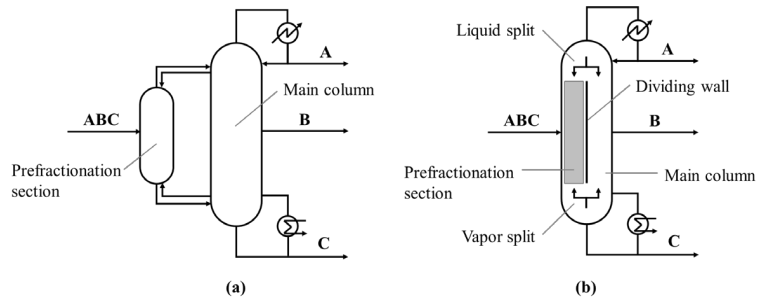

Figure 1 – (a) Petlyuk column and (b) Dividing-wall column.

The dividing-wall column (DWC), depicted in Figure 1b, is the industrial implementation of the Petlyuk column in a single shell, generating greater integration and cost reduction. Besides the greater energy efficiency, the DWC offers a further advantage, compared to conventional columns, of producing high purity side products and separating several pure components in a single unit (Dejanović et al., 2010).

Authors have developed different conceptual design methods for FTC columns, such as the Petlyuk and the DWC, and reported gains in energy efficiency compared to conventional distillation column sequences. Halvorsen and Skogestad (2003) developed the V-min Diagram Method for the minimization of energy requirement in multicomponent distillation systems. The method is based on the Underwood equations, considering constant molar flows, an infinite number of theoretical stages and constant relative volatilities. The authors have shown that the FTC configuration always presents a lower energy consumption, when compared to the C2C configuration, for the separation of an N-component mixture. The V-min Diagram Method can be summarized in a graphical representation, which is a useful tool for the conceptual design of FTC configurations. Dejanović et al. (2011) developed a method, based on the V-min Diagram (Halvorsen and Skogestad, 2003), to determine the optimal number of stages and reflux ratio of a DWC for a three-product separation. The authors reported a 43% reduction in energy consumption using the DWC compared to a conventional indirect sequence.

Although many conceptual design methods have been developed, the design and optimization of an FTC multicomponent distillation column is a non-linear, multivariable and mixed-integer problem with a non-convex objective function with several local optimums (Vazquez-Castillo et al., 2009). Gómez-Castro et al. (2008) studied the design and optimization of dividing wall columns using a genetic algorithm. The objective function was evaluated using Aspen PlusTM process simulator which was coupled with MatlabTM for solving the optimization problem. The authors report that the method appears to be suitable for the design of dividing-wall columns. This optimization method, however, have drawbacks related to implementation complexities. Thus, the development of a straightforward optimization method for DWCs would be useful.

Statistical approaches have been shown to be promising for process optimization studies (Van Duc Long and Lee, 2012). Response surface method (RSM) is a collection of statistical techniques used for studying the relationships between measured responses and independent input variables. In the present paper, RSM is used for the optimization

of the main design parameters of a DWC aiming lower energy and investment costs. The separation of a benzene, toluene and p-xylene ternary mixture (BTX) in a DWC investigated by Premkumar and Rangaiah (2009) is used as a case study.

2. Simulation model and optimization method

2.1. Simulation

A shortcut design method is essential for ascertaining reasonable estimates for more precise simulations. The V-min diagram method proposed by Halvorsen and Skogestad (2003) calculates the minimum vapor and liquid flows required to perform all binary separations on a given mixture, assuming an infinite number of stages. The V-min diagram method will be used as a shortcut method for ascertaining the initial guess for the rigorous simulation.

The DWC can be simulated in Aspen PlusTM through a thermodynamically equivalent configuration using one to four columns. The four-column model (Dejanović et al., 2011) is usually harder to initialize and converge, however, offers more flexibility when performing process optimization (Nguyen et al., 2016). The rigorous model calculation was performed by a RadFrac four-column model in Aspen PlusTM. The number of stages in each column, products flows rates, reflux ratio, boil-up ratio and liquid and vapor feed flows to the pre-fractionator were set according to the V-min diagram. For simplification purposes, the column pressure was maintained constant at 10 bar. The Reflux ratio, side-product flow and boil-up ratio were set as variables for the design specification for the top, middle and bottom products, respectively.

The case study is the separation of a hydrocarbon mixture (benzene, toluene, p-xylene), as proposed by Premkumar and Rangaiah (2009). Feed conditions are set at 100 kgmol/h of saturated liquid at 10 bar. Molar feed composition is 33% benzene, 33% toluene and 34% p-xylene. The top, middle and bottom products specifications are 99.5% benzene, 91% toluene and 92% p-xylene, respectively. The UNIQUAC method was used for vapor-liquid equilibrium calculations.

2.2. Optimization

The main design parameters for the DWC are the number of stages in the top (NC1), bottom (NC22), and pre-fractionator (NC1) sections and the internal vapor (VFC1) and liquid (LFC1) flows to the pre-fractionator. For simplification purposes, the number of stages at the two sides of the partitional wall were considered the same. The simple yet effective objective function $\Phi = N_T(R + 1)$, where N_T is the total number of stages and R is the reflux ratio, was suggested by Dejanović et al. (2011) for measuring the optimal relation between stage and reflux requirements for the DWC.

Design of experiments (DOE) was used as part of the RSM sequential procedure for identifying the DWC optimal design region. For the first factorial design, factor levels were chosen by single-factor testing (Van Duc Long and Lee, 2012). As the V-min diagram method considers an infinite number of theoretical stages, the method of steepest descent was used next to move sequentially in the direction of the minimum response, based on the statistically significant effects computed by the first DOE. Then, factorial and central composite designs are performed sequentially at the new region to fit first and second order models, so that an optimal response can be reached. All experimental designs and ANOVA analysis were performed using the MinitabTM software.

3. Results and discussions

For the first design of experiments, a 2^5 complete factorial design with one central point was carried out. The maximum values of the design parameters were taken from the V-min diagram and the minimum values by single-factor testing. All main design parameters were considered statistically significant at a 95% confidence level. The path of steepest descent was calculated based on the design parameters main effects and levels. A minimum response in the path was identified and a new full factorial design was performed at the minimum response region as the central point. Factor levels for all design parameters are presented in Table 1 (design # 1). The summarized results for design no. 1 are presented in Table 2. The ANOVA analysis was carried out using a 95% confidence level to evaluate the significance of the design parameters. One can notice that the liquid and vapor flows to the pre-fractionator are only significant as interaction effects. This finding is in accordance with Dejanović et al. (2011), who identified a flat region around the optimal point, indicating that the objective function is not sensible to these two main effects. The low F-Value (11.04) for this model indicates that a first-order model is not suitable for the DWC. From this point, a central composite design will be used attempting to fit a second-order model. As the number of stages in the top section (NC21) and the internal vapor (VFC1) and liquid (LFC1) flows to the pre-fractionator are no longer statistically significant to the model, they were held constant at the central values of 17 stages, 72.3 kgmol/h and 118.4 kgmol/h, respectively. The factor levels for this central composite design is summarized in Table 1 (design # 2).

Table 1 – Parameters design levels.

Design #	Design type	Design parameters	Coded levels		
			Low (-1)	Center (0)	High (1)
1	Factorial	NC1	36	46	56
		NC21	12	17	22
		NC22	21	26	31
		LFC1/kgmol.h ⁻¹	62.3	72.3	82.3
		VFC1/kgmol.h ⁻¹	108.4	118.4	128.4
2	Central composite	NC1	25 (-1.414)	46	67 (-1.414)
		NC22	12 (-1.414)	26	40 (-1.414)
3	Central composite	NC1	24 (-1.414)	31	38 (-1.414)
		NC22	4 (-1.414)	11	18 (-1.414)

Table 2 – Summarized results from ANOVA analysis for fitted models.

Model	Order	No. of simulations	Significant factors			F-Value
			Linear	Interaction	Square	
1	first	33	NC1	NC21*VFC	-	11.04
			NC22	LFC1*VFC1		
2	second	13	NC1	-	NC1 ²	174.59
			NC22			
3	second	13	NC1	NC1*NC22	NC1 ²	1256.30
			NC22			

A 2^2 ($\alpha = 1.414$) central composite design was performed for fitting a second-order model. Table 2 shows that model 2 is significant with an F-Value of 174.59. The contour plot in Figure 2a indicates that, although the model is significant, it is still not in the optimal response region. Therefore, to approximate the model to the optimal response region, a second steepest descent is performed using the minimum values from the contour plot in Figure 2a to redefine factor levels. The factor levels for the new central composite design are shown in Table 1 (design # 3). The summary results for the new second-order model is shown in Table 2 (model 3). The large F-Value (1256.30) indicates that the model is statistically significant. The new contour plot in Figure 2b shows that the steepest descent method was able to move the model in the direction of the minimum response of -0.1571 (≈ 32 stages) for NC1 and 0.6143 (≈ 15 stages) for NC22.

Table 3 compares the C2C and DWC configuration investigated by Premkumar and Rangaiah (2009) and the new DWC configuration optimized using the RSM. The new DWC configuration presents a lower number of stages and slightly lower energy requirements than the DWC suggested by Premkumar and Rangaiah (2009), which means savings in operating and capital costs. Those savings are probably possible due to better values for the vapor and liquid internal flows to the pre-fractionator, which were not informed by Premkumar and Rangaiah (2009). Compared to the C2C configuration, the new DWC shows savings about 44% in reboiler and condenser duties, confirming the reduction in energy consumption while ensuring the same product quality.

Figure 2 – Contour plots for models (a) 2 and (b) 3.

Table 3 – Comparison between C2C and DWC configuration.

Design parameters	C2C configuration ^a			DWC ^a	DWC (RSM)
	C1	C2	Total		
No. of stages	31	40	71	68	62
No. of stages (top, middle, bottom)	-	-	-	17, 35, 16	17, 31, 14
Condenser duty / kW	1,476	876	2,352	1,306	1,296
Reboiler duty / kW	1,508	890	2,398	1,355	1,345

^aPremkumar and Rangaiah (2009)

4. Conclusions

A straightforward method for design and optimization of a DWC using the DOE and RSM was presented in this paper. The steepest descent method was proven efficient for moving sequentially in the direction of the minimum response by changing the main parameters values according to their effects and factor levels. The final second-order model was statistically significant and the optimization of the final two main design parameters resulted in a DWC six-stage lower than the one reported in the literature with savings of 44% in reboiler and condenser duties compared to the C2C configuration for the same aromatic separation. This work shows the systematics, low computational effort and simplicity of the RSM for optimizing the DWC design.

Simulation/optimization of bio-hydrogenated diesel process with techno-economic analysis

Pooreerat Tawai^a, Kitipat Siemanond^{a*}

^aThe Petroleum and Petrochemical College, Chulalongkorn University, 254 Soi Chulalongkorn 12, Phayathai road, Bangkok 10330, Thailand;
Pooreerat.t@gmail.com, Kitipat.s@chula.ac.th

Abstract

In this study, Pro II and general algebraic modeling system (GAMS) software were applied to synthesize and optimize the Bio-hydrogenated diesel (BHD) process. This research had been divided into three main parts. The first part was focused on conceptual process simulation of BHD process. The operating condition analysis method represented operating parameters at 325°C, 500 psig with NiMo/Al₂O₃ catalyst. The final commercial products were n-hexadecane and n-octadecane. The input information such as reaction conditions, conversion of each reaction, production yield and products purity were provided by petrochemical industry in Thailand. The second part was concentrated on process improvement in energy efficiency by mathematical programming which was used for designing heat exchanger network (HEN) or heat integration of the process. It decreased operating cost and saved hot and cold utility usages. In final part, techno economic analysis was a key factor that played an important role on investment decision by using economic parameters of net present value (NPV), internal rate of return (IRR) and payback period (PBP). The BHD plant capacity was 10,000 Liters/day which used palm oil as feedstock. The energy consumption was optimized by HEN designed by GAMS programing. The simulation result showed the production rate was 12,374.09 Liters/day, the conversion of biodiesel range was 99.83%, and product yield and purity of commercial product were 79.89 and 99.92% respectively. BHD process required 7 heat exchangers resulting in the reduction of energy consumption on heater from 1,335,233 kJ/h to 655,905 kJ/h or heating utility was saved about 50%. Moreover, BHD process made profit over 45.67 million Baht with PBP of 9.4 years and IRR at 25.40%.

Keywords: Palm oil, Bio-hydrogenated diesel, Techno-economic, Simulation

1. Introduction

Nowadays, consumption of energy from fossil is increasing the growth of transportation and population. Most of automobiles use diesel engine. Using diesel produced from non-renewable resource. Therefore, it is necessary to find a new energy resource that can supply the global energy demands. One of the most important renewable energies is bio-hydrogenated diesel (BHD) which has a similar properties as diesel where the main composition is C₁₄-C₂₂ and it can be produced from vegetable oil (palm, soybean, and jatropa), animal oil and waste cooking oil. Bio-hydrogenated diesel or (BHD) is produced by triglyceride reacting with hydrogen. Reaction of bio-hydrogenated diesel (BHD) consists of 3 main reactions. First is decarboxylation reaction (DCO₂), where carbon dioxide is removed with endothermic reaction. Second is decarbonylation reaction (DCO), where this reaction is also endothermic reaction for carbon monoxide and water removal. Last is hydrogenation (HDO) which is exothermic reaction. This

reaction eliminates oxygen to form water and produce the same number of carbon atom as reactant (Mathias Snare et al., 2006).

In industrial process, the simulation software was the most popular method for designing and developing process because almost industrial process had to spend a lot of money on investment cost such as processing equipment, operating cost, raw materials and transportation. Therefore, it was essential to estimate the process expense and revenue by using techno economic analysis before investment decision. The purposes of this work were to provide the appropriate product to meet the operating plan, to minimize energy consumption by HEN, and to estimate profitability project.

1.1 Properties and Specification

The main feedstock of palm oil was 500 Kg/h. The properties of feedstock were shown in Table 1.

Table 1. Properties of palm oil feed at condition 25.00 °C and 500 psig

Palm oil	
Component	%wt
Linoleic	100
Oleic	200
Palmitic	300

Table 2. Properties of BHD product

BHD Product			
Component	% wt	Component	% wt
LINOLEIC	0.0041	CO	0.0044
H ₂	0.0965	CO ₂	0.0271
STEARIC	0.0106	PALMITIC	0.1328
OLEIC	0.0014	NC17	4.2742
NC16	156.74	NC15	2.7533
H ₂ O	0.0355	NC18	235.7

The process simulation results showed the BHD production rate was 12,374.09 Liters/day, the conversion of biodiesel, product yield, and purity of commercial product were 99.83%, 79.89%, and 99.92% respectively. The product specifications were shown in Table 2.

1.2 BHD reactions

Bio-hydrogenated diesel (BHD) was from exothermic reaction between triglyceride and hydrogen. The operating parameters were 325°C and 500 psig with NiMo/Al₂O₃ catalyst. The final commercial or BHD products were n-hexadecane (NC16) and n-octadecane (NC18). The conversion of biodiesel was at 95.00%. The overall reactions of bio-hydrogenated diesel production were shown as following equations.

2. Methodology

This step had been divided into three main parts. The first part was the process simulation of a base-case BHD process from petrochemical industry in Thailand including feedstock composition and thermodynamic properties. The second part was energy efficiency improvement by using GAMS for heat exchanger network (HEN) design. The final part was techno-economic analysis for overall process.

2.1 Process simulation

The BHD process had been divided in three parts which were conversion reactor, separation product and product storage. The base case of the BHD production process which used palm oil as a raw material was simulated by simulation software (Pro II). For the thermodynamic model of biodiesel production, NRTL-RK model was applied due to the BHD process was operated under severe condition. In addition, chemicals component in BHD process were non-ideal liquid-liquid mixtures (A. Kantama et al.,

2015). This process started from preheated palm oil at 325 °C and 500 psig. Compressed hydrogen at 500 psig which was mixed together with palm oil were fed to reactor requiring only conversion of palm oil at suitable condition (325°C, 500 psig). The products from the conversion reactor were sent to flash drum for separating water and gas. Hydrogen from gas products was recycled to the reactor. The liquid products were sent to the distillation column to separate hydrocarbons C₁₅-C₁₈ from BHD at the top of column and unreacted palm oil at the bottom. Then unreacted palm oil was recycled to the reactor.

2.2 Heat integration

HEN was designed for reducing heating and cooling utilities of the base case. This HEN model by GAMS was based on the minimum temperature approach (ΔT_{min}) at 10°C. The base case consisted of five hot and three cold streams. The base case consumed the hot and cold utilities about 1,335,233 and 679,317.9 kJ/h respectively as shown in Figure 1.

2.3 Techno economic analysis

The overall concept of techno economic analysis consisted of two main parts. The first part was process simulation. This part started from process design diagram by using palm oil at 500 kg/h as feedstock. After that, the process would be modified by applying heat exchanger network (HEN) for reducing operating cost. The second part which was techno-economic for capital and operating cost calculation. The modified process would be evaluated by cash flow diagram (profitability analysis) and sensitivity analysis.

3. Result and discussion

3.1 Process simulation

The simulation result showed that this process converts 500 kg/h of palm oil to 12,374.09 liters/day of BHD products. The conversion of biodiesel was 99.83%, yield and commercial product purity were 79.89 and 99.92% respectively.

3.2 BHD improvement process

The base case consumed the hot and cold utility about 1,335,233 and 679,317.9 kJ/h respectively. The modified BHD required 655,905 kJ/h and no requires cold utility as shown in Table 3. The modified BHD process with HEN was shown in Figure 2.

Table 3. Heating and cooling utilities saving

	Heating utility (KJ/Hr)	Cooling utility (KJ/Hr)
Base case without HEN	1,335,233	679,317.90
Modified case with HEN	655,905	0
Saving (%)	50.88	100

Figure 1. Base case of BHD process

Figure 3. Total capital cost of BHD process

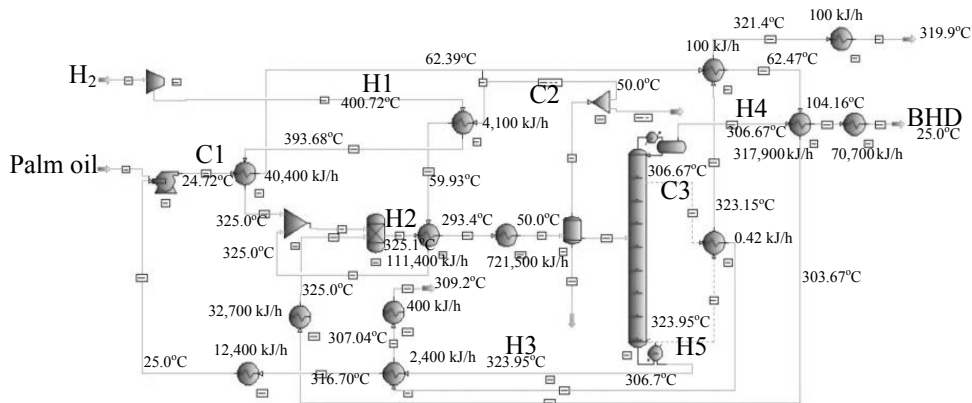

Figure 2. The modified process with HEN

3.3 Techno economic analysis

Equation 1 was applied for calculating the chemical Engineering Plant Cost Index (CEPCI) by updating the equipment costs to the year 2017.

$$\text{Present cost} = \frac{\text{Capital cost index in 2017}}{\text{Capital cost index in 2000}} \times \text{previous cost} \quad (9)$$

3.3.1 The total capital cost (CAPEX)

Each of processing equipment was designed based on mass and energy balance for calculating the purchased cost. The installation cost of BHD process and the laborer wage were included with the total capital cost. This process investment cost was around 63 million Baht. The result showed that F.O.B equipment cost was the largest fraction of overall capital cost at 28.73 million Baht whereas the lowest capital cost was electrical equipment and materials at 0.29 million Baht. There was only a 2 million Baht different between working capital equipment and machinery at 8.22 and 10.26 million Baht respectively as shown in Figure 3.

3.3.2 Total expense cost (OPEX)

The total expense cost was around 117 million Baht/year which was evaluated to cover on general expense, indirect expense, operating cost and variable cost. The annual operating cost which was calculated based on daily operating cost was 0.67 million Baht/year. The BHD process was operated 24 h for 350 days/year and there were 3 shifts which are 7am-3pm, 3pm-11pm and 11pm-7am per day (k.W.Cheah et al., 2017) so this process investors had to hire labor 3 persons/shift for controlling all equipment. For the total expense cost, it showed that raw material which was the highest proportion of overall expense cost was equal 97.44 million Baht/year. Another part that affected to the total expense cost was utility cost (9.59 million Baht). The laboratory charge which was the least fraction of total expense cost was 0.07 million Baht/year as shown in Figure 4.

3.3.3 Total revenue

Commercial product of this process was biodiesel. The capacity of process was 12,374.09 Liters/day by assuming operating time 350 days/year so total revenue was equal 136.42 million Baht/year as shown in Table 4.

Table 4. Total revenue of BHD

Commercial product	quantity(l/day)	price (baht/l)	baht/year
BHD	12,374.09	31.5	136,424,342.25

3.3.4 Cash flow analysis

Evaluated economic information which was shown in Table 5 was used for designing cash flow diagram. From Figure 5, the cash flow diagram presented data relating to level of BHD process finance from the process started up at first year to the end of process at eleventh year. It could be clearly seen that the BHD process finance dramatically decreased in both rate of return which were 10 and 15% in the first four year because this process was under construction and testing period in first year and the revenue of process had to pay tax so cash flow diagram showed negative value. After that the BHD process finance significantly increased from the fifth year to the end of process because this process could make profit from selling commercial product which was biodiesel. The economic analysis was evaluated the overall profits of BHD process in term IRR, NPV and PBP by assuming rate of return at 10 and 15% as shown in Table 6. The result from rate of return at 10% indicated that this process would obtain profit in 9.5 year (PBP) with NPV 45.47 million Baht and IRR 25.01%. Similarly to rate of return at 10%, the rate of return at 15% illustrates that this process had NPV 25.59 million Baht, PBP 10.8 year and IRR 25.01%.

3.3.5 Sensitivity analysis

In this study, the uncertain variables of BHD process were analyzed by sensitivity method for finding variables that had influence on BHD production cost. All uncertain parameters were varied in ranging 10% (price increasing and decreasing up to 10%). From sensitivity analysis data it could be concluded that biodiesel price had a largest impact on BHD production whereas the lowest impact on BHD production was total capital cost as represented in Figure 6.

Figure 5. Cash flow analysis of BHD process

Table 5. Evaluated economic information

Process information	Baht
Total capital cost	54,787,127.39
Working capital (15%)	8,218,069.11
Depreciation (10%)	5,478,712.74
Total expense	117,144,152.86
Total revenue	136,424,342.25

Table 6. Overall profits of BHD process

Rate of return	IRR	NPV (Baht)	PBP (year)
10%	25.40%	46,725,489.37	9.4
15%	25.40%	26,620,795.71	10.5

Figure 4. Total expense cost

Figure 6. Sensitivity analysis of BHD process

Conclusion

BHD process could be produced from palm oil with conversion reactor at 325°C and 500 psig. The process simulation result represented conversion, yield and purity at 99.83, 79.89 and 99.92% respectively. After that the modified process with HEN could reduce hot utility for 50% requirement. Final part, techno-economic analysis at 10% rate of return shows that, NPV was equal 45.67 million Baht, PBP 9.4 year and IRR 25.40%. At the same way, this process had 25.59 million Baht of NPV, PBP 10.5 year and IRR 25.40% at 15% rate of return. Additional, NPV was positive value therefore BHD process was worth for investment.

Abstract

This work tackles the simultaneous optimization of utility systems, Rankine cycles and heat exchanger networks (HEN). Thanks to the combination of two superstructures (Rankine cycle and HEN), all heat integration options between heat sources/sinks and Rankine cycle can be considered, and the trade-off between efficiency and plant costs is optimized. On the other hand, the resulting MINLP is extremely challenging due to its large number of binary variables and bilinear terms. We present an ad-hoc bilevel decomposition algorithm based on the McCormick relaxation with reinforcement constraints, piecewise linearization of the cost functions and “nested” integer cuts. The algorithm is applied to literature and real-world case studies to show its effectiveness compared to commercial MINLP solvers and metaheuristic algorithms.

Keywords: nonconvex MINLP, bilevel decomposition, McCormick relaxation, utility systems, Rankine cycle superstructure.

1. Introduction

The heat integration problem involves the design and synthesis of the Heat Exchanger Network (HEN) and the utility systems necessary to provide thermal, refrigeration, mechanical and electric power to the process units of energy systems and chemical processes. A key role is often played by steam cycles and, in general, Rankine Cycles, because of their capability of converting waste heat into useful mechanical power and/or achieving high efficiency by cogenerating heat/steam and power for the plant. Several authors, for instance (Papoulias & Grossmann, 1983; Bruno et al., 1998), proposed approaches to improve the design of steam cycles and steam networks. However, the optimization of the steam generator layout (pre-heating, evaporation and superheating) and of the possible integration options with the process heaters/coolers is not dealt with. Previous studies mainly focus either on the design of utility systems or on the synthesis of HEN, and the two problems are carried out sequentially. Only a few studies tackle both problems together: (Marechal & Kalitventzeff, 1998), (Mian et al. 2016), (Duran & Grossmann, 1986), (Hipólito-Valencia et al., 2013) and (Yu et al., 2017), adapted the sequential framework for HEN synthesis while, more recently, (Martelli et al. 2017) and (Elsido et al., 2017a) proposed a simultaneous approach.

In this work, we present an ad hoc bilevel decomposition to tackle the general model proposed by (Martelli et al., 2017) and extended by (Elsido et al., 2017a) for the

simultaneous optimization of utility systems, Rankine cycles and heat exchanger networks. The model enables the automated generation of Rankine cycles (e.g., Steam Cycles, Organic Rankine Cycles, Heat pump cycles), recovering heat from one or more heat sources, and the HEN of the overall heat integration (i.e., considering also the internal heat exchanger arrangement of the boilers).

2. Mathematical model

The problem of simultaneous optimization of utility systems, Rankine cycles and HEN can be stated as follows: “Given the set of hot and cold streams of the process (i.e., heat sources/sinks), the process needs of hot water/liquid and steam/vapor, the technical limitations (e.g., forbidden/forced matches, no stream splitting, etc.) and economic data (e.g., price of fuels, price of electricity, cost models of process units, etc.), determine the optimal configuration of the Rankine Cycle, the mass flow rates and the optimal HEN.”

The model is based on the SYNHEAT superstructure (Yee & Grossmann, 1990) for the optimal design of heat exchanger networks. The SYNHEAT model is extended to include the streams of the heat recovery cycle, with variable mass flow rate.

The thermodynamic cycles are modelled with a very general “ p - h superstructure” (Elsido et al., 2017a, 2017b), capable of reproducing many configurations of Rankine cycles, both power cycles and inverse cycles (refrigeration cycles or heat pumps), steam cycles or Organic Rankine Cycles (ORC), with single or multiple pressure levels, as well as heat/steam distribution networks. A schematic representation of the Rankine cycle superstructure proposed to tackle the heat recovery steam cycle design problems proposed in this work is represented in Fig. 1. The steam cycle can be designed with up to three levels of pressure. Cycle pressures and temperatures are not optimized. All components have a binary activation variable (ν). Economizers, evaporators, superheaters, reheaters, and condensers are also part of the HEN (i.e., they are streams with variable flow rates).

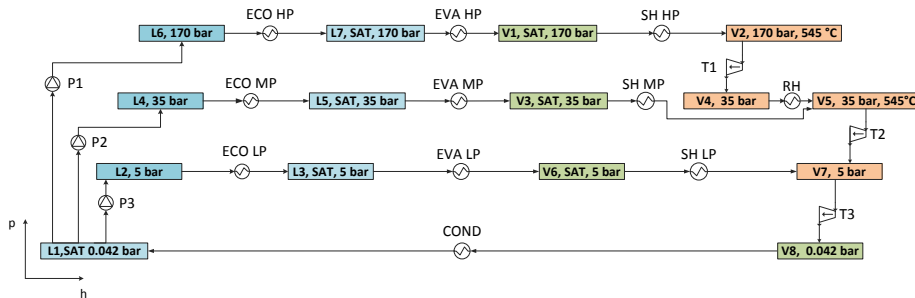

Figure 1: The steam cycle “ p - h superstructure” with three levels of pressure used in this work.

The main constraints are: overall heat balance for each stream (Eq.1); heat balance for stage for non-isothermal streams (Eq.2); feasibility of temperatures (Eq.3); calculation of approach temperature differences (Eq.4); logical constraints such as upper bounds on heat loads, existence of components, no stream splitting, forced and forbidden matches; mass and energy balances on components (Eq.5 and Eq.6). The objective function is the Total Annual Cost (TAC) of the overall plant including HEN, utilities and Rankine cycle, minus revenues (Eq.7). The extended model is a challenging nonconvex Mixed Integer NonLinear Program (MINLP), because of the logarithmic mean temperature difference (LMTD) terms in the objective function (Eq.7) and the bilinear products in the energy balances of the streams with variable mass flow rate (Eq.2).

$$(Tin_i - Tout_i) \cdot F_i \cdot Cp_i = \sum_k \sum_j q_{ijk} + qcu_i, \forall i \quad (1)$$

$$(Tout_j - Tin_j) \cdot F_j \cdot Cp_j = \sum_k \sum_i q_{ijk} + qhu_j, \forall j$$

$$(t_{i,k} - t_{i,k+1}) \cdot F_i \cdot Cp_i = \sum_j q_{ijk}, \forall i, k \quad (t_{j,k} - t_{j,k+1}) \cdot F_j \cdot Cp_j = \sum_i q_{ijk}, \forall j, k \quad (2)$$

$$t_{i,k} \geq t_{i,k+1}, \forall i, k \quad t_{j,k} \geq t_{j,k+1}, \forall j, k \quad (3)$$

$$dt_{ijk} \leq t_{i,k} - t_{j,k} + \Delta T_{ij,max} (1 - z_{ijk}), \forall i, j, k \quad (4)$$

$$\sum_{in} F_{c,in} - \sum_{out} F_{c,out} = 0, \forall c \quad (5)$$

$$\sum_{in} F_{c,in} h_{c,in} - \sum_{out} F_{c,out} h_{c,out} + Q_{c,in} - Q_{c,out} - P_{c,out} = 0, \forall c \quad (6)$$

$$TAC = \sum_c FC_c y_c + \sum_{ijk} FC_{ij} z_{ijk} + \sum_c VC_c F_c^\alpha + \sum_{ijk} VC_{ij} \left(\frac{q_{ijk}}{U_{ij} LMTD_{ijk}} \right)^\beta - R \quad (7)$$

3. Bilevel decomposition

While (Mistry & Misener, 2016) proposed an outer approximation algorithm for the global solution of a similar problem with bilinear terms and LMTD, this work proposes a bilevel decomposition. In the first stage (i.e., the “master” problem), a linearized and relaxed version of the original problem (MILP) is solved, then, in the second stage, for fixed binary variables, the continuous variables are re-optimized solving a nonconvex nonlinear program (NLP). Two nested loops of integer cuts allow exploring different system configurations very efficiently.

3.1. Master problem

The master problem includes all the linear constraints of the full MINLP problem while the bilinear terms ($F_i t_{i,j,k}$) in the energy balance constraints in Eq.2 (due to the variable mass flow rates of utility streams, F) are linearized with McCormick relaxations (McCormick, 1976), as shown in Eq.8. Since for each utility component the lower bound of F is zero when the component is not selected ($y = 0$) and F^L when it is selected ($y = 1$), the auxiliary variable θ is needed to replace the product between t and y .

$$\begin{aligned} Ft &\geq Ft^L + F^L \theta - F^L yt^L & Ft &\geq F^U t + Ft^U - F^U t^U \\ Ft &\leq Ft^U - F^L yt^U + F^L \theta & Ft &\leq F^U t + Ft^L - F^U t^L \\ \theta &\geq yt^L & \theta &\geq t + yt^U - t^U & \theta &\leq yt^U & \theta &\leq t + yt^L - t^L \end{aligned} \quad (8)$$

Since the relaxation of the energy balance equations of temperature stages (Eq.2) overestimates the availability of high temperature heat, the heat cascade (Papoulias & Grossmann, 1983) constraints (i.e., the linear heat balance constraints for each temperature zone defined by the inlet temperature of streams) are included in the MILP. These constraints guarantee heat transfer feasibility and tighten the relaxation.

The nonlinear terms for the calculation of the areas of the heat exchangers, using Chen approximation (Chen, 1987) for the LMTD, are linearized with first order Taylor's series expansions. The exponential expression of the costs of components, such as heat exchangers and turbines, are linearized with piecewise linearization.

3.2. NLP subproblem

In the second stage, the binary variables from the solution of the master problem (i.e., the plant configuration and heat exchangers layout) are fixed. The continuous variables of the nonlinear subproblem are optimized with a nonlinear optimization algorithm, with the TAC as objective function. The solution of the subproblem yields a valid upper bound for the problem.

3.3. Nested integer cuts and termination criterion

In each iteration, the MILP master problem and the NLP subproblem are solved in sequence, and integer cuts are added to the master level at each iteration to exclude the binary solutions already evaluated. Fig. 2 shows the scheme of the algorithm. Two types of integer cuts are added in nested loops: the outer loop adds "utility cuts" on the binary selection variables of the utilities and Rankine cycle components (y), while the inner loop, for fixed utility selection/cycle configuration, adds "HEN cuts" on the selection of heat exchangers (z). "HEN cuts" are added at each iteration, while "utility cuts" are added after $N_{I,MAX}$ iterations without solution improvement. The algorithm stops after $N_{TOT,MAX}$ iterations without solution improvement.

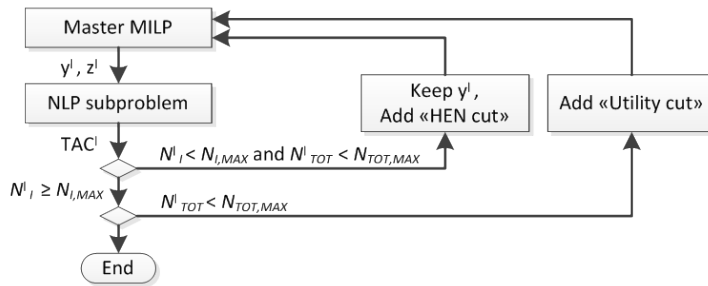

Figure 2: Scheme of the algorithm. For each iteration l , N^l_I and N^l_{TOT} count the number of iterations with no solution improvement respectively in the inner loop and overall.

4. Test cases

The methodology is used to optimize the design and the HEN of three different real-world test cases reported in literature.

- Design and HEN of a Heat Recovery Steam Cycle (HRSC) of a Combined Cycle (Martelli et al., 2017). The only hot process stream is the stream of flue gases of a gas turbine. The steam cycle superstructure is represented in Fig.1. The full MINLP problem has 2,060 variables (446 binaries) and 4,245 equations.
- Design and HEN of a geothermal Organic Rankine Cycle (ORC). The only hot process stream is represented by geothermal hot water. The ORC superstructure, with pentane as working fluid, and the data for the problem are described in (Elsido et al., 2017b). The full MINLP problem has 1,231 variables (270 binaries) and 2,371 equations.

- Design of HRSC and HEN of an Integrated Gasification Combined Cycle (IGCC) plant (Martelli et al., 2017) with 9 hot process streams and 4 cold process streams in addition to the streams of the superstructure. The steam cycle superstructure is the same as for the Combine Cycle test case. The full MINLP problem has 8,608 variables (1,999 binaries) and 15,737 equations.

For all test cases, Rankine cycle pressures and temperatures have not been optimized. The proposed bilevel decomposition algorithm is solved using CPLEX as solver for the MILP master problem and the Sequential Quadratic Programming algorithm of SNOPT for the NLP subproblem. The results are compared with two alternative solution strategies: direct solution of the nonconvex MINLP problem with the global MINLP solver BARON (Tawarmalani & Sahinidis, 2005), and a meta-heuristic two-stage algorithm, consisting of the Variable Neighbourhood Search (VNS) in the first stage for the binary variables and SNOPT for the real variables, as described in (Martelli et al., 2017). Computational results are reported in Table 1.

Table 1. Computational results of the test problems.

	BARON	Two-stage (Martelli et al. 2017)	Bilevel (this work)
Combined Cycle			
Best solution found, M\$/y	-37.0	-42.8	-42.8
Computational time, s	20,000 (limit)	6,000	120
Number of iterations		50,000	50
ORC			
Best solution found, M\$/y	-0.277	-0.321	-0.357
Computational time, s	20,000 (limit)	4,000	41
Number of iterations		20,000	48
IGCC			
Best solution found, M\$/y	No feasible sol.	-86.7	-88.5
Computational time, s	20,000 (limit)	6,000	2,000
Number of iterations		10,000	60

It should be noticed that a negative value of the objective function represents a revenue. In all cases, BARON has the worst performances in solving the challenging nonconvex MINLP problem among the three methods. Indeed, it reaches suboptimal solutions for the Combined Cycle and the ORC cases and not even finding a feasible solution for the IGCC test case. On the other hand, the bilevel decomposition method is very effective, finding the best solutions in all cases (16-29 % better objective values than BARON) with a computational time up to 2 orders of magnitude shorter than to the other two approaches.

5. Conclusions

We presented an ad-hoc bilevel decomposition method to solve complex optimization problems for the simultaneous design of utility systems, Rankine cycles and HEN. The literature and real-world case studies proved that the bilevel decomposition method, compared to commercial MINLP solver and meta-heuristic two-stage algorithm, is the most effective both in terms of computational time and quality of the solutions found.

Nomenclature

Indices

i, j hot/cold process or utility stream
 k index for temperature stage
 c component of Rankine cycle
 in input, out output
 L, U lower/upper bound
Parameters
 C_p heat capacity
 T_{in}, T_{out} inlet/outlet temperature
 U heat transfer coefficient
 ΔT_{max} upper bound for temp. difference
 h enthalpy
 FC fixed cost for component/exchanger
 VC flow/area cost coefficient
 α, β exponent for component/area cost

Binary Variables

z existence of heat exchanger
 y existence of utility/Rankine cycle component

Continuous variables

F mass flow rates of streams (fixed for process streams)
 t temperature of streams at a stage
 dt approach temperature difference
 $LMTD$ log mean temperature difference
 q, q_{cu}, q_{hu} heat exchanged
 Q thermal power
 P electric power
 R revenues from electricity selling
 TAC Total Annual Cost
 θ auxiliary variable for McCormick relaxations

Energy and exergy analysis for cryogenic process design/retrofit

Nattawat Threerachannarong^a, Kitipat Siemanond^{a*}

^a*The Petroleum and Petrochemical College, Chulalongkorn University, Bangkok, Thailand*

kitipat.s@chula.ac.th

Abstract

While the oil price has been decreasing dramatically, downstream petrochemical industries using by-products from upstream process such as methane, ethane, and others are still growing due to demand of domestic products e.g., plastic and resin. The downstream process like LNG production or Gas separation processes needs refrigeration system for cooling the natural gas to reach the proper condition which requires high energy consumption of compressor work, evaporator and condenser. To gain more benefit, reduction of utilities are the main goal. For this purpose, exergy analysis has been applied with pinch analysis called Extended Pinch Analysis and Design (ExPANd) (Aspelund et al., 2007) to reduce that work by adjusting the pressure and temperature. Besides that, graphical and mathematical models have been used to identify efficient condition by using the exergetic temperature concept (Marmolejo-Correa et al., 2012) which is the energy quality parameter. This parameter can be used to conduct the $T^{E^T} - \dot{E}^T$ diagram (Exergetic composite curves) defining the utility consumption that should be reduced by exergy target.

Keywords: Energy analysis, Exergy analysis, Cryogenic process, Optimization

1. Introduction

Low-temperature process which is refrigeration system requires high energy usages for cooling from shaft-work required at compressors and utilities. Consequently, many industrial processes have been improved to gain more profit. In the past, many methodologies to reduce utility consumption and work consumption are proposed such as Pinch Analysis using recovery energy and required energy from steams in process to identify new heat exchanger network (HEN). Although, Pinch Analysis (PA) (Linnhoff and Hindmarsh, 1983) is useful to reduce utility's usage by heat integration, this technic uses only temperature as design variable but pressure is not considered. Therefore, Exergy Analysis (EA) (Linnhoff and Dhole, 1992) was combined with PA to minimize energy consumption by including pressure as design variable. EA has been integrated with the traditional Pinch Analysis, which is called Extended Pinch Analysis and Design (ExPANd) (Aspelund et al., 2007). This method has potential to synthesize the improved design of compressor and expander sequence in term of utility's consumption if the existing plant still has expansions or compressors available. In addition, Exergetic temperature (Marmolejo-Correa et al., 2012) which is the energy quality parameter for identifying the exergy target (exergy loss) and utility's usage in the process is applied in ExPANd. In this research, the case study of liquefied natural gas (LNG) production with refrigeration system; from Pro/II's tutorial as shown in Fig. 1 is used to study optimization of energy consumption.

Figure 1: (a) Flowsheet of LNG production from Pro/II's tutorial

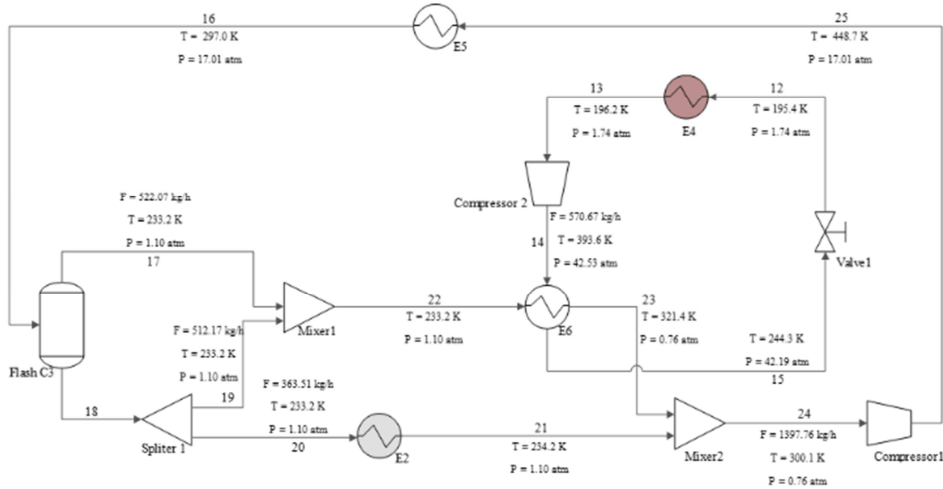

Figure 1: (b) Flowsheet of Base-case refrigeration system

2. Methodology

2.1. Extended Pinch Analysis and Design (Aspelund et al., 2007)

A general methodology is used for designing process by manipulating process streams to reduce utility usage and optimize shaft-work. This methodology is powerful to identify the suitable pressure and temperature for streams, this solution becomes very complex when process has many streams and units operations. Thus, there are heuristic rules to find the favourable ways for manipulating pressure and make the suitable decision for complex design. For example; one of favourable rule, the supply pressure is higher than the target pressure for a cold stream, the available expander should be added in that stream to obtain cold utility and shaft-work from expander when Composite curves requires cold utilities. Other rule is for hot gas or dense fluid with target pressure equal to the supply pressure be compressed to above the pinch point, and cooled to near the pinch point for increasing hot duty. After that, expander will be added in the same stream to adjust pressure to target pressure, besides, this expander generates the additional work and the cold duty. This model consists of four parts: the pinch operator, pressure operator, exergy operator and objective function is shown Fig. 2.

Figure 2: Diagram of identifying the proper state for adding compressor or expander (Aspelund et al., 2007)

The pinch operator is the heart of the optimization model because all streams must be concerned in this operator. Therefore, this model will create a lot of temperature intervals to support varied temperature from calculation and create the new Composite curves to define utility consumption. The pressure operator defines the appropriate compressors or expanders and the proper outlet pressure of these units by using the reversible and adiabatic compression or expansion of an ideal gas that can be formulated as followings:

$$\frac{T_S}{T_1} = \left(\frac{P_2}{P_1}\right)^{\frac{K-1}{K}} \text{ or } (K-1) \ln P_1 + K \ln T_S = (K-1) \ln P_2 + K \ln T_1 \quad (1)$$

$$(T_1 - \tilde{T}_S) = (T_1 - T_S)\eta_c \quad (2) \quad (T_1 - \tilde{T}_S)\eta_e = (T_1 - T_S) \quad (3)$$

$$W_c = Fc_p(\tilde{T}_S - T_1) \quad (4) \quad W_e = Fc_p(T_1 - \tilde{T}_S) \quad (5)$$

The exergy operator's main purpose is to calculate of the exergy of process streams formulated as follows:

$$Ex_{hu} = Q_H \left(1 - \frac{T_0}{T_H}\right) \quad (6) \quad Ex_{cu} = Q_C \left(\frac{T_0}{T_C} - 1\right) \quad (7)$$

Lastly, the objective function is minimization of the combination of results from pinch operator, pressure operator and exergy operator.

$$\text{Objective function} = \text{Min}(Ex_{hu} + Ex_{cu} + W_c + W_e) \quad (8)$$

2.2. Exergetic temperature (T^{ET}) (Marmolejo-Correa et al., 2012)

The exergetic temperature is the energy quality parameter to propose the $T^{ET} - \dot{E}^T$ diagram that plots exergy sources and exergy sinks by defining reference temperature (T_0). Especially, this diagram is proposed parallel with traditional composite curves (CCS). The exergy deficit and surplus are the utility's usage for upper and lower exergy pinch point, respectively. The exergy destruction can be defined by the boundary temperature of hot stream and cold stream form composite curves into the $T^{ET} - \dot{E}^T$ diagram. Moreover, the exergy targets are used for synthesis process by manipulating operating condition as follows: minimum exergy requirement, minimum exergy rejection, minimum exergy destruction and maximum exergy recovery.

$$T^{ET} = \left[T_0 \left(\frac{T_2 - T_1}{T_0} - \ln \frac{T_2}{T_1} \right) \right] \quad (9)$$

$$\dot{E}_{\text{Requirement, min}} = \dot{E}_{\text{Deficit, min}} + \dot{E}_{\text{Destruction, min}} \quad (10)$$

$$\dot{E}_{\text{Rejection, min}} = \dot{E}_{\text{Surplus, min}} - \dot{E}_{\text{Destruction, min}} \quad (11)$$

3. Results

According to the Fig. 1, this LNG production consists one hot stream (Natural gas) and two cold refrigerants (Ethane and Propane). ExPANd model is applied to indicate the proper sequence of adding expander or compressor. The exergetic temperature concept is used to conduct the $T^{E^T} - \dot{E}^T$ diagram for manipulating the appropriate condition to improve the utility consumption using the exergy targets (Eq.9 to11).The model formulations (Eq.1 to8) are used to find the minimum utility. The efficiency factors for work by compressor and expander (η_c and η_e) are constant at 0.8. Moreover, the constraints for pressure and temperature can be defined between the supply value and the target value. Eq. 1 to 3 are used to define the intermediated temperature after passing through turbo machines (compressor or expander). Eq.4to5 are used to calculate work output from turbo machines. Eq.6to7 are used to identify exergy energy for hot and cold utilities. Furthermore, Eq.8 is the objective function in optimization model. Considering the base case, there are compressor work as 155.41 kW, no hot utility and the cold utility as 232.85kW. For overall process, the exergy requirement and rejection are -56.52 kW and 0 kW, respectively. Hence, two cold streams are necessary used as variable stream (10 to 11 and 8 to26). For the first cold stream, $F_{c_p}=0.14$ kW/K, $T_{in}=229.3$ K, $T_{out}=305.4$ K, $P_{in}=45.25$ atm, $P_{out}=17.23$ atm and $\kappa=1.65$. For the other, $F_{c_p}=0.15$ kW/K, $T_{in}=167.1$ K, $T_{out}=298.2$ K, $P_{in}=17.01$ atm, $P_{out}=1.0$ atm and $\kappa=1.55$. When assuming flow rates and heat capacities constant, six available turbo machines can be added in this process to gain better profits.

In case 1, this process added five expanders, three expanders are located between stream No.10 and 11 and the others are located between stream No. 8 and 26. In term of energy, the cold utility is around 175 kW and the produced work is 39 kW.

S12 → 26	160.37	298.15	1.01	S12 → 26	212.98	298.15	1.01

In case 2, this process added five expanders and one compressor, two expanders and one compressor are located between stream No.10 and 11 and the others are located between stream No. 8 and 26. The improved process uses only the hot utility is around 77kW without the cold utility.

In case 3, no utility consumption is included as the constraint to optimize. This process added four expanders and two compressors. Two compressors and one expander are added in each stream. The diagram of improved LNG production is shown Fig.4.

Lastly, in case 4, the exergetic concept is applied in the ExPANd model using the same six available turbo-machines and $T_0 = 298.15$ K. The new sequence is similar to the case2 but the operating conditions are different. Below T_0 , there are no both of exergy requirement and exergy rejection. Above T_0 , The exergy requirement and exergy rejection are 0 kW. The $T^{E^T} - \dot{E}^T$ diagram is shown Fig. 5. The results of temperature and pressure for these units are shown in Table1. The saving of utilities consumption and shaft-work is shown Table2.

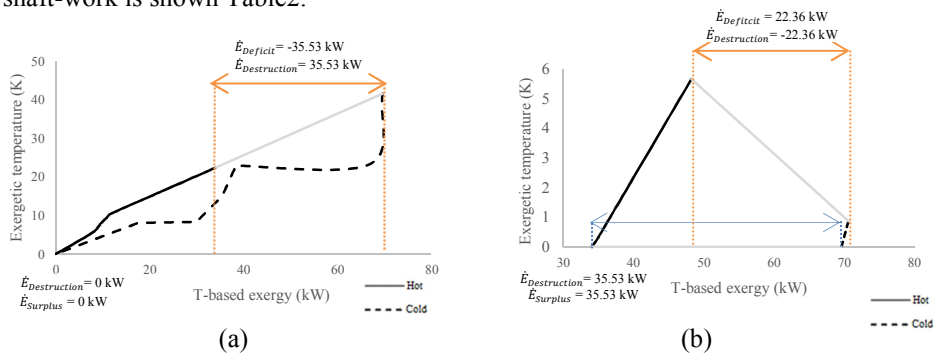

Figure 5: $T^{E^T} - \dot{E}^T$ diagram for Case 4 (a) below T_0 , and (b) above T_0

Table 2: Saving utility results

Case	W_c (kW)	W_e (kW)	Hot utility (kW)	Cold Utility (kW)	Overall saving
Base case	0	0	0	232.85	0
Improved case 1	0	39.00	0	174.75	97.1
Improved case 2	3.15	41.01	77.05	0	193.66
Improved case 3	18.76	48.14	0	0	262.23
Improved case 4	9.80	47.51	0	0	270.56

4. Conclusions

In this study, the synthesis for heat integration with the turbo-machine can be used to reduce the utility consumption. The energy and exergy analysis can be defined the new operating condition and synthesis for the process having the available turbo-machines. Although this methodologies can improve the utility consumption, the calculation of pressure operator is not more accurate. Because the equations are used for the ideal gas. For the optimization, the objective function is the minimum of energy consumption or maximum saving energy usage without concerning the capital cost. The results show the case 4 is the optimal solution because it does not use the utilities and the generated work of the expander overcomes the required work of compressor. In addition, this process can be still improved. For example, the variable stream can change to the others and the operating conditions of refrigeration system are manipulated.

Notation

c_p	heat capacity, kJ/kg K	Q_H	hot utility used, kW

Abstract

Currently, the global ammonia/urea productions are continuously increasing. Since the demand of crops has been increased, production of fertilizer seems to be suitable for Thailand, a country with primary agricultural development. The purposes of this work are to design conceptual processes of ammonia/urea plants and to do economic analysis and feasibility study. This paper consists of two main parts; simulation of ammonia/urea plants and techno economic analysis. First, the simulation software PRO/II is used to simulate the base-case process. From the base-case studies the principal route of urea production is originally from carbon dioxide and ammonia, which are produced from nitrogen and hydrogen. All conditions and input parameters are obtained from petrochemical industry in Thailand. Finally, techno economic analysis is a key of feasibility study to estimate investment cost and the profitability of project. This technique represents the capital expenditure, the operating expenditure, net present value, payback period, and return of investment. Economic evaluation of the process represented core factors that affect the economic feasibility which are production rate, the conversion of methane to hydrogen, feed temperature of individual reactors, conversion ratio of each reactions, operating pressure, feed temperature to the ammonia/urea synthesis reactors and energy management. The results are expected to be conceptual manufacturing processes of ammonia with the capacity of 3,264 ton per day and urea with the capacity of 2,000 ton per day by using methane as feedstock.

Keywords: Ammonia, Urea, Techno-economic, Simulation

1. Introduction

Ammonia is colourless, pungent gas and a weak alkaline which is very soluble in water. It consisted of nitrogen and hydrogen with formula NH_3 . Ammonia is manufactured by mainly nitrogen and hydrogen in an industrial process called the Haber process. Ammonia is the initial chemical material for several industries. Approximately 88% of apparent ammonia consumption was for fertilizer production, including the manufacture of synthetic fibers and coolers etc. Urea (NH_2CONH_2) is an organic compound of nitrogenous compound containing a carbonyl group attached to two amine groups. It is solid odourless white crystals and non-combustible. Urea is mainly used to produce fertilizer as well. During the production, a lot of money is invested on feedstock, utilities, chemicals, equipment, operating cost and treatment unit in order to produce marketable process industry products on time. Techno-economic analysis is significant

financial decision that can help to estimate the total investment cost and the profitability of this project.

1.1. Properties and Specification

The main feedstock of natural gas is 152 ton/h. The properties of feedstock are shown in Table 1. The ammonia production is 3,264 ton/day of 99.95% purity ammonia. The ammonia product specifications are shown in Table 2. The urea production is capable of processing 2,000 ton/day of 99.99% purity urea. The product specifications are shown in Table 3.

1.2. Ammonia synthesis reactions

Ammonia is produced from nitrogen and hydrogen. Hydrogen is obtained by natural gas (methane) reacting with steam. Nitrogen is obtained by burning hydrogen in air. The operating condition use high temperature about 450-500°C and high pressure about 80-90 bar. The reaction mixture is cooled so that the ammonia is liquefied and removed. The remaining nitrogen and hydrogen are recycled. The overall reaction of ammonia production is shown as following equations.

Primary reforming:

Secondary reforming:

Shift conversion:

Carbon dioxide removal:

Ammonia converter:

1.3. Urea synthesis reactions

Urea synthesis is mainly the reaction between ammonia and carbon dioxide. The operating condition use high pressure 20-25 bar with temperature 150-220°C. The overall reaction of urea production is shown as equation 10 -12.

Table 1. Compositions of natural gas feed at condition 15.556°C and 340 psig.

		Urea price (₺/tons)	9,744
		Annual urea capacity (tons/year)	730,000
		Ammonia processing capacity (tons/day)	3,264
		Ammonia price (₺/tons)	9397.5
		Annual ammonia capacity (tons/year)	1,191,360

1.4. Techno Economic Analysis

Techno Economic Analysis is to estimate costs of investment and the profitability of project. This cost assessment technique represents the capital expenditure, the operating expenditure, net present value, pay-back period, and return of investment. These data are used to design and to develop the final ammonia/urea process. For cost indexes the most common one is from IHS CERA index. The equipment costs were estimated by using a guide to chemical engineering process design and economics book shown as equation 13.

$$\text{Present cost} = (\text{capital cost index in 2017} / \text{capital cost index in 2000}) \times \text{previous cost} \quad (13)$$

1.5. Sensitivity Analysis

For ammonia and urea processes, these variables help to identify the main factors affecting the plant feasibility; (a.) Production Rate: varied to keep the feed rate of natural gas as low as possible. (b.) Stream/methane Ratio: varied to maximize the conversion of methane to hydrogen. (c.) Feed Temperatures of the Shift Reactors: varied to control the conversion of CO to CO₂. CO is converted to methane because of carbon dioxide removal reaction leading to high inert CH₄ concentration in the synthesis loop and decreasing profitability. (d.) Air/methane Ratio: varied to maximize methane conversion to hydrogen where H₂/N₂ ratio is 3:1. (e.) Synthesis Loop Pressure: varied to the appropriate pressure for ammonia/urea synthesis reaction. (f.) Feed Temperature to the Ammonia Reactor: varied to lowest temperature. (g.) Conversion percentage: varied to reach optimal condition in each reaction.

2. Methodology

Methodology consists of three parts: simulation of ammonia and urea processes and techno-economic analysis.

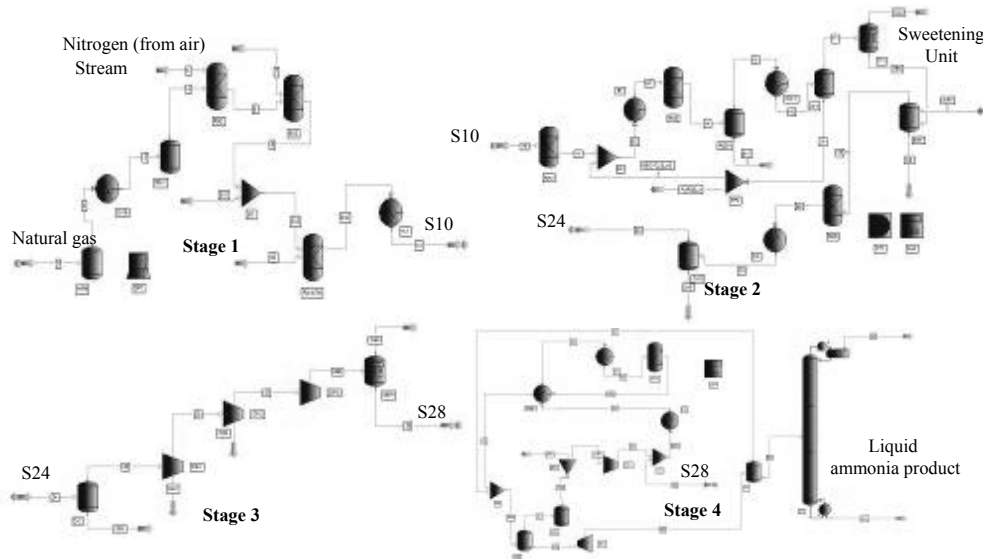

Figure 1. The simulation of ammonia production

This simulation contains three sections: ammonia manufacturing, urea manufacturing, and sweetening process sections.

2.1 Process flow diagram (PFD) – A conceptual design of ammonia production

This ammonia producing process has been simulated by commercial software PRO/II program version 9.4 using SRK thermodynamic model to achieve the ammonia specification. The ammonia plant has production capacity 3,264 ton per day shown in Figure 1. The ammonia manufacturing process is divided into four stages: stage 1 catalytic reforming to produce hydrogen from natural gas containing methane and steam, stage 2 shift conversion and methanation units to purify syngas by removal of carbon dioxide and carbon monoxide, stage 3 compression unit to increase required pressure of syngas, and stage 4 the ammonia conversion.

2.2 Process flow diagram (PFD) - A conceptual design of urea production

The urea plants are capable of producing 2,000 ton per day. The urea producing process has been simulated using NRTL thermodynamic model. This process is to convert CO₂ and synthetic ammonia with high pressure form into urea which is shown in Figure 2.

2.3 Process flow diagram (PFD) - A conceptual design of sweetening process

The objectives of this section are to eliminate carbon dioxide from the ammonia production and to ensure the specification of carbon dioxide is about 0.005-0.2 mole%. AMINE thermodynamic model was used to eliminate impurities. The sweetening unit is displayed in Figure 3.

3. Result and discussion

3.1 Energy requirement of processes

For ammonia plant, total energy consumption in stage 1, stage 2, stage 3, and stage 4 are shown in Table 5. Stage 2 consumes largest amount of energy of 1.03433×10^{12} kJ/h. Cooler (E-3) consumes energy about 50% and the rest 50% is heater (E-5). For urea plant, Urea production consumes energy about 1945.5431×10^6 kJ/hr. Cooler consumes

energy about 81% from overall, the second is reactor “RX2” with 8% including 11% of other units (2% of flash drum, 2% of reactor RX3, 3% of crystalizer, 2% of dryer DR1 and 2% of freezer). Basically, sweetening plant consists of absorber and regenerator columns, a valve, an exchanger and two expander vessels. This process consumes energy about 3791.5721×10^6 kJ/h where reboiler, condenser and cooler (E1) consume energy of 52%, 31%, and 17%, respectively.

3.2 Project economic assessment

Summation of parameters for economic assumptions used to evaluate the techno-economic models are given in Table 4. The cash flow statement summarizes the overall cash flows of both income and outcome of the project as a result of operating activities, investments and financing activities. To maximize profits of this project, there are significant factors are shown in Table 6 which impact on project cash flows. Economic evaluation is set by 10% and 15% of interest rate. Net Present Value (NPV) is analysis of the sum of the present values of future cash flows that invest on project. For urea plant, calculation of equipment cost is based on material and energy balance, operating condition, material handling. Due to the total capital investment (CAPEX) evaluation, F.O.B equipment cost have the biggest impact on capital investment. It's about 415.72 million Baht for urea manufacturing. Total production cost (OPEX) evaluation shows that raw material cost is the largest value about 4.97 billion Baht per year. As a result of the total capital investment (CAPEX) evaluation for ammonia manufacturing, F.O.B equipment cost have a huge investment reached 47.160 billion Baht. In term of total production cost(OPEX), raw material cost is the largest value about 54.926 billion Baht per year.

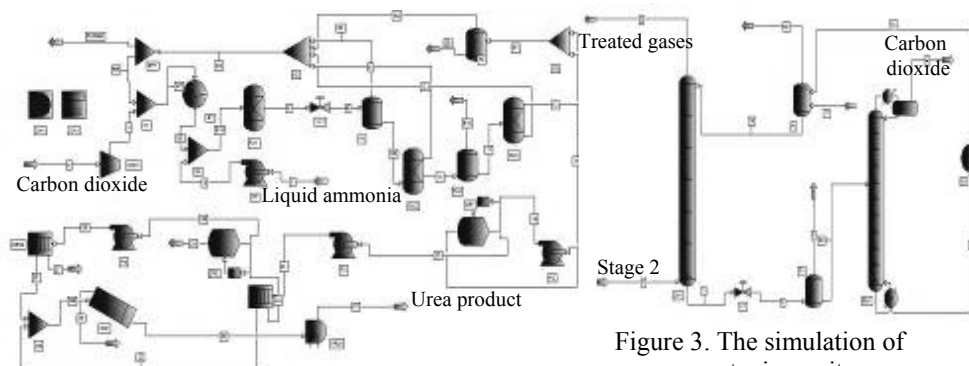

Figure 2. The simulation of urea production

Figure 3. The simulation of sweetening unit

4. Conclusion

Ammonia production is significant material to produce urea. The mainly route of ammonia production was done by Haber process. In this paper, PROII was used to simulate ammonia and urea processes. The capacity of ammonia process is 3,264 ton per day by using natural gas as feedstock. Urea process has the capacity of 2,000 ton per day. The financing decision data for urea manufacturing represented in Table 6. Economic evaluation of urea manufacturing found that NPV is positive value and payback period within 2.75 years. This project is acceptable. In consequence of the total capital investment (CAPEX) evaluation for ammonia manufacturing have a huge investment reached 47.160 billion Baht. Now that total expense is more than total

revenue cost and NPV value is negative. Therefore, ammonia plant is not worth to investment. For the final investment decision, there are 2 cases; Case I: Ammonia and Urea project and Case II: Urea project. By solving an unprofitable project, in this case the major source of ammonia is made from natural gas as the result of high cost of raw materials price so it could end up with investing on only urea project and imported ammonia instead of building the new ammonia plant. Since urea manufacturing is more attractive to invest and high profit. Improvement steps for heat exchanger network will be represented in the future work. Reduction of energy consumption of hot and cold utilities will be considered including the modified heat exchanger investment cost.

Table 6. Technical information and key process parameters in each project.

Abstract

While the importance of the Food-Energy-Water Nexus (FEW-N) has been widely accepted, a holistic approach to facilitate decision making in FEW-N systems, along with a quantitative index assessing the integrated FEW-N performance is rather lacking. In this work, we propose a FEW-N metric along with a framework to facilitate decision making for FEW-N process systems through a FEW-N integrated approach.

The framework and metric are illustrated through a case study on a dairy production and processing plant. The dairy industry is a significant user of water and energy, with water being a top issue for most dairy industries and organizations worldwide. Following the framework, we develop a mixed-integer scheduling model, with alternative pathways, that faithfully replicated the major food, energy, and water aspects of a real cottage-cheese production plant. Using the developed FEW-N metric we were able to optimize the cottage-cheese plant process and observe different trade-offs between the FEW-N elements.

Keywords: Food-Energy-Water Nexus, Multi-Objective Optimization.

1. Introduction

The Food-Energy-Water Nexus (FEW-N) is becoming an increasingly significant and active area of research in Process Systems Engineering. Elements of the FEW-N are tightly interlinked and interdependent. For example, 70% of global water use and 30% of global energy use goes towards food production (Garcia and You, 2016).

However, interactions and trade-offs between FEW elements, as well as trade-offs with factors relevant to a decision maker (e.g. Profit), remain difficult to quantify. From a process systems engineering perspective, this makes it very challenging to account for the trade-offs between elements when designing optimized process systems.

The goal of this work is to provide ideas and analysis towards the development of a FEW-N metric, and develop a methodology that will account for the interactions between elements in the FEW-N in a manner that is specific enough to be used in process optimization.

2. FEW-N metric

2.1. Elements and Dependencies of the FEW-N metric

The FEW-N metric can be decomposed into dimensions, indicators, and indexes. In our case-study for example, a dimension we consider is the “Water Dimension.” Indicators for the “Water Dimension” include the amount of water used for cleaning and water used for pasteurization. These “Water Indicators” are then normalized to develop a “Water Index.” This index is then aggregated with the other indices to form a metric.

To develop and analyse a FEW-N metric, we have firstly detailed its components and aggregated their dependencies, illustrated in Table 1.

Table 1 Components and dependencies of the FEW-N metric

Dimensions	<ul style="list-style-type: none"> • FEW elements (produced or used) • Dimensions can include any other decision elements that are relevant to the decision maker (e.g. profit)
Indicators	<ul style="list-style-type: none"> • The method used to measure/quantify each dimension element • The boundary definition of the process system
Dimensional Index	<ul style="list-style-type: none"> • Normalization scheme • Mathematical Form of the metric
Composite Metric	<ul style="list-style-type: none"> • Weight assigned to each index • Mathematical Form of the metric

All dependencies must be developed through extensive research and analysis for each particular process system, therefore a single metric for all FEW Nexus systems is unlikely. Therefore, a methodology for developing such a metric for FEW-N systems will be presented.

The FEW-N metric developed in this work is meant to be used as an ‘optimizable’ measure of a process system’s impact on the FEW-N. The purpose of the metric is not to describe the system relative to other completely different process systems, but to compare the system to other iterations or alternatives of the same system.

2.2. Mathematical Form of the metric

We have tested four different mathematical forms for aggregating FEW elements along with any other element that interest the decision maker (e.g. cost, safety, environmental impact) into one composite metric. For all methods, the objective is to maximize the metric. Metrics include: i) linear average (LA), ii) bilinear average (BA), iii) trilinear average (TA) and iv) quadrilinear average (QA). Metrics are all determined using Eq. 1.

$$r^{\text{th}} \text{ order average} = \frac{\text{Sum of all } r^{\text{th}} \text{ order multiplicative combinations of decision indexes}}{C_r^n} \quad (1)$$

where C_r^n is the total number of possible r^{th} order combinations of n decision indexes. In our study, each index is given the same weight.

2.2.1. Linear average (LA)

The mathematical form of this metric is the simple arithmetic mean of the dimension indexes. Emphasis can be placed on one or more elements by multiplying the element index by a weighting factor. The key property of LA is that it implies perfect substitutability between the elements of the FEW-N. That means that an improvement in one area can be neutralized by proportional worsening in another area.

2.2.2. Higher order averages (BA, TA, QA)

Weighting for those mathematical forms is done by raising the indexes to the power of the weight factor. With increasing order of the average the substitutability between dimensions is decreasing, until the order is equal to the number of dimension elements, where it allows for the least substitutability, and gives the greatest implicit weight to elements that are low in value.

2.3. Normalization scheme

The decision indexes are normalized to values between 0 and 1. The normalization is based upon the maximum and minimum values of each element index that are possible in the process system under investigation. A value of 1 represents the ‘best-case’ scenario (e.g. minimum energy, maximum food, etc.) for the element in the process system.

The proposed metrics were applied to the cottage cheese plant case-study to determine the effect of the mathematical form of the metric on the optimal solution.

3. Case study: Cottage cheese plant

To develop and test our metric and methodology, we used a cottage cheese plant (CCP) case study taken largely from the work of Stefanis et al. (1997). We made considerable additions to Stefanis’ model to better represent the FEW-N trade-offs.

The dairy industry consumes a huge amount of energy and water. In the United States alone, there are over 5,000 dairy plants that discharge over 200 billion liters of waste – water. This waste water is high in Biological Oxygen Demand and contains harmful pollutants and suspended solids and therefore must be treated in energy intensive processes. Still, roughly 40% of this wastewater is discharged directly into bodies of freshwater (Northwest Food Processor Association, 2017).

Cottage cheese in particular requires a large amount of water to be produced, somewhere between 0.8 and 12.4 kg of water per kg of milk processed (Northwest Food Processor Association, 2017). For these reasons, a cottage cheese plant is an excellent case study to observe the FEW Nexus interactions.

3.1. Process description

The process is largely taken from Stefanis et al. (1997), and modifications were made to introduce energy and water elements in the process. The plant specifications are kept the same as in Stefanis et al. (1997), with the required production of cheese being 137.7 t over 5508 h/y production time. Skimmed milk is fed to the process and after pasteurization, is mixed with culture in up to three vat processors with different design specifications for 240 minutes to produce curd and whey. Optionally, the curd is stored before further processing.

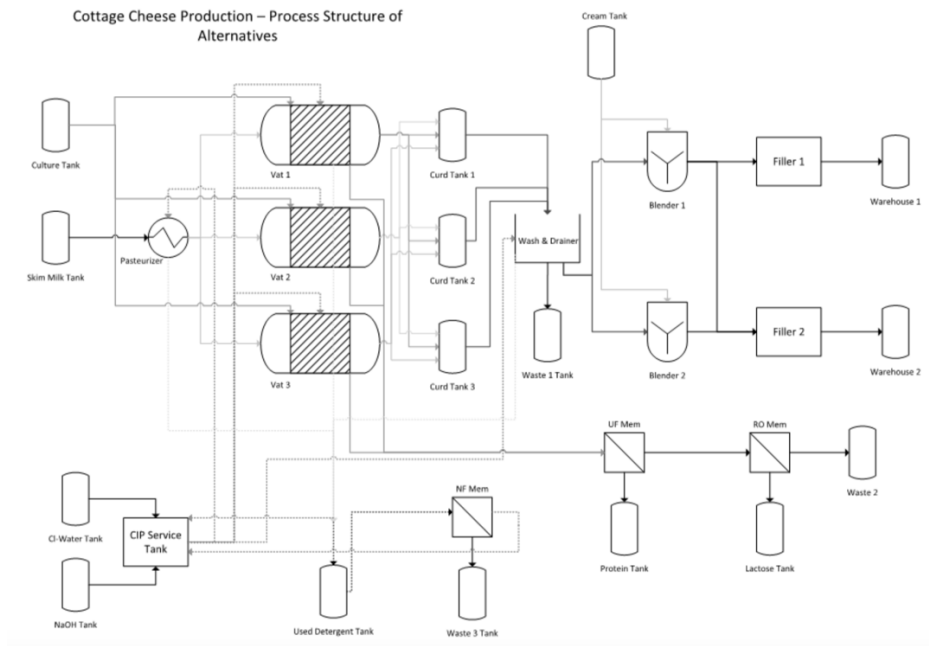

Figure 1 Flowsheet of the Cottage Cheese Plant

The curd is then drained (30 min) and the solidified curd is blended with cream for 60 minutes to produce cottage cheese which is then filled into different size containers (Fillers 1 and 2). The final products are then stored in warehouses for delivery.

The whey by-product is further processed to recover the concentrated protein and lactose (sold as by-products) in two membrane separation stages: the ultrafiltration stage (240 min) and the reverse osmosis stage (60 min). For constant recovery, the ultrafiltration stage is maintained at 4 atm pressure drop while protein by-product recovery and waste generation depend on the operating pressure of the reverse osmosis unit (1.7 - 3.8 atm).

Cleaning-in-Place (CIP) is an essential part of dairy plant operation. All units that involve heating of milk must be cleaned after each use. For this case study, this means that the Pasteurizer, all Vats, and the Drainer must all be cleaned.

Cleaning takes 30 minutes and uses 100 kg of detergent. Detergent is made in the CIP Tank by mixing chlorinated water with NaOH to form a 0.5% NaOH solution. After cleaning, roughly half of the detergent can be recycled. Used detergent is then either stored or sent to nanofiltration (60 minutes) for 90% recovery of clean detergent.

3.1.1. Food aspect of the CCP

The food aspect of the process does not only include the cheese produced, that is constant at 137.7 t per year of operation, but also includes the protein and lactose by-products. Although the amount of cheese and protein produced never varies, there is variability in the amount of lactose that is produced. This variability stems from the pressure of the reverse osmosis unit. At higher pressures, more lactose is produced at increased economic and energy cost.

3.1.2. Energy aspect of the CCP

The energy required to operate the ultrafiltration, nanofiltration, and reverse osmosis units was taken into consideration the same way as in Stefanis et al. (1997). The energy required to raise the cleaning water from room temperature to 50°C was also accounted for and the higher the amount of cleaning, the more energy required (Clark and Potter, 2007). Moreover, we included the energy required to refrigerate the stored milk, cheese, curd, and cream in their respective storage tanks (Sun et al., 2017). These calculations all assumed a constant value for the amount of energy lost per unit time and a coefficient-of-performance for refrigeration. Finally, the amount of energy required to operate the pasteurizer as a function of throughput was accounted for.

3.1.3. Water aspect of the CCP

The water aspects of the process included the steam used for pasteurization, the water used for cleaning, the water used for washing curd (roughly 2.5 times the amount of milk processed) (Clark and Potter, 2007), and the waste water generated by the process. The amount of Waste 2 generated varied with the amount of lactose produced. The more lactose produced, the lower the amount of Waste 2, at the expense of higher energy and operating costs.

The developed scheduling model was implemented in GAMS and consisted of 4,096 equations, 1,241 integer variables and 2,518 continuous variables. The detailed model was excluded here due to page restrictions but can be provided upon request.

4. Optimal solutions

The dimension elements of the FEW-N metric for the case study included the three FEW-N elements and the profit element (Revenue – Operating/Fixed Cost). For each FEW-N metric an optimization problem was formed with objective to maximize each the metric subject to the constraints of the CCP schedule model. For comparison purposes, another four optimization problems were formed and solved to maximize profit and food produced, and minimize energy used and water used.

All optimization problems were solved to 2% optimality using global optimization solvers (BARON and ANTIGONE) for mixed-integer non-linear optimization problems.

The numerical solutions for of each problem created from the metrics are presented in Table 2 and are compared with the value of each metric for various objectives that a decision maker may consider. Objectives included: maximize profit, maximize food production, minimize energy use, and minimize water use. The solution schedule for the LA metric is presented in Fig.2. The full detailed numerical solutions, along with the schedules for BA, TA and QA FEW-N metrics were excluded from the document due to page limitations but can be provided upon request.

Table 2 FEW-N metric value

	Optimal	Maximum Profit	Maximum Food	Minimum Energy	Minimum Water
LA	0.823	0.598	0.598	0.378	0.765
BA	0.660	0.297	0.297	0.085	0.567
TA	0.496	0.098	0.098	0	0.405
QA	0.345	0	0	0	0.279

Figure 2 Optimal Schedule for maximum LA FEW-N metric

5. Conclusions

In this work, we were able to define a framework for the development of a quantitative index assessing the integrated FEW-N performance of different process systems that can be used to facilitate decision making in process optimization. The metrics developed were able to accurately quantify the impact of the CCP system on the FEW-N and are general enough that they can be adjusted and applied to a wide variety of process systems while considering any number of decision elements. For the CCP process, it was observed that using any of the mathematical forms of the FEW-N metric we were able to get much better FEW-N solution that optimizing different FEW-N elements individually.

Abstract

Pillow-plate heat exchangers (PPHE) are fabricated as stacks of pillow plates with alternating inner and outer channels. In this contribution, we show results of a numerical investigation of the turbulent single-phase flow ($3000 \leq Re \leq 8000$) in the outer channels performed with the aid of the OpenFOAM[®] simulation software. Several turbulence models based on different approaches (RANS, DES, LES) were tested. The simulation results were compared with pressure loss measurements conducted earlier by our group. Despite inherent simplifications, some advanced RANS models are capable of adequately capturing the complex fluid dynamics in the outer pillow-plate channels, showing results comparable to those of the more time-consuming LES simulations.

Keywords: Pillow plates, Computational Fluid Dynamics, Numerical simulations, Turbulent transport, Heat exchanger.

1. Introduction

Pillow-plate heat exchangers (PPHE) represent an innovative and promising alternative to conventional equipment. The waviness of the pillow plates promotes lateral mixing and turbulence, which results in a good thermo-hydraulic performance, offering a significant energy-saving potential. However, the implementation of PPHE is still limited due to the lack of comprehensive data and publicly available proven design methods, while the range of applicability of existing correlations has not yet been fully determined. To overcome this problem, our group has been intensively studying this equipment type over the past years, using both theoretical and experimental methods. In this contribution, we consider the turbulent single-phase flow ($3000 \leq Re \leq 8000$) in the outer channels formed when several pillow plates are arranged in parallel to stacks.

Nowadays, the range of turbulence models available within modern CFD codes is large illustrating the fact that no single model is suitable for all scenarios. Apart from the Direct Numerical Simulation (DNS), traditionally, two families of models exist: i) SRS (Scale Resolving Simulation) in the form of Large Eddy Simulation (LES) resolve the largest turbulent scales within a flow; ii) RANS (Reynold Averaged Navier Stokes), or URANS (Unsteady-RANS) eddy-viscosity models, which compute mean flow with no attempt to resolve spatial or temporal scales. In recent years, Hybrid SRS/URANS

models have started to appear within codes, such as detached eddy simulation (DES), which combines LES with the use of economical well-tuned URANS in the simulation of near wall flows. Using an appropriate turbulence model is necessary for obtaining reliable results. For this reason, we tested several turbulence models based on different approaches (RANS, DES, LES) with the aid of the open source OpenFOAM® (OF) simulation software. The main objective of this paper is the performance evaluation of simpler turbulence models, including URANS and hybrid SRS, when describing the complex flow in the outer channel of a pillow plate in comparison with LES simulations.

2. Materials and Methods

2.1. Geometry creation and discretization

The genuine pillow-plate geometry has been obtained using forming simulations (Piper et al. 2015), an approach which adequately imitates the hydroforming process during the real manufacturing of pillow plates and thus permits an accurate reconstruction of the wavy pillow-plate channels for all possible variations of the geometric parameters. The computational domain has been defined by exploiting all the existing symmetry planes and the periodicity of the flow to reduce the computational effort. For the domain discretization, a structured body-fitted grid has been adopted. This grid type is ideal for wavy surfaces, since the cells align with the geometry contours, and this property leads to high-quality cells favourable for numerical accuracy and convergence. The grid has been generated by using the commercial software STAR-CCM[†]. Afterwards, the grids have been properly converted for the use in OF release 4.1. The meshes obtained had over 6 million cells. Thanks to the significant refinements applied to the walls, it was possible to reach y^+ values below unity in all the cases simulated in this study.

2.2. Numerical setup

The resolution of transient flow has been achieved with the prebuilt Eulerian solver *pisFoam*, which is the transient solver for incompressible flows using the well-established predictor–corrector PISO (pressure implicit with splitting of operators) algorithm for pressure-velocity decoupling. All diffusive and advection terms were approximated with a second-order accuracy, while a blended first/second order implicit scheme (Crank-Nicolson) was used for time integration. The time step has been varied to assure a maximum Courant number less than 1 for all simulations performed. In our study, the Reynolds number is defined by using the mean stream velocity and the hydraulic diameter, evaluated as the quadruple ratio of the total domain volume and the wet surface given by the two domain walls.

2.3. Turbulence modelling

Since flow separation is expected to occur in the pillow-plate outer channels, it is extremely important to appropriately resolve the velocity boundary layer. The use of standard wall functions (SWF) is expected to be invalid here, because of flow separation and recirculation. On the contrary, Low-Reynolds-number (LRN) turbulence models do not require the specification of the wall-functions for the near-the-wall region treatment, but require a finer mesh for the near-wall region, resulting in higher computational costs. In the LES framework, the ‘unresolved’ turbulent viscosity relates directly to the sub-grid scales (SGS). The Smagorinsky (1963) eddy viscosity is one of the simplest SGS models, but several alternatives exist, a promising one being the WALE (Nicoud and Ducros, 1999), which represents a good compromise between accuracy and computational cost.

Considering advantages and disadvantages of the methods mentioned, in the present work, both RANS and LES were compared. The adopted turbulence treatments are listed in Table 1.

Table 1. Applied turbulence models.

Family	Model	Wall	Notes
RANS	R k- ϵ	SWF	two-equation k- ϵ with realizable option (Shih et al., 1995)
	RNG k- ϵ	SWF	two-equation k- ϵ with renormalization group (Yakhot et al., 1992)
	SA	LRN	one-equation Spalart and Allmaras (1992)
	LL k- ϵ	LRN	two-equation k- ϵ Lien and Leschziner (1993)
	k-kL- ω	LRN	three-equation k-kL- ω (Walters and Cokljat, 2008)
URANS	k- ω SST	LRN	two-equation k- ω with shear stress transport (Menter, 1994)
SRS-	DES k- ω	---	k- ω SST Detached Eddy Simulation (Menter et al., 2003)
URANS	SST		
SRS	LES (SM)	---	Smagorinsky (1963) constant coefficient sub-grid
	LES	---	Wall Adapting Local Eddy Viscosity sub-grid (Nicoud and Ducros, 1999)
	(WALE)		

2.4. Boundary conditions

To reduce the computational effort, we used periodic boundary conditions in the problem under study. However, a specified pressure gradient is needed to drive the flow. This means that the values of pressure on the left and right edges of the domain must be different, and thus, applying periodic boundary conditions directly on the pressure is not possible. An easy strategy to overcome this problem is to split the local pressure into two parts: a linearly-varying component and a residual component, $p = P + p'$. In this way, it is possible to fix the applied pressure gradient (the gradient of the linearly-varying component), which is constant and can be interpreted as a source term, $-\partial P/\partial y = F$, and numerically resolve only the perturbations in pressure, represented by the residual component $\partial p'/\partial y$. In addition, the source term introduced, which acts as a volume force in every point of the domain, can easily be tuned to suitably change the flow conditions. In particular, for each turbulent model investigated, this parameter has been progressively increased from a certain starting condition, verifying the convergence of the system at each of the assumed values. Thus, each simulation is initialised with a velocity field very similar to the sought solution, and in this way, instability and convergence problems are reduced.

2.5. Code validation

In Figure 1, the specific pressure loss determined by CFD simulations is validated using the data obtained from experiments performed by our group (Piper et al. 2016). The numerical results agree well with the experiment over the entire range of Reynolds numbers investigated here (3000-8000). The best fit shows a relative error around 5 % for the DES simulation, whereas for the other cases, the deviation varies from 10 to 20%. Surprisingly the k- ω SST model exceeds 50% deviation from the expected values. This means inadequacy with regard to the phenomenon in question. It is interesting to note that the LES approach with SM sub-grid model also fails, at least in the configuration adopted in the present study, in evaluating pressure losses along the outer channel, with an overprediction of more than 20%, whereas the simplest model, SA, yields just around 10% underestimation.

Figure 1. Comparison of numerical and experimental results for pressure loss in the outer pillow-plate channel for $3000 \leq Re \leq 8000$.

3. Results and Discussion

Figure 2 qualitatively shows the vortex structures arising upstream of the welding spots. They result from the significant cross-section variation in stream-wise direction of the outer channel, which leads to an adverse pressure gradient and causes boundary layer separation. The fluid located in the vortices is transported spirally outwards away from the troughs; it is then directed diagonally into the next downstream trough.

Figure 2. Illustration of the characteristic flow pattern in the outer pillow-plate channel, with vortex structures (represented by streamlines) arising near the welding spots ($Re=8000$).

The size of these vortices can be evaluated more clearly by the regions of negative wall shear stress τ_w in Figure 3, indicating recirculation of the flow. The recirculation zones cause form drag, which contributes approximately 50% of the Darcy friction factor. After boundary layer re-attachment, the flow is re-accelerated out of a trough.

Figure 3. Comparison of shear stress profiles at inferior wall for $Re=5000$. a) DES $k-\omega$ SST; b) $k-\omega$ SST; c) $k-kL-\omega$; d) SA. Size of recirculation zones is represented by $\tau_w, \leq 0$. τ_w [$m^2 s^{-2}$] is rescaled by dividing by the density of the fluid (water at 25 °C).

We also investigated the evolution of the Darcy friction factor $\zeta_{\Delta p}$ in the range $3000 \leq Re \leq 8000$. Based on previous studies, the best fit for the Darcy friction factor for the outer channel is represented by $\zeta_{\Delta p} = 3.46Re^{-0.39}$ with a maximum deviation of 2% (Piper et al. 2016). This relation has been employed as reference in Figure 4, where the $\zeta_{\Delta p}$ prediction by all the investigated turbulence models are compared. Similar results to what seen for Δp can be drawn for the prediction of $\zeta_{\Delta p}$, with $k-\omega$ SST model giving the worst performance (over 50% deviation from the expected value). Nevertheless, all the other models, regardless of their prediction capacity on pressure losses, are able to adequately capture the trend of the coefficient and provide values very close to the expected ones. Also in this case, the best fit is given by the DES $k-\omega$ SST model.

Figure 4. Evolution of the Darcy friction factor in the outer pillow-plate channel as a function of the Reynolds number.

4. Conclusions

The turbulent single-phase flow in the outer channel of a pillow plate was investigated using OpenFOAM[®]. Several turbulence models were tested. DES $k-\omega$ SST seems to be

an optimal approach: it provides the best agreement with experiments, has lower computational costs and is easier to configure compared to LES simulation. Some advanced RANS models are also capable of adequately capturing the complex flow in the outer pillow-plate channels, showing results comparable to those of the more time-consuming LES simulations. In particular, k - kL - ω ensure a reasonable fit to experiments, thanks to the improved wall treatment, whereas SA shows the ability to catch the average characteristics of the flow in a very satisfactory way considering its inherent simplicity, and certainly, it is a choice to be preferred for general studies. On the contrary, k - ω SST seems to be inadequate in our case, despite that it is known to be a well performing model for the simulation of flows subject to separation.

Abstract

The two decomposition methods Dulmage-Mendelsohn (DM) decomposition and bordered block transformation (BBTF) have been examined on their capabilities to eliminate convergence problems during the iteration of large, nonlinear equation systems as they occur frequently in process modeling. They both divide the overall system into lower dimensional subsystems, which can be solved separately in sequence. Exemplarily these methods were applied on the model of a reactive distillation column, where the decomposed systems show a higher robustness with respect to systematically selected initial points compared to the original system. Nevertheless, the improvement in DM seems small since a large subsystem with 576 of the 664 model equations remains. The convergence result from the iteration of the BBTF decomposed system depends a lot on the initial values for certain strongly coupled variables called tearing variables. In future, methods will be investigated and may also be developed to further reduce the dimension of the subsystems in DM and provide accurate initial values for the tearing variables in BBTF.

Keywords: Numerical methods, Efficiency, Robustness, Condition number

1. Introduction and Motivation

In order to enhance the economic potential of processes in chemical industry their concepts become steadily more complex due to the increasing usage of recycles or multiple operations within one apparatus as in process intensification. The occurring interrelations cause difficulties for both physical modeling and the applied numerical algorithms to solve the equation system. In this contribution, the focus is laid on the numerical aspects of the process model solution.

A strategy to overcome the convergence problems is to subdivide the overall system into subsystems, which can be solved independently in sequence. Two of these decomposition methods, the Dulmage-Mendelsohn (DM) decomposition and the bordered block transformation (BBTF) are examined here. In the worst case, each subsystem is theoretically as ill-conditioned as the original system. Consequently, for most cases the condition number of the subsystems will improve significantly. Apart from that, the computational effort is reduced due to solving lower dimensional systems in sequence. Two decomposed versions of a reactive distillation column will exemplarily be investigated based on these assertions.

2. Solving Nonlinear Equation Systems

The solution of nonlinear systems is divided among three different classes of algorithms: Direct substitution methods (e.g. Wegstein, Dominant Eigenvalue) typically suffer from stability issues in case of ill-conditioned systems; residual minimization techniques (e.g. MATLAB's `fsolve`) face issues with the nonuniqueness of solutions of squared nonlinear systems. Next to those, the (quasi-)Newton-type class of algorithms combined with globalizing line search techniques is the workhorse for many difficult nonlinear systems. They solve equation systems of the form:

$$0 = F(x) \tag{1}$$

by calculating a Newton step Δx_k to the next iteration point x_{k+1} via:

$$J(x_k) \cdot \Delta x_k = -F(x_k) \tag{2}$$

While the various Newton implementations differ in how the Jacobian matrix J is computed (e.g. Broyden's approximation, analytic Jacobian) and whether the full Newton step is performed (dampening and line search techniques), they almost all have to solve a linear system for each Newton step. Therefore, well-known techniques, which improve the condition of linear systems such as row and column scaling or those which reduce numerical costs by permuting rows and columns can also enhance the iteration performance of Newton-type algorithms.

In this study, the numerical performance is evaluated by the number of equation calls also called function count until a solution is found and the condition of the initialized system is measured by the condition number based on the Euclidean norm.

2.1. Decomposition Techniques

The core of most decomposition methods is the permutation of columns and rows. During the solution of a nonlinear systems the row and column order of the Jacobian matrix J is rearranged for the solution of each linear Newton step. Given that J contains the first derivatives of all equations with respect to all variables a permutation of the rows implies a rearrangement of the equations and a permutation of columns changes the order of all variables.

2.1.1. Dulmage-Mendelsohn Decomposition

In DM the original Jacobian is converted to an upper block triangular matrix by maximizing the number of blocks along the diagonal. Dulmage and Mendelsohn (1958) explain this procedure in detail. Fig. 1 shows the incidence matrix of the Jacobian belonging to a tray-based column model. Starting from the first block on the bottom right of J the blocks are solved in sequence. Already calculated variables from former blocks act as constants values in the following. Thus, all entries above the diagonal are previously determined quantities. The number of variable dependencies within the equations increases from the bottom right to the top left, causing highly dependent equations to be solved last.

2.1.2. Bordered Block Transformation

In contrast to DM, BBTF turns the Jacobian to a lower block triangular form as shown in Fig. 1 for the examined example. Erisman et al. (1985) present the principle of the method in more detail. During the restructuring highly linked variables called "tearing variables" are separated and shifted to the right of J . Hence, the dimension of the blocks can be further reduced. The solution process is divided into an inner and an outer loop. It starts with the inner iteration from the block in the

upper left corner of J . All blocks are then solved in sequence for a constant set of tearing variables. During the outer iteration the tearing variables are iterated within the “tearing equations”, wherein all other variables from the inner loop are kept constant. The algorithm converges on satisfying a certain tolerance for the outer loop.

3. Decomposition of a reactive distillation model

Representatively a model for the production of Methyl-Tert-Butylether (MTBE) in a reactive distillation column has been built and used for investigations on both decomposition methods.

MTBE appears as additive in fuels and as solvent or extracting agent in the chemical industry. As discussed by Taylor and Krishna (2000) the conventional process requires a reactor followed by three extraction columns to cope with the arising azeotropes of the reaction mixture. Through the combination of reaction and distillation the extend of the process reduces to only one column. Nevertheless this leads to a more complex process model and a higher challenge in solving the related equation system.

3.1. Model description

MTBE is synthesized by the reaction of Methanol with Isobutene at the presence of another olefin, which is N-Butene in this case. Neglecting the side reactions, the reaction:

is considered in the liquid phase of the model. Amberlist 15 acts as a solid caterlyst in the reactive part of the column.

The classical equilibrium stage approach is applied which involves thermal, mechanical and chemical equilibrium between liquid and vapor phase on all stages. Nevertheless the reaction kinetics are considered in the liquid phase based on data from Rehfinger and Hoffmann (1989) and Sundmacher and Hoffmann (1994). The real fluid behavior of the liquid phase is described by UNIFAC, while the vapor phase is assumed to behave as ideal gas. All thermo-physical and component-dependent properties are taken from CHEMCAD (2017). The whole process is modeled as steady-state.

Since the focus of this work is the observation of the decomposition methods the model validation through experimental data is not amplified here. Beside this the model consists of only two rectifying and one reactive stage to keep the restructuring comprehensible. More complex reactive distillation models that can also describe the dynamic behavior of those processes were set up and experimentally validated by Reepmeyer et al. (2004) and Forner et al. (2006). The entire model encompasses 664 nonlinear algebraic equations. It has been implemented in our department's modeling and code generation software MOSAICmodeling, that is presented by Merchan et al. (2016). Both decomposition methods are already integrated in MOSAICmodeling and were used on the test system. Subsequently, the original and decomposed versions were exported to MATLAB and iterated with the Netwon-based Trust-region-dogleg-solver.

3.2. Observation of the decomposed systems

Fig. 1 presents the incidence Jacobian matrices of the original and the decomposed systems. The DM decomposition retains a quite large block with a dimension of 576 equations and variables. This block contains the whole UNIFAC-model and conservation balances which are both strongly coupled through the mole fractions and stage temperatures.

The BBTF identifies the mole fractions of all three components that take part in the reaction referring to eq.3 and the stage temperatures as tearing variables. This sums up to 12 tearing

variables. As a result the block dimension along the diagonal can be drastically reduced to a dimension of 3 at maximum.

3.3. Test methods and results

Starting at one solution of the equation system each iteration variable is separately varied between ± 5 and 30 % while keeping the other variables at their solution value. This is done for the original and the decomposed systems to generate the same set of initial points. For each equation system a total number of 5312 iterations was performed. Fig.2 shows the ratio of successful runs to performed runs over the perturbation of the variables for all three systems. Since the number of converging iterations does not differ much between increasing and decreasing the variable values by a certain percentage (the maximum difference is five iterations), only the average value is shown.

BBTF features the best convergence performance in this case. The ratio of successful iterations stays constant at 98 % in the examined range. The number of failed iterations refers to the perturbation of the tearing variables. Even for a perturbation of 5 % these iterations do not succeed. In contrast the perturbation of all other variables does not influence the convergence result at all. Hence the convergence of a BBTF decomposed system highly depends on the initial guess of the tearing variables, while the initial guess of the remaining variables can be arbitrary.

As expected, the number of successful iterations decreases with higher perturbations for the other two systems. The DM seems to be a bit more robust than the original system. Interestingly in both versions the perturbation of certain variables leads to failing iterations for all tested perturbation values. These variables can be identified as quantities of the UNIFAC model, to be exact they are the van der Waals volumina and surfaces that determine the combinatorial component of the activity coefficient. Per definition they are both related to the molar fractions that were identified as highly linked variables and could spread any deviation directly into other parts of the equation system. On top they occur in exponential expressions that are strongly non-linear and obviously not well described by any linear approximation of a Newton-based algorithm.

Next to the convergence performance the computational effort to iterate the three systems has been investigated. Therefore, all variables were perturbed at once by ± 3 %. Subsequently the systems were solved with the same solver settings (maximum number of function calls per block: 30000, Step size tolerance: 10^{-6} , function tolerance: 10^{-10}). During iteration the function calls have

Figure 1: Incidence Jacobian matrices of the original equation system (top), the DM decomposed system (center) and the BBTF decomposed system (bottom)

Figure 2: Ratio of converged to total iterations by variable wise perturbation at the initial point

Table 1: Function counts to solver termination at 3% perturbation of all variables

System	Function Counts		Solved
	(+3%)	(-3%)	
BBTF	in: > 10 ⁶ out: 693	in: > 10 ⁶ out: 1078	no
BBTF (TV=const.)	in: 303054 out: 110	in: 121265 out: 44	yes
DM	14254	13094	yes
Original	15960	15295	yes

been tracked to finally calculate the total function count until the solver terminates. The results are presented in Table 1.

Although the residual series of the BBTF decomposed system seemed to converge, it could not be properly reduced after more than one million function calls within the inner iterations. Both outer iterations ($\pm 3\%$ perturbation) were terminated by deceeding the set step size tolerance. When keeping the tearing variables at their solution values the solver needed a total sum of 303164 function calls to succeed at a perturbation of +3 % and less than half the number at a perturbation of -3 %. Hence in BBTF both the convergence and the efficiency of the solving procedure depend a lot on values of the tearing variables.

The best performance shows the DM decomposed system closely followed by the original system. Presumably the performance of the decomposed system would be much better in a more decoupled system. For this example, 97 % of the function counts are used within the large block with its 576 equations.

Finally, the conditions of the systems along their iteration trajectories are examined by recording their condition numbers. It is started from the initial point where all variables exceed their solution by 3 %. Surprisingly, the condition number of the original and the decomposed system differ only marginally for their first 17 iteration steps. This encourages the suspicion that the DM decomposition cannot efficiently uncouple the overall system into lower dimensional blocks in this case. Hence the problematic terms causing the high condition numbers are probably still part of the large block. The number of iterations until a solution is found equals 23 for both systems, although less function calls are necessary to solve the lower dimensional large block of the decomposed system. From iteration step 17 to 23 the condition numbers vary by roughly $2 \cdot 10^{18}$. This could be the result of slightly differing final values of the iteration variables. Using the same solver settings the original version might be more accurate since both iterations finish by deceeding the function tolerance. In the iteration of

Figure 3: Condition numbers along iteration trajectories of the original system and the largest blocks of the DM decomposed system

From iteration step 17 to 23 the condition numbers vary by roughly $2 \cdot 10^{18}$. This could be the result of slightly differing final values of the iteration variables. Using the same solver settings the original version might be more accurate since both iterations finish by deceeding the function tolerance. In the iteration of

the original system the quadratic sum of more function residuals has to fulfill this criterion.

The condition numbers of the outer iteration of the BBTF decomposed system do not change much and lie all within the range $4.879 \pm 0.0005 \cdot 10^{13}$. This is the best conditioned system of the three examined versions. The condition numbers of the inner blocks are negligibly small.

4. Conclusion and Outlook

The effect of the Dulmage-Mendelsohn decomposition and bordered block transformation on a nonlinear algebraic equation system referring to a stationary reactive distillation model has been examined concerning convergence, computational effort and conditioning.

The results show that the DM decomposed system features a small improvement to the original system regarding the convergence behavior and the decrease in numerical costs during iteration. Nevertheless, a large block remains, that probably hinders the efficiency to be further increased. This block is caused by the used UNIFAC model where mole fractions and temperatures induce a strong coupling between the equations in the system. A concept to eliminate this problem is to decompose the large block by DM as well and solve it in an inner iteration. This will be part of our future investigations.

For known solutions of the tearing variables the BBTF seems to be quite robust to any perturbation of the inner iteration variables. Due to the low dimensional blocks the condition can be improved by five orders of magnitude to the original system. Still the numerical costs are quite high. Even when the tearing variables are initialized with their solution values the solver requires roughly 20 times more function calls than the other system modifications. This is the result of a very low rate of convergence. When the tearing variables differ only slightly from their solution the low convergence velocity can lead to a stagnating minimization of the function residuals. The BBTF gives a better numerical performance in systems with a smaller number of tearing variables as discussed in Bublitz et al. (2017). Further test cases will be performed to identify a limit for the number of tearing variables where the numerical costs are still reasonably low. Besides, methods as the one of Baharev et al. (2017) which systematically generate initial values close to the solution will be examined in order to provide a sufficient set of initial values for the tearing variables and achieve a certain level of efficiency during the iteration of a BBTF decomposed system.

Abstract

The methylene blue was degraded by photo-fenton over Fe-diatomite prepared by dry impregnation method. The characterizations of catalyst were studied by XRD, XRF and BET surface area. The photo-fenton reaction conditions were studied as parameters of the H₂O₂ concentration, the amount of Fe-diatomite, the initial concentration of methylene blue and the initial pH of solution, which were designed by central composite design (CCD) based on response surface methodology (RSM) to accomplish the optimal condition. The results showed that the optimum condition was at the initial H₂O₂ concentration of 116 mg/L, the Fe-diatomite of 1 g/L, the initial MB concentration of 200 mg/L and the pH of 5.8. It could predict the decolorization value of 100% and reduce the total organic carbon (TOC) to 72.3%. Finally, the validation was tested in 5 runs at the optimization about 99.2±0.2% which implied that the regression model is in a good agreement.

Keywords: Central Composite Design (CCD), Photo-fenton, Methylene blue, Fe-diatomite, Heterogeneous catalyst.

1. Introduction

Dyes, which usually contaminate in the effluent, are non-degradable and toxic, and have the carcinogenic nature. Thus, dye-contaminated wastewater should be treated before being discharged into environmental. Methylene blue (MB), a kind of dye, is commercially amiable which is always released from the washing process.

Therefore, MB contaminated in wastewater must be worried. Photo-fenton is one of advanced oxidation processes (AOPs) which can treat the pollutants into green products with smaller molecules. Heterogeneous catalysts used in Photo-fenton process are interested because they are easier to be separated after reactions than homogeneous catalysts. Diatomite is mainly composed of silica and some irons which would enable it to use as a photo-fenton catalyst (Khraisheh et al., 2005)

Response surface methodology (RSM) is a statistically method widely used to design an experiment, explain the main and interaction effects of the independence variables, and determine the optimal condition with a limited number of experiments (Song et al., 2014). Along with RSM, central composite design has been applied to design the experiments using statistical software. In AOPs, central composite design has been used to identify the factors to be studied with methylene blue removal (Mazaheri et al., 2016)

Finally, central composite design was used in this study to identify the optimum condition in photo-fenton using Fe-diatomite to remove colour from the synthetic dye wastewater. Also, response surface methodology was applied to estimate their optimal value. Knowing the optimal condition using statistical computer software can help, and make it easy, to determine the main and interaction effects.

2. Experimental

2.1 Catalyst Preparation and Characterization

A natural diatomite from Lampang (Thailand) was chosen as the raw material. FeSO₄ of 0.02 mole was dropped into diatomite by using dry impregnation method. The chemical compositions of Fe-diatomite were analyzed by X-ray fluorescence (a Bruker S1 Turbo SD, Germany) with CuK α radiation. The crystalline structures of diatomite and Fe-diatomite were characterized by X-ray diffraction (XRD; Bruker AXS-D8; Karlsruhe, Germany) using CuK α radiation ($\lambda = 15406 \text{ nm}$) with an anode current of 30 mA and an accelerating voltage of 40 kV. The samples were scanned from 5 degree to 80 degree (2 theta) in the scanning step of 0.02 degree at a rate of 5 degree per min. The surface area, pore volume and average pore diameter were determined by nitrogen adsorption-desorption measurements (BET method).

2.2 Experimental Design

Methylene blue (C₁₆H₁₈ClN₃S, MW 319.85 g/mol) purchased from Sigma Aldrich (Germany) was chosen as the synthetic model dye. All other analytical grade chemicals were purchased from UNILAB (Thailand) and LABSCAN (Thailand). The experimental design and data analysis were carried out using the software MINITAB version 16.0. The experimental was designed by central composite design at four-factor (X_1 : the H₂O₂ concentration, X_2 : the amount of Fe-diatomite, X_3 : [MB]₀ and X_4 : the initial pH) and three-level (low, medium, high) as shown in Table 1. The total numbers of 31 experimental runs were conducted to assess the effects of independent variable on the efficiency of photo-fenton process. The decolorization efficiency (%) in Eq.(1) as a response function was optimized to achieve a desire value by response optimizer.

$$\% \text{ Decolorization Efficiency} = \left(\frac{c_0 - c_t}{c_0} \right) \times 100 \quad (1)$$

where c_0 is the initial concentration and

c_t is the measured MB concentration after 30 min of reaction.

2.3 Experimental Run

The photo-fenton oxidation condition from CCD was carried out in a 500-mL batch stirrer photo reactor and the catalyst was added to the 300 mL of methylene blue solution. The sample was stirred about 10 min in the dark for adsorption process, and then the samples were collected, and the initial methylene blue concentrations were analyzed. After that, the amount of H₂O₂ was added into the sample, and the solution was stirred for 30 min. Then, the samples were collected, and the concentrations of methylene blue were analyzed at the end of run. The maximum wavelength of 464 nm was applied for the UV detector.

Table 1 The central composite design of photo-fenton process

Factors		Level		
		-1	0	1
Initial H ₂ O ₂ concentration (mg/L)	X ₁	50	75	100
Fe-Diatomite (g/L)	X ₂	0.4	0.6	0.8
initial MB concentration (mg/L)	X ₃	300	400	500
pH	X ₄	3	5	7

3. Results and Discussion

3.1 Characteristic of Fe-Diatomite Catalyst

Figure. 1 The XRD pattern of Fe-diatomite

From X-ray fluorescence analysis, the results showed that Fe-diatomite had 66.9%wt silica as its main constituents. The iron oxide was 7.48 %wt upon the impregnation of Fe ions in diatomite. The XRD pattern for Fe-diatomite was showed in Figure.1. The XRD pattern evidenced the presence of quartz with $2\theta = 20.86, 26.64$ (JCPDS: 46-1045) (Inchaurredo et al., 2017) and did not show the peak related to iron oxides. Diatomite is naturally-occurring clay in the earth crust. It typically consists of silica as the main component and a small amount of iron oxide. The BET surface area of Fe-diatomite was 20.40 m²/g. The pore volume and average pore diameter were 0.071 ml/g and 12.9 nm, respectively.

3.2 Response Surface Methodology and Optimization

The results of decolorization of methylene blue in photo-fenton process of all conditions designed by central composite technique were estimated by least-square technique to determine the regression quadratic equation as shown in Eq.(2):

$$Y = \beta_0 + \sum_{i=1}^4 \beta_i X_i + \sum_{i=1}^4 \beta_i^2 X_i^2 + \sum_{i=1}^3 \sum_{j \neq i}^4 \beta_{ij} X_i X_j \pm \varepsilon \quad (2)$$

where Y is the response (decolorization efficiency, %) $\beta_0, \beta_i, \beta_i^2$ and β_{ij} are the constant coefficients, X is the independence variable that X_1, X_2, X_3 and X_4 are the H_2O_2 concentration, the amount of Fe-diatomite, the initial methylene blue concentration and the initial pH, respectively, and ε is the experimental error. The regression quadratic equation was resulted in Eq.3:

$$Y = 25.81 + 1.05X_1 + 12.01X_2 - 0.08X_3 + 4.53X_4 - 0.00420X_1^2 - 0.370X_4^2 \quad (3)$$

The predicted results can be calculated by Eq.(1). Then, the internal standard residual was applied to check how well the model satisfies the assumption of the analysis of variance (ANOVA).

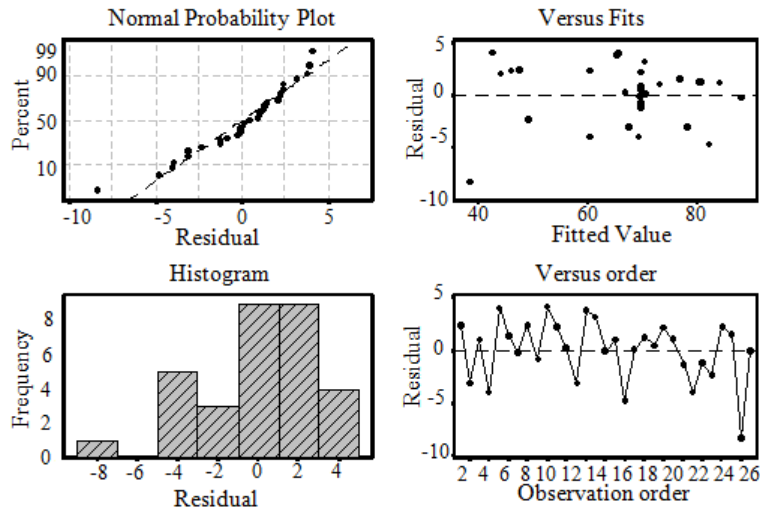

Figure.2 Internal standard residual plots versus normal probability, histogram, fit and order.

As illustrated in Figure.2, a normal probability plot of standard residual from least-square-fit plot showed the data along a straight line. The frequency of residual in normal distributions was shown in the histogram. The residual versus the fitted value showed randomly scattered around the zero line, which recommend that the data seemed to show the relatively-constant variance across the predicted value and had no outliers or influential observations (Sriprom, 2015). In addition, the standard residuals versus observation showed fluctuation around the center line, indicating that the data were distributed well (Wantala, 2013).

A good agreement has been achieved between the predicted results and the experimental results with R^2 of 95.17% as shown in Figure.3. This observation indicated that the purposed model showed adequate approximation of main variable effect on methylene blue removal with a difference of about 5%.

Figure. 3 The observed value (%) plotted against the predicted values (%)

At 95% confidence, the independence variable of H₂O₂ concentration, the amount of Fe-diatomite, the initial methylene blue concentration and the initial pH are the significant effects on percent decolorization of methylene blue ($P_{\text{value}} < 0.05$).

(a)

(b)

(c)

Figure. 4 The percent depolarization of main effects (a) surface plot (b) and contour plot (c)

The main effects were shown in Figure 4(a) indicating that the H₂O₂ concentration, the amount of Fe-diatomite and the initial pH were increased with increasing decolorization

efficiency. However, decolorization efficiency was decreased with the increasing initial concentration of methylene blue. As depicted in Figure. 4(b) and 4(c), the percent of methylene blue removal increased clearly as the H₂O₂ concentrations and the amounts of Fe-diatomite increased.

Finally, MINITAB 16.0 software was used to optimize the model for the maximum % decolorization of methylene blue. The results showed that the optimum condition was found at the initial H₂O₂ concentration of 116 mg/L, the Fe-diatomite of 1 g/L, the initial MB concentration of 200 mg/L and the pH of 5.8. It can predict the value of 100% decolorization and reduce the total organic carbon to 72.3%. The prediction of model was verified by additional 5 runs under the optimum condition, resulting in a color removal of 99.2±0.2%. It can be seen that experimental value closely agrees with the predicted values of 100%, showing that RSM was an effective and reliable method for estimating the optimum condition.

4. Conclusion

In this study, the Fe-diatomite prepared by dry impregnation method in high Fe content could be applied in photo-fenton process to decolourize the synthetic dye wastewater containing methylene blue. It was seen from the results that the H₂O₂ concentration and the amount of Fe-diatomite were shown in the significant terms on the decolourization percent of dye in synthetic wastewater. The optimum condition was found at the initial H₂O₂ concentration of 116 mg/L, the Fe-diatomite of 1 g/L, the initial MB concentration of 200 mg/L and the pH of 5.8. It can predict the value of 100% decolorization and reduce the total organic carbon to 72.3%. In the future, this optimum condition can be used with the actual dye wastewater treatment.

Abstract

Wastewater treatment plants (WWTP) are one of the most energy intensive public utilities. The valorization of the biogas produced from the sludge in combined heat and power (CHP) systems allows important energy and emissions reduction, particularly if highly efficient engines, like solid-oxide fuel cells (SOFCs) are used.

This paper proposes a two-stage stochastic optimization approach to assess the market potential for SOFCs in WWTPs in Europe. Despite the biogas availability is a challenge to guarantee continuity of operation, the results show that the WWTP is a promising market to pave the way for SOFC cost reduction and further technological learning.

Keywords: solid-oxide fuel cells, stochastic optimization, wastewater treatment, biogas.

1. Introduction

SOFCs are one of the most promising options in the technological transition of the energy systems towards a carbon-constrained world because of the high efficiencies at which they can operate. They play an important role within the decarbonisation strategies in Europe. In particular, when fueled with WWTP-biogas, they would operate at zero net emissions (EC, 2017). Currently, the high investment costs of SOFCs are the major limitation to the deployment of the technology.

The technical and economic feasibility of SOFC integration into WWTPs also relates to the biogas availability on a daily and seasonal basis (Giarola et al. 2017). Optimization approaches have proven to be necessary to determine the optimal SOFC operations within large systems (Hawkes et al. 2009). In particular, the optimal generator dispatch can effectively be assessed using stochastic optimization when uncertainty on key inputs is considered (Nowak and Römisch, 2000, Ramadhani et al, 2017).

This work proposes a two-stage stochastic MILP (Mixed Integer Linear Programming) optimization model which aims to minimize the expected total system costs of a SOFC-energy provision system integrated with WWTPs, and determine the optimal system dispatch. The deterministic model proposed in (Giarola et al., 2017), later extended to a stochastic approach in (Sechi et al., 2017) is further developed to include a Pareto frontier optimisation with respect to the number of modules. The model is iteratively applied to a set of case studies, corresponding to the typical WWTP capacity ranges in Europe and builds a Pareto frontier of two competitive variables, the SOFC utilization factor and the number of modules installed. In doing so, it determines the optimal number of modules corresponding to each plant size accounting for uncertainty in the biogas availability.

2. Methods

The model here described proposes a generic framework to determine the optimal size as well as dispatch of a biogas-fed SOFC CHP system integrated to a WWTP. It extends the stochastic model proposed in (Sechi et al., 2017) to a Pareto approach, where the number of generators is optimised *a posteriori*, compromising the technology utilization and the biogas exploitation rate. The system refers to a generic plant with the layout of Fig.(1).

Figure 1. WWTP layout including the SOFC installation in the energy provision system. E_i and NG are the electricity and natural gas from the grid, BG and BG_n are the biogas produced from the anaerobic digester and the unexploited one, H_f and E_f represent the heat and electricity produced by the SOFC-CHP system.

The objective function in Eq.(1) is the minimization of the total costs: the expected operational costs OP_s depending on the scenario s of biogas availability; fixed costs (annualised capital costs, CC , and yearly maintenance costs, MC) dependent on the number of modules; start-up and shut-down costs (FC_t) of each module.

$$\min \sum_s p_s \cdot OP_s - CC - MC - \sum_t FC_t \quad (1)$$

The first stage of the stochastic model include not only the binary variable to set the on/off status of each generator at time t but also the electrical and thermal output. In the second stage, the recourse variables are the natural gas and the electricity bought from the grid, the biogas storage level, the amount of biogas unexploited. The number of SOFCs to install is set as a parameter in the model and the optimization is sequentially performed for each one of these configurations. The Pareto front approach is adopted as two conflicting objectives are involved: the total costs of the SOFC-CHP plant and its utilization factor, i.e. the actual number of operating hours of the system.

Further constraints involve the limit on nameplate capacity of the generators, on the capacity of the boiler as well as operational regimes for each SOFC module (i.e. nominal and partial load). Constraints regarding maximum ramp-rates, minimum duration of shut-downs and start-ups have been imposed to avoid thermal cycling and rapid damage of the device. Finally, a periodic boundary condition between begin and end of a year on the gas holder levels were set to extend the yearly optimization to multiple years.

3. Bottom-up approach to the estimate of the market potential

Figure 2 summarizes the approach used to extend the optimisation of specific case studies to the European scale. A set of representative case studies was defined corresponding to five capacity ranges of WWTP selected according to a statistical analysis of a WWTP Database (EC, 2016), the Waterbase-UWWTD. The database is conceived to contain the data of quality and quantity of the sludge collected as well as of the discharge of waste water of the WWTPs present in Europe. Although the source is quite fragmented, plants are always characterized by the number of people equivalent (P.E.), as a measure of the plant capacity. From the original set of plants, a first discriminant was applied to define the economic feasibility of the anaerobic digestion process; in Europe, the minimum size is typically 20,000 P.E.. Moreover, only plants equipped with a secondary treatment, which is fundamental to perform the stabilization of the sludge and the production of biogas, were considered for the integration with SOFCs. In total, the number of suitable plants was around 6,400.

A subdivision of the plants was performed to identify different segments of the potential market for the SOFCs. Five case studies or WWTP capacity ranges were selected: extra-small (XS), small (S), medium (M), large (L) and extra-large (XL). The capacity corresponding to the median of each interval, was used in the optimization of the number of modules. Also, each WWTP capacity range, was characterized by a suitable nameplate capacity of the SOFC module. For example, for the M case the SOFC size used was 58.3 kW as in DEMOSOFC project. SOFC techno-economic characteristics were defined within the framework of the DEMOSOFC project (DEMOSOFC, 2016).

Figure 2. Methodology to the case study definition

3.1. Monte Carlo scenario generation, thermal and electric WWTP load

A Monte Carlo simulation integrated in a random walk algorithm was developed in MATLAB® (Sechi et al, 2017) to develop the scenarios of daily biogas profiles. A statistical analysis was applied to an industrial datasets of biogas daily flows spanning 3 years (SMAT, 2017). The seasonal probability profiles of biogas were regressed using daily biogas flow values disaggregated into seasons. 200 Monte Carlo simulations were performed using an average value of seasonal production and a standard deviation as percentage of the average production and the ratio of seasonal production.

The average value of biogas production of the most productive season was calculated from the number of person equivalent provided by the UWWTD assuming a constant specific biogas production (10 litres/P.E./day). In fact, the person equivalent unit is legally a measure of the maximum organic load produced by the WWTP during a year.

The archetypal profile for the XS, S and M capacities were defined using standard deviation and seasonal ratios as calculated from the industrial data provided by the SMAT Collegno plant (180,000 P.E.); while for the larger capacities, L and XL, the characteristics of the Castiglione Torinese plant (Italy) were set.

The data for the electric load (Table 1) were selected from the statistical surveys performed in the framework of a European project (Enerwater, 2017). The median value of the consumption corresponding to the appropriate WWTP capacity range was used and fixed as constant during all the operating hours in a year.

Table 1. Size and specific electricity consumption of the WWTP case studies (i.e. capacity ranges)

Case study	Case studies, P.E.	SOFC nameplate capacity, kW	Electric Consumption, kWh/P.E./day
XS	30,000	10	48
S	90,000	10	42.3
M	210,000	58.3	37.6
L	450,000	100	37.6
XL	1,100,000	150	37.6

3.2. Natural Gas and Electricity Prices

Industrial electricity and natural gas prices were obtained from Eurostat as a function of the annual electricity and heat consumption. The values used in the model were the average prices over the 28 European countries.

3.3. Bottom-up approach to SOFC market potential estimate

Finally, for the assessment of the maximum SOFC capacity that could be potentially installed in Europe, the optimal number of modules was linearly extrapolated from the case study to each WWTP capacity range selected from the UWWTD database, and later multiplied by the market share of each capacity range.

4. Results and discussion

The two-stage stochastic model for the Pareto front optimization was solved using CPLEX in GAMS[®].

The results in terms of technology utilization (i.e. number of operating hours to total hour in a year), operating costs, total costs (including maintenance and clean-up costs) are presented for the medium capacity case study (M) in Figure 3. It can be noted that there is a minimum of costs when the number of cells is between 3 and 4, and keep increasing where a bigger number of modules is installed. It appears from the cost trends, that the marginal improvement due to the introduction of a new module becomes negative and the benefits of the co-generation cannot compensate the incurred fixed costs. From the technical prospective, the minimum costs configuration, represents also the maximum utilization ratio of the available biogas in the SOFC system, which is around 1 % (not shown here).

Figure3: Optimal cells number for the medium WWTP size (M)

Table 2. Results of the Pareto front optimization. The table reports: the total installed capacity (Total SOFC capacity), the number of modules and the nameplate capacity of the modules used in each case study (XS, S, M, L, XL) as well as the technology utilization ratio.

Case study	Median WWTP size (P.E.)	SOFC nameplate capacity, kW	Optimal Number of SOFC	Total SOFC capacity, kW	Technology utilization, %
XS	30,000	10	3	30	80
S	90,000	58.3	2	117	59
M	210,000	58.3	3-4	233	72
L	450,000	100	6	600	77
XL	1,100,000	150	10-11	1,500-1,650	77-66

For the M (medium size) case study, the Pareto frontier optimization results were consistent with the results of the deterministic study conducted for the Collegno plant, (Giarola et al. 2017). While according to the deterministic study, 3 modules were needed for the minimum operating costs of the plant, the stochastic study gave an optimal number of modules between 3 and 4 depending on the biogas fluctuations.

The market potential in Europe was determined correlating the optimal number of modules with the WWTP capacity range. The results extended to a European level show that the potential for SOFC in the niche market of WWTPs, could be in the range of 400 and 800 MW, depending on the biogas availability.

Table 3. Results of the regression analysis: potential SOFC capacity to install for each WWTP capacity range

Case study	Capacity range, P.E.	Total SOFC Potential capacity, MW
XS	20,000-60,000	135
S	60,001-150,000	164
M	150,001-350,000	136
L	350,001-750,000	144
XL	750,000- greater than 1,100,000	226

5. Conclusions

This work has proposed a bottom-up approach to estimate the market potential of solid oxide fuel cells integrated in waste water-treatment plants in Europe. In doing so, the model optimizes the expected total cost of the system and the optimal number of modules to be installed accounting for a notable source of uncertainty, the daily biogas fluctuations. The results suggest that an overall SOFC capacity between 417 and 800 MW could be installed in Europe. This value would correspond to a cumulative number of 58.3 kW - units greater than 10,000 which would enable capital cost reduction of more than 60 % (Ammermann et al., 2015) on the current capital costs and would pave the way for further technology deployment.

Abstract

The ultimate goal of the Texas A&M Superfund program is to develop comprehensive tools and models for addressing exposure to chemical mixtures during environmental emergency-related contamination events. With that goal, we aim to design a framework for optimal grouping of chemical mixtures based on their chemical characteristics and bioactivity properties, and facilitate comparative assessment of their human health impacts through read-across. The optimal clustering of the chemical mixtures guides the selection of sorption material in such a way that the adverse health effects of each group are mitigated. Here, we perform (i) hierarchical clustering of complex substances using chemical and biological data, and (ii) predictive modeling of the sorption activity of broad-acting materials via regression techniques. Dimensionality reduction techniques are also incorporated to further improve the results. We adopt several recent examples of chemical substances of Unknown or Variable composition Complex reaction products and Biological materials (UVCB) as benchmark complex substances, where the grouping of them is optimized by maximizing the Fowlkes-Mallows (FM) index. The effect of clustering method and different visualization techniques are shown to influence the communication of the groupings for read-across.

Keywords: Clustering, dimensionality reduction, predictive modeling, read-across.

1. Introduction

Climate change has become one of the major risk factors for chemical contamination events. Therefore, precise and rapid examination of the complexity of the hazardous chemical exposures is essential to identify the potential adverse health impacts, and subsequently to provide immediate solutions and/or prevent further catastrophic events. At Texas A&M Superfund Research Program (TAMU SRP), we aim to develop

comprehensive tools and models for addressing exposure to unknown chemical mixtures, and accordingly design solutions for the community during environmental emergency-related contamination events (TAMU Superfund Research Center, 2017). In this paper, we present two applications where data analysis, modeling and dimensionality reduction techniques guide experimental design and decision-making in biomedical and environmental areas.

First, we aim to design a framework for optimal grouping of unknown chemical mixtures based on their multi-dimensional analytical chemistry and bioactivity profiles. Detailed chemical characterization of a chemical mixture is challenging due to the variation in chemical composition during environmental emergencies. To provide rapid solutions, grouping an unknown chemical mixture to a group of well-studied, “known”, chemicals is critical. Here, the hypothesis is that, once an unknown chemical mixture is grouped into a cluster of known chemicals, read-across between cluster members would bridge the gap between data-poor and data-rich chemical substances. To do this, we use an integrated data analysis framework with dimensionality reduction and clustering techniques. Furthermore, we optimize the clustering structures by incorporating the Fowlkes-Mallows (FM) index, a measure for comparative assessment of clustering quality. Secondly, the environmental chemical contaminants can easily get mobilized, subsequently contaminate soil, and threaten the safety of the municipal water and food supply during environmental emergencies. In order to minimize the adverse health effects of chemical exposures, we aim to identify and develop novel broad-acting, high-capacity sorbents, enterosorbents, which can be implemented in diets to reduce the bioavailability of chemical mixtures. Here, the selection of the optimal sorption material for a given chemical mixture is a challenging and iterative task, where the chemical-sorbent property space needs to be explored iteratively to fine-tune and guide the experimental designs. Therefore, we perform predictive modeling of sorption activity of materials via regression techniques.

2. Data Acquisition

2.1. Derivation of Analytical Chemistry and Bioactivity Profiles of Complex Substances

In order to explore a more suitable clustering algorithm that may be used to establish the chemical and biological similarity between complex substances or mixtures, we use several recent examples of substances of Unknown or Variable composition Complex reaction products, and Biological materials (UVCB substances) as a benchmark. These include CON01-CON05 as Straight Run Gas Oils (SRGO); CON12-CON18, CON20 as Vacuum & Hydro-treated Gas Oils (VHGO); A083/13, A087/13, A092/13 as Heavy Fuel Oils (HFO), and CON07, CON09 as Other Gas Oils (OGO). These are complex petroleum substances that are products of oil refining that contain hydrocarbons in the range from C9-C25, C13-C30, C20-C50, and C10-C27 respectively (Grimm et al., 2016). Categorization of petroleum substances is based on the manufacturing process and physico-chemical properties. Petroleum substances are highly complex and may be variable in composition, hence they are excellent examples of UVCBs that present a major challenge in terms of substance identification, classification and grouping. In addition, gaps in available toxicity data create challenges for regulatory decision-making on these substances. In this study, a measure of chemical composition of the reported UVCB substances was derived using Ion Mobility Mass Spectrometry (IM-MS) analysis (Grimm et al., 2017). IM-MS analysis provides chemical fingerprint of

substance complexities by yielding the m/z (mass divided by charge number), drift time (time for each ion to traverse within a homogeneous electric field in the ion mobility spectrometer) and abundance. Here, the IM-MS data involves information on the sample-specific heteroatom class distribution based on relative abundance of individual features yielding 82 unique heteroatom classes as features. In addition, the bioactivity characteristics of the selected UVCB substances are derived from *in vitro* models. Specifically, the dimethyl sulfoxide (DMSO)-soluble extracts of UVCB substances are exposed to induced pluripotent stem cell-derived cardiomyocytes and hepatocytes. The resulting concentration-response curves are used to derive ToxPi scores, which serve as the final bioactivity data with 16 features (Grimm et al., 2016).

2.2. Characterization of Broad-Acting Enterosorbents for Mitigation of Chemicals

Several different sorbent materials (e.g., activated carbon and processed sorbent material) are experimentally tested and characterized for various hazardous chemicals. For each sorbent material, equilibrium isothermal analysis has been performed by fitting the experimental data to multiple isotherm equations. This analysis enables the calculation of various material-toxin properties including, binding affinity (K_d), capacity (Q_{max}) and relative surface binding in water. These material-toxin properties are previously found to be the most important features for identifying optimal binding *in vivo* (Phillips, 2008) and can be used to build predictive models which will guide the selection of toxin binders for future testing. In this study, we use the first set of experimental data on the aforementioned sorbent materials with following chemicals: pentachlorophenol (PCP), benzo(a)pyrene (BaP), lindane, diazinon, zearalenone, aldicarb, 2,4-Dinitrophenol (DNP) and aflatoxin (only with processed sorbent material). The data includes information on chemical binding capacity (Q_{max}) and logP, which characterizes the difference in solubility of a solute in two immiscible phases at equilibrium (i.e. octanol and water). As water and octanol being polar and nonpolar solvents, respectively, the logP value provides a measure for the hydrophobicity or hydrophilicity of the substance.

3. Methodology

3.1. Clustering of Complex Substances

In this study, we use hierarchical clustering with 3 distinct agglomeration methods, i.e. Ward's method, average linkage, and complete linkage along with 3 different correlation metrics, namely Kendall, Pearson, and Spearman correlations. This yields 9 different clustering algorithms for testing. Furthermore, an integrated dimensionality reduction and clustering analysis is performed to assess the effect of principal components analysis (PCA) on the clustering results. For each principal component subset, clustering is performed iteratively using all listed algorithms. The quality of the clustering structure is optimized by maximizing the FM index. FM index provides a measure of similarity between two clustering trees, between clustering trees generated based on 9 aforementioned algorithms and a reference categorization of the complex substances based on their manufacturing streams (i.e. HFO, SRGO, etc.). The optimal clustering tree and corresponding algorithm are reported when the highest FM index is achieved. In future studies, we aim to utilize Support Vector Machine-based feature selection algorithm as an alternative dimensionality reduction technique, which has been successfully applied in bioinformatics (Kieslich et al., 2016).

3.2. Predictive Modeling of Material Sorption Activity on Chemicals

We implement linear and nonlinear regression techniques (Boukouvala and Floudas, 2017) to postulate a surrogate model that will guide iterative experimental design for maximizing the sorption activity of broad-acting materials. Regression is performed by minimizing the least-squares error between the actual experimental values and model predictions. In this study, linear, general quadratic, and signomial function of order 1 are investigated as candidate surrogate models to predict relative sorption level of the material. The goodness-of-fit for each model is assessed using coefficient of determination (R^2), and root-mean-square error (RMSE).

4. Results

4.1. Optimal Clustering of Complex Substances based on Chemical and Biological Data

We present feature intensity maps of 18 tested complex substances using their relative abundance of heteroatom class distributions in Figure 1A. Intensity map highlights the most informative features that separate the substances into categories by providing qualitative and quantitative compositional comparison. The results show that N1 heteroatom class is the most predominant feature with 33.41% presence among all substances. This is followed by N1 S1, O1, N2 S1, and N1 13C1 heteroatom classes with 13.53%, 8.29%, 6.76, and 3.76% occupancy. Relative occupancy of the 5 most descriptive heteroatom classes within each substance category is presented in Table 1.

Table 1. Identification of the top 5 descriptive features (heteroatom classes) for each category.

Substance Category	Heteroatom Class	Relative Occup. (%)	Substance Category	Heteroatom Class	Relative Occup. (%)
HFO	N1	32.57	VHGO	N1	33.66
	N1 S1	10.03		N1 S1	13.49
	N2 S1	9.32		O1	8.22
	N2	8.40		N2 S1	7.11
	N1 13C1	6.99		N1 O1	3.49
OGO	O1	34.48	SRGO	N1	45.50
	O1 13C1	7.61		N1 S1	20.29
	N2 O1 S2	7.38		N2 S1	6.56
	N1 O1	5.81		O1 S2	6.00
	N2 O1 S1	4.12		N1 13C1	4.24

Among all the clustering algorithms, highest FM index (0.669) is achieved with the integrated PCA - hierarchical clustering with complete linkage using Kendall correlation. The same clustering algorithm without dimensionality reduction (82 features) reveals the FM index of 0.325 (Figure 1A). Similarly, bioactivity profiles obtained from two cell types, namely cardiomyocytes and hepatocytes, are depicted via feature intensity map in Figure 1B. Figure 1B demonstrates that the most distinctive biological features of HFO category result from 4 hepatocyte phenotypes, e.g. mitochondrial integrity intensity, viability, mitochondrial integrity, and total area of live cells. Moreover, the top informative features for VHGO category belong to 2 cardiomyocyte phenotypes, e.g. peak amplitude and mitochondrial integrity. OGO and SRGO categories reveal similar biological features that are mostly part of

cardiomyocyte phenotypes, where OGO diverges with the lack of 2 hepatocyte phenotypes, e.g. mitochondrial integrated intensity and total area of live cells, as well as 3 cardiomyocyte phenotypes e.g. mitochondrial integrity, nuclei count, and viability. In clustering analysis, highest FM index (0.805) is achieved with the integrated PCA - hierarchical clustering with 4 features through complete and average linkage using Spearman correlation. On the other hand, the same clustering algorithm without dimensionality reduction generates FM index of 0.768 with 16 features (Figure 1B).

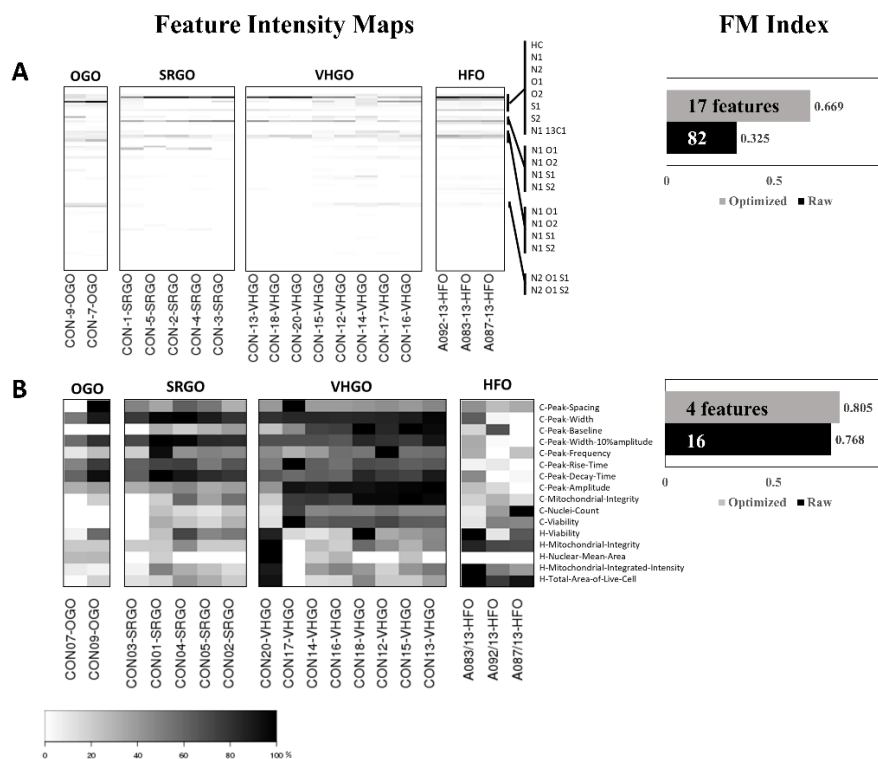

Figure 1. (A) Chemical and (B) bioactivity profiling and cluster analysis of UVCB substances based on IM-MS and human induced pluripotent stem cell analysis data set, respectively. Feature intensity maps (informative features are provided in the side bar; features starting with “C-“ and “H-“ belong to cardiomyocyte and hepatocyte phenotypes, respectively). FM index from clustering studies are provided in bar plots before and after dimensionality reduction.

4.2. Surrogate Modeling for Sorbent Materials

In order to perform predictive modeling of sorption activity of two sorbent materials based on Q_{\max} and $\log P$, we have used 3 different surrogate model types, namely linear, general quadratic, and signomial of order 1. Table 2 and 3 demonstrate the surrogate model parameters along with the corresponding coefficient of determination (R^2), and root-mean-square error (RMSE). Complex surrogate models are avoided to prevent overfitting in the regression analysis. The results show that quadratic functional forms perform better than the others, where the goodness-of-fit should be improved with additional experimental data. The analysis presented here is performed first on mono-constituent chemicals that are anticipated to be part of environmental mixtures and serves as an initial starting point of an iterative data-driven procedure which aims to maximize sorbent activity by

providing feedback for future experiment designs. Here, by locating and reporting the sample space spanned by Q_{\max} and $\log P$, where maximum sorption activity is achieved with the best surrogate models (i.e. quadratic functions), we provide feedback to experimental collaborators to design further set of experiments. In the future studies, more chemical properties such as chemisorption indices, specificity, affinity, capacity, and enthalpy will be included in characterization of chemical-sorbent relationship along with designable (morphological and functional) properties of the sorbent material. Then, predictive modeling of the interconnected relationship between the various sorbent properties and sorbent activity will facilitate the exploration of the large chemical-sorbent property space and guide future experimental designs to maximize sorption. Finally, for a mixture of chemicals, % binding can be estimated by analyzing; (i) fraction of each compound in mixture, and (ii) Q_{\max} of each compound in mixture. These will be used to generate predictive models for mixture of chemicals in solution.

Table 2. Surrogate models for sorption activity of activated carbon using Q_{\max} and $\log P$.

Model Type	R ²	RMSE	Surrogate Model Form, y=%bound
Linear	0.472	0.282	$y = 0.070 + 0.761Q_{\max} + 0.210 \log P$
Quadratic	0.872	0.139	$y = -3.480 + 11.714Q_{\max} + 7.904 \log P - 7.044Q_{\max}^2 - 6.188Q_{\max} \log P - 4.787 \log P^2$
Signomial Order 1	0.498	0.275	$y = 1.010Q_{\max}^{0.574} \log P^{0.090}$

Table 3. Surrogate models for sorption activity of processed sorbent material using Q_{\max} and $\log P$.

Model Type	R ²	RMSE	Surrogate Model Form, y=%bound
Linear	0.546	0.204	$y = 0.248 + 0.576Q_{\max} - 0.132 \log P$
Quadratic	0.627	0.185	$y = -0.253 + 1.279Q_{\max} + 1.576 \log P - 0.269Q_{\max}^2 - 0.923Q_{\max} \log P - 1.121 \log P^2$
Signomial Order 1	0.516	0.211	$y = 0.715Q_{\max}^{0.619} \log P^{-0.049}$

5. Conclusions

Here, we present an application of data analysis, modeling, and dimensionality reduction techniques in biomedical and environmental setting. Our analysis provides comprehensive data-driven tools for (i) optimal grouping of an “unknown” mixture with “known” chemicals that enables read-across, thus rapid decision-making during environmental emergencies, and (ii) guide experimental setups to achieve optimal entero-sorbent material designs that can mitigate the adverse effects of the chemical exposure. This research was funded by U.S. National Institute of Health grant P42 ES027704.

Abstract

In this contribution we deal with a critical problem in the numerical modelling of the dispersed phase flow systems using population balances. To solve this problem, we derived a Meshless Moving Particle Method (MMPM) which is based on coupling information and function approximation theories to recover the complete particle size distribution in a grid free environment. The particles, which adapt their positions according to population integral properties, are allowed to propagate using a few number of ODEs. These particle positions are found exactly the same as those predicted by the Chebyshev-QMOM; however, without iterative eigenvalue calculations. The overall complexity of the method is $O(N)$ where N is the number of moving particles. The MMPM is validated using many test cases with known analytical solutions including microbial cell dynamics in a constant abiotic environment. The sequence of the continuous approximations of the number concentration function is found to converge with an order $O(1/N^c)$ with $c > 1$.

Keywords: Meshless Methods, Moving Particles, Population Balances, Modelling.

1. Introduction

The population balance equation (PBE) which governs the space-time evolution of discrete phase systems, at micro or macro state levels, finds numerous applications including inanimate particles and animate cells (Ramkrishna and Sing, 2014). The complexities in the solution of the PBE are twofold: The latent functional in the integral source term and its spatial geometrical dependencies in practical cases. Since its first appearance in the early of sixties, it has received a great attention by researchers as well as practitioners both on mathematical and numerical modelling levels where latest reviews are found in Ramkrishna and Sing (2014) and Ferreira et al. (2017). In spite of the intensive research in the last decades, which is concerned with fast numerical solvers based on the moment methods, numerical solutions which are able to conserve particle integral properties suffer from losing the particle size distribution. The latter is required in industrial particulate systems where it is used to determine mechanical and physiochemical system properties, for online control purposes (Attarakih et al., 2012), to evaluate the negative particle fluxes at zero particle size as in the case of droplet evaporation (Vie et al., 2013) and to accommodate time varying boundary conditions in age-structured models of hematological disease (Foley and Mackey, 2009). In the present work, we overcome the lost size distribution problem, while estimating accurately the required particle mean properties, by introducing a unique converging

sequence of continuous approximations to the PBE on moving particles. The moving particles become a necessity when fixed discretization of the particle phase space requires a huge number of grid points due moving distribution functions.

2. The Meshless Moving Particle Method (MMPM)

Given $f(\zeta, t)$ as a number concentration function in a homogenous space with particle property phase space ζ , the PBE for growth, breakage and aggregation is written as:

$$\frac{\partial f(\zeta, t)}{\partial t} + \frac{\partial [G(\zeta, S)f(\zeta, t)]}{\partial \zeta} = L\{f\} \quad (1)$$

In the above equation, particles are allowed to grow or shrink due to mass transport to or from its continuous surrounding phase through the variable S at a rate $G(\zeta, S)$ at any given instant t . The volumetric source term $L\{f\}$ represents the loss and formation of particles due to instantaneous breakage and aggregation events. Eq.(1) can be solved using the moment methods with QMOM as a closure rule because of the general dependencies of the interaction frequencies in $L\{f\}$ on ζ . The popularity of these methods results from the non-stiff ODEs in terms of $f(\zeta, t)$ moments and the accuracy of the moving Gauss quadrature used to integrate the source term. As discussed in section 1, the moment methods destroy the number concentration $f(\zeta, t)$ due to moment construction over the particle phase space. The reconstruction of this function from its low-order moments faces the uniqueness and stability problems and often results in assuming parametrized distribution like the generalized lambda distributions. Since the objective is to reconstruct a unique and non-negative number concentration function, the maximum entropy functional is the ideal choice (Attarakih and Bart, 2014). This results in a number distribution that is statistically most likely to occur with Lagrange multipliers in terms of its moments. This method still suffers from averaging the spatial velocity in the convective term and hence prevents its dependence on particle size which is required for momentum balances in multifluid models. Moreover, the number of low-order moments is increased for accurate reconstruction of asymmetric and bimodal number concentration functions. These problems arise due to ignorance of local information about the number concentration function. In this regard, Attarakih and Bart (2017) introduced a novel maximum entropy solution by maximizing the Shannon maximum entropy subject to the available local information of $f(\zeta, t)$:

$$f(\zeta, t) = \exp \left(\sum_{j=0}^{N-1} \alpha_j(t) Le_j(\zeta) \right) \quad (2)$$

In this work, the resulting continuous Lagrange multiplier is expanded by a complete set of orthogonal Legendre basis functions Le_j with a closed set of expansion coefficients α_j . This solution is consistent with the expected values $E\langle Le_j, f \rangle$ with respect to $f(\zeta, t)$ and satisfies the positivity condition imposed on $f(\zeta, t)$. Instead of using fixed sampling (collocation) points to calculate α_j , we introduce the essence of the MMPM by discretization of the initial particle phase space ζ into an ordered particle positions $\Xi_0 = \{\zeta_0 < \zeta_1 \dots < \zeta_{N-1}\}$ which should be consistent with at least $N+1$ low-order moments of the initial particle distribution. These positions are found by using the recently developed Chebyshev-QMOM algorithm which is more robust than the PD algorithm (Attarakih et al., 2017). Now, the coefficients $\alpha_j(t)$ are calculated from the function

values $f(\zeta, t)$ by applying the orthogonal collocation method in a moving sense where Eq.(1) is transformed into a system of ODEs that are exactly satisfied at a moving set of moving particles $\Xi_t = \{\zeta_0(t) < \zeta_1(t) \dots < \zeta_{N-1}(t)$ and is given by:

$$\frac{df(\zeta_i(t), t)}{dt} + \left[\gamma_i(t)[Le'(\zeta)]^T \alpha(\zeta, t) + \frac{dG(\zeta_i(t), S)}{d\zeta} \right] f(\zeta_i(t), t) = L\{f(\zeta_i(t)), \zeta_i(t)\} \quad (3)$$

$$\gamma_i(t) = G(\zeta_i(t), S) - \frac{d\zeta_i(t)}{dt} \quad (4)$$

Where γ_i represents the net growth velocity which is a contribution of physical particle growth ($G(\zeta, S)$) and the moving particle velocity $d\zeta/dt$. Note that $Le'(\zeta)$ is a column vector of Legendre polynomial derivatives. The gradient of $f(\zeta, t)$ due to growth is computed by exact differentiation of Eq.(2). This is an exact meshless moving differential quadrature (DQ) which alleviates the problem of FDS's that require a huge number of grid points. To calculate the moving particle velocity $d\zeta/dt$ we employed the inversion of a few number of low-order moments using the Chebyshev-QMOM algorithm. However, for pure particle growth, Eq. (4) is reduced exactly to:

$$\frac{d\zeta_i(t)}{dt} = G(\zeta_i(t), S) \quad (5)$$

Where ζ obtained from this equation is exactly the same as that computed from the Chebyshev-QMOM algorithm. This implies that the moving particles speed cannot be less or greater than their growth velocity. This elegant mathematical and physical consistency persists irrespective of the functional form of the growth function and is valid for multidimensional PBEs with pure growth. Moreover, since particle growth conserves the total number of particles, the moving quadrature weights are constant. Using Eqs.(3) and (4 or 5) the elements of $\alpha(t)$ in Eq.(2) are found from:

$$\alpha_j(\zeta(t)) = \frac{2N+1}{2} \sum_{m=0}^{N-1} \omega_m Le_j(\chi_m) \ln[f(\zeta(\chi_m(t)))]], j = 0, 1, \dots, N-1, \quad (6)$$

Note that $\zeta(\chi(t)) = \zeta_0(t) + ((\zeta_{N-1}(t) - \zeta_0(t))/2)(\chi + 1)$ and $\chi \in (-1, 1)$, $m = 0, 1, \dots, N$ are the moving roots of the shifted Legendre polynomials and χ and ω are the fixed Gauss-Legendre quadrature nodes and weights respectively. On the other hand, in the absence of growth from Eq.(3), the moving particles feels a negative particle growth (evaporation) in case of particle aggregation and positive growth (condensation) due to particle breakage. This growth term act as a buffer which resists the changes in the source term and hence keeps the functional profiles ($f(\zeta, t)$) smooth w.r.t. time. It is interesting to note in cases of equal binary particle breakage and growth rates and in case of equal breakage and aggregation rates the particles velocity will be reduced to zero. It is clear from this brief discussion that source terms of aggregation and breakage mechanisms can be modelled as a positive and negative growth terms respectively. This lead us to unify our solution framework and think of finding characteristic (eigenvalues) lines similar to that of pure growth. Since Eqs.(5) reproduce exactly the set of the eigenvalues predicted by the Chebyshev-QMOM algorithm, the reverse is correct when dealing with the PBE with source term. In this case, the eigenvalues produced by the Chebyshev-QMOM algorithm are the characteristic lines of the PBE in the presence of source term. Therefore, the moving particle velocities $d\zeta_i/dt$ are derived from the slopes of the eigenvalues calculated by the Chebyshev-QMOM algorithm.

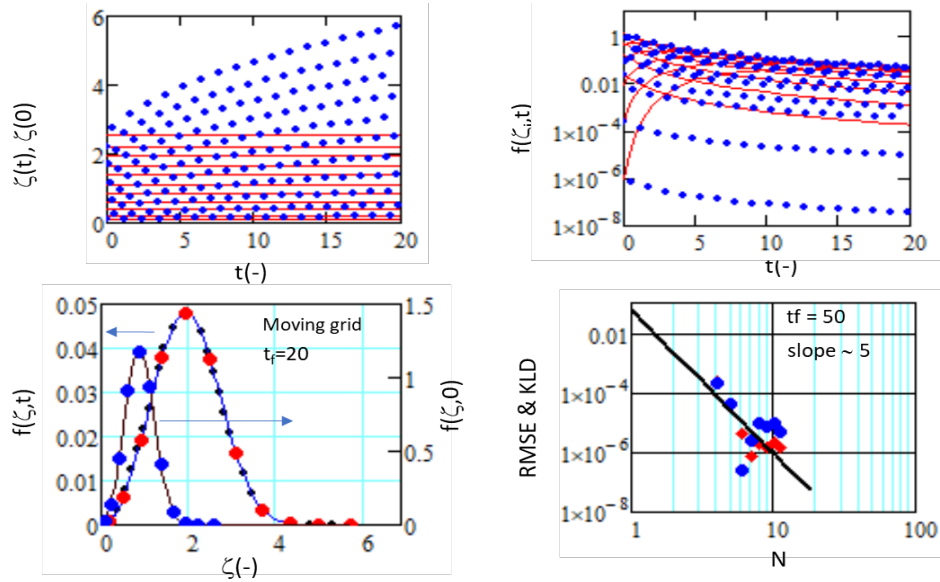

Figure (1): Solution of the PBE with constant particle aggregation using the moving and fixed particle trajectories with their function values (filled circles on moving particles).

After careful analysis of this algorithm, the velocity of the moving particles is given by:

$$\frac{d\zeta_i(t)}{dt} = \zeta_i(0)\eta(\mu_0(t), \mu_1(t), \dots), \quad i = 0, 1, \dots, N - 1 \quad (7)$$

The function η is expressed in terms of low-order moments of $f(\zeta, t)$ using the Chebyshev-QMOM. Our undergoing research shows that the space of the moments can be reduced where simple expressions for $\eta(\mu_0, \mu_1, \dots)$ is derived. The set of Eqs.(2) to (7) defines completely the numerical model for the MMPM for the solution of the PBE.

3. Numerical Results and Discussion

3.1. Numerical Analysis

The proposed MMPM is first validated against analytical solution of the PBE for constant kernel aggregation in closed homogeneous space. This is used to explore the numerical features of the MMPM on moving and fixed particles. The eleven initial moving particles were generated from the initial condition $(3\zeta^2 \exp(-\zeta^3))$ using the Chebyshev-QMOM (Attarakih et al., 2017) with 22 low-order moments without placing bounds on the minimum and maximum particle sizes. These particles are shown on the upper panel (left) of Figure (1) as solid lines while the moving particles are shown as small filled circles. The velocities of these moving particles are estimated from Eq.(7). Also, these initial positions along with the tabulated values of Gauss-Legendre quadrature's weights and nodes are used to calculate the coefficients of the Legendre polynomials from Eq.(6). It is clear that the fixed grid has two drawbacks: The first one is its inability to accommodate the newly born particles after $t \sim 5$, and the second one is the departure of the characteristic particles away from the fixed ones as time increases.

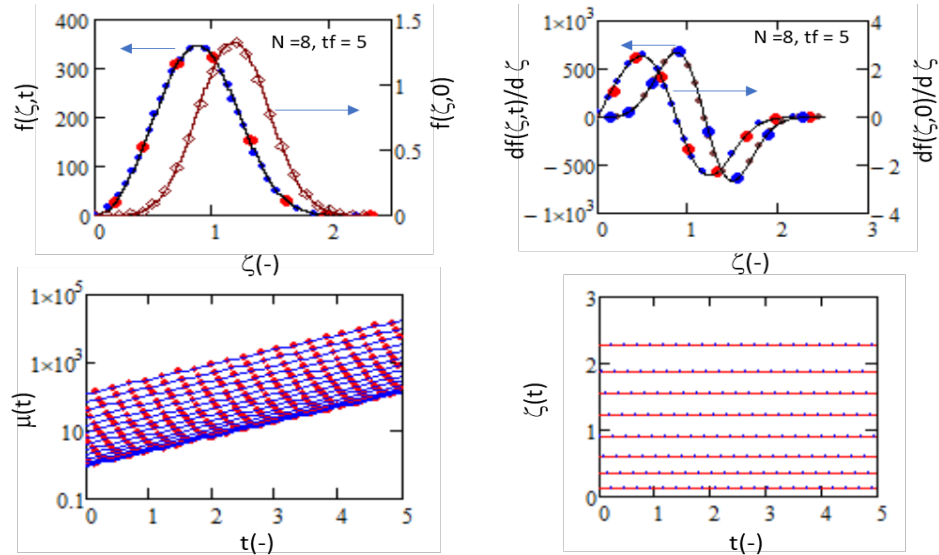

Figure (2): Microbial cell dynamics with binary division and growth using the MMPM as compared to analytical solution (solid line).

This results in discretization inconsistency unless suitable algorithm is used to conserve the desired particle integral properties. On the other hand, the moving particle trajectories conserve exactly $2N$ low order integral properties since particle positions are determined based on these moments. The sampled values of $f(\zeta_i, t)$ are calculated on these moving particles using Eq.(3). The evolution of these values in time are shown in Figure (1) upper panel (right) as compared to the fixed particle trajectories. It is clear that the sampled values at moving particles are evolved smoothly compared to that of fixed particles. This makes efficient use of the ODE solvers and reduces the CPU time by a factor of order 5. The reconstructed continuous functional at $t = 20$ is shown in Figure (1) bottom panel (left) along with the analytical solution (solid line). It is clear that the numerical solution at the moving particles (filled large circles) and the interpolated ones (small filled circles) are indistinguishable from the analytical solution using only 11 particles. The remarkable convergence of the continuous solutions is supported by the rapid error decrease based on the root mean square error (RMSE) and Kullback-Leibler divergence (KLD) (Attarakih and Bart, 2014) as shown in Figure (1) lower panel (right) where the slope of the convergence line is ~ 5 .

3.2. Case study: Microbial cell dynamics in constant abiotic environment

This case describes simultaneous cell growth and division. It presents microbial cell dynamics in abiotic environment with a constant quantity of substrate (S). To allow for an analytical solution, an isothermal batch chemostat, constant abiotic environment, single cell growth rate is proportional to its mass, and dividing cells partition their material uniformly to the two daughter cells, were assumed. The intercellular state is represented here by the cell size (ζ). The cell mass is transformed into cell diameter (ζ) with an assumed spherical shape where analytical solution was derived in Attarakih et al. (2015). This analytical solution is compared to the MMPM as shown in Figure (2) upper panel (left) which shows the dynamic evolution of the microbial cell population under simultaneous growth and division. It is evident that the MMPM follows with a high accuracy the evolution of the population dynamics using only 8 particles. Actually,

since the rate of growth equals the rate of particle loss by division, an equilibrium is achieved between growth and particle division. This results in stationary particle diameter as shown in the lower panel of Figure (2) (right). Actually, all mean cell lengths (ζ_{10} , ζ_{30} , ζ_{32} ... etc.) are constant as function of time. From this one can calculate $\zeta(t)$ and particle weight without resorting to the Chebyshev-QMOM algorithm. Finally, the numerical derivative of $f(\zeta,t)$ required for the evaluation of the growth source terms is calculated using the DQ and the results are compared to the analytical values as shown in Figure (2) upper panel (right) thanks to the orthogonal expansion of the maximum entropy functional and its exact derivative.

4. Summary and Conclusions

A MMPM is derived and validated for the solution of PBE with particle growth, breakage and aggregation. The MMPM is validated using cases with known analytical solutions. The sequence of the continuous approximations is found to converge in terms of the Kullback-Leibler distance and the RMSE with order $O(1/N)$. As a case study, the MMPM is applied to simulate the microbial cell dynamics which includes simultaneous cell growth and division in a constant abiotic environment. The results show that the MMPM tracks the dynamic evolution of the microbial cell population using only 8 moving particles with the conservation of the first 16 population low-order moments.

Abstract

Aim of this article is to estimate and discuss the economic and environmental impacts for the obtainment of CO₂ in such conditions to be injected as enhanced oil recovery (EOR) fluid. Particularly, this study focuses on the compression sector design needed to process the CO₂ coming from an already existing absorption plant. Currently, 18.68 kmol/h of a high-purity CO₂ stream may be used for injecting and increasing the production of a pilot crude oil well near the location of the industrial plant. However, it is still necessary to perform an economic evaluation to quantify the investment and the operating costs that the compression involves.

An optimization problem for minimizing the energy consumption of the new sector while increasing the pressure of the stream is solved. It has been found that the conditions to obtain the lower energy requirement are a 4-stage compressing layout with a pressure ratio equal to 4 and intercooling units of 41.73 °C. After discussing these results, an economic assessment to estimate investment, operating and utility costs is presented. Although the installation cost for the additional sector is more than 3000 kUSD, the investment might be compensated with the increasing production of the well under study. In addition to this, the development of EOR projects could create a market in a region where the technology is still not considered.

In the final part of the article, CO₂, CH₄, H₂O wastes and combustion gases emissions are calculated. As expected, almost the total amount of the vented CO₂ can be captured for this double-purpose technology, increasing the total incomes while geologically confining large-volumes of this pollutant and greenhouse gas.

Keywords: Sustainability, Economic assessment, Environmental impact, CO₂ EOR, CO₂ absorption process.

1. Introduction

Several industrial processes produce highly concentrated streams of carbon dioxide (CO₂) as a by-product (Herzog, 2011). For instance, the absorption of CO₂ from natural gas by using alkanolamines produces a high purity CO₂ stream, with a molar concentration over 87 % in most of the cases (Peters et al., 2011; Ahmad et al., 2012; Banat et al., 2014; Al-Lagtah et al., 2015; Gutierrez et al., 2016; Gutierrez et al., 2017).

As it can be inferred, this large amount of CO₂ produced continuously may be used for improving the crude oil production, during the stage of enhanced oil recovery (EOR). In this regard, the CO₂ for EOR has already demonstrated to be a technical and economic success in different locations for a number of years (Khan et al., 2013). Having a paramount potential for carbon dioxide capture and storage (CCS), the CO₂ EOR significantly increases the production of mature wells while decreasing the greenhouse gas emissions on a large-scale (Brush et al., 2000; Peters et al., 2011).

Different studies have assessed the economics involved in the installation of a CO₂ absorption for EOR purposes (Peters et al., 2011; Mazzetti et al., 2014; Kazemi et al., 2014; Suleiman et al., 2016). Peters et al. (2011) developed an economical model to calculate the capital investment and the gas processing cost of an amine-based process. To assess the economics, they performed a simulation model in Aspen HYSYS, where they assumed a molar concentration above 90 % CO₂ in the acid gas.

Mazzetti et al. (2014) estimated the costs of CO₂ removal from natural gas with subsequent geological storage by using a suitable simulation model. Particularly, they estimated the total capital cost to obtain CO₂ for EOR in North Europe, with an MDEA-based absorption process. From the economic viewpoint, they stated that large-scale EOR projects could cover the necessary expenditures to improve remote fields' production.

Kazemi et al. (2014) simulated an alkanolamine process with Aspen HYSYS and performed an economic assessment with Aspen Economic Analyser. Based on a typical gas produced in Iran, they compared the performance of the process with three other technologies in regard to their capital and annual costs, for different sour gas molar flows.

Suleiman et al. (2016) evaluated two absorption processes using a feed flow of 1245 kmol/h to produce a clean natural gas with purity of 99 %. Those authors used simulation models to define stream properties, heat duties, power requirements and equipment sizes. For the economic assessment, they introduced suitable raw material costs, working capital, capital of investment, and total annual incomes.

With reference to previous works, the alkanolamine process to clean the natural gas while obtaining a side-product CO₂ stream has been extensively studied worldwide. However, the economic assessment performed by the predecessors consider the units of absorption and regeneration only, and exclude the conditioning of the CO₂ to be used in different applications. This paper presents and discusses the optimal design, the economic evaluation, and the environmental impact to condition CO₂ for EOR. Although the costs of CO₂ obtainment and storage appear to be high, we discuss the sustainability and the effect of the investment in the region under study.

2. Location and process description

The southern Neuquén basin (NQNB) of Argentina is the location selected because its crude oil chemical properties favor the implementation of CO₂-EOR (Gallo and Erdmann, 2017). Large-scale volumes of CO₂ are emitted throughout this area from gas & oil processing industries, mining companies and power generation plants. Particularly, CO₂ coming from natural gas absorption plants is of special interest in this work for their permanent availability.

This typical CO₂ absorption process features two main operations. In the former, the acid gases of the natural gas are chemically absorbed by an alkanolamine liquid stream. In the latter, that rich amine leaving from the bottom of the absorption tower is sent to a stripping column, where the CO₂ is recovered at higher purity.

3. Methodology

Initially, the steady-state of the process to remove CO₂ from a natural gas stream is simulated in Aspen HYSYS (Aspen Tech., 2012). In the simulation model, a combination of the Non-Random Two-Liquid method for electrolytes (eNRTL) and the Peng- Robinson Equation of State for vapor phase is applied for the prediction of the thermodynamic properties (Song and Chen, 2009). Material streams, flowrates, compositions and conditions are taken from an existing MDEA-based absorption plant in Argentina (Figure 1).

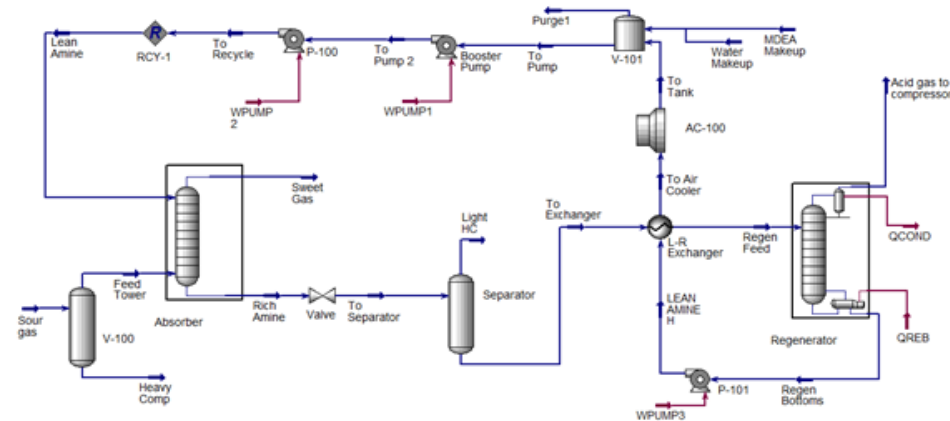

Figure 1. MDEA-based absorption plant for removing CO₂ from natural gas.

18.68 kmol/h of acid gas at 47.27 °C are obtained from the top of the stripping column, composed by CO₂ (87.93 mol%), water (9.32 mol%), methane (1.33 mol%), and heavy hydrocarbons. However, the pressure of the stream is considerably low (14.50 psia) and thus a subsequent compressing system should be design to properly dispose this high purity CO₂ stream.

According to empirical considerations, a 4-stage compression system might be implemented to increase the pressure of the acid gas leaving the plant. In the sector to be designed, the available variables are the temperature of the intercooling stages and the pressure ratio of each compressor. Centrifugal compressors with 75 % adiabatic efficiency are assumed and logical operators (SET and ADJUST) are used to unify the compression ratios and the cooling temperatures (Figure 2).

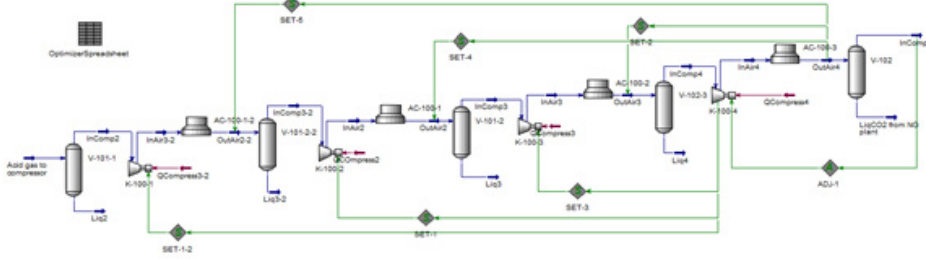

Figure 2. Compression and intercooling of 4-stages for CO₂ conditioning.

After modelling the compression sector, we propose a minimization problem to define the optimal conditions. Eq. (1) summarizes the mathematical expression representing the minimum problem to solve.

$$\begin{aligned}
 & \min_{u_1, u_2} (Q_{Total}) \\
 & \text{s. t.:} \\
 & 2 \leq u_1 \leq 10; \\
 & 25 \leq u_2 \leq 55; \\
 & y_{CO_2}^{Prod} > 0.87 \\
 & P_{CO_2}^{Prod} > 6,000 \text{ kPa}
 \end{aligned} \tag{1}$$

Where $Q_{Total} = Q_{Compressing} + Q_{Cooling}$ (MJ/h) is the duty needed for the compression and the cooling stages. u_1 represents the pressure ratio for each centrifugal compressor, u_2 the temperature after the cooling units (°C), $y_{CO_2}^{Prod}$ and $P_{CO_2}^{Prod}$ the purity and the pressure of the CO₂ product stream.

Similar to Kazemi et al. (2014), we employ Aspen Economic Analyser to estimate capital costs, operating costs and utility costs of each process. Using Aspen Energy Analysis and material balances, we also estimate the greenhouse gases emissions (GHG) particularly CO₂, H₂O, and CH₄ for the studied alternative.

4. Results and discussion

In Table 1, the values of optimal Q_{Total} , u_1 , and u_2 are shown. As it can be seen, the compression ratio remains equal to 4 for design purposes, and the temperature of the intercooling stages slightly under the initial acid gas temperature.

Table 1. Optimal values of Q_{Total} , u_1 , u_2 , $y_{CO_2}^{Prod}$, and $P_{CO_2}^{Prod}$ for the 4-stage process design.

Q_{Total} (MJ/h)	u_1	u_2 (°C)	$y_{CO_2}^{Prod}$	$P_{CO_2}^{Prod}$ (kPa)
639.85	3.849	41.73	0.9777	6,865

A total equipment cost of 3,828 kUSD is estimated for this design, distributed in accordance with the Figures 3 (a) and (b). Concerning the distribution of the investment cost, the compressors represent 86 % of the total investment.

Figure 4(a) shows the total operating and utility costs. The values observed might be attributed to the significant consumption of electricity.

Figure 4(b) presents the distribution of the energy consumption. Contrary to the expected, the highest consumption corresponds to the air-cooling system due to temperature drops of around 40°C.

Figure 3. Investment cost (kUSD) per each (a) compressor, and (b) cooling unit of the 3 and 4- Stages system.

Figure 4.(a) Operating and utility costs (kUSD/y); (b) Distribution of the heat duty (MJ/h).

Even though the total cost for including the compression section falls in the order of million USD, the income for the industry should also increase. Gallo and Erdmann (2017) estimate a production of more than 2 bbl of crude oil per CO₂ ton, injected in a sample well of the NQNB.

Figure 5 shows the leaks to the environment. Molar flows (kmol/h) of CO₂, H₂O, CH₄, and other GHG are plotted. Respect to the combustion GHG emissions, they were estimated assuming hot oil burning in the stripping column. As it can be observed, the CO₂ wastes remain almost negligible with the addition of the compression section.

Fig. 5. Comparison of gases leaks (kmol/h).

5. Conclusions

An optimal design to condition CO₂ for EOR purposes is presented. According to the study, a total amount of 18.26 kmol/h of high purity CO₂ at 6865 kPa can be obtained from an already existing gas plant for improving crude oil production. Although the investment for the additional sector to start is over 3,000 kUSD, the investors should also take into account that not only the CO₂ emissions are almost reduced to zero but also that the EOR may start a market in the NQNB where this technology is not still exploited.

Abstract

Digital manufacturing promotes the use of innovative technologies in the global market landscape and provides effective and efficient Supply Chain Management Systems. The purpose of this research is to contribute to the automation of an industrial warehouse by elaborating a novel software simulation tool for solving a classical NP-hard optimization problem, the Capacitated Vehicle Routing Problem with Multiple Trips (CVRPMT). The software tool promotes the use of Automated Guided Vehicles (AGVs) in industrial facility layouts and is based on an existing software framework, developed in the C# programming language. At this study we first formulate the mathematical model for the CVRPMT, we implement a hybrid metaheuristic Ant Colony Optimization (ACO) algorithm and develop a friendly Graphical User Interface (GUI) for scheduling and monitoring the AGVs' activities.

Keywords: Ant Colony Optimization (ACO), Metaheuristic, Software Tool, C#, CVRP.

1. Introduction

The Vehicle Routing Problem (VRP) is a well-documented and widely discussed NP-hard problem. The question in hand considers the optimal route for visiting a predefined number of customers under the constraint that the total travelled distance is minimized. Among a great deal of variations, we could distinguish the Capacitated Vehicle Routing Problem (CVRP) which extends the basic scheme by identifying the vehicle's capacity and the customer's demand. For solving the VRP we focus on the Ant Colony Optimization (ACO) algorithm, taking into consideration its swarm intelligence features and its correspondence with modern agent based architectures.

Mazzeo and Loiseau (2004) elaborated on an ACO algorithm for the CVRP, and identified the optimal route based on transitional rules. They presented the pheromone levels for reducing the number of ants used, as well as heuristics for confronting problems with more than 50 nodes. Gajpal and Abad (2009) presented an Ant Colony System (ACS), and implemented local search methods for solving the VRP namely: Simultaneous Pick-Up and Delivery (VRPSD), Backhauls and Mixed loads. The final algorithm uses a step-oriented scheme for optimizing the final solution (2-opt): (i)customer insertion/interchange, and (ii)sub-path exchange multi-route scheme.

Moreover, they provide a detailed explanation of the ACS for VRPSD and use the elitist ants' solution for updating the ant trails. Skinderowicz (2017) used Simulated-Annealing (SA) as a local search method to improve his results, and presented (i)SA with ACS, (ii)enhanced ACS and (iii)Sequential Ordering Problem -3-exchange. Based on a known solution, which may not be the best, the algorithms continuously optimize the results, improve the quality of the final solution and are very efficient. Finally, Ismkhan (2016) handles large-scale optimization problems, that confront issues regarding optimal memory usage, time complexity constraints and total performance. The author proposed efficient methods, for redefining the levels of pheromone and speeding up ACO in a local level.

Literature review provided an insight to the work of other researchers and motivated us to develop the proposed algorithm and the software tool. Our scope is to create an open source software simulation framework with a user-friendly Graphical User Interface (GUI) for optimizing intralogistics, using swarm optimization techniques. The presented work is motivated from ACO methods to simulate the pick-up and delivery of goods in a warehouse and optimize the AGVs' schedule (De Santis et al., 2017) and even the use of time windows in order picking (Sholz et al., 2017). The remainder of the manuscript is organized as follows. In Section 2 the Mathematical Model is presented, in Section 3 we explain the ACO, in Section 4 we present the proposed extensions and finally in Section 5 we conclude with computational results, conclusions and future research work.

2. Formulating the mathematical model

The first step in our research was the implementation of the CVRPMT's mathematical model. Given a complete graph $G=(B,A)$, where $B=\{0, \dots, N+1\}$ is the vertex set with 0 being the starting station and $N+1$ the exit station for all AGVs and A the arc set, we identify the optimal freight transport sequence. Our scope is to minimize the total distance travelled while picking loads from the shelves (loading nodes) of a warehouse and transferring them to the exit station using $v=\{1,2, \dots, V\}$ AGVs, while each AGV makes $t=\{1,2, \dots, T\}$ trips (Toth and Vigo 2001). A trip is a complete AGV's route from the starting to the exit station after it has visited the required loading nodes, for picking the total number of loads (demand). The total number of trips from all the available AGVs is called a tour. The model could be considered as CVRP taking into consideration that (i) vehicles have two distinct nodes a starting and an exit station (the starting and ending nodes are not the same) and (ii) each vehicle can be used in more than one trips.

3. Ant colony optimization algorithm

ACO is a metaheuristic, probabilistic algorithm proposed by Dorigo (1992) and is based on the behaviour of real ants trying to find the shortest path to gather their food supplies. Dorigo and Gambardella (1997) proposed a modified ACO version the Ant Colony System (ACS) that includes two main procedures (i) the tour construction, and (ii) the pheromone update. In the tour construction each ant selects the next loading node based on the transition probability Eq. (1) incase node $j \in N_i$, otherwise $p_{ij} = 0$ (Dorigo and Gambardella, 1997; Yousefi khoshbakht and Sedighpour, 2011). N_i is the set of all the feasible nodes (ants can visit them), τ_{ij} is the amount of pheromone deposited on arc (i,j) , η_{ij} is a visibility term calculated as the inverse of the distance

between node i and node j Eq. (2), γ_{ij} is the savings algorithm Eq. (3) and finally the heuristic parameters α , β and λ are the values for the pheromone concentration, the ant's visibility and the distance savings. Furthermore, in ACS the ant selects the next visiting node, following a state transition rule, based on a uniformly distributed variable q $[0,1]$, while the ant selects either the typical exploration rule or the greedy choice. If $q > q_0$ the transition probability for the exploration rule is selected otherwise the ant visits the next available node from Eq. (4). The pheromone values update considers both the global and the local pheromone update rule. The global pheromone update rule force updates only to the arcs that belong to the best solution found using Eq. (5) where L^{best} is the length of the best-known tour T^{best} and ρ is the global pheromone decay parameter. In our algorithm the global decay parameter is not constant, but it's calculated according to Eq. (6). The local pheromone update rule is activated whenever an ant finishes a tour and the visited arcs pheromone level is updated according to Eq. (7), where ξ is the local pheromone decay parameter and τ_0 is the initial pheromone value. Eq. (8) indicates the value of τ_0 where L^{NB} is the length of the tour constructed by the Nearest Neighbor algorithm and $Size$ is the total number of loading nodes to be visited including the starting and ending stations.

$$p_{ij} = \frac{\tau_{ij}^{\alpha} \eta_{ij}^{\beta} \gamma_{ij}^{\lambda}}{\sum_{l \in N_i} \tau_{il}^{\alpha} \eta_{il}^{\beta} \gamma_{il}^{\lambda}} \quad (1)$$

$$\eta_{ij} = \frac{1}{c_{ij}} \quad (2)$$

$$\gamma_{ij} = c_{i0} + c_{0j} - c_{ij} \quad (3)$$

$$j = \arg \max_{z \in N_i} \tau_{iz}^{\alpha} \eta_{iz}^{\beta} \gamma_{iz}^{\lambda} \quad (4)$$

$$\tau_{ij} = (1 - \rho) \tau_{ij} + \rho \left(\frac{1}{L^{best}} \right) \quad \forall (i, j) \in T^{best} \quad (5)$$

$$\rho = \frac{\tau_{ij}}{\tau_{\min} + \tau_{\max}} \quad (6)$$

$$\tau_{ij} = (1 - \xi) \tau_{ij} + \xi \tau_0 \quad (7)$$

$$\tau_0 = \frac{1}{L^{NB} Size} \quad (8)$$

4. The proposed hybrid ACO algorithm for the CVRPMT

Both ACO and ACS provide near to optimal solutions to the CVRPMT for a certain complexity level. The accuracy of the algorithm is decreased as the number of loading nodes and AGV's increase. Therefore, we implemented a hybrid version for confronting specific drawbacks of ACO and provide reliable results. To begin with, ACO is easily trapped on a local minimum, thus we used local search algorithms. The 2-opt local search solves the Traveling Salesman Problem (TSP). In CVRPMT each trip can be considered as an individual TSP, and that improves the overall performance by terminating the procedure when it fails to come up with an optimized solution after 500 consecutive iterations. While 2-opt is a very powerful algorithm that produces very promising results it has a major drawback; it can be applied on an individual trip and not to the whole tour. To overcome this problem, two common CVRP algorithms have been implemented: (i) the loading node insertion and (ii) the swapping local search (Abdulkader et al. 2015). The loading node insertion algorithm detaches a node from a vehicle's trip and it attaches on it another available one taking into consideration the capacity constraints. Otherwise, the algorithm swaps this node with another one, belonging to any other trip. This procedure continues until the algorithm finds no improvement for 20 consecutive iterations. Furthermore, to overcome the pheromone over-concentration, we implemented the MAX-MIN Ant System (Stützle and Hoos, 2000) where we set upper and lower limits for the pheromone levels of each arc. Finally, to increase accuracy, we implemented the SA algorithm (Skinderowicz, 2017) where the active solution technique is used in global pheromone update rule. The initialization of the algorithm requires a matrix of every node's real distance from all the other nodes calculated using the k-star algorithm, a matrix that stores the demand of every loading node and finally the values of all the parameters. The algorithm calculates the number of vehicles for keeping up with the total demand, the nearest neighbour solution, the visibility and saving parameters of every arc and the initial pheromone levels. Then it calculates the temperature value for the SA with random solutions. In the proposed algorithm every ant represents the whole fleet of vehicles and starts from node 0 (starting station) selecting randomly the next loading node. The total load of the ant's first vehicle is updated, while the ant continues to the next loading node using the state transition rule, taking into consideration the vehicle's capacity constraint. When the vehicle meets its capacity, it travels to node N+1 (exit station) and the second vehicle begins from node 0 following the same process. Multiple trips are required in case all vehicles have been used, and in this case vehicles use node N+1 as the starting station. The process terminates when all the loads are transferred. When the first ant finishes its tour the local pheromone levels are updated. When all the ants create a complete tour the algorithms swap and insertion, as well as 2-opt local search are used in the best solution found by them. Finally, the best improved solution is used by the SA technique to update the global pheromone levels completing the first iteration. The best solution is proposed when all the iterations are over.

5. Results and Conclusions

As identified from the literature review, the majority of the available benchmarks are using the CVRP algorithm (not the CVRPMT), and therefore the authors adjusted the proposed model, in order to compare the outcome of their algorithm to the CVRP benchmark results. Each benchmark was tested with the proposed ACO algorithm and after multiple executions of our model for every benchmark; the mean values of the

results are presented in Table 1. The results indicate that the model is well suited even for large scale problems and provides effective and efficient solutions. It must be stated that the authors identified specific parameter values that provide optimized results for all the benchmarks (Table 2).

Table 1 Algorithm's Results

Benchmark	Number of Vehicles	Number of Nodes	Best Known Solution	Proposed Model Results	Dev%
E-n22-k4	4	22	375	375	0.00%
B-n31-k5	5	31	672	672	0.00%
A-n39-k5	5	39	822	822	0.00%
A-n45-k6	6	45	944	944	0.00%
E-n51-k5	5	51	521	521	0.00%
A-n53-k7	7	53	1010	1016	1.58%
P-n55-k7	7	55	568	577	1.58%
P-n76-k4	4	76	593	611	3.04%
P-n101-k4	4	101	681	719	5.58%

Table 2 Optimized parameter values

a	b	γ	ξ	q0	M	MaxIterations
1	2	2	0,1	0.9	10	3000

Finally, the authors present a software tool (Figure 1) that uses the optimized parameter values and is based on an open source framework developed in the C# programming language (Bechtis et al., 2018). The framework enables practitioners and academics to design the facility layout of a plant by loading an image of the layout and further importing all the appropriate entities (boundaries, shelves and loads, obstacles and compartment dividers, the vehicles' and their starting position, the exit station). Load entities are considered as Pick Up and Delivery (P/D) nodes and vehicles navigate in the facility and pick up loads under specific capacity requirements. In order to calculate the distances in the facility layout the framework uses the A* algorithm and calculates the shortest path taking into consideration the P/D nodes, the vehicles' starting node, the vehicles exit station, the obstacles and the compartment dividers. The implemented ACO algorithm is integrated with the framework and executed in order to determine the total trips travelled by each vehicle. In the ACS window we can define all the required parameters (from Section 4) and run the simulation. As a last step, a schedule of the vehicles' trips is presented to the end user.

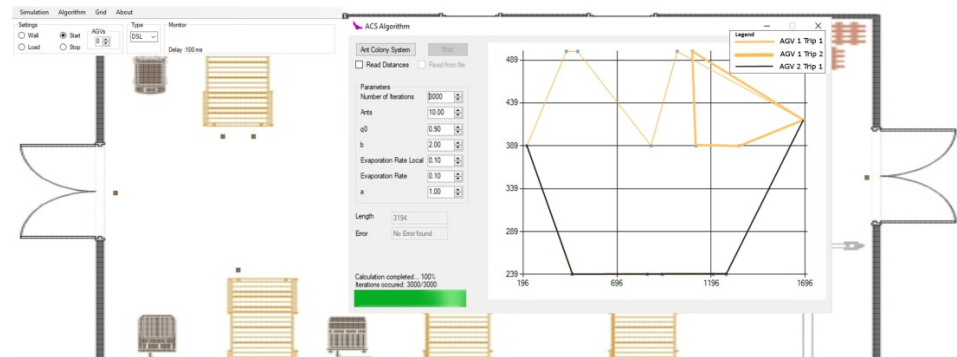

Figure 1 Overview of the GUI with the ACS module

As an extension for future research work, the authors will consider to integrate the algorithm to a software tool for last-mile logistics, taking into account predefined time windows. The implementation could use GPS data and travel distances from real Case Studies.

Abstract

The assessment of the sustainability level achieved by electricity mixes is a crucial step in the change towards a more sustainable energy system. Here we assess the three dimensions of sustainability -the economic, environmental and social performance- of the 28 EU members electricity mix in 2015 by combining life cycle assessment, data envelopment analysis (DEA) and mathematical programming tools. Our method encompasses three main steps: i) the efficiency assessment of the electricity portfolios of the 28 EU countries via DEA ii) the optimization of inefficient countries portfolios by means of solving the EffMixF model that we pose in this work, and iii) the efficiency evaluation of the optimized electricity portfolios obtained in STEP 2. The EffMixF model takes into account the main technical constraints involved in electricity generation within each country, complementing standard DEA in order to extend previous research and obtain more realistic information for policy-making. We find that 12 countries are inefficient, being United Kingdom, Lithuania and Italy the ones with the lowest efficiency. In our main findings, we determine that inefficient countries have to reduce the non-renewable electricity sources by 10% (with respect the total electricity production) in order to become efficient.

Keywords: Optimization, Sustainability, DEA, Electricity mix, Eco-efficiency

1. Motivation

The transition to a more sustainable energy production is one of the foremost challenges in our era. The sustainability concept includes economic, environmental and social aspects, where each of them can be quantified by an extensive diversity of indicators. Finding a way to combine all these metrics into a unique score in an objective and systematic method is the main difficulty when assessing the sustainability level of a system. In this respect, DEA arises as a promising methodology. This method, evaluates the relative efficiency of a set of options (called decision making units, DMUs) by using a large number of indicators (inputs and outputs) (Cooper et al., 2011). The DMUs deemed efficient are the vertices of an efficient frontier. Furthermore, DEA provides improvement targets for inefficient DMUs that, if attained, would make them efficient. These targets are obtained by projecting each inefficient DMU to the efficient frontier,

being each projection the linear combination of the reference set –i.e., efficient DMUs of the facet where the inefficient one is projected-. However, the practical feasibility of DEA targets is controversial among the scientific community.

In this work, we extend previous research by suggesting a new approach where standard DEA is supplemented with a novel projection step using optimization tools. In particular, we assess the 28 EU members efficiency in 2015 taking into account eight sustainability indicators covering the economic, environmental and social dimensions. Then, we study if DEA targets are indeed attainable and propose a best-scenario electricity mix for each inefficient country. With this purpose, we pose and solve the EffMixF optimization problem which considers real potentials for the renewable sources as well as techno-economic constraints and the reliability of the supply. This model allows projecting inefficient DMUs towards the more fitting point of the efficient facet (rather than a particular point of it, as in standard DEA), thus granting higher chances to achieve efficiency.

2. Methods

2.1. Data used

We use the electricity portfolio data of the 28 EU countries in 2015 from the Eurostat Energy Statistics -energy datasheets- (European Union, 2016). These datasheets disaggregate the electricity production into 12 energy sources, from which we consider nine: the most representative technology for each energy source (see Table 1). Then, we calculate the environmental, economic and social performance of each country's mix (i.e., inputs and outputs) using indicator coefficients for each technology, see Table 2.

Table 1. Technologies and assumptions used in our study.

Name used ^{a,b}	Technology
Gases	Natural gas CCGT plant
Nuclear	Pressure water reactor
Petroleum Products	Petroleum, heavy fuel oil
Solid Fuels	Coal plant
Biomass and Renewable wastes	Biomass CCGT plant
Geothermal	Deep geothermal
Hydro	Run-of-river
Solar	Photovoltaic open ground installation
Wind	Onshore wind

a) In bold dispatchable technologies (DP). b) In gray shade, renewable technologies.

Table 2. Environmental, economic and social indicators considered.

Indicator name	Abbreviation	Unit	Source
Climate change	GWP100	kg CO _{2e} /kWh	(Wernet et al., 2016)
Fossil depletion	FDP	kg Oil _e /kWh	(Wernet et al., 2016)
Human toxicity	HTPinf	1,4-DCB _e /kWh	(Wernet et al., 2016)
Ozone depletion	ODPinf	kg CFC-11 _e /kWh	(Wernet et al., 2016)
Total land occupation	TLOP	m ² /yr/kWh	(Wernet et al., 2016)
Water depletion	WDP	m ³ /kWh	(Wernet et al., 2016)
Levelized cost of electricity	LCOE	USD/MWh	(NEA et al., 2015)
Total job-years	Job-yr	Job-yr/GWh	(Wei et al., 2010)

In our study, we take into account the country potentials for the renewable electricity sources except for biomass -embedded in set *RP*- (Eea, 2009; EREC, 2011; Pirker et al., 2011), as well as the capacity factors for all the technologies (NEA et al., 2015).

2.2. Step 1: DEA model

In Step 1, we assess the electricity mix efficiency of each EU member through DEA, a methodology that evaluates the relative performance of a set of DMUs translating multiple inputs into multiple outputs. We therefore consider each country as a DMU consuming seven inputs and producing one output. With the given data, DEA determines an efficiency score for each DMU (θ), which is expressed as the weighted sum of outputs divided by the weighted sum of inputs. This θ is assessed by optimizing the weights attached to each input and output. In particular, we use the Variable Returns-to-Scale (VRS) input-oriented model (Cooper et al., 2011). Additionally, DEA provides the improvement targets required by the inefficient DMUs to become efficient as the difference between their initial inputs and outputs and the values attained when radially projected on the efficient frontier.

2.3. Step 2: EffMixF model

The EffMixF model -defined for each inefficient country i - contains two sets of equations: (i) those related with electricity generation; and (ii) those related with the DEA targets we aim to achieve.

2.3.1. Electricity generation

The total electricity generated (E_{Gen}) in each country i must be preserved. For this, we define an electricity mix merging standard (Mix^{ST}) and back-up (Mix^{BU}) generation using the existing technologies j . Note that we do not consider electricity trade among countries, as we aim to improve the efficiency of the electricity generated rather than consumed.

$$\sum_j (Mix_{ij}^{ST} + Mix_{ij}^{BU}) = E_{Gen}_i \quad (1)$$

We ensure the reliability of the supply via Eq. 2, where we use the back-up parameter (Gross et al., 2006) ($BUP=50\%$) to indicate the capacity of dispatchable (DP) sources required to holdup each unit of non-dispatchable installed.

$$\sum_{j \in DP} Cap_{ij}^{BU} \geq BUP \sum_{j \in DP} Cap_{ij}^{ST} \quad (2)$$

Cap^{ST} and Cap^{BU} are the capacities installed for standard and back-up technologies. Note that only the dispatchable technologies can participate as back-up sources.

The amount of electricity generated for both standard and back-up purposes are given by the product between the corresponding installed capacities, the capacity factor (Cf) and the total number of hours in a year (H).

$$Mix_{ij}^{ST} = Cap_{ij}^{ST} Cf_{ij} H \quad \forall j \quad (3)$$

$$Mix_{ij}^{BU} = Cap_{ij}^{BU} Cf_{ij} H \quad \forall j \quad (4)$$

Additionally, we consider the potential available (PT_{ij}) for electricity generation in each renewable source included in the set RP , preventing unrealistic solutions (Eq. 5).

$$Mix_{ij}^{ST} + Mix_{ij}^{BU} \leq PT_{ij} \quad \forall j \in RP \quad (5)$$

We impose that the nuclear electricity produced cannot be higher than the existing due to the nuclear energy policy reversal of some EU countries (Müller and Thurner, 2017).

2.3.2. *DEA linkers*

The equations in this section connect the electricity mixes modeled via Eq. 1 to 5 with the DEA targets from STEP 1. First of all, we force inputs z and outputs y to be equal or better than the initial ones (Imp_{iz} and Out_{iy}):

$$\sum_j (CT_{ijz}^{INP} (Mix_{ij}^{ST} + Mix_{ij}^{BU})) \leq Imp_{iz} EGen_i \quad \forall z \tag{6}$$

$$\sum_j (CT_{iyy}^{OUT} (Mix_{ij}^{ST} + Mix_{ij}^{BU})) \geq Out_{iy} EGen_i \quad \forall y \tag{7}$$

Being CT_{ijz}^{INP} and CT_{iyy}^{OUT} the inputs and outputs coefficients for each country/technology.

In Eqs. 8-10 we assess the distance (in the space of inputs and outputs) between the efficient DEA facet and the inputs and outputs attained with the new Suggested mix:

$$\sum_{i \in RS_i} (\lambda_i Imp_{i,z}) EGen_i + S_z^N = \sum_j (CT_{ijz}^{INP} (Mix_{ij}^{ST} + Mix_{ij}^{BU})) \quad \forall z \tag{8}$$

$$\sum_{i \in RS_i} (\lambda_i Out_{i,y}) EGen_i - S_y^P = \sum_j (CT_{iyy}^{OUT} (Mix_{ij}^{ST} + Mix_{ij}^{BU})) \quad \forall y \tag{9}$$

$$\sum_{i \in RS_i} \lambda_i = 1 \tag{10}$$

Where λ_i is the linear coefficient for countries i' belonging to the reference set of country i (RS_i), and S_z^N and S_y^P are the inputs (z) and outputs (y) slacks for country i . Note that here λ_i is a decision variable (and not the value provided by DEA in STEP 1), thus allowing EffMixF to project inefficient countries onto a whole efficient facet.

In Eq. 11, we present the overall model, which guarantees the electricity supply whilst approaching as much as possible the efficient facet provided by the original DEA.

$$\begin{aligned} \text{minimize} \quad ObjFun_i &= \sum_z (S_z^N / Imp_{iz}) + \sum_y (S_y^P / Out_{iy}) \\ \text{s.t. Eqs 1-10} & \\ Mix_{ij}^{ST}, Mix_{ij}^{BU}, Cap_{ij}^{ST}, Cap_{ij}^{BU}, S_z^N, S_y^P, \lambda_i &\geq 0 \quad \forall y, z, j \end{aligned} \tag{11}$$

3. Results and Discussion

Firstly, in STEP 1 we obtain the efficiency for each EU country using the VRS method. These efficiencies (see Table 3) range from 0.8 to one, and reveal that 12 out of the 28 countries analyzed are inefficient ($\theta < 1$), being United Kingdom, Lithuania and Italy, the ones presenting the lowest efficiency (0.84, 0.86 and 0.89 respectively).

Table 3. Efficiencies of the 28 EU member countries given by ISO 3166-2 code.

Code	Efficiency	Code	Efficiency	Code	Efficiency	Code	Efficiency
AT	1.00	EE	0.99	HU	0.93	NL	1.00
BE	0.96	ES	0.95	IE	1.00	PL	1.00
BG	1.00	FI	0.90	IT	0.89	PT	0.96
CY	1.00	FR	1.00	LT	0.86	RO	1.00
CZ	0.98	GB	0.84	LU	1.00	SE	1.00
DE	1.00	GR	1.00	LV	0.92	SI	1.00
DK	1.00	HR	1.00	MT	1.00	SK	0.92

Pie charts in Fig. 1 compare the Current (internal ring) and Suggested mixes (external ring) for each inefficient country (STEP 2). Broadly speaking, non-renewable electricity sources continue being the biggest part of the mix (mean of 58%), regardless of being displaced in part by renewable sources (10% of electricity production).

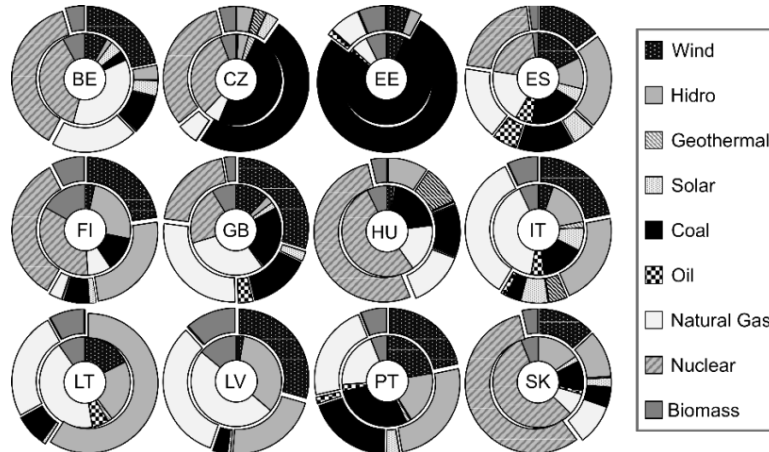

Fig. 1. Current (internal rings) and Suggested (external) electricity portfolios.

As a general trend, we found that hydropower and wind are the technologies that need to be promoted in order to improve the environmental impact. On the other hand, coal is the one to be used to improve the economic performance (LCOE), and solar the social one, as is the one that more jobs-year generates.

To conclude, we use DEA to assess again the efficiency of the 28 EU countries (STEP 3) using, on the one hand, the Current mixes for the countries deemed efficient in STEP 1 and the Suggested mixes for the inefficient ones (STEP 2). We find that all the efficiencies were improved in the Suggested mixes (see Table 4). More specifically, five out of the 12 countries originally found inefficient in STEP 1 were found weakly efficient when their Suggested mixes were considered. The reason for this is that, even though their efficiency is one, they cannot achieve an *ObjFun* of zero -they present slacks- indicating they cannot attain the strongly efficient frontier.

Table 4. Efficiencies of the Suggested electricity mixes of the inefficient EU countries.

Code	Efficiency	Code	Efficiency	Code	Efficiency	Code	Efficiency
BE	0.99	ES	1.00	HU	0.94	LV	0.97
CZ	1.00	FI	1.00	IT	1.00	PT	1.00
EE	0.99	GB	0.92	LT	0.96	SK	0.99

4. Conclusions

We posed and solved a new approach that combines a VRS DEA model with an optimization problem (EffMixF) that takes into account exhaustive techno-economic features. We used this approach to study the 28 EU members electricity mix for the year 2015 covering the three sustainability pillars: the economic, environmental and social.

Firstly, we applied DEA to the EU countries, finding 12 of them inefficient. Then, we posed and solved the EffMixF model to obtain new portfolios enhancing inefficient

countries. This model considers the key technical constraints needed when modeling the electricity generation within each country (renewable sources potentials, capacity factors, reliability of the supply). We found that none of the inefficient countries reached the strong frontier, which demonstrates that the original targets given by DEA are not attainable. The reason for this is the limited availability of intermittent sources, which makes it necessary to use a certain percentage of dispatchable sources, as well as the constraints that prevents the worsening of any indicator with respect to the Current values. Nevertheless, the efficiencies obtained with the Suggested mixes are in all the cases higher than with the Current ones, as verified in the second DEA assessment.

Finally, it is significant to note that the efficiency scores and portfolios attained depend completely on the indicators considered. However, our framework is flexible enough to incorporate diverse indicators and/or constrains, providing in all the cases feasible and sensible solutions. Therefore, the methodology we propose can be used to guide policy makers, as it indicates which technologies should be boosted (or hindered) to improve the sustainability efficiency of each inefficient country.

Abstract

A reduced coupled 2D-CFD and Population Balance Model (PBM) framework (Alzyod et al., *Comput. Aided Chem. Eng.*, 40, 61-66) is extended to model the mass transfer behaviour of pulsed sieve plate liquid extraction columns. The Euler-Euler approach is used to model the two phase flow inside the column, while the One Primary One Secondary Particle Method (OPOSPM), the simplest form of SQMOM, is utilized as a reduced population balance solver. The proposed framework is numerically tested and the results are compared with the published experimental data. The required breakage and coalescence parameters to perform the 2D-CFD simulation are estimated using PPBLab software, where a 1D-CFD simulation using a multi-sectional grid is performed. A very good agreement is obtained at the experimental and the numerical validation levels.

Keywords: 2D-CFD, OPOSPM, PPBLab, Population balances, Pulsed columns.

1. Introduction

Pulsed liquid extraction columns have the advantage over the other extraction equipment, where they find many applications in chemical, biochemical and pharmaceutical industries. Unlike the agitated extraction equipment, pulsed sieve plate extraction columns provide a wider operational range and require less maintenance efforts (Haverland and Slater, 1994). The applied pulsation intensity characterizes the flow patterns inside the column and increases the available interfacial area, which enhances the column efficiency. The available lumped correlations and mixture models are still insufficient to describe the actual behaviour of the dispersed phase, where they ignore the droplet-droplet and the interphase interactions (Attarakih et al., 2015). These interactions include: breakage, coalescence and interphase mass transfer. To take all of these interactions into account, a coupled PBM and CFD framework can be used. The required information about the velocity field and energy dissipation is provided by the CFD solver, while the droplet-droplet interactions are taken into account using the PBM. In this regard, OPOSPM is considered as an attractive reduced PBM in terms of simplicity and computational cost. OPOSPM is the simplest special case of the general Sectional Quadrature Method Of Moments (SQMOM), where it directly conserves the zero moment and third moment of the droplet size distribution (Attarakih et al., 2009;

2016). In contrast to the moments based methods, OPOSPM avoids the divergence problems arise when applying the classical inversion algorithms to close the source terms, which makes it a stable framework. A first attempt to couple OPOSPM and CFD solvers was done by Drumm et al., (2010) to model a lab scale RDC liquid extraction column. In the same direction, Jaradat et al. (2011) simulated a pulsed sieve plate column using the LLECMOD software and Attarakih et al., (2015) implemented OPOSPM to simulate the hydrodynamics and mass transfer behaviour of a pilot plant RDC column. In a recent work, Alzyod et al., (2017) presented a coupled OPOSPM-CFD framework for modelling the hydrodynamics behaviour of a pulsed sieve plate extraction column. In this contribution, we extended this work to model the mass transfer behaviour of pulsed sieve plate liquid extraction columns. The proposed framework is tested and the results are compared with the published experimental data by Garthe (2006). The required breakage and coalescence parameters to perform the 2D-CFD simulation are estimated using PPBLab software (Attarakih et al., 2012; 2017). A positive validation at the numerical and experimental levels is obtained.

2. Coupled OPOSPM-CFD framework

The two phase flow inside the column is modelled using Euler-Euler approach. The continuity transport equation for the i^{th} phase is given by (Drumm et al. 2010):

$$\partial_t (\alpha_i \rho_i) + \nabla \cdot (\alpha_i \rho_i u_i) = 0 \quad (1)$$

Where α_i and u_i are the volume phase fraction and the velocity of the i^{th} phase respectively. The momentum balance equation for the i^{th} phase is given as follows:

$$\partial_t (\alpha_i \rho_i \bar{u}_i) + \nabla \cdot (\alpha_i \rho_i \bar{u}_i \bar{u}_i) - \nabla \cdot \tau_i = -\alpha_i \nabla p + \alpha_i \rho_i g + F_i \quad (2)$$

In Eq.(2), τ_i is the stress tensor, p is the pressure shared by all phases, g is the gravitational acceleration vector, and F_i represents the interphase forces. In this work, only the drag force is taken into account as recommended by Drumm et al., (2010). Based on this, the interphase momentum exchange coefficient is given by:

$$K_{ij} = 3\alpha_i \alpha_j \rho_j C_D |u_i - u_j| (u_i - u_j) / 4d_{30} \quad (3)$$

Where, d_{30} is the mean droplet diameter, and C_D is the drag coefficient, which is given by Kumar and Hartland (1985). The turbulence flow is modelled using the mixture $\kappa - \varepsilon$ model. Moreover, the required droplet diameter (d_{30}) to close Eq.(3) is obtained by solving the total number balance equation coupled with Eq.(1). The total number balance equation of the dispersed phase is given by (Attarakih et al., 2016):

$$\partial_t (\alpha_d \rho_d N) + \nabla \cdot (\alpha_d \rho_d u_d N) = \alpha_d \rho_d [(\mathcal{G} - 1)\Gamma(d_{30})N - 0.5\omega(d_{30}, d_{30})N^2] \quad (4)$$

Here, N is the total number concentration of the droplets, \mathcal{G} is the number of daughter droplets produced due to the breakage events, and Γ and ω are the breakage and coalescence kernels respectively. The mean mass droplet diameter is given by:

$$d_{30} = \sqrt[3]{6\alpha_d/\pi N} \quad (5)$$

In this work, the required breakage and coalescence kernels to close Eq.(4) are given by Coualoglou and Tavlarides (1977) as follows:

$$\Gamma = c_1 \frac{\varepsilon^{1/3}}{d^{2/3}(1+\alpha_d)} \exp\left(-\frac{c_2\sigma_d(1+\alpha_d)^2}{\rho_c \varepsilon^{2/3} d^{5/3}}\right) \quad (6)$$

$$\omega = c_3 \frac{\varepsilon^{1/3}}{1+\alpha_d} (d+d')^2 (d^{2/3} + d'^{2/3})^{1/2} \exp\left(\left(-\frac{c_4\eta_c\rho_c\varepsilon}{\sigma_d^2(1+\alpha_d)^3}\right)\left(\frac{dd'}{d+d'}\right)\right)^4 \quad (7)$$

The parameters c_i appearing in Eqs.(6 & 7) are fitting parameters. More information concerning the parameters estimation procedure is given in the numerical and experimental validation section. Here, σ_d is the dispersed phase interfacial tension, and ε is the energy dissipation. The required energy dissipation correlation to perform the 1D-CFD simulation, as implemented in PPB Lab software, is given by Milot et al., (1990):

$$\varepsilon = C_5 (Af)^3 / H_c \quad (8)$$

Where, c_5 depends on the column geometry, and H_c is the compartment height. The solute mass transfer conservation equation for the i^{th} phase is given by (Attarakih et al., 2015):

$$\partial_t (\alpha_i \rho_i c_i) + \nabla \cdot (\alpha_i \rho_i u_i c_i) = \rho_i \zeta a_p K_{od} (m c_c - c_d) \quad (9)$$

Where, c_i is the solute concentration in the i^{th} phase, a_p is the available interfacial area ($a_p = 6\alpha_d/d_{30}$), and K_{od} is the overall mass transfer coefficient. The factor ζ appears in Eq.(9) has a value of -1 and 1 for the continuous and dispersed phases respectively. The overall mass transfer coefficient is given by:

$$k_{od} = (m/k_c + 1/k_d)^{-1} \quad (10)$$

Where m is the solute distribution coefficient, k_c and k_d are the individual mass transfer coefficients of the continuous and dispersed phases respectively. More information concerning the individual mass transfer coefficients is given in the numerical and experimental validation section.

3. Computational domain and boundary conditions

In this work, FLUENT 18.2 is utilized, where Eqs.(3-7) and Eqs.(9-10) are implemented as user defined functions. The column used in simulation is a pilot plant sieve plate liquid-liquid extraction column based on the experimental work of Garthe (2006). The detailed dimensions are shown in Table (1). In the present work, only the active height of the column is considered, where an axisymmetric grid is used to model the active

height as shown in Figure (1). To reflect the actual column geometry, the sieve plate hole diameter is kept constant and the pitch diameter is varied to achieve the experimental free area value.

Table (1): Sieve plate liquid extraction column geometry (all dimensions are in m)

Column active height	Column diameter	Hole diameter	Free area
2.95	0.08	0.002	20%

A velocity inlet boundary is used at the bottom of the column, while a pressure outlet boundary condition is used at the top. Moreover, a sinusoidal pulsed velocity is used at the bottom of the column to take the pulsation effect in to account as follows:

$$u(t) = u_c + \left(d_p^2/d_c^2\right)A \sin(2\pi Ft) \quad (11)$$

Where d_p and d_c are the piston and the column diameters respectively, A is the pulsation amplitude, and F is the pulsation frequency.

Figure (1): Part of the computational domain and the implemented boundary conditions.

4. Numerical and experimental validation

The 2D-CFD framework prediction is validated using the published experimental data by Garthe (2006) using toluene (d)/acetone/water chemical system. The dispersed and continuous phases inlet velocities are 40 and 48 litter/h respectively. The pulsation intensity is fixed at a value of 2 cm/s. The inlet dispersed phase solute concentration is 0.4 kg/m^3 , while the inlet continuous phase solute concentration is 53.5 kg/m^3 . The initial conditions are zero for both droplets number and the dispersed phase volume fraction, while the initial concentration is the same as in the continuous phase inlet feed. The coalescence and breakage kernels parameters are estimated using PPBLab software, where the parameters values are estimated by matching the 1D-CFD simulation hydrodynamics predictions with the experimental data. The obtained breakage and coalescence kernels are given by: $c_1 = 0.001$, $c_2 = 100 \text{ m}^{-2}$, $c_3 = 0.05$, and $c_4 = 1.33 \times 10^{10} \text{ m}^{-2}$ respectively. Figure (2.A) shows a comparison between the predicted average energy dissipation by the 2D-CFD model and the predicted values using Eq.(8). It is clear that the correlation of Milot et al., (1990) shows a good agreement with the 2D-CFD result. Indeed, this is a substantial validation step because the estimated breakage and coalescence models parameters using PPBLab software, as a 1D-CFD simulation environment, depend on the energy dissipation. Figure (2.B) shows a comparison between the simulated mean droplet diameter and the experimental data, where a very good agreement is obtained using both simulation tools. Here, a multi-sectional grid (w.r.t. droplet diameter and solute concentration) is used to perform the 1D-CFD simulation to numerically validate the 2D-CFD simulation results. Figure (3.A) depicts a comparison between the simulated light phase solute concentration profiles and the

experimental data. In this work, the continuous phase mass transfer coefficient is given by Heertjes (1954), while the dispersed phase mass transfer coefficient is given by Kronig and Brink (1950) respectively. Both CFD simulation tools show a very good agreement with the experimental data. However, a better prediction using PPBLab software is observed at the bottom of the column. This is because PPBLab's software PBM solver has the advantage as a detailed multi-sectional numerical solver. Figure (3.B) depicts the effect of the solute mass transfer process on the dispersed phase interfacial tension, where the interfacial tension is decreasing along the column height. Therefore, the droplet breakage is enhanced and the droplet size is shifted toward smaller values.

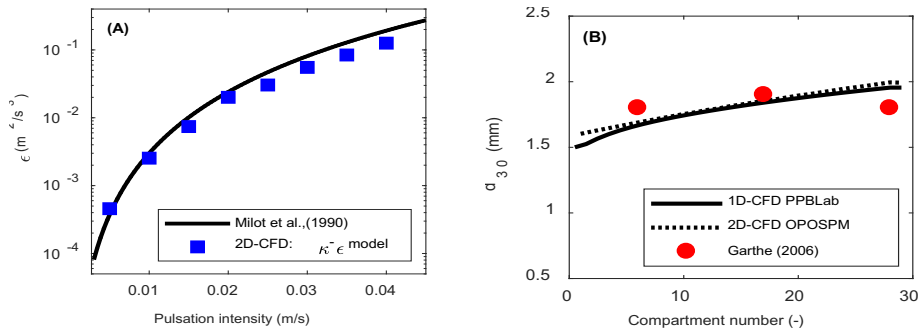

Figure (2): A) Comparison between the simulated average energy dissipation using 2D-CFD model and the predicted values using the correlation of Milot et al., (1990). B) Comparison between the simulated mean droplet diameter values and the experimental data (Garthe, 2006).

Figure (3): A) Comparison between the simulated light phase solute concentration profiles and experimental data (Garthe, 2006). B) Effect of the solute mass transfer process on the light phase interfacial tension along the column height.

5. Conclusions

In this work, a 2D OPOSPM-CFD framework is extended to model the mass transfer behaviour of pulsed sieve plate liquid extraction columns. To perform the 2D-CFD simulation, PPBLab software, as a 1D-CFD model, is used to estimate the required breakage and coalescence kernels parameters. Both simulation frameworks are able to predict the hydrodynamics and the mass transfer behaviour as compared with the published experimental data. In this regard, PPBLab software has the advantage in terms of CPU time and the grid generation.

Abstract

Policies are encouraging to reduce emissions in all sectors, due to the high energy demand during the life cycle of the processes. Constructions are not an exception and policies are encouraging to reduce energy demand in buildings. Although new constructions are reducing their energy demand according to new directives, without interventions in the actual building stock, the European goals proposed for 2050 cannot be achieved.

Insulation is known to achieve an important reduction in the energy demand in the operation phase of the buildings. Despite that, this implementation carries out an initial investment in both, cost and impact, which suggest that using low embodied materials, such as bio-based materials, could improve this solution. Despite their good thermal properties, these new materials are not arriving at the actual market for insulators. In order to improve this scalability, an evaluation of the efficiency of different materials is carried out, with a following combination of the efficient materials in order to generate new hybrid solutions. These hybrid materials cope to simplify the applicability of bio-based materials, generating sandwich panels or combined mats to generate materials similar to the commercialized ones which have an increasing market nowadays.

The methodology presented combines Data Envelopment Analysis (DEA) and Building modelling simulation. Using thermal simulations of EnergyPlus and the evaluation of efficiency and further projections of DEA.

Seven bio-based materials and polyurethane for comparison have been studied, with a thickness that varies from 1 cm and 26 cm in increments of 5 cm. DEA analysis is used to quantify the efficiency score of the different thicknesses of the materials. The non-efficient materials are projected to this frontier, achieving a combination of materials. Those combinations have been analysed in order to model only the feasible solutions, which have proved to achieve efficiency in all the combinations proposed.

Keywords: DEA, life cycle assessment, bio-based materials, buildings, thermal insulation

1. Introduction

Reducing the primary energy consumption seems one of the rows to achieve a sustainable development, so focusing in one of the main consumers of this energy is essential. In Spain, buildings represent a 32% of this primary energy demand, which main consumption is done in conditioning the building. Insulation of the building has been proved to achieve an important reduction in this consumption. Despite that, this implementation should be carried out in a sensible way, as in the majority of the cases the materials used are high embodied energy materials which can counter-effect the improvements achieved counting the whole life cycle of the solution.

To skip this trade-off, bio-based materials may represent an important alternative, as their thermal and acoustic properties are really competitive comparing with commercial ones. Despite that, the commercial scalability of those materials is growing slowly what suggest that a major boost for trade is required. Taking into account this fact and the high demand for sandwich panels in the building sector, a hybrid generation of insulation materials could generate a change in the actual commercial tendency of bio-based materials.

Previous research has been carried out combining Data Envelopment Analysis (DEA) and LCA, but only a little research has been carried out in the building sector and only one has combined LCA+DEA with the evaluation of the efficiency of constructions sets (Iribarren (2015)).

A systematic methodology to evaluate the ecoefficiency of these materials and a further generation of hybrid combinations is proposed via a Data Envelopment Analysis (DEA). This methodology consists in a benchmarking of the different solutions against predefined inputs and outputs. The main goal of this research is focused on the opportunity for the non-efficient solutions, which can be projected to the efficient frontier generating hybrid combinations of different materials in order to control their properties and achieve new materials.

2. Methodology

The methodology we propose allows assessing the ecoefficiency of candidate alternatives (i.e., materials and thicknesses) and systematically generate ecoefficient materials combinations from inefficient ones. This strategy comprises three main steps and integrates energy simulations, life cycle cost and impact as well as DEA.

The first step corresponds to the data generation, where each alternative is simulated in a building model providing the energy requirements. These requirements are then used to calculate the total life-cycle cost and impact associated with each alternative. The second step consists in an objective reduction, which is carried out in order to simplify subsequent calculations by ruling out of the analysis redundant indicators. In the third step, which is the core of our methodology, we apply DEA to benchmark the efficiency of the different alternatives. To this end, each alternative is modelled as a decision-making unit (DMU) whose performance is evaluated from the cost and impact indicators determined in step one and retained after step two. The efficient alternatives (efficiency score of 1), would be saved as a reference. Conversely, the non-efficient would be used to systematically identify hybrid materials potentially ecoefficient (see further details in section 2.3). Finally, these hybrid candidates would be simulated in the

cubicle model and a second DEA would be used to compare their performance with that of the ecoefficient alternatives already identified in step three.

2.1. Model definition, energy simulation and cost and environmental evaluation

To analyse the performance of the different materials, a cubicle-like building has been modelled in EnergyPlus. In energy terms, this software includes the equations set which define the energy consumption of the building taking into account the climate conditions and the heat and mass transfer balances. This simulation provides the energy demand during a specific time period (1 year). This energy demand and the materials stock of the building are used to evaluate the environmental impact associated with each category and the total cost of the different solutions to evaluate. The different impact categories and the cost would be different inputs of our model, while the output selected is an output dummy that quantifies if the solution achieves the defined conditions of the building (1 fulfilled, 0 not fulfilled). Finally, the impacts and cost associated with each combination of material and thickness correspond to a DMU in DEA.

To quantify the inputs of each DMU, 2 different databases have been used, in order to quantify the cost and the environmental impact of the solutions. On the first hand, for the total cost of the solutions, iTEC database has been used to achieve the price of all the conventional construction materials, whereas, for the bio-based materials, their cost has been extracted directly for different suppliers. The total cost of the materials used (Menoufi (2012)) is supposed to be invested during the first year of the insulation of the building. Furthermore, the electricity price has been extracted from iTeC, in this case, the cost of energy is paid each year with an annual increment of 5%.

On the other hand, for the environmental impact, each material has been evaluated with all the impact categories of Ecoindicator99; each one has been calculated based on the mass used. The impact of the electricity has been evaluated with the impact of low voltage electricity of the Spanish mix for 1 kWh.

2.2. Objective Reduction

In order to eliminate the redundant objectives, a dimensionality reduction analysis is carried out. This analysis can be done in the inputs, outputs or both, in this methodology it has been carried out only in the inputs. The different inputs may differ in the magnitude order between them, in order to solve the problems originated by the nature of the data; each input and output is normalized between 0 and 1.

Seven of the total inputs have been extracted from the further analysis due to their redundancy with the other inputs. The final objectives chosen are Land Occupation, Ozone layer depletion, Fossil Fuels, Mineral extraction and Total cost.

2.3. DEA application

A combined method of LCA + DEA is applied in this research; the main reason for the inclusion of DEA methodology is due to the necessity to implement its projection method. Despite that, it is also a beneficial methodology in order to quantify the efficiency of the different insulation materials and thicknesses.

Due to the nature of our inputs and outputs, an input-oriented method is required, which determines the proportional reduction in inputs required by an inefficient solution in order to become efficient, while the output is constant. The model used corresponds to BCC model (Cook (2009)).

Once identified the efficient frontier with the efficient solutions, all the inefficient solutions are projected to the frontier with a Radial Projection (Cook (2009)). Each non-efficient DMU projected to the efficient frontier achieves a combination of different DMUs, with a specific material and thickness.

After this combination, a deeper analysis has to be done in order to verify the manufacturing possibility of mixing the different DEA suggested materials. The different restrictions applied are shown on the following list:

- PU used for comparative; PU mixings are excluded from the following steps.
- Cellulose installation method is not compatible with other materials.
- Natural fibres can be combined in order to produce mats with other materials.
- Wood and cork can be used as external layers of sandwich panels.
- Not more than 3 materials combined would be used as hybrid solutions.

Finally, the proposed combinations are evaluated in order to verify their efficiency.

3. Results and discussion

We next present and discuss the results of the applying methodology to seven bio-based materials and polyurethane. For each material, six different thicknesses have been analysed, 0.01, 0.06, 0.11, 0.16, 0.21 and 0.26 cm. The first analysis corresponds to the efficiency of the different solutions, as it is shown in figure 1, 21 solutions are efficient, against 27 non-efficient ones.

As it is shown, wool is efficient in five out of six thicknesses, this is due to its thermal properties and its low cost which helps to achieve the efficiency. On the other hand, cork does not achieve efficiency in any of its solutions. This can be explained because their properties are really similar to wood and hemp but with a higher price and impacts.

Figure 1: Efficiency score of the different insulation layers.

We can also see that thicker insulation layers achieve better efficiencies than lower ones. This can be explained because thicker layers require less energy demand and the electricity mix in Spain is expensive and dependent on fossil fuels, which tends to penalize those solutions with higher energy demand. When we take into account the projected solutions, 27 different combinations are achieved, mixing between two and four different materials as it is shown in figure 2. If the restrictions proposed in section 2.3 are considered, only seven combinations are feasible, which correspond to different thicknesses combining cotton and hemp.

The most used solutions with a higher percentage of material used correspond to cellulose and hemp. PU is also used in a lot of combinations, but the percentage used is lower than in the cellulose and hemp. Those two materials are more widely used due to their good properties and the low cost and environmental impact. On the other hand, wool solutions despite being efficient in the majority of its thickness is not a reference set of nearly any solutions. This is due to that wool solutions are in the extremes of the efficient frontier and radial projections hardly ever project in this section.

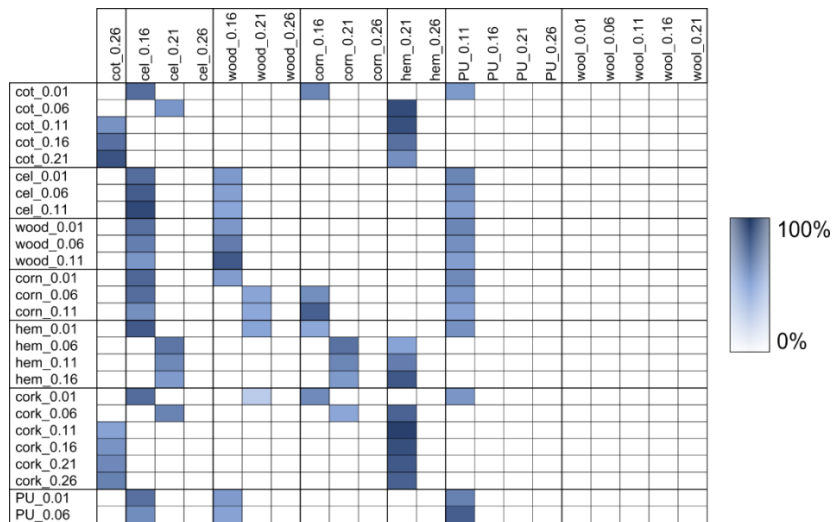

Figure 2: Projected combinations of the non-efficient solutions against efficient ones.

Once the solutions are selected, the thicknesses of each material are achieved with the combination of the percentage of the materials and the thickness of the selected DMU, achieving the following hybrid materials:

Table 1: Combination materials and thicknesses.

Hybrid Materials	Total Thickness (cm)
6cm Cotton + 17cm Hemp	23
13cm Cotton + 11cm Hemp	24
20cm Cotton + 5cm Hemp	25
2cm Cotton + 19cm Hemp	21
5cm Cotton + 17cm Hemp	22
8cm Cotton + 15cm Hemp	23
9cm Cotton + 13cm Hemp	22

All the thickness vary between 21 and 25cm, this higher thickness minimizes the energy consumption. These values are achieved due to the low impact of those materials and the reasonable cost of them, which penalize the energy consumption against the installation of thicker layers of insulation.

Finally, figure 3, shows that all the solutions suggested by our model achieve an efficiency score of 1. This proves that our methodology can generate hybrid combinations which achieve efficiency but with more balanced properties due to the mix of different materials.

Figure 3: Final efficiency scores for all the insulation layers.

4. Conclusions

A methodology which systematically provides combinative solutions of insulation materials have been proposed and proved its results in a modelled building. The objective reduction proposed has been able to reduce 7 inputs out of 12, this has helped to eliminate redundant solutions that do not provide new information compared to the actual results.

A total of 21 out of 48 solutions have achieved an efficiency score of 1 without requiring to be combined with other materials. Thick insulation layers are requested in order to achieve efficiency in the majority of the solutions, this proves that reducing the energy demand with insulation achieves lower costs and impacts according to the eco-efficiency score obtained.

Only 7 from 21 hybrid combination were feasible solutions due to the restrictions of the model. More similar materials should be applied in order to increase the number of applicable solutions. Extracting PU would also help to find more applicable solutions. All the 7 hybrid combinations have been able to achieve an efficiency score of 1, providing new materials which could be implemented as insulation layers.

Abstract

In this work, we study the performance of the mixed-integer nonlinear programming solver extended cutting plane (ECP) for solving simulation-based optimization problems. This solver, unlike other commercial derivative-based solvers such as the ones based on the branch and bound or outer approximation algorithms, does not require solving a nonlinear programming problem in each major iteration. This is an important feature of the ECP solver, since solving simulation-based nonlinear programming problems is a complex task due to the absence of accurate derivatives. The approach has been applied in the economic optimization of a rigorous tray-by-tray distillation column.

Keywords: Simulation-based optimization, MINLP, extended cutting plane, Aspen Hysys.

1. Introduction

Sequential modular flowsheeting programs are widely used by chemical engineers for the design and test of chemical processes, both in research and industry. These software packages include thermodynamic libraries and tailored numerical models for a variety of unit operations that lead to accurate predictions for the simulated processes. However, regards to optimization, in particular with problems involving both discrete and continuous decision variables, modular process simulators have not reached the same degree of maturity. This short of optimization problems, called mixed-integer nonlinear programming (MINLP) problems, are the most general, and also the most common in process system engineering.

Significant research efforts for overcoming this weakness or lack of robust and reliable optimization tools embedded in the modular process simulators is currently underway. In essence, in simulation-based optimization, the key issue is how to tackle the optimization of a black-box function.

There are two main approaches to address this problem. We can try to tackle the problem directly and connect the process simulator with an external solver taking advantage of the connectivity capabilities of some modular process simulators. Derivative-based or derivative-free optimization (DFO) solvers can be used. In addition to the difficulties related to the optimization of nonlinear and non-convex problems (intrinsic to some unit operations and the thermodynamic models), the following main

challenges arise. One of the major difficulties is related to the inherent numerical noise of some unit operations. From the simulation point of view, this noise is completely negligible, but in optimization we need accurate derivatives. In a modular process simulator, the only way of getting derivative information of the objective and/or constraint functions is by numerical differentiation, which limits the accuracy and effectiveness of derivative-based solvers.

This problem can be overcome by using derivative-free optimization solvers, since they only require the values of the objective function. Of course, there are significant drawbacks of not having derivative information, and we cannot expect the same performance of the derivative-based methods. The size of the problem that can be efficiently solved by DFO solvers does not exceed a few tens of variables. In addition, these methods do not guarantee the optimality of the solution found. They require a large number of function evaluations, and they exhibit poor performance in highly constrained systems. Despite these difficulties, derivative-based and derivative-free solvers have been employed successfully. For example, Navarro et al. (2014) developed a modelling system that integrates Aspen Hysys with the MINLP logic based outer approximation algorithm. The particle swarm optimization (PSO) algorithm has been used by Javaloyes et al. (2013) for the economic optimization of different distillation processes. And most recently, Ibrahim et al. (2017) used Aspen Hysys and the genetic algorithm for the optimization of crude oil distillation units.

The second approach is based on building a hybrid model replacing the most complex unit operations or set of unit operations by analytically tractable and computationally cheap surrogate models. Then, the subsequent optimization of the resulting model (involving unit operations at the level of the process simulator and explicit surrogate models) can be done using conventional MINLP solvers. For example, Henao and Maravelias (2011) replaced complex unit operations with neural networks models. Then, they use commercial MINLP solvers for solving different chemical process synthesis problems. Quirante et al. (2015) used Kriging surrogate models and derivative-based solvers for the economic optimization of different distillation processes.

The objective of this work is to study the performance of the MINLP derivative-based extended cutting plane (ECP) solver (Westerlund and Pettersson, 1995) for solving simulation-based optimization problems. Despite the challenges related with the calculation of the derivatives, it has been proven that derivative-based solvers can be employed. However (as far as the authors are aware), the proposed approaches do not exploit the main features of the ECP. The ECP solver does not require solving a nonlinear programming (NLP) problem in each major iteration as other state-of-the-art solvers, such as the branch and bound or outer approximation. Solving simulation-based NLP problems is a nontrivial task due to challenges related to the calculation of the derivatives commented above. Thus, finding a solution that satisfies the KKT conditions might be difficult. In addition, the integer/binary variables represent logic decisions, and they represent the structure of the flowsheet for the simulated process. For such variables, it is not possible to run the simulator with non-integer values, and therefore, it is not possible to use a standard branch and bound or outer approximation method for solving the simulation-based problem. The application of the proposed approach to the optimization of a rigorous tray-by-tray distillation column is discussed in this work. The results are compared with the solution found by the derivative-free PSO algorithm.

2. Basics of the Extended Cutting Plane

The ECP method was originally presented as a method for solving convex MINLP problems. The MINLP problems considered here are non-convex, which will require extra attention. The MINLP problems considered here can be formulated as follows

$$\begin{aligned} & \min f(\mathbf{x}) \\ \text{s.t. } & g_j(\mathbf{x}) \leq 0 \quad \forall j = 1, \dots, m, \\ & \mathbf{x} \in \mathbb{R}^N, \text{ some } x_i \in \mathbb{Z}. \end{aligned} \quad (1)$$

Here some of the constraints functions and/or the objective function will be considered as black box functions, and the functions values are given by the process simulator. The main idea behind the ECP method is to construct a linear approximation of problem (1). At iteration k , a linear approximation of MINLP problem (1) is given by

$$\begin{aligned} z^k &= \min \mu \\ \text{s.t. } & f(\mathbf{x}^i) + \nabla f(\mathbf{x}^i)^T (\mathbf{x} - \mathbf{x}^i) \leq \mu \quad \forall i = 1, \dots, k-1, & \text{MILP} \\ & g_j(\mathbf{x}^i) + \nabla g_j(\mathbf{x}^i)^T (\mathbf{x} - \mathbf{x}^i) \leq 0 \quad \forall j \in A_i, \forall i = 1, \dots, k-1, & \text{master} \\ & (\mathbf{x}, \mu) \in \mathbb{R}^{N+1}, \text{ some } x_i \in \mathbb{Z}, \end{aligned} \quad (2)$$

where \mathbf{x}^i are the trial solutions obtained in previous iterations and A_i contains the indexes of the violated constraints at iteration i . By solving problem (MILP master) we obtain a new trial solution \mathbf{x}^k . For convex problems, we know that in case all constraints are satisfied within the desired tolerance and

$$f(\mathbf{x}^k) - z^k \leq \varepsilon, \quad (3)$$

then the solution \mathbf{x}^k is optimal. In case the criteria are not met we continue and the next MILP problem will then contain more linearizations or so called cutting planes. For convex problems the linearizations will underestimate the real functions, which guarantee that no feasible solutions are excluded from the search space, and after some iterations the procedure will converge to the optimal solution.

3. Using the Extended Cutting Plane method for non-convex problems

Since the problems we consider here are non-convex we cannot guarantee that we will find the global optimal solution, and the goal will be to obtain a good feasible solution without having to evaluate the black box function too many times. The main difficulty when applying a linearization based method such as ECP to a non-convex problem is the fact that the linearizations are not necessarily underestimating the real functions. Therefore it is possible that the optimal solution is excluded from the search space by one of the cutting planes. Even worse, it is possible that all feasible solutions are excluded from the search space and that there are no solutions that satisfies problem (MILP master). For the optimization problems considered here we noticed that this issue does occur, and the problem (MILP master) becomes infeasible. This is a known problem, and to handle this issue we use an approach where we solve an optimization problem to restore feasibility of the MILP master problem. If the MILP master problem becomes infeasible, we solve the following feasibility problem

$$\begin{aligned}
& \min \sum_j \sum_i w_i r_{j,i} \\
& \text{s.t. } f(\mathbf{x}^i) + \nabla f(\mathbf{x}^i)^T (\mathbf{x} - \mathbf{x}^i) \leq \mu \quad \forall i = 1, \dots, k-1, \\
& \quad g_j(\mathbf{x}^i) + \nabla g_j(\mathbf{x}^i)^T (\mathbf{x} - \mathbf{x}^i) - r_{j,i} \leq 0 \quad \forall j \in A_i, \forall i = 1, \dots, k-1, \\
& \quad (\mathbf{x}, \mu) \in \mathbb{R}^{N+1}, r_{j,i} \in \mathbb{R}_+, \text{ some } x_i \in \mathbb{Z},
\end{aligned} \tag{4}$$

where $r_{j,i}$ is a new variable which allows a violations of the cutting planes. By solving problem (4), we find the minimum modification of the cutting planes needed in order to make problem (MILP master) feasible. The objective of problem (4) is given by the sum of the residuals $r_{j,i}$ with weights w_i . The weights are used to penalize the residual of the cutting planes differently. Here we have chosen the weights as follows

$$w_i = i^2, \tag{5}$$

where i is the iteration index. By this approach, we allow for larger modifications of the cutting planes added in early iterations compared to the cutting planes added in the later iterations. By solving problem (4) we obtain the minimum residuals $r_{j,i}^*$, and we modify the cutting planes in the problem (MILP master) according to

$$g_j(\mathbf{x}^i) + \nabla g_j(\mathbf{x}^i)^T (\mathbf{x} - \mathbf{x}^i) - 1.5 \cdot r_{j,i}^* \leq 0 \quad \forall j \in A_i, \forall i = 1, \dots, k-1. \tag{6}$$

The cutting planes are relaxed by a factor 1.5 times the minimum modification to further extend the search space, and avoid running into an infeasible MILP problem in the next iteration. The weights of the residuals in problem (4) are introduced to reduce the change of cycling. Without the weights it would be possible to add several cutting planes in one iteration and basically remove them in the next iteration. As for the penalty approach used in DICOPT, we cannot guarantee that this technique will find a solution to non-convex MINLP problems, but for the problems considered here it worked well.

4. Simulation-based optimization approach

A scheme of the proposed approach is shown in Figure 1. The first step is to build a superstructure that includes all the alternatives of interest of the process that we want to optimize. Once the flowsheet is implemented at the level of the process simulator, the objective function must be defined. Typical objective functions such as the total annual cost (TAC), net profit or energy costs can be used according to our main interest. The objective function, as well as the optimization solver, the interface module, and all the auxiliary files are implemented in Matlab. The interface module is a key file in the

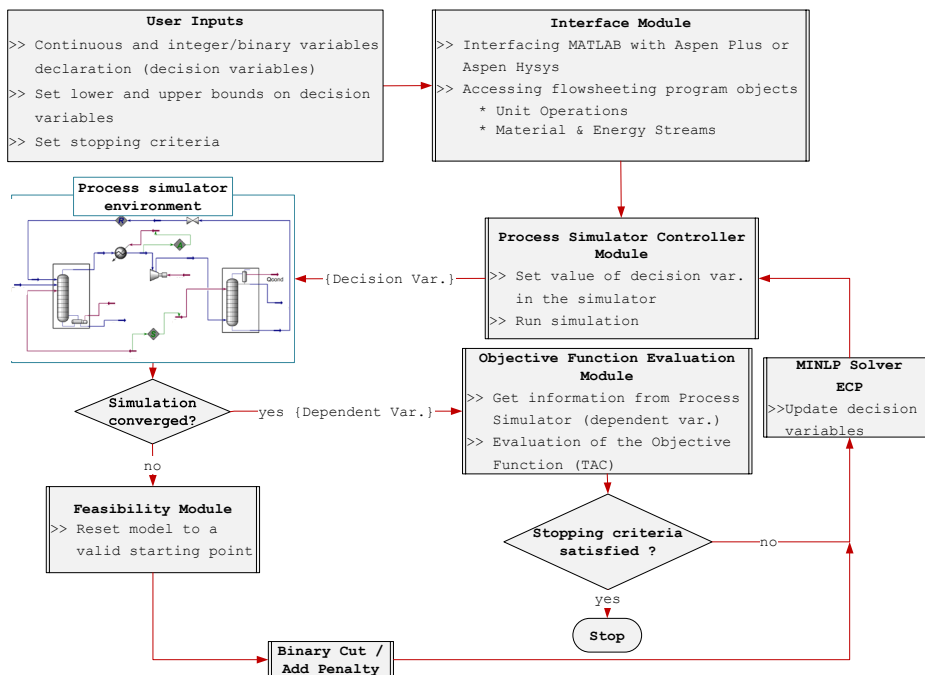

Figure 1. Algorithm flowchart for the simulation-based optimization processes using the ECP.

approach. Sequential modular process simulators such as Aspen Hysys or Aspen Plus can be accessed from external programs via the binary-interface standard Component Object Model (COM), by Microsoft. Thus, we can modify the flowsheet topology and operating conditions of our superstructure according to the values of the decision variables.

After the interface module and objective function have been implemented in Matlab, the algorithm can be executed. First of all, it is necessary to set the upper and lower bounds on the decision variables as tight as possible to avoid convergence problems. Then, the solver is initialized and the values of the decision variables are sent to the process simulator. At this point, the flowsheet is automatically updated and converged. The process simulator returns all the dependent variables needed for computing the objective function and constraints. New values of the decision variables are calculated by the MINLP solver.

5. Case Study

In this work, we consider the economic optimization of a conventional distillation column. The problem can be stated as follow. Given is the feed with known composition and the required purity of the products (distillate and residue). The objective is to determine the optimal number of trays and feed location, as well as the operating conditions that minimizes the total annual cost (TAC). The TAC comprises the annualized investment cost (or capital cost) of the main equipment, and the most relevant operating cost

$$TAC\left(\$/y\right) = C_{op} + FC_{cap}, \quad (7)$$

where C_{op} is the operating cost in (\$/y), C_{cap} is the total cost of installed equipment in (\$), and F is the annualization factor for the capital cost, which can be obtained from Eq. (8), and takes into account the fractional interest rate per year, i , and the years over which the capital is to be annualized, n .

$$F = \frac{i(1+i)^n}{(1+i)^n - 1} \quad (8)$$

The equipment cost (distillation column and heat exchangers) is based on the cost correlations given by Turton et al. (2008). Steam and cooling water are the main utilities considered in the calculation of the operating costs, based on 8,000 operating hours per year. Figure 2 shows the superstructure implemented in the process simulator. The optimal number of trays and feed location are given by the number of active trays in the rectifying (NR) and stripping (NS) section. The problem formulation is also shown in Figure 2. The decision variables are the number of active trays in the rectifying, and stripping section, which are integer variables, and the reflux ratio, RR , boilup ratio, BR , and top pressure, P_{top} , which are continuous variables. The function f_{CDC} refers to the implicit block in the process simulator that contains the set of equations describing the behaviour of the distillation column.

5.1. Results

The results of the optimization of the proposed case study are summarized in Table 1. We solved the problem using the ECP solver and the PSO. Since the PSO is a stochastic DFO algorithm, we run the problem several times. The solution shown in Table 1 is the best one found so far. ECP gave both a better solution and with less function evaluations.

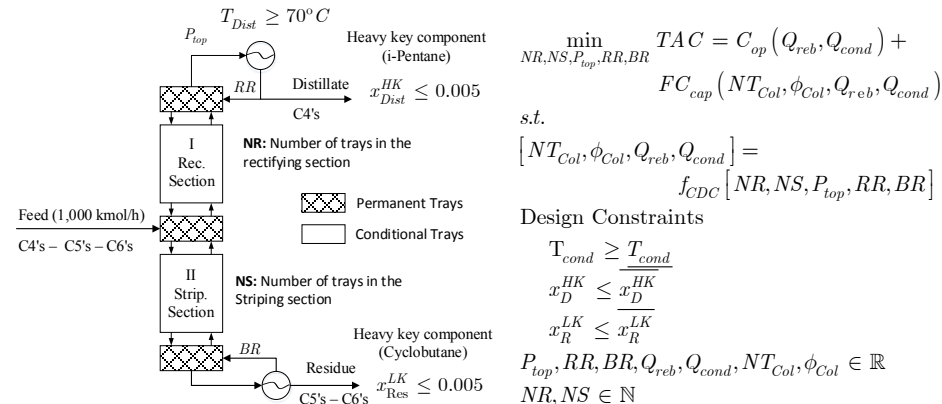

Figure 2. Superstructure representation for the optimal number of trays, feed location and operating conditions of a conventional distillation column, and problem formulation.

Table 1. Results for the optimization of a distillation column using the ECP and PSO algorithms.

Solver	TAC (MM\$/y)	NR	NS	RR	BR	P (bar)	No. Iter.	No. Fun. eval.	Time (s)
ECP	3.185	26	29	2.56	1.70	9.25	88	528	407
PSO	3.334	25	25	2.92	1.87	10.9	160	1600	830

6. Conclusions

Here we have studied the performance of the ECP algorithm for solving a bench mark simulation-based optimization problem. The results are encouraging. Further examples comprising complex flowsheets with recycle streams and large number of unit operations must be done in future work to test the robustness of the proposed approach.

Abstract

This paper proposes a methodology for ontological engineering with an aim to develop reusable ontologies. The proposed methodology combines experience of developing ontology engineering using a ‘good’ practice with established methodologies and concomitantly implementing reusability in the eSymbiosis ontology.

Keywords: Ontological Engineering, Methodology, Ontology Reuse.

1. Introduction

Existing methodologies in ontology engineering focus on good practice of ontology development with primary aim in developing a consistent ontology with a complete description of the domain by following certain and established principles. To our knowledge, the existing methodologies do not appear to consider reusability as a main objective during the process of developing an ontology. Although the main objective of ontology engineering is and should remain to create ontologies which represent knowledge in the domain and which is useful for respective purposes, we argue that a higher level of reusability could be achieved by considering and following comparatively simple steps in ontology design. The proposed methodology, the MetROn, is a result of the experience gained in the course of the eSymbiosis project (Cecelja et al. 2013, Trokanas et al. 2013, Trokanas et al. 2012). The proposed methodology does not intend to dictate how to develop a correct ontology, rather than how to correctly develop an ontology.

2. Reusability characteristics

Representing knowledge is undoubtedly the most important aspect of ontology; there is no point in putting an extra effort in trying to assure reusability of an ontology that is irrelevant to the domain. Existing systems, such as ontology matching, alignment or evaluation, work under an assumption that the ontologies are somehow suitable for the task at hand. Apart from representing the appropriate knowledge, there are various aspects of an ontology that support in facilitating the reusability aspect.

2.1. Modularisation

Modularisation (Morbach, Wiesner & Marquardt 2009, Doran, Tamma & Iannone 2007) extends in three dimensions of the ontology: i) domain, ii) level, and iii)

properties. Domain modularisation refers to the creation of different modules at the domain level. The main criteria are the knowledge representation and the intended use of the ontology in domain modularisation. By using different and more importantly modules representing distinct parts of the domain, the ontology can be reused as a whole, but also in parts, as demonstrated by the example of eSymbiosis ontology in Figure 1, where distinct segments of the domain refer to processing technologies, materials, description of the process using attributes, and description of participants.

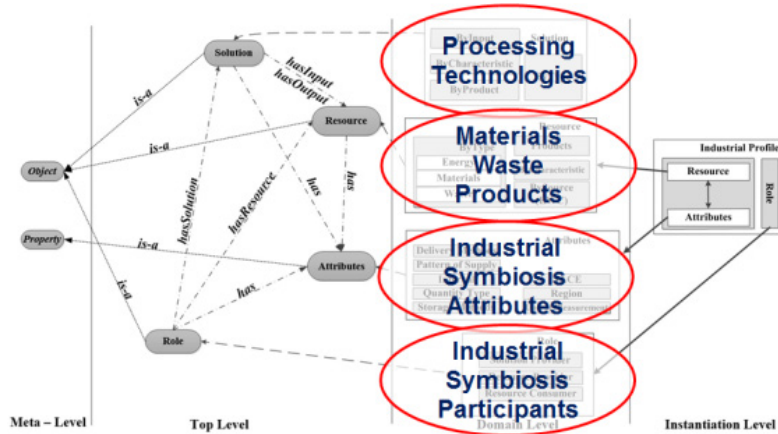

Figure 1 eSymbiosis ontology domain modularisation

Level modularisation serves a similar purpose as the domain modularisation (Figure 2); it is used to differentiate the whole level of abstraction instead of distinct knowledge segments. It is more useful for the reuse of top-level and meta-level ontologies, which usually consist of fewer classes and properties in comparison to the domain level.

Figure 2 eSymbiosis ontology level modularisation

As with concepts, modularisation of the properties in the ontology is also possible and useful. Properties can be grouped along their range, their function, or both. Grouping along the range supports reusability of separate modules of the ontology while grouping along the function supports the reusability of the ontology as a whole, but it also supplements the represented knowledge, as it enables the use of these properties in an application in a more structured approach aiding specific functionalities of the user requirements.

2.2. Naming conventions

Although ontologies are tools for semantic representation, syntactic information still plays an important role in comparing, reusing and generally managing ontologies. It is therefore important for the ontology developers to use consistent terminology and natural language in general; i.e. interchangeably using spellings of both British English and American English can cause discrepancies at large scales. Moreover, naming conventions to improve the readability of an ontology from consistent use of capitalisation for the concept name containing more than one word, as well as use of prefix “has” for properties are known as a good practice that can help towards more accurate similarity calculation and, more importantly, make the ontology more comprehensible (Noy, McGuinness 2001).

2.3. Coherent modelling

Coherent modelling (Fernández-López, Gómez-Pérez & Juristo 1997) has a certain overlap with naming conventions; besides the language used for modelling, it is also important to be consistent with the encoding of the ontology. Here, encoding refers to the use of data types (integers, floats etc.), to the use of external resources, to the use of inverse properties, and also to the modelling of restrictions on properties. For example, an ontology will be inconsistent if a float type is inserted in a slot which has been defined as the integer. The use of unnecessary external resources limits similarity calculations in the process of reusability.

2.4. Detailed annotations

Annotations are key to manual reuse of an ontology (Trokanas, Cecelja & Raafat 2014). They are very helpful to provide definitions, comments and explanations and they can also provide synonyms helping towards better syntactic similarity without the use of external lexicons and vocabularies. Annotations are also used for multilingual modelling.

2.5. Minimum restrictions

Restrictions on properties are application specific. It is therefore good practice to keep them to a minimum when publishing an ontology for reuse. By only defining restrictions at a high level, each module of the ontology is easier to reuse.

3. The MetROn methodology

The proposed metROn methodology combines steps from established methodologies in ontology engineering and experience from developing and implementing the eSymbiosis ontology (Trokanas et al. 2013, Trokanas, Cecelja & Raafat 2014).

3.1. Define domain and application of the ontology

Most of the existing methodologies agree upon the importance of the first step, which is the domain and application of the ontology should be clearly defined. This might include competency questions, market research, user interaction or contribution from domain experts or stakeholders. Competency questions are although useful in ontology

engineering, they are generally replaced by the user requirements if the ontology is developed with a specific application in mind.

3.2. Consider reusing existing ontologies

Redundant efforts can be saved by identifying existing ontologies in the same or complementary domains. As a matter of guidance, existing ontologies are available from the literature as well as from a number of libraries, such as Watson and Swoogle. Reusing of ontologies is a demanding and troublesome task primarily because of the fact that many of the ontologies described in literature are not publicly available, but also often inconsistent. Finally, ontologies that are not updated become more difficult to reuse mainly due to the unavailable repositories (external resources).

3.3. Identify existing classifications, vocabularies and standards

Along with the ontologies suitable for reusability, other sources of useful and structured information can be used. These include existing classifications (e.g. European Waste Catalogue), domain vocabularies (e.g. WordNet), industrial standards (e.g. ISA88) and mark-up language specifications (e.g. B2MML).

3.4. Identify terminology

Terminology of the identified from the source described in 3.3, but also from other sources such as literature, reports, white papers etc. Term identification is performed either manually or automatically with the use of term extraction tools such as TerMine which provide links to ontology editors such as Protégé.

3.5. Define the classes

Once terminology has been defined, concepts representing classes should be organised into groups and respective hierarchy (Figure 3). In consequence, the initial structure of the ontology is formed with distinct modules. There are four suggested approaches for this step.

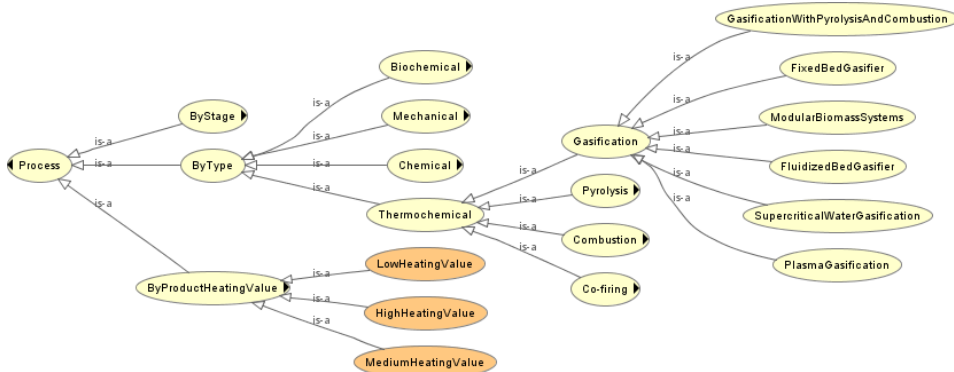

Figure 3 Organising taxonomical structure

The top-down approach begins with the modelling of the high-level concepts first (more general), i.e. Process, ByType, and then moving onto the more detailed concepts, i.e. Thermochemical, Pyrolysis etc. The bottom-up approach is the opposite to top-down; it begins with the modelling of the more specific concepts, i.e. PlasmaGasification,

FixedBedGasifier, which are subsequently organised in more general concepts, i.e. Gasification, Thermochemical. The middle-out approach is usually the first step in ontology design and it begins with modelling concepts which are not categorised as top or bottom level concepts. Still, following middle-out approach is problematic, since it requires knowledge of the ontology structure. The most realistic approach in ontology development, however, is the combination of all the approaches (hybrid). The actual approach the developer will use is dictated by the available knowledge for the domain. Modelling begins from the concepts that are supported by established knowledge and expertise and moves organically to either more detailed or more general concepts.

3.6. Define properties

Properties are derived from the identified terms and are generally dictated by the application requirements in the domain. The definition of properties should start from the top level of the ontology taking advantage of inheritance, therefore reducing the required effort and following good practice.

3.7. Consider reusing existing ontologies

At this stage, reusing existing ontologies step is revisited. This time the aim is not to find ontologies that represent the domain in question, but to identify supplementary ontologies instead. For the case of eSymbiosis ontology, this refer to ontologies representing units of measurement, geographical information etc.

3.8. Create namespaces

Ontologies that are being reused should have meaningful namespaces and the same principle applies for the developed modules of the ontology. The use of meaningful namespaces makes the ontology more comprehensible and serves the very practical purpose of modelling. To explain, the ontology engineer will have to type concept names extensively while modelling properties and restrictions on properties are still in place. As a result, using meaningful namespaces reduces the required effort significantly.

3.9. Define restrictions

Restrictions on properties are application specific. Restrictions are essential in applications that require inference of the ontology. Modelling restrictions at the highest level possible is not only good practice but it also allows for easier manipulation of the restrictions for reuse purposes.

3.10. Annotate the ontology

Annotation of the ontology has a two-fold purpose. Annotation are application specific, i.e. concept names and application information, but it can also be very helpful for reuse, i.e. by providing synonyms and explanations for concepts.

4. Conclusions

MetROn is a methodology for ontology engineering that focuses on developing ontologies that can be reused without compromising the usability of the ontology. The proposed methodology is a result of the experience gained through the development of the eSymbiosis ontology. It has also been validated through the development of another ontology the BiOnto, an ontology for biomass and bioprocessing technologies.

Abstract

Cooling water from the cooling water system is frequently used to reject process heat in chemical industries. The performance of chemical processes could be greatly affected by varying conditions of cooling water. Therefore, there is a need of integration between chemical processes and cooling water system for effective use of cooling water and improve the performance of chemical processes. In this work, a nonlinear programming formulation is developed for operational optimization of integrated recirculating cooling water system and chemical processes. The model is solved to local optimality using CONOPT in GAMS. The results demonstrate the total profit can be significantly improved by 337 k£/y through integration compared to that without integration.

Keywords: optimisation, integration, cooling water, nonlinear programming

1. Introduction

The recirculating cooling water system consisting of cooling towers, cooler network and piping network is widely used to reject process heat in chemical industries in order to keep chemical processes working efficiently and safely. The performance of chemical processes could be greatly affected by varying conditions of cooling water, resulting in a trade-off between process economics and the operating cost of the cooling water system (Song et al., 2017). Therefore, integration of the cooling water system and chemical processes is substantial to improve the overall economics.

Previous studies mainly focused on operational optimization of the cooling water system without integration of chemical processes. For instance, Castro et al. (2000) developed a model for the cooling water system based on the regression model of cooling towers. Modelling cooler network only involves energy balance without considering heat transfer. Cortinovis et al. (2009) proposed a model for the cooling water system where the cooling tower is modelled based on simple mechanism. Modelling the cooler network considered both energy balance and heat transfer. Song et al. (2017) developed a nonlinear model for the cooling water system. When modelling cooling tower, water evaporation was related to both water conditions and ambient air conditions. The cooler network in series and parallel configurations were taken into account, which are not addressed in Castro et al. (2000) and Cortinovis et al. (2009).

There were also some studies on optimization or analysis of integrated cooling towers and condensing turbines without simultaneous optimization. Barigozzi et al. (2014) proposed a modular-based optimization method for integrated cooling tower and condensing turbines to maximize the net power output. Laković et al. (2015) analyzed the effect of ambient air conditions on the energy efficiency of power plants having cooling towers and condensing turbines.

To the best of our knowledge, simultaneous optimization of integrated cooling water system with chemical processes has not been addressed. In this paper, we develop a nonlinear programming model for simultaneous optimization of integrated cooling water system with chemical processes. The model for the cooling water system from Song et al. (2017) is used to determine optimal water and air flowrate to each cooling tower and water distribution in chemical processes. The computational studies demonstrate the total profit can be significantly improved by 337 k£/y through simultaneous optimization compared to separate optimization of the cooling water system and chemical processes.

2. Problem statement

Figure 1 shows a simplified integrated cooling water system with chemical processes including a condensing turbine in a refinery. There are i ($i = 1, 2, \dots, J$) chemical processes and J ($j = 1, 2, \dots, J$) cooling towers. The chemical processes whose economics is affected by operating conditions of the cooling water system are included in the set \mathbf{I}_p . The temperature of a chemical process i after cooling must satisfy some limit. While each chemical process has its own cooler or condenser, each cooling tower has one corresponding fan and pump. In other words, there are also J fans and J pumps. The water fed into a cooler can be from a cooling tower or at least one of other coolers.

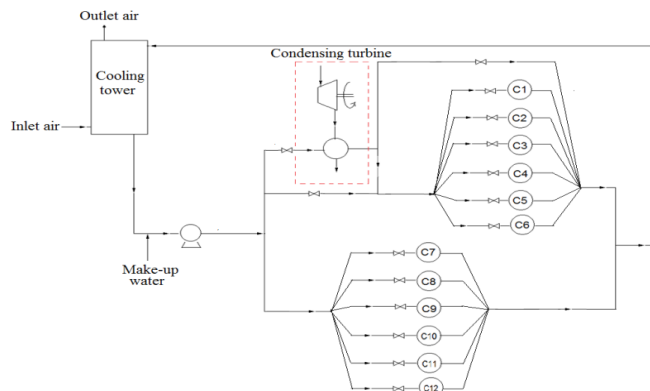

Figure 1 A simplified integrated cooling water system with a condensing turbine in a refinery

Given: characteristics of cooling towers, ambient air conditions, process specifications, cooler configurations and pipe specifications, temperature limit for chemical processes after cooling. *Determine:* cooling water flowrate in individual coolers and towers, air flowrate in individual towers, cooling water temperature produced by towers, the performance of processes, the overall economic performance of integrated cooling water system and processes. *Assumptions:* (i) uniform cross-sectional area of towers; (ii) no supersaturated air from towers; (iii) the properties of cooling water related to

temperature are calculated at the mean temperature of inlet and outlet of individual coolers; (iv) heat loss to the environment is negligible; (v) heat transfer coefficient of processes is constant.

The objective is to maximize the overall profit which is calculated as the revenue from chemical processes minus the operating cost of cooling water systems.

3. Mathematical formulation

3.1. Objective function

The objective function is to maximize total profit, which is represented by eq. (1).

$$TP = \sum_i EP(i) - C1 \cdot \sum_j m_m(j) - C2 \cdot \sum_j [P_p(j) + P_f(j)] \quad (1)$$

where, $m_m(j)$ is make-up water consumption in cooling tower j , $P_p(j)$ is power consumption by pump j , $P_f(j)$ is power consumption by fan j , $C1$ is unit cost of make-up water and $C2$ is unit cost of power, $EP(i)$ is the economic profit from chemical process i , which is influenced by its mass flowrate [$m_p(i)$], the temperature before cooling [$t_{pi}(i)$] and after cooling [$t_{po}(i)$]. The detailed model for process economics very depends on what the process is used for. Therefore, the general formulation is expressed for all the processes with cooling demand as eq. (2). A detailed process economic model for condensing turbines is developed and presented in Appendix.

$$EP(i) = f[t_{po}(i), m_p(i), t_{pi}(i)] \quad (2)$$

3.2. Cooling water system modelling

The model for the cooling water system from Song et al. (2017) is used as follows.

3.2.1. Cooling tower modelling

The temperature of water leaving cooling towers is calculated by eq. (3).

$$t_{wo}(j) = t_{wi}(j) - \gamma1 \cdot NTU(j)^{\gamma2} \cdot m_{wi}(j)^{\gamma3} \cdot m_a(j)^{\gamma4} \cdot (t_{wi}(j) - t_{wbi})^{\gamma5} \quad (3)$$

where, NTU is the characteristics of cooling tower j , $m_{wi}(j)$ is the mass flowrate of cooling water fed to tower j , $m_a(j)$ is dry air mass flowrate, $t_{wi}(j)$ and $t_{wo}(j)$ are cooling water inlet and outlet temperature of tower j respectively, t_{wbi} is ambient wet bulb temperature and $\gamma1$ - $\gamma5$ are coefficients.

The humidity of air leaving towers [$w_o(j)$] is calculated by eq. (4). The water evaporation rate [$m_e(j)$] is predicted by the mass balance, which is expressed as eq. (5). The water consumption [$m_m(j)$] is calculated by eq. (6).

$$w_o(j) = (\beta1 + \beta2 \cdot (t_{wi}(j) - t_{wo}(j)) + \beta3 \cdot (t_{abi} - t_{wbi}) + \beta4 \cdot (t_{wi}(j) - t_{wbi})) \cdot m_{wi}(j)^{\beta5} \cdot m_a(j)^{\beta6} + \beta7 \cdot w_i \quad (4)$$

$$m_e(j) = m_a(j) \cdot (w_o(j) - w_i) \quad (5)$$

$$m_m(j) = \frac{cc \cdot m_e(j)}{cc - 1} \quad (6)$$

where, w_i is ambient air humidity ratio, t_{dbi} is ambient temperature, cc is the cycles of concentration, defined as the ratio between the concentration of dissolved solids in the circulating water and in makeup water, and β_1 - β_7 are coefficients.

Note that the coefficients in eqs. (3) - (6) are regressed using the least square method with the measured data or the operating data.

3.2.2. Cooler network modelling

Energy balance and heat transfer equations for coolers are used to calculate the temperature of water and processes leaving coolers. The heat transfer coefficient of water flowing in the tube side is calculated by the equation from Wang et al. (2012), and that of processes is set to be constant as the flowrate of processes is constant. Cooler network in both parallel and complex configurations are modelled by mass and energy balance.

3.2.3. Piping network modelling

Piping network models are developed by mechanical energy conservation to predict water distribution in chemical processes and power consumption of pumps.

3.3. Chemical processes modelling

The temperature of processes after cooling impacts the thermal and economic performance of processes. Although the detailed model for the calculation of the temperature depends on whether there is a phase change during heat transfer, the elements that influence the temperature are clear, including the water mass flowrate used to cool down process i [$m_c(i)$], the supply temperature of water to cool down process i [$t_{ci}(i)$], the heat capacity flowrate of process i [$CP_p(i)$] and the temperature of process i before cooling [$t_{pi}(i)$]. Generally the temperature of process i after cooling [$t_{po}(i)$] is given by,

$$t_{po}(i) = T[m_c(i), t_{ci}(i), CP_p(i), t_{pi}(i)] \quad (7)$$

The entire model is nonlinear programming (NLP) optimization model, which is solved to local optimality using the solver CONOPT in the software GAMS.

4. Case studies

We use the proposed model to solve three cases involving a forced draft wet cooling tower, a condensing turbine and 12 processes with corresponding coolers, as shown in Figure 1. While in case 1, the operating cost of the cooling water system is minimized without considering the power profit from the condensing turbine, the power generation from the condensing turbine is maximized without considering the operating cost of the cooling water system in case 2. In case 3, the overall profit of the cooling water system and the condensing turbine is maximized. The computational results are listed in Table 1.

From Table 1, it can be clearly observed that there is a trade-off between the cooling water system and the condensing turbine. When the power from the condensing turbine is maximized without considering the operating cost of the cooling water tower, it led to the highest operating cost of the cooling tower. This is similar for case 1 where the

operating cost of the cooling tower is minimized only, resulting in the lowest power generation from the condensing turbine. After simultaneous optimization of the integrated cooling water system and the condensing turbine, the maximum profit of 8,743 k£/y is achieved, which is improved by 337 k£/y compared to case 2. Although there is little difference of the overall economics between case 1 and case 3, the optimal circulating cooling water flowrate in case 3 is about 6416 t/h, which is 367 t/h more than that of 6047 t/h in case 1.

5. Conclusions and future work

In this paper, an equation-based NLP optimisation model was successfully developed for the integrated cooling water systems and chemical processes with cooling demand to improve the overall process economics. The proposed NLP model is solved to local optimality using the solver CONOPT in GAMS. The computational studies demonstrate the total profit can be significantly improved by 337 k£/y through simultaneous optimization compared to separate optimization of the cooling water system and chemical processes. Future work is to investigate integration of the cooling water system with other processes such as compressor inter-cooling, condensation of light components for distillation, and pre-cooling for compression refrigeration.

Table 1 Comparative results for cases 1-3

Units	Results	Base case	Case 1	Case 2	Case 3
Cooling water system	Circulating water flowrate (t/h)	7,560	6,047	9,000	6,414
	Air flowrate (t/h)	8,237	7,267	12,053	7,258
	Operating cost (£/y)	2,012k	1,813k	2,416k	1,844k
Condensing turbine	Inlet cooling water mass flowrate (t/h)	5,287	3,908	6,796	4,246
	Condensate temperature from the condenser (°C)	48.8	50.9	46.7	50.4
	Power generation (kW)	13,360	13,190	13,528	13,234
	Profit from power generation (£/y)	10,688k	10,552k	10,822k	10,587k
Total profit (£/y)		8,676k	8,739k	8,406k	8,743k

Appendix

The detailed model between a cooling water system and condensing turbines is described as heat transfer in condensers

$$Q_{ds}(i) + Q_{cn}(i) = m_c(i) \cdot C_{pw}(i) [tco(i) - tci(i)] \quad (\text{A.1})$$

$$A(i) = \frac{Q_{ds}(i)}{U_{sd}(i) \Delta t_{dsm}(i)} + \frac{Q_{cn}(i)}{U_{cn}(i) \Delta t_{cnm}(i)} \quad (\text{A.2})$$

where $m_c(i)$ is mass flowrate of cooling water in condenser i , $C_{pw}(i)$ is specific heat capacity of cooling water in condenser i , $A(i)$ is the area of the condenser i , $Q_{ds}(i)$ and

$Q_{cn}(i)$ are the cooling duty of the desuperheating and condensing zones in condenser i respectively, $U_{sd}(i)$ and $U_{cn}(i)$ are the overall heat transfer coefficient of the desuperheating and condensing zones respectively, $\Delta t_{dsm}(i)$ and $\Delta t_{cmm}(i)$ are the logarithmic mean temperature of the desuperheating and condensing zones respectively.

$$\Delta t_{dsm}(i) = \frac{[T_{out}(i) - tco(i)] - [T_{cc}(i) - tcc(i)]}{\ln\left\{\frac{[T_{out}(i) - tco(i)]}{[T_{cc}(i) - tcc(i)]}\right\}} \quad (\text{A.3})$$

$$\Delta t_{cmm}(i) = \frac{[T_{cc}(i) - tcc(i)] - [T_{cc}(i) - tci(i)]}{\ln\left\{\frac{[T_{out}(i) - tco(i)]}{[T_{cc}(i) - tcc(i)]}\right\}} \quad (\text{A.4})$$

where, $tci(i)$ and $tcc(i)$ are the inlet and outlet cooling water temperature of the condensing zone, $tco(i)$ is the outlet cooling water temperature of the desuperheating zone, $T_{out}(i)$ is the temperature of the steam leaving turbine i , $T_{cc}(i)$ is the saturated temperature of the steam at the vacuum pressure in condenser i .

The enthalpy of the steam leaving turbine i is calculated by,

$$H_{out}(i) = H_{in}(i) - (H_{in}(i) - H_{is}(i))\eta_{is}(i) \quad (\text{A.5})$$

where $H_{in}(i)$ and $H_{out}(i)$ is specific enthalpy of steam entering and leaving turbine i respectively, $H_{is}(i)$ is specific enthalpy of steam at the outlet pressure having the same entropy as the inlet steam in turbine i , $\eta_{is}(i)$ is the isentropic efficiency of turbine i . The expressions for the relationship among the temperature, pressure and specific enthalpy of steam in IAPWS-IF 97 (2007) are employed to calculate $H_{in}(i)$, $H_{out}(i)$, $H_{is}(i)$ with the temperature and pressure of steam in the corresponding condenser.

Power generation of condensing turbine i ($W_t(i)$) is calculated by Eq. (13).

$$W_i(i) = m_s(H_{in}(i) - H_{out}(i))\eta_m(i) \quad (\text{A.6})$$

where $m_s(i)$ is the mass flowrate of steam into turbine i , $\eta_m(i)$ is the mechanical efficiency of turbine i .

Abstract

Although various kinds of kinetic models were proposed to describe the dynamic behaviour of biologically reacting systems, very little studies have been carried about biosurfactant formation. Its sustainable production, in renewable culture medium, is even more complex. In this sense, emerges the Genetic Algorithm (GA), an effective stochastic global search algorithm inspired in the evolution theory that has been showing a great potential to find optimal solutions in complex systems. This work aims to evaluate the GA's estimation of parameters involved in biosurfactant production from agro-industrial waste using *Bacillus subtilis*. Three different models were proposed to describe biomass growth, substrate consumption, biosurfactant synthesis and dissolved oxygen in the medium. The technique's quality was evaluated by the sum of squared errors (SSE) and correlation coefficient (R^2). The results indicated that the best model to describe the system's dynamics obtained SSE lower than 1 and R^2 superior to 0.97 for almost all the variables.

Keywords: Genetic Algorithm; Biosurfactant Production; Agro-industrial Waste.

1. Introduction

Biosurfactants are surface active molecules that have several applications in petrochemical, food and cosmetics industries, besides an important role in environmental protection, oil spills control, biodegradation, and detoxification of oil contaminated industrial effluents and soil (Khopade et al., 2012). Multiple microorganisms are capable to synthesize biosurfactants from renewable sources that includes agro-industrial wastes such as wheat bran, glycerol from biodiesel synthesis, corn steep liquor and potato peels (Amodu et al., 2016).

Even though many studies have been reported about biosurfactant synthesis, very restricted information is available with respect to its kinetic production, as well as renewable substrate's consumption. This knowledge is essential to optimize and economically favour biosurfactant production in industrial scale, still considered an expensive process.

However, math modelling is complicated once it deals with the metabolism of living organisms, which makes system's behaviour slightly predictable. In these cases,

numerical methods based on gradient are not applied because they often get stuck at local minima. On the other hand, Artificial Intelligence is employed to model and optimize high complexity systems, such as biochemical processes, where the use of exact methods are considerably limited (Link & Weuster-Botz, 2006, Pappu & Gummadi, 2017, Dhanarajan et al., 2017). Stochastic approaches, as Genetic Algorithm, are appreciably strong and effective for its purpose. They are considered the most proper way to find the optimal solution since they are based on probability rules (Chowdhury & Garai, 2017).

This work aims to find the best kinetic model to describe substrate consumption, biomass growth, product formation and dissolved oxygen concentration of a biosurfactant production process performed by *Bacillus subtilis* in renewable medium. The model that best represent the set of variables had its parameters estimated using GA as the global optimum search mechanism.

2. Process Description

The experimental procedure was developed by Santos (2015) and the data was used to model and optimize system's behaviour. The fermentation was carried by *Bacillus subtilis* in a residual glycerine and peel beet broth medium for 24 h. The computational method was realized in MATLAB R2017a with the aid of Global Optimization Toolbox. The optimization function pursues the minimization of the sum of quadratic errors between the experimentally determined concentrations and those obtained through the GA. The tested models were adapted from Monod's (1942), Ghose-Tyagi's (1979) and Megee's et al. (1972) original proposals. At the end of the simulation, the code exhibits the optimized parameters, variable's graphical trend, SSE and R².

2.1 General Equations

The mass balance equations in batch bioreactor that describe the biomass growth, substrate consumption, and dissolved oxygen are listed by Eq. (1) to Eq. (4).

$$\frac{dX}{dt} = \mu_x X \quad (1)$$

$$\frac{dS}{dt} = -\mu_S X + \frac{1}{2} k_1 S_C^k - \mu_{mO_2} S P^n \quad (2)$$

$$\frac{dC_{O_2}}{dt} = k_L a (C_{O_2s} - C_{O_2}) - Q_{O_2} X \quad (3)$$

$$Q_{O_2} = m_o + \frac{\mu_x}{Y_o} \quad (4)$$

where X, S and P are biomass, substrate and biosurfactant concentrations (g L⁻¹), respectively. Additionally, μ_x and μ_S are the specific growth and substrate rates (h⁻¹), S_C is the sucrose concentration (g L⁻¹), μ_{mO_2} is the maximum oxygen consume rate (h⁻¹) and n, k and k_1 are kinetic parameters. The variable $k_L a$ refers to oxygen's volumetric transfer coefficient (h⁻¹), C_{O_2s} is the saturated oxygen concentration (g L⁻¹), Q_{O_2} is the specific consumption rate (g_{O₂} g_{cells}⁻¹ h⁻¹), m_o is the gas' maintenance coefficient (g_{O₂} g_{cells}⁻¹ h⁻¹) and Y_o is the conversion factor to cells (g_{O₂} g_{cells}⁻¹).

2.2 Individual Model Equations

As this paper works with different proposals for microorganism behaviour, the particular equations of each model are exhibited in Table 1. Monod indicated that

specific growth rate depends only on substrate concentration while Ghose-Tyagi suggested that the reaction product could be an inhibitory factor and Megee proposed that the microorganism may consume two different substrates.

Table 1. Individual equations for each tested model.

	Monod	Ghose-Tyagi	Megee
μ_x	$\mu_m \frac{S}{(K_S + S)}$	$\mu_m \frac{S}{(K_S + S)} (1 - \frac{P}{K_p})$	$\mu_m \frac{S_1 S_2}{(K_{S1} + S_1)(K_{S2} + S_2)}$
μ_s	$Y_{xs} \mu_{O_2} \frac{S}{(m_S + S)}$	$Y_{xs} \mu_{O_2} \frac{S}{(m_S + S)}$	$\frac{\mu_x}{Y_{xs}} + m_s$
μ_{O_2}	$\frac{C_{O_2}}{(K_{O_2} + C_{O_2})}$	$\frac{C_{O_2}}{(K_{O_2} + C_{O_2})}$	-
$\frac{dP}{dt}$	$\mu_{O_2} k_3 e^{-m} S^N X - k_2 S P^N$	$k_3 \mu_x X - k_2 S P^N$	$\mu_{O_2} k_3 e^{-m} S^N X - k_2 S P^N$

Notice that μ_m is the maximum specific growth rate (h^{-1}), Y_{xs} is the theoretical biomass yield and K_S and m_S are the saturation constant and maintenance coefficient for substrate (gL^{-1}). The variable μ_{O_2} is the oxygen consumption rate (h^{-1}), K_{O_2} is the oxygen's saturation constant ($g L^{-1}$) and C_{O_2} refers to its concentration ($g L^{-1}$). Finally, k_2 , k_3 , m and N are kinetic parameters and K_p is the inhibition product constant ($g L^{-1}$).

3. Results and Discussion

The kinetic performance of each model for substrate consumption, product formation, cell growth and dissolved oxygen can be measured by R^2 and SSE between the experimental and simulated data. Both decisive criteria are displayed in Table 2. The graphical results for dissolved oxygen and biosurfactant concentrations are exhibited in Figure 1 and Figure 2, respectively. The asterisks represent the experimental values, measured by Santos (2015), and the curves show the dynamic trend calculated by GA.

Once the substrate is consumed by the microorganism, glucose concentration experimental data presented a decrease tendency over 24 h. Ghose-Tyagi's and Megee's models performed the expected decay, stabilizing close to zero in the end of the experiment. The latter best illustrated glucose pattern, achieving $R^2 = 0.9718$. In contrast, Monod's equation did not show the awaited conduct and neither match the experimental data.

The rise and stability of cell concentration during the experiment, was observed in all the simulated models. However, Monod's model was not capable to recognize the existence of an inflection point around 12 h, caused by reduction in growth velocity. On the other hand, both Ghose-Tyagi's and Megee's equations showed trends very near to reality, designing almost perfectly the exponential and stationary phases of biomass growth curve. Yet, R^2 reveals that Megee reached better results.

Every tested model presented a decline pattern for dissolved oxygen in medium. This conduct is expected once biosurfactant is produced by an aerobic route. Although Monod's and Megee's models attained R^2 values close to 1, both reached zero around

10 h of experiment, which do not agree with experimental data. Therefore, neither of them described the awaited behaviour. Ghose-Tyagi's was the only model to correctly predict dissolved oxygen's evolution, obtaining $R^2 = 0.9898$.

Figure 1. Dissolved oxygen results for Monod, Ghose-Tyagi and Megee models.

Figure 2. Biosurfactant results for Monod, Ghose-Tyagi and Megee models.

In respect of biosurfactant production, any of the tested models were able to represent the real trend. Experimental data reveals that biosurfactant production initially increases, but around 9 h it switches the behaviour, exhibiting a fall followed by stability. Monod's and Ghose-Tyagi's models were able to keep up only with the firsts experimental points. On the other hand, Megee's model indicated proper conduct, producing a peak right where the experimental data also presented the maximum point. In addition, it shows the subsequent stabilization approximately at the same time as the experimental data.

Considering the system's complexity, little understanding of microorganism metabolism and lack of knowledge about biosurfactant synthesis kinetics, there are great difficulties to express mathematically the process' behaviour. In addition, renewable media are natural sources that have multiple components in different concentrations. The amount and proportion of these substances are not well known and can influence the development of the microorganisms.

Despite the challenge, Megee's model has proved to be promising to further studies in the area. Although improvements in the equations are crucial to achieve better R^2 , the model's ability to represent the product curve similarly to experimental trend is a notable indication that future in-depth analysis should have optimistic results.

Table 2. R² and SSE for each model.

	Monod	Ghose-Tyagi	Megee et al.	
R ²	Glucose	0.7329	0.9521	0.9718
	Biosurfactant	0.2849	0.0399	0.4162
	Biomass	0.7655	0.9885	0.9941
	Dissolved Oxygen	0.9709	0.9898	0.9705
SSE	1.7021	0.8442	0.6059	

The simulations, as well as SSE and R², indicated that, among all the tested models in this work, Megee’s is the most suitable model to portray *Bacillus subtilis*’ biosurfactant production in agro-industrial waste medium. It presented the higher R² for three of the four variables studied and values greater than 0.97 for almost all of them. Moreover, the SSE is the closest to zero of all models. The optimum parameters calculated by GA for Megee’s model are shown in Table 3.

Table 3. Optimum parameters calculated by GA for Megee’s model.

k ₁	k _L a	Y _{xs}	m _S	K _S	μ _{mO2}	K _{O2}	μ _m	k ₃
0	0.9151	6.75	0.0528	0.2695	0.4179	0.0152	10.50	43.90
m _o	Y _o	N	K	k ₂	K _p	N	M	
0.0083	32.96	0.7828	17.67	0.2651	23.07	1.739	0.1625	

4. Conclusion

Computer simulations are essential to optimize and reduce the costs of biosurfactant production in industrial scale. In this sense, Artificial Intelligence methods such as GA are usually applied. In this paper, three different kinetic models were tested for biosurfactant synthesis from *Bacillus subtilis* in agro-industrial waste growth medium through optimization strategy. Glucose, biomass and dissolved oxygen concentrations had great fitting values in all models. In contrast, the lack of knowledge about biosurfactant production kinetics together with the unpredictability of microorganism metabolism causes great obstacles for math modelling this variable’s behaviour. Still, Megee’s model showed to be promising to further studies. Despite the complexity, the simulations showed optimistic results: SSEs for all models were below 2, implying the errors were acceptable, and most R² near to 1, emphasising the ability to anticipate the experimental data. Although further studies are necessary to better understand the microorganism metabolism in complex growing medium and improvements in the equations are vital, Genetic Algorithm as optimization strategy was satisfactory to provide the model parameters.

Comparison of reformulations of the Duran-Grossmann model for Work and Heat Exchange Network (WHEN) synthesis

Haoshui Yu, Matias Vikse, Truls Gundersen*

*Department of Energy and Process Engineering, Norwegian University of Science and Technology, Kolboern Hejes v. 1A, NO-7491 Trondheim, Norway
truls.gundersen@ntnu.no*

Abstract

Work and Heat Exchange Networks (WHENs) have received increasing attention from both researchers and engineers during the last 5-10 years. The Duran-Grossmann model (Duran and Grossmann, 1986) can deal with heat integration problems with variable process streams. In WHENs, however, the identity of streams (hot/cold) can also change. Therefore, a revised Duran-Grossmann model applied to WHENs without knowing the identity of streams a priori is proposed. The revised Duran-Grossmann model consists of both binary variables and non-smooth functions. To facilitate the solution of the model, the non-smooth functions (max operators) can be reformulated in three ways. The first method is to reformulate the max operator using a Smooth Approximation (Balakrishna and Biegler, 1992). This function incorporates a small parameter, which may lead to either an ill-conditioned approximation or loss of accuracy if poorly chosen. The second method is using Explicit Disjunctions based on principles of the Duran-Grossmann model (Grossmann et al., 1998). To avoid using a max operator, disjunctions explicitly revealing the relationship between the stream inlet/outlet temperatures and pinch candidate temperatures are applied. The last method reformulates the max operator with Direct Disjunctions (Quirante et al., 2017). The max operator picks up the maximum value of two variables, thus it can be straightforward reformulated by a disjunctive programming approach. Even though these three reformulations of the Duran-Grossmann model have been previously investigated, considering uncertain stream identities applied to WHENs has not yet been reported. In this study, all the reformulations and models are implemented in the GAMS (Brooke et al., 1998) modelling framework. For a case study without isothermal streams, Smooth Approximation performs better than the other two formulations.

Keywords: Duran-Grossmann Model, Reformulations, Work and Heat Exchange Networks, Disjunctive Programming, MINLP

1. Introduction

Heat integration focusing on reducing hot/cold utilities is an important technique because thermal energy contributes significantly to the total cost of a process (Huang and Karimi, 2013). If heat integration and process optimization are performed simultaneously, more benefits can be obtained. Duran and Grossmann proposed a mathematical model for simultaneous process optimization and heat integration (Duran and Grossmann, 1986). The Duran-Grossmann model is a powerful tool to solve the heat integration problem with variable process streams. This model has been

successfully applied to organic Rankine cycles system recovering low-temperature waste heat (Yu et al., 2017a), processes for liquefaction of natural gas (Wechsung et al., 2011), and fuel cell systems (Marechal et al., 2005).

Temperature and pressure are both important parameters in the chemical industry. If the pressure is considered while designing Heat Exchange Networks (HENs), the new topic Work and Heat Exchange Networks (WHENs) arise. Pressure specifications on the process streams make the problem more challenging compared with conventional HENs. Holiastos and Manousiouthakis (2002) proposed a mathematical model minimizing hot/cold/work utility cost for HENs. They proposed the term “work utility”, which refers to the generation or consumption of work (electricity or shaft work). Fu and Gundersen (2015a) presented a systematic graphical design procedure for integration of compressors in HENs above ambient temperature. They concluded that compression should be performed at pinch or ambient temperature to achieve minimum exergy consumption. Fu and Gundersen also studied the integration of expanders into heat exchanger networks above (Fu and Gundersen, 2015b) and below (Fu and Gundersen, 2015c) ambient temperature. These studies have similar conclusions about how to optimally integrate pressure changing streams into a background process with minimum exergy consumption. Wechsung et al. (2011) combined Pinch Analysis, Exergy Analysis, and Mathematical Programming to synthesize HENs below ambient temperature with compression and expansion of process streams. The pinch operator is based on the simultaneous heat integration and process optimization idea proposed by Duran and Grossmann (1986).

Since the thermodynamic path and the identity (hot/cold) of process streams are uncertain in WHENs, classical heat integration methods cannot be applied. **In addition**, the identity of streams can also temporarily change in WHENs. This paper mainly applies a revised Duran-Grossmann model to WHENs without knowing the identity of streams a priori. There are three different reformulations for the revised Duran-Grossmann model. This study mainly focuses on the effect of reformulation on revised model.

2. Mathematical model

The WHENs problem can be stated as follows: Given a set of process streams with supply state and target state (temperature, pressure), as well as hot, cold and power utilities; design a network consisting of heat transfer equipment such as heat exchangers, heaters and coolers, and pressure manipulation equipment such as expanders, compressors, pumps and valves with minimum Exergy Consumption or Total Annual Cost.

Since the identity of streams in the WHEN is unknown a priori, the Duran-Grossmann model cannot be applied directly and is extended to a new model using binary variables to denote the identity of streams. In the extended Duran-Grossmann model, separate sets of hot and cold streams no longer exist. Binary variables are used to distinguish hot and cold streams automatically in the model. The extended Duran-Grossmann model is formulated as follows.

Min obj = Exergy Consumption

$$\text{s.t. } h(\omega, x) = 0 \quad (1)$$

$$g(\omega, x) \leq 0 \quad (2)$$

$$T_s^p = T_s^{in} + y_s \cdot HRAT \quad (3)$$

$$QSOA(x)^p = \sum_{s \in S} (1 - y_s) FCp_s \left[\max \{0, T_s^{in} + y_s \cdot HRAT - T^p\} - \max \{0, T_s^{out} + y_s \cdot HRAT - T^p\} \right] \quad (4)$$

$$QSIA(x)^p = \sum_{s \in S} y_s \cdot FCp_s \left[\max \{0, T_s^{out} + y_s \cdot HRAT - T^p\} - \max \{0, T_s^{in} + y_s \cdot HRAT - T^p\} \right] \quad (5)$$

$$Z_H^p(x) = QSIA(x)^p - QSOA(x)^p \quad (6)$$

$$Z_H^p(x) \leq Q_{HU} \quad (7)$$

$$\Omega(x) + Q_{HU} - Q_{CU} = 0 \quad (8)$$

$$\Omega(x) = \sum_{s \in S} (1 - y_s) FCp_s (T_s^{in} - T_s^{out}) - \sum_{s \in S} y_s \cdot FCp_s (T_s^{out} - T_s^{in}) \quad (9)$$

x represents the flow rates and temperatures of the streams involved in heat integration. ω represents all other process variables. Eqs. (1) and (2) denote the process constraints. y_s is a binary variable to denote the identity of any stream $s \in S$, where $y_s = 1$ is used for cold streams. $QSOA$ and $QSIA$ denote the heat load of hot and cold streams above each pinch candidate $p \in P$. $Z_H^p(x)$ is heat deficit above each pinch candidate. $\Omega(x)$ is the heat load difference between hot and cold streams. $HRAT$ denotes the heat recovery approach temperature. The objective function is minimizing the exergy consumption of the system. A detailed model description is beyond the scope of this paper and will be presented as an extended journal publication.

3. Model reformulation

The new model incorporates max operators in Eqs. (4) and (5), which result in non-differentiabilities at T^p . Max operators represent a challenge for deterministic solvers and have to be removed before solving the model. In this study, three methods are proposed to reformulate the model.

3.1. Smooth Approximation

A method using smooth approximations is proposed by Balakrishna and Biegler (1992). Yu et al. (2017b) applied this smooth approximation to design an ORC system recovering waste heat. The max operator is smoothed by the approximation shown in Eq. (10), which can be used to replace the max operators in Eqs. (4) and (5).

$$\max \{0, x\} \cong \frac{1}{2} (x + \sqrt{x^2 + \varepsilon}) \quad (10)$$

ε is a small constant, typically between 10^{-3} and 10^{-6} .

3.2. Explicit Disjunction

To remove the nonsmooth max operator in the Duran-Grossmann model, Grossmann et al. (1998) proposed a disjunctive formulation. The key idea of the disjunctive formulation is the explicit treatment of three possibilities for process stream temperatures: a process stream is totally above, totally below or across the pinch

candidate temperature. As a result, the disjunctions in Eq. (11) can be applied to replace the max operators in Eqs. (4) and (5). R is a large enough parameter to relax the corresponding constraints for hot or cold streams.

$$\left[\begin{array}{c} Y1_{sp} \\ T_s^{in} + y_s \cdot HRAT \geq T^p \\ T_s^{out} + y_s \cdot HRAT \geq T^p \\ T_s^{in,p} = T_s^{in} + y_s \cdot HRAT - T^p \\ T_s^{out,p} = T_s^{out} + y_s \cdot HRAT - T^p \end{array} \right] \vee \left[\begin{array}{c} Y2_{sp} \\ T_s^{in} + y_s \cdot HRAT \geq T^p - y_s \cdot R \\ T_s^{out} + y_s \cdot HRAT \geq T^p - (1 - y_s) \cdot R \\ T_s^{in} + y_s \cdot HRAT \leq T^p + (1 - y_s) \cdot R \\ T_s^{out} + y_s \cdot HRAT \leq T^p + y_s \cdot R \\ T_s^{in,p} = (1 - y_s)T_s^{in} - (1 - y_s)T^p \\ T_s^{out,p} = y_s \cdot T_s^{out} + y_s \cdot HRAT - y_s \cdot T^p \end{array} \right] \vee \left[\begin{array}{c} Y3_{sp} \\ T_s^{in} + y_s \cdot HRAT \leq T^p \\ T_s^{out} + y_s \cdot HRAT \leq T^p \\ T_s^{in,p} = 0 \\ T_s^{out,p} = 0 \end{array} \right] \quad (11)$$

$$QSOA(x)^p = \sum_{s \in S} (1 - y_s) FCP_s(T_s^{in,p} - T_s^{out,p}); \quad QSLA(x)^p = \sum_{s \in S} -y_s \cdot FCP_s(T_s^{in,p} - T_s^{out,p})$$

The disjunctive model can be reformulated by the Big-M method or convex hull method. In this study, LogMIP (Vecchietti and Grossmann, 2004), a specially designed program for disjunctive programming, is adopted as the solver.

3.3. Direct Disjunction

Recently, Quirante et al. (2017) proposed a novel robust alternative disjunctive reformulation. This reformulation shows better relaxation gaps and reduced number of equations and variables. The max operator is directly replaced by a disjunction without physical insights. This reformulation has fewer Boolean variables compared with the previous disjunctive reformulation by Grossmann et al. (1998). The max operator is expressed as follows:

$$\phi = \max(0, c^T x)$$

To avoid using max operators and smooth approximations, the direct disjunctive model is proposed as follows:

$$\left[\begin{array}{c} Y \\ c^T x \geq 0 \\ \phi = c^T x \end{array} \right] \vee \left[\begin{array}{c} -Y \\ c^T x \leq 0 \\ \phi = 0 \end{array} \right]$$

$$Y \in \{True, False\}$$

Then the above disjunction is applied to Eqs. (4) and (5) in the model. The resulting disjunctions are shown in Eq. (12). The Direct Disjunction model is formulated with Eq. (12) to replace the max operators in the model, and it is also solved by LogMIP.

$$\left[\begin{array}{c} Y_{in} \\ T_s^{in} + y_s \cdot HRAT - T^p \geq 0 \\ \phi_{in} = T_s^{in} + y_s \cdot HRAT - T^p \end{array} \right] \vee \left[\begin{array}{c} -Y_{in} \\ T_s^{in} + y_s \cdot HRAT - T^p \leq 0 \\ \phi_{in} = 0 \end{array} \right]$$

$$\left[\begin{array}{c} Y_{out} \\ T_s^{out} + y_s \cdot HRAT - T^p \geq 0 \\ \phi_{out} = T_s^{out} + y_s \cdot HRAT - T^p \end{array} \right] \vee \left[\begin{array}{c} -Y_{out} \\ T_s^{out} + y_s \cdot HRAT - T^p \leq 0 \\ \phi_{out} = 0 \end{array} \right] \quad (12)$$

$$QSOA(x)^p = \sum_{s \in S} (1 - y_s) FCP_s(\phi_{in} - \phi_{out}); \quad QSLA(x)^p = \sum_{s \in S} -y_s \cdot FCP_s(\phi_{in} - \phi_{out})$$

4. Case study

This case study is adopted from the study by Fu and Gundersen (2015a). The stream data is listed in Table 1. C1 needs to be compressed from 100 kPa to 300 kPa. The hot and cold utilities are supplied at 400°C and 15°C respectively. The model proposed in this study can determine the optimal temperature of C1 before compression. The results are consistent with the study by Fu and Gundersen (2015a). For detailed results, please refer to their study (Fu and Gundersen, 2015a). It should be noted that disjunctive programming models can be reformulated into MINLP models by the Big-M or convex hull methods with LogMIP as the solver for the Explicit and Direct Disjunction models. BARON (Tawarmalani and Sahinidis, 2005) is adopted as the MINLP solver.

Table 1. Stream data for the case study

Stream	T^{sup} (°C)	T^{or} (°C)	FCp (kW/°C)	ΔH (kW)	P^{sup} (kPa)	P^{or} (kPa)
H1	300	50	4	1000	-	-
H2	120	40	4	320	-	-
C1	70	380	3	930	100	300
C2	30	180	3	450	-	-

Table 2 shows the computational performance of each reformulation. It is clear that Smooth Approximation performs much better than the other two reformulations in this case. Smooth Approximation has fewer continuous variables and significant fewer binary variables. The computation time is also considerably less than the other two reformulations. The Direct Disjunction model has more disjunctions and continuous variables but fewer binary variables compared with the Explicit Disjunction model. The convex hull reformulation is better than the Big-M method in this study for both Explicit and Direct Disjunction. This case is a simple and small size problem and only non-isothermal streams are considered. It should be emphasized that the Smooth Approximation might cause numerical problems when isothermal streams or multiple utilities are involved. For cases without isothermal streams, Smooth Approximation performs better than other reformulations. More examples will be tested in future work.

Table 2. Computational results for the case study

Items	Smooth Approximation	Explicit Disjunction		Direct Disjunction	
		Big-M	Convex hull	Big-M	Convex hull
Disjunctions	-	49	49	98	98
Continuous Variables	168	411	908	462	994
Binary Variables	4	151	151	102	102
CPU time (s)	17.5	207.3	196.3	76.6	61.2

5. Conclusions

An extended Duran-Grossmann model is applied to WHENs in this study. Three different reformulations of the model are presented. Even though these three reformulations have been investigated before, reformulations considering uncertain stream identities applied to WHENs have not yet been reported. The computational efforts and results of different reformulations have been compared. For the case study, the results show that the Smooth Approximation outperforms the other two reformulations. However, this case study represents a small size problem. Large problems will be tested in future work. Isothermal process streams and multiple utilities

should also be considered. The small parameter ε in the smooth approximation and the Big-M value in the disjunctive programming models have significant influence on the solution of the problems. More detailed investigations will be performed in future work.

Abstract

Biorefining is a dynamic field with ever growing number of computer models developed, heterogeneous data acquired and generally new knowledge generated in large volumes, all to serve functions at different scales and for different purposes. Sharing and reusing of these resources, especially models and data, inherently saves developing time, but also enables solving ever more complex problems and addressing ever more complex functions. This, in turn, necessitates efficient networking tool to allow for publishing, discovery, but also inferring new knowledge and integration of resources, dominantly computer models.

This paper introduces a semantic networking facility developed to enable an efficient reuse and sharing of knowledge and resources in the domain of biorefining. This networking facility, which is built around model integration platform, allows for knowledge and other resources in the domain of biorefining to be accessible by humans, but also by agents and services. It is organised as a collaborative, WiKi like platform, aiming to facilitate collaboration and to bring biorefining community together by sharing knowledge and resources. The operation of the proposed facility is supported by a biorefining domain ontology, but also by Semantic Media Wiki extension. The features of the Biorefining Semantic Wiki include semantic repository of the biorefining models, model discovery and integration tool, supply chain networking and demonstration, documentation, including published article repository and discovery, forum for the community and with active social media of the biorefining community. The operation of Biorefining Semantic Wiki has been implemented as a semantic web service and its operation verified in practice.

Keywords: wiki, semantic technologies, biorefining community, knowledge sharing

1. Introduction

There is lack of online knowledge sharing and collaboration environments in the domain of biorefining despite the fact that the benefits of these have been widely acknowledged. The field of biorefining comes with a vast amount of heterogeneous models and data in different formats and produced by different developments and for different purposes, which have potential to be available to share and reuse. To this end, we propose a semantic networking facility developed to enable an efficient reuse and sharing resources whilst providing access to the knowledge in the domain of biorefining to both humans and machines. The operation of the proposed facility is supported by the biorefining domain ontology (Koo et al., 2017b), Web Ontology Language Semantic Mark-Up for Services (OWL-S) framework and Media Wiki extended by Semantic

Media Wiki which annotates the pages with machine processable information. Main services include i) semantic repository for biorefining datasets and models, ii) model and data discovery and integration tool, iii) repository of publications and recorded documentation and respective discovery facility, iv) repository of practical experimentation, implementation and case studies, and v) forum for the community including active social media of the biorefining community (Figure 1). Implemented as a multilingual web service, the proposed facility serves different categories of users; i) administrator ensuring a smooth operation, ii) editor auditing contributions and changes, iii) publications authors, iv) contributor of datasets and other resources, and v) subscribers benefiting directly from the facility.

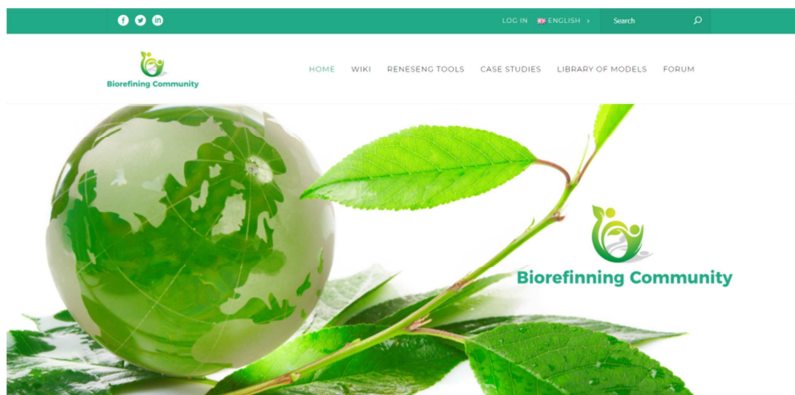

Figure 1 Homepage of the Semantic Networking Facility.

2. The Architecture and Features

2.1. Semantic repository of biorefining models

Important component of this facility is the biorefining dataset and model repository at different scales. The repository is populated by users the biorefining community members, who want to share model(s) or data. Each model and dataset is considered as a web service and is semantically described in terms of its functionality, inputs required for a successful execution, outputs generated in the course and after the execution, and preconditions for the model to run. This knowledge is acquired through a registration phase where model descriptions are registered as the ontology instances. The actual models and datasets remain with the owner and assuring a full ownership hence further motivating sharing with no risk of losing the respective intellectual proprietary or commercial value. In terms of technology this is accomplished by using OWL-S framework (Martin et al. 2007), a set of interlinked ontologies for semantically describing web services and combined with the biorefining domain ontology InterCAPEmodel (Koo et al., 2017a). To this end the InterCAPEmodel ontology provides i) classification and relations for semantically describing datasets and models for the purpose of registration, and ii) common vocabulary for model and dataset discovery and integration (Koo et al., 2017a).

2.2. Model discovery and integration tool

Efficient discovery and integration of biorefining models and data remain to be a challenging task due to the large amount as well as the heterogeneity. The process has

been developed by the CAPE-OPEN standard which supports model reusability and interoperability (Braunschweig et al., 2004). Still, efficiency and flexibility in model and data discovery and hence integration remains a challenge primarily because the model interface semantics are implicit, understandable by humans, but difficult to allow for automation controlled by machines. In order to automate model discovery and subsequently model integration, we propose a semantic service which annotates biorefining models with a machine readable description. To this end, models and data are semantically described using the key parameters and during the registration stage when the semantic repository is populated. The discovery process is supported by the well-established OWL-S framework and relies on the semantic annotation of models and data, and the input/output matching approach introduced by Cecelja et al. (2015). Here, the input/output matching is a two-stage matching process including i) matching the tacit properties established by calculating similarity measures which define the level of compatibility between the requesting and candidate models and data ii) matching the explicit properties by input/output property matching, and iii) ranking of the candidate models by their similarity measure. A dedicated Input/Output matchmaker is developed in JAVA performing matching and ranking by the level of semantic similarity.

2.3. Biorefining Semantic Wiki

Wikis are a very popular collaboration tool operation on the web and many online communities employ wikis to exchange knowledge. Wiki manage online content in a quick and easy way, mainly as plain text. Best known example of Wiki is Wikipedia. In terms of technology and implementation Wikipedia is powered by Media Wiki engine, open software initially developed for Wikipedia and later on used by many wiki projects. Although the data in this Wikis is structured, it is unclear to computers because it is not represented in a machine-processable way. Users can easily link between two articles in wikis to indicate a relationship but not so to indicate the nature of that relationship in a way that is computationally accessible to the system or to external developers. To improve this a wiki can use the Semantic Media Wiki (SMW) extension which enables to semantically annotate wiki pages with explicit, machine-readable information, based on which the wiki contents can be browsed, searched, and reused in novel ways. The representation difference between a wiki and a semantic wiki is illustrated in Figure 3 with the case of an article about London (Figure 2) and giving specific information about it as area and population. Annotation of pages in SMW is established using properties and types. Properties are used to express binary relationships between one semantic entity (as represented by a wiki page) and some other such entity or data value (Krötzsch et al., 2007).

The image shows a screenshot of a Semantic Media Wiki (SMW) page for "London". The page is titled "London" and includes a navigation menu on the left with options like "Main Page", "People", "Events", "Help", "browse", "RDF Feeds", and "Recent changes". The main content area displays a paragraph: "London is the capital of [England](#) and of the [UK](#). As of [2005](#), the total resident population of London was estimated [7,421,328](#). Greater London covers an area of [609 square miles](#)." Below this, there is a "Facts about London" section with a table of properties and values:

Property	Value
Area	1.5773e+9 m ² (157,730.276 ha, 1,577.303 km ² , 609 miles ²)
Capital of	England, and United Kingdom
Population	7,421,328

The "Category" is listed as "City". The page also includes a "Log in / create account" link in the top right corner and tabs for "article", "discussion", "edit", and "history".

Figure 2 A semantic view of London from Krötzsch et al 2007.

A semantic wiki is set up and integrated with the proposed facility where experts of the domain can use this dedicated online space to publish the output of their work in the form of scientific articles, case studies or other forms, participate in discussions and contribute in or benefit from the advancement of the biorefining field.

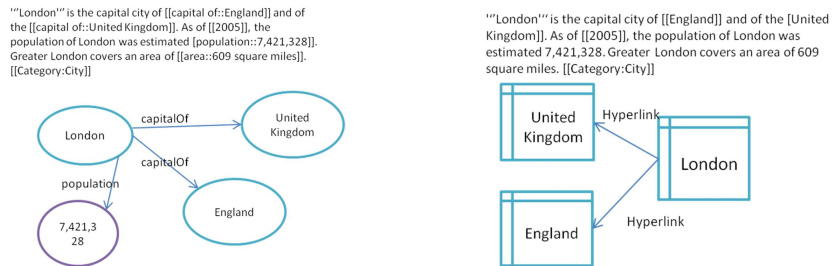

Figure 3 A page about London in MediaWiki (right) and in SMW (left).

The use of semantic annotation becomes beneficial when exploiting the semantics described in those annotations. SMW offers several features for that. In the example of London from Figure 2 is shown also a section called *Factbox* which summarises the given annotations *area*, *capital of* and *population*. The *Factbox* supports browsing the wiki based on its semantic content by showing the annotations (reference) in that page, all annotations where the given page is used as value and performing an inverse search for all pages with similar annotations by using the magnifier icon behind each value (Figure 2). The *RDF Feed* link in the *Factbox* allows exporting data in RDF format.

SMW includes as well a query language to access the wiki knowledge and the possibility to map all formal semantics of annotations to the OWL DL ontology language. SMW query language can be used to directly query the wiki, or to add the answer to a page by creating an inline query. In the OWL DL mapping all normal pages correspond to abstract individuals, properties correspond to OWL properties, categories correspond to OWL classes, and property values can be abstract individuals or typed literals using appropriate URIs as identifiers to prevent confusion with URLs of the wiki's HTML documents.

All together and with the compatibility to both OWL and RDF this enables a maximal reuse of SMW's data.

2.4. Forums and social profiles

The forum for sharing knowledge, ideas and solutions to different problems that the individuals of the community face in their research is part of the semantic networking facility in a dedicated area. The forum is managed and maintained by an administrator but the users are free to share their opinions and to create new topics for discussion or to ask for help and support from experts of the biorefining domain.

Social profiles of Facebook, Twiteer and LinkedIn are integrated with the semantic publishing facility and the biorefining community can easily share the contents of the biorefining domain with other networks. Further, if the users own an FOAF ("friend of a friend") (Kalemi and Martiri 2011) profile or would like to use the FOAF ontology to say thing about people of the community and their relation with other people or objects, they can accomplish this by importing the ontology in the semantic wiki. FOAF is ontology to describe people and their social network in a semantic way. FOAF could get used within many wikis for annotating user pages, or describing articles about people.

3. Use Cases

3.1. Discovering models

The following is a use case of model discovery for the purpose of model integration. As the first step (Figure 4, Step 1) the user defines the request which contains the functionality of the requesting model, the characteristics and the inputs that it needs.

Step 1

Figure 4 Demonstrating model discovery and integration functionality.

As a second step (Figure 4, step 2) a list of candidate models will be listed, ranked based on the quantified semantic relevance between the requesting model and the candidate models that have been previously stored in the repository. Based on this result and other details that come with each candidate model, the user can choose the model that will be integrated with the requesting model.

3.2. Populating the semantic wiki

In this use case we demonstrate how we create a page containing information about a journal article titled “A semantic framework for enabling model integration for biorefining”, define the authors, say thing about the authors using the FOAF ontology terms. In Figure 5 is given the code behind the wiki page that the user sees in Figure 6. Properties as *Has author*, *Has Doi* are self defined and the properties *name*, *mbox* and *homepage* are imported from FOAF ontology.

Model Integration

A semantic framework for enabling model integration for biorefining

Authors Linsey Koo Nikolaos Trokanas Franjo Cecelja

<https://doi.org/10.1016/j.comchemeng.2017.02.004>

Abstract

This paper introduces a new paradigm for establishing a framework that enables interoperability between process models and datasets using ontology engineering.

Semantics are used to model the knowledge in the domain of biorefining including both tacit and explicit knowledge, which supports registration and instantiation of the models and datasets.

Semantic algorithms allow the formation of model integration through input/output matching based on semantic relevance between the models and datasets. In addition, partial matching is employed to facilitate flexibility to broaden the horizon to find opportunities in identifying an appropriate model and/or dataset. The proposed algorithm is implemented as a web service and demonstrated using a case study.

4. Conclusions

A semantic publishing facility has been introduced to bring together the biorefining community. Through this platform the members of biorefining community at different level of expertise can share the results of their work in various formats, models and data, as well as successful case studies. The benefit of using the tools offered by the platform and the solutions are provided from other experts through forums and discussion pages. As future work we plan to improve and add more tools to our list, to enrich the repository of model and article and to motivate the community to be active in all collaborative activities that the platform offer.

Abstract

In this work, the effects of waste-based energy closed-loop integration under internal energy demand uncertainty on the multi-objective optimization of supply chains (SC) is analysed and compared. The proposed approach is based on developing a waste-based closed-loop energy integration MOO model to optimize the strategic and tactical decisions of country-size SCs in the presence of conflicting objectives. A stochastic multi-scenario mixed-integer linear program (MILP) is proposed and the capabilities of the approach are illustrated through a case study from a Sugar cane industry reported by Mele, et al. (2011). Additionally, this approach enables to consider and manage the financial risk associated to the different strategic/tactical decisions, resulting in a set of Pareto optimal solutions. It is shown that the stochastic solution improves the economic performance of the SC in comparison with the deterministic one at any level of the environmental impact. In fact, the stochastic approach optimizes the conflicting objectives as well as improves the whole system robustness compared to the deterministic one and should be therefore the preferred choice in practice.

Keywords: waste-based energy, multi objective optimization, risk management, Optimization under uncertainty, closed-loop energy integration

Introduction

Waste-based energy integration provides an effective solution for both problems; it increases the waste valorisation while cogenerating energy. Optimization of waste-based energy generation supply chains has recently received much attention. In this regard, several models have been proposed as decision support tools for strategic analysis, along with tactical planning of bio-energy SCs.

Perez-Fortes et al., (2014) and recently Cambero, et al., (2016) proposed Multi objective models focused on proposing an optimal design/planning of a biomass conversion system along with optimizing economic benefits environmental impacts associated with all the SC stages. However, these authors have not proposed a closed-loop energy integration model within multi objective optimization framework for a generic SC.

Regarding uncertainty management, extensive studies have been done focusing on demand in SCs (Ruiz-Femenia et al. 2013), but to the best knowledge of the authors,

only the works by Sabio et al. (2014), and Guillen-Gosalbez & Grossmann (2009 & 2010) have studied the effect of uncertainties in the environmentally conscious SCs. These authors introduced a multi objective mixed-integer linear program that explored a simultaneous optimization the economic and environmental performance of the SC under uncertain conditions. However, and further investigation opportunities cannot be taken into account, demand uncertainty in energy closed-loop integration SCs has not been targeted in their models. Accordingly, the proposed approach is to merge generic SCs with biomass SCs and develop a waste-based closed-loop energy integrated MOO model considering energy demand uncertainty to optimize the strategic and tactical decisions of country-size SCs in the presence of conflicting objectives.

Problem statement

According to the approach previously outlined, the proposed model determines a generic waste-based energy integration SC network that is illustrated in Fig. 1. The goal of the study is to determine solutions associated with structural and operational decisions that can be considered more reliable. These decisions include the number, location and capacity of the process plants (including the technologies selected in each of them); warehouses and cogeneration units to be set up, and their capacity expansion policy; and the transportation links between the SC entities. The operational decisions are the cogeneration level, the production rate at the plants in each time period, the flows of materials between plants, warehouses and product markets, and the sales of final products and excess energy.

The SC configurations obtained by means of deterministic mathematical programming can be compared with those determined by different stochastic scenarios representing different approaches to face uncertainty. Additionally, this approach enables to consider and manage the financial risk associated to the different design options, resulting in a set of Pareto optimal solutions that can be used for decision-making.

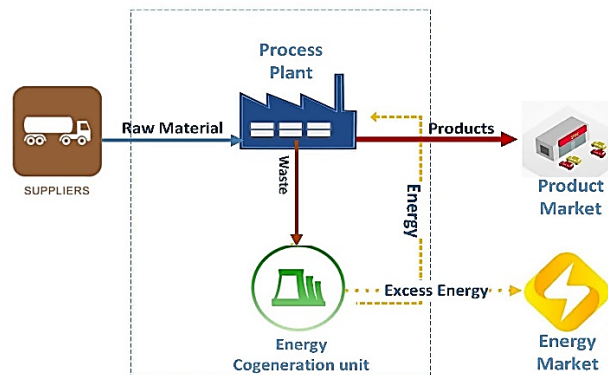

Fig 1. Waste-based Energy closed loop Integration SC

The result of the model provides sets of Pareto solutions to be used by the decision maker in order to take the optimum tactical/strategical decision.

Multi objective stochastic Model

The proposed approach relies on a two-stage Stochastic Mixed Integer Linear Programming (MILP) to incorporate the uncertainty associated to the energy demand. In

this line, the uncertainty is represented by a set of scenarios with given probability of distribution and the mathematical formulation of such model is described as following.

A stochastic programming MILP model based on the one introduced by Mele et al. (2011) is proposed. The model equations are classified into four main blocks: mass balance equations and capacity constraints of the production process section, mass/energy balance equations and capacity constraints of the energy cogeneration section and objective function equations.

3.1 Energy cogeneration section

The amount of cogenerated energy ($Qe_{g,t,sc}$) in region g time period t for scenario sc is less than the energy amount produced from the wastes of process plants ($w_{g,t,sc}$) (Eq. 1). ρ is energy output per metric unit of the waste mass (Illukpitiya et al. 2013).

$$Qe_{g,t,sc} \leq \rho \times w_{g,t,sc} \quad \forall g, t, sc \quad (1)$$

The total amount of energy generated ($Qe_{g,t,sc}$) is also limited by the internal energy demand ($ED_{g,t,sc}$) (Eq. 2)

$$Qe_{g,t,sc} \geq ED_{g,t,sc} \quad \forall g, t, sc \quad (2)$$

and the cogeneration unit capacity ($CogenCap_{g,t}$) (Eq. 3).

$$Qe_{g,t,sc} \leq CogenCap_{g,t} \quad \forall g, t, sc \quad (3)$$

The operational cost ($OprCost_{t,sc}$) associated to each cogeneration unit is determined for each time period (Eq. 4). CE is defined as the cost of producing a unit of energy.

$$OprCost_{t,sc} = \sum_g Qe_{g,t,sc} \times CE \quad \forall t, sc \quad (4)$$

The excess energy is marketed and the associated revenue ($Rev_{t,sc}$) is given in Eq. 5.

$$Rev_{t,sc} = \sum_g (Qe_{g,t,sc} - ED_{g,t,sc}) \times EPrice \quad \forall t, sc \quad (5)$$

3.2 Objective functions

The whole SC system whose model has been described before must attain two targets: the economic objective is represented by the NPV whereas environmental concerns are quantified by the global warming potential (GWP).

3.2.1 Expected Net present value

Different NPV values are obtained for each scenario under study (NPV_{sc}) once the uncertainty is unveiled. The model described before must account for the maximization of the expected value ($E[NPV]$) of the resulting NPV distribution, which can be computed by performing an average of the aforementioned NPVs as stated by Eq. (6):

$$E[NPV] = \sum_{sc} Prob_{,sc} \times NPV_{sc} \quad (6)$$

3.1.1.1 Financial risk

For the two-stage stochastic problem, the financial risk associated with the economic objective is determined with the help of the following constraints:

$$DRisk = \sum_{sc} Prob_{,sc} \times \delta_{sc} \quad (7)$$

$$\delta_{sc} \geq \Omega - NPV_{sc} \quad \forall sc, \delta_{sc} \geq 0 \quad (8)$$

The resulting objective functions are finally expressed as follows:

$$\text{Min}\{-E[NPV]; GWP\} \quad \text{S.t. constraints 1-8 and the constraints proposed by (Mele et al., 2011)} \quad (9)$$

The solution of this problem consists of a set of Pareto optimal SC configurations. These are obtained in this work by applying the ε -constraint method.

Case Study

It is revisited herein the first example introduced by Mele et al., (2011) that addresses the optimal retrofit of an existing sugar cane industry established in Argentina. There are 5 different technologies available to manufacture 2 main products: ethanol and sugars. Nominal capacity of the sugar mill and distillery plants are 350 and 300 thousand tons per year. A time horizon is divided into a set of time periods, and a specific geographic area is divided into a set of regions where the facilities of the SC can be configured. Each region has an associated supply (sugar cane crop) capacity in every time interval. The by-product (bagasse) is supposed to be sent to cogeneration units to generate electricity as added-value product. Energy demand uncertainty is represented by 3 scenarios. On the basis of Illukpitiya et al. (2013) assumptions, the estimated total electricity requirement for internal use in the processing plants is 160 kJ per kg of cane. It is assumed that the nominal capacity of the power plant is 8.33 MW and the power generation is available on a continuous basis for at least 7800 h annually. The electricity market price and the operational cost of electricity generation are 0.15USD/kWh and 0.08USD/kWh respectively.

Results

Figure 2 compares the results obtained by the deterministic and stochastic approaches. Not only the deterministic model exhibits less $E[NPV]$, but it also presents higher probabilities of low profits. For instance, the deterministic solution exhibits a 10% probability of NPV below 3M\$, while the stochastic configuration yields only a 1.5%. In addition, in Fig. 2, both solutions are compared under the same CO2 emissions level.

The associated operative Pareto curves show how the stochastic solution performs better than the deterministic one for the entire range of CO₂ emissions levels. It is also interesting to point out that, for the same cogeneration capacity of 8.33MW (Fig.3), the stochastic solution allows operating at most for energy demand so that leads to involve more regions in generating waste-based energy and using waste as bio energy. In other words, cogenerated energy in the whole SC not only meets the internal energy demand but also the excess energy can be marketed to increase NPV by 10%.

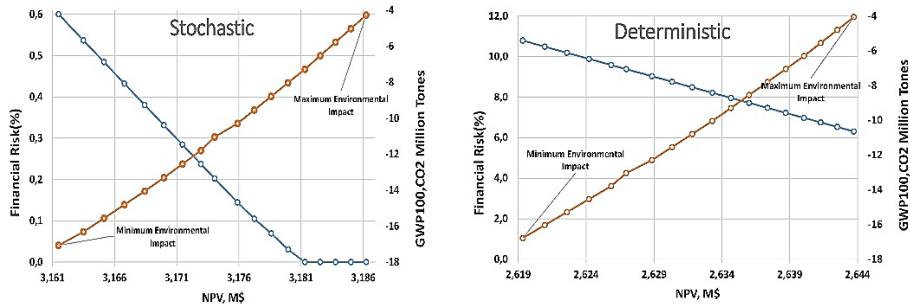

Fig. 2 Pareto set of solutions GWP100 vs NPV and associated Financial Risk

Fig. 3 Energy generation per Region in Deterministic and Stochastic solutions

Fig. 4 Disposal Cost Reduction vs Sugar Cane Purchasing Amount

The results show (Fig. 4) that the stochastic energy demand scenarios lead to overall disposal costs decrease 3.1% in the stochastic solution while only by 12% increase in

purchasing amount of sugar cane not only the energy demand can be satisfied but also it can be marketed by adding 97.5 Million USD to the annual revenue.

Conclusions

This work has addressed the optimal design and planning of waste-based energy integrated SC under uncertainty. In order to discover further investigation opportunities, the problem is mathematically formulated as a bi-criterion stochastic MILP that accounts for the maximization of the expected NPV and minimization of the environmental impact (in terms of GWP). The effects of this uncertainty are accounted as a risk associated to the NPV, which has been introduced as an additional constraint into the model. Then, this risk can be managed to reduce the probability of having low profit. The capabilities of the model were highlighted through its application to a case study. The proposed stochastic approach maximizes the expected profit while satisfying at the same time a minimum environmental impact. Numerical results show that the stochastic solutions improves the deterministic one and should be therefore the preferred choice in practice. The optimal solutions are obtained according to the amount of waste used to cogenerate energy, which is directly related to the objectives. The interaction between the design objectives has been shown. This way of generating different possible configurations will help the decision-maker to determine the best design according to the selected objectives.

Abstract

This paper is concerned with assessing the behaviour of entropy, or the production of entropy, when analysing the performance of a reactive system in which Plug Flow Reactors (PFR) are used. To describe the process properly when using this type of reactor, the well-known balances of mass and energy have been turned to, besides the balance of entropy as its set is more appropriate for describing the processes with constraints of Nature, which they normally undergo. The strategy adopted consisted of minimizing entropy production. The aim was to keep the correlations of force between energy and entropy, given by the Gibbs energy, in balance with a minimal disturbance in the level of organization of the reactive system. A simple exothermic reactive system was evaluated for several wall temperatures. For the conditions analysed, no significant difference was noted between the entropy production profile and its minimum. Moreover, the results indicate a positive correlation with the wall temperature either of conversion or of the entropy production rate throughout the length of the reactor. The conclusion that can be drawn reveals that the reactive system operates under the minimum entropy condition and that the analysis developed, based on entropic modelling, succeeded in presenting essential and decisive details for assessing and improving the performance of a PFR either from a design or from an operational point of view.

Keywords: minimum entropy, optimization, PFR, thermodynamics

1. Introduction

The chemical industry is continually faced with an aggressive market, and constantly needs to upgrade processes, to reduce systemic costs and additionally to comply with increasingly severe, new environmental regulations.

To deal more appropriately with the aforementioned problems, the authors of this study considered that the following statement of O'Connell (2017) was worth further examination, namely that there seems to be less exploration of entropy generation in chemical process systems, where chemical reactions and diffusive mass transfer are involved, especially in reaction-separation.

Therefore, this paper focuses on the analysis of entropy in seeking a solution for these problems in the context of the author's research interest, which is as follows: given that Plug Flow Reactors (PFRs) are among the most used models in the industrial sphere, mainly for chemical reactions in the gas phase, it is vital to analyse them so as to tackle the above-mentioned problems. To describe the process properly using this type of reactor, the well-known balances of mass and energy have been systematically used,

based on First Principles. Although the First Law of Thermodynamics can result in an energy balance *par excellence*, it does not deal adequately with the constraints of Nature which the processes undergo, and this may generate sub-optimal results (Manzi and Carrazoni, 2008). Since the description of the general problem cannot be appropriate, then the introduction of the entropy balance can make the approach more realistic. In reactive systems the correlations of force between energy and entropy expressed by Gibbs free energy, $g = h - Ts$, plays a pivotal role from either the thermodynamic or economic point of view (Andresen, 2011).

Given that the classical methodologies for designing reactive systems have sought to lead the process to a minimum energy condition (Bejan, 1996) and considering that the natural tendency for increasing entropy is always present, it is desirable to reduce the energy bound together with the increase in entropy because this will make the process more spontaneous. On the other hand, an increase in entropy can be sufficiently high for it to affect the level of organization of the reactive system. Consequently, this will generate an undesirable large number of by-products. Because such by-products should be removed, treated and disposed of, the overall energy cost can be very high.

Thus, the aim of this paper is to assess the behaviour of entropy, or particularly, the production of entropy, when analyzing the performance of a reactive system. The strategy adopted for minimizing the entropy production rate was developed considering that concentration can be expressed as a function of temperature, which makes the implementation of the procedure straightforward. A simple exothermic reactive system was evaluated for several wall temperatures, aiming at also the generation of concentration and temperature profiles. Moreover, the area depicted under the profile of the entropy production has been considered for analysis with the wall temperature and conversion throughout the length of the reactor.

2. Theoretical Background

A PFR can be represented by a set of partial and differential equations of mass and energy along the length of the reactor. Some assumptions on the modelling are made: radial gradients are neglected, the volumetric flow rate is constant, the diffusion terms are negligible, which is valid when the linear velocity is high, and the drop in pressure does not generate external heating, cooling or even work.

The mathematical modeling is given by:

$$\frac{\partial C_i}{\partial t} + \frac{\partial C_i}{\partial z} v_z = -r_i \quad (1)$$

$$\rho c_p \frac{\partial T}{\partial t} + \rho c_p \frac{\partial T}{\partial z} v_z = \Delta H_R (-r_i) \pm \dot{Q} \quad (2)$$

where r_i is the reaction rate based on the Arrhenius equation.

Additionally, the entropy balance is embedded in the model and this results in:

$$\frac{\rho c_p}{T} \frac{\partial T}{\partial t} + \frac{\rho c_p}{T} \frac{\partial T}{\partial z} v_z = \frac{\dot{Q}}{T} + \dot{\sigma} \tag{3}$$

in which $\dot{\sigma}$ denotes the entropy production rate.

As the main purpose is to minimize the entropy production rate, some aspects should be observed. According to Hardy (2014), the idealization of a reversible process is regarded as useful because almost all real processes are irreversible. Thus, the minimization leads the system for reversibility, which is associated with a steady state. This is the reason why only Eqs. (1), (2) and (3) in their particular steady states will be considered in this paper. Making use of such a consideration, as well as of the equations given above, the relationship that represents the entropy production rate can be found as follows:

$$\dot{\sigma} = \frac{\Delta H_R}{T} (-r_i) \tag{4}$$

Considering the PFR is in a certain number of blocks or sections, the balance equations can be applied in each of these blocks. For each block, the values for concentration (C) and temperature (T) can be found, thus generating profiles of concentration and temperature throughout the length of the reactor.

Since the minimum entropy rate is a function of temperature and concentration, to make the minimization procedure easier, Eq. (4) must be re-arranged so that it becomes dependent only on a single variable. By solving jointly Eqs. (1) and (2), a temperature/concentration pair is generated for each section, and so it is not difficult to find the functional relationship between temperature and concentration. By choosing a small interval for the section, it is easier to find one variable as a function of the other by linear interpolation. Such a procedure ensures that the linearization does not have large deviation values. What remains to be done is to consider the classical criterion for establishing the minimum, that is, to express Eq. (4) as a function either of temperature or concentration, and to apply the derivative related to the chosen variable, making it equal to zero. The strategy is shown in Fig. 1

Figure 1: Sequential pairs (C_i, T_i) generated along the length of the reactor and pairs used for the interpolation procedure.

3. Results and Discussion

A case study, based on the classical work of Bilous and Amundson (1956), is presented which applies the methodology shown in this paper. A simple reaction $A \rightarrow B$, first order and exothermic, is carried out in an unpacked PFR that is submitted to several

constant wall temperatures. Some details, kinetics and thermodynamics, about simulation are presented in Table 1.

Table 1: Nominal operating conditions and kinetic parameters for the PFR

E	$9.405 \times 10^7 \text{ J/(kg.mol)}$	M	$0.0073 \text{ (m}^3.\text{K)/mol}$
k_0	$6.566 \times 10^{10} \text{ s}^{-1}$	N	$3.33 \times 10^{-3} \text{ s}^{-1}$
R	$8.314 \text{ cal/(mol.K)}$	C_0	$2 \times 10^{-4} \text{ mol/m}^3$
T_0	340 K		

The parameters M and N refer to simplified terms in the energy balance where

$$M = -\frac{\Delta H_R}{\rho c_P} \quad \text{and} \quad N = \frac{2h}{r \rho c_P}.$$

Fig. 2 shows the profiles of concentration and temperature found by simulating several wall temperatures. Some of these profiles present a peak, indicating that the reaction is completed at this point.

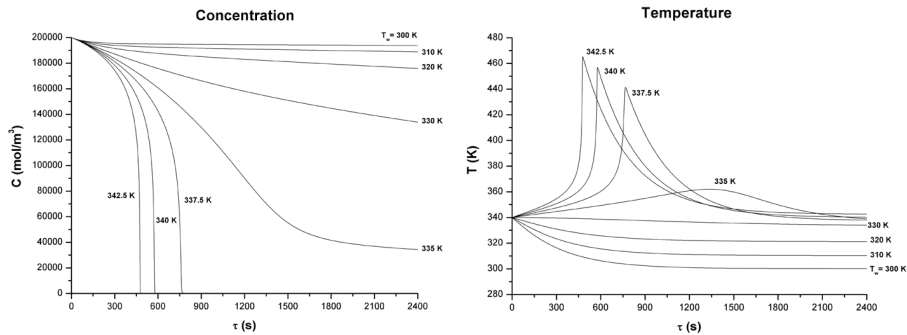

Figure 2: Concentration and temperature profiles submitted to several wall temperatures

Fig. 3 shows the behaviour of the rate of entropy production, its minimum value and the areas corresponding to the entropy production for some temperatures. The area under the curve of the entropy production rate denotes the entropy production throughout the length of the reactor.

By analysing jointly the conversion given in Fig. 2 and the entropy production rate profiles in Fig. 3, it is easy to verify that an increase in the wall temperature generates a desired increase in the conversion but an undesired increase in the entropy production, throughout the length of the reactor.

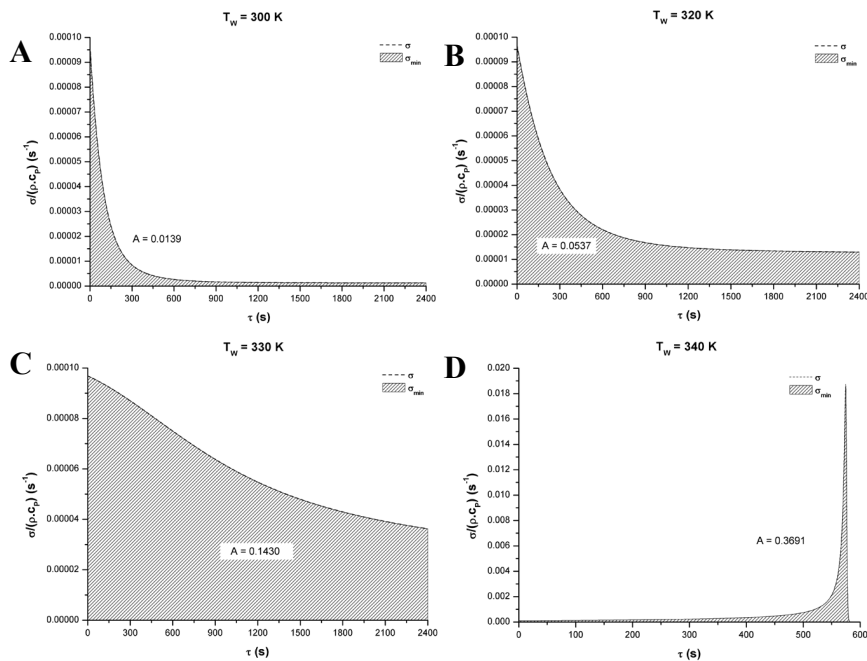

Figure 3: Entropy production and the behavior of the entropy production rate and their minimum values for some wall temperatures. A) $T_w = 300\text{K}$ B) $T_w = 320\text{K}$ C) $T_w = 330\text{K}$ and D) $T_w = 340\text{K}$.

In this case, the profiles of the entropy production rates and their minimum values have followed the same trajectory, indicating that such systems work close to reversibility, thus yielding their best performances. For the sake of clarity, to understand for what reasons the entropy production rate has the same behavior as its minimum value, the following should be taken into account. The velocity of the fluid or of the energy associated with it has been considered constant with a little dispersion, along the length of the reactor, which is quite reasonable. This means that the energy spectrum or the probability density function for the energy is substantially closed. Thus, the change in the kinetic energy that corresponds to the magnitude of the work available for breaking the chemical bonds desired is very appropriate, because this generates collisions and complete ruptures between molecules, which can lead to yielding the desired product. In other words, the work is very close to the energy required to break the chemical bonds. From this, it can be inferred that the question of selectivity is directly involved in the energy distribution function and that the ratio of the sections of the energy distribution function can provide a good approximation of the degree of selectivity.

Since concentration and the entropy production have been shown to have significant and particular correlations with the wall temperatures for the reaction type considered, then such a feature can give rise to an economic analysis that depends on each process type as well as on the constraints imposed by the *modus operandi*. This must be carried out by assuming a trade-off between conversion and the entropy production in order to yield the most favourable cost-benefit ratio, the aim of which is to extract the best operating conditions and configuration for the process.

4. Conclusions

In this paper, model-building has been presented for a PFR, which takes into account both Laws of Thermodynamics, including the entropy balance, besides kinetic concepts. Some simplifications have been considered by neglecting mainly the radial gradients and the diffusion terms. These assumptions are valid when the linear velocity is high enough. Such an approach has enabled the entropy production rate to be derived.

A strategy was developed for obtaining the profiles of conversion, temperature and for the minimum entropy production rate, in which linearization and optimization procedures were introduced as a subroutine in the main scheme of the optimizer.

The results showed that the profiles for the minimum entropy production rate and its minimum follow the same trajectory, indicating that PFRs work under the minimum entropy conditions and this is strongly desired.

Finally, the conclusion that can be drawn is that the methodology developed, based on modelling entropy, proved to have a significant analytical potential, which presents essential and decisive details for assessing and improving the performance of a PFR either from a design or an operational point of view. What remains to be done is to undertake an economic analysis for each process considered and to assume that a trade-off between conversion and the entropy production will result in the best cost-benefit.

Abstract

This work focuses on the exergy analysis of an extractive distillation column in the second-generation bioethanol production process. The study of the exergy performance of the separation and purification section is relevant from a thermodynamic point view due to the large amount of the energy consumed by their unit operations. A sensitivity analyses of the separation section, the location of the feeding stages for the solvent and the ethanol-water azeotropic mixture, the reflux ratio and solvent/feed ratio were performed for obtaining the minimum energy consumption in the column reboiler. Finally, the profiles of exergy components, irreversibilities and the exergy efficiency for the base case and enhanced case were compared. The results show a 29.21 % decrease on the irreversibilities and a corresponding increase of 22.82 % in the exergy efficiency for the separation section. The simulation as well as the sensitivity analyses were done using a connection between the process simulator Aspen Plus v 8.8 and Excel.

Keywords: Exergy analysis, bioethanol, sensitivity analysis, extractive distillation.

1. Introduction

Bioethanol is an organic biofuel that has been identified and utilized as an alternative fuel to reduce the fossil fuels usage. The production of bioethanol consists of numerous unit operations that allow obtaining high-purity grade ethanol from lignocellulosic biomass that constitutes a renewable substrate that may contribute to environmental sustainability. This raw material can be obtained from agricultural residues at low-cost and high availability and its main constituents are cellulose, hemicellulose and lignin (Limayem and Ricke, 2012).

Despite the advantages of second-generation bioethanol, the high energy consumption in pretreatment, fermentation and separation sections have limited its industrialization to only a few countries like Brazil or USA (Waldron, 2010). These countries are developing research with the aim of maximizing process efficiency. Exergy analysis is a powerful tool that allows evaluating and analyzing processes by identifying their imperfections due to thermodynamic irreversibilities.

Therefore, the objective of this work is to perform an efficiency analysis that provides exergy profiles within the purification section and to present opportunities for improvements in the design of an Extractive Distillation Column (EDC). The aim is to reduce energy consumption in a bioethanol production process by using a computer-aided based approach.

2. Exergy Analysis

Exergy is the maximum theoretical work that can be obtained from a system when it is brought to thermal, mechanical and chemical equilibrium with an environmental state of reference. Exergy content in open systems can be classified by its origin: a) exergy accompanying energy flows and b) exergy accompanying material flows. For material flows, exergy can be further divided into: thermo-mechanical or physical exergy and chemical exergy (Marmolejo-Correa and Gundersen, 2015).

Thermo-mechanical exergy in Eq. (1) is defined by differences in enthalpy ($H-H_0$) and entropy ($S-S_0$) from the current conditions of the system (T, P) to the ambient conditions (T_0, P_0). Where T and P stand for temperature and pressure, respectively.

$$E^{ph} = H - H_0 - T_0(S - S_0) \quad (1)$$

Chemical exergy for a non-ideal mixture is shown in Eq. (2) and proposed by Szargut (1989), where x_i are mole fractions, ε_i are the standard chemical exergy and γ_i are the activity coefficient of each component.

$$E^{ch} = \sum_{i=1}^n (x_i \varepsilon_i + x_i \ln \gamma_i x_i) \quad (2)$$

The irreversibility rate (I) in the EDC is calculated developing an exergy balance as shown in Eq. (3), where, E_{IN} and E_{OUT} are the total exergy rates entering and exiting the column, respectively. $\sum E^Q$ is the total exergy flow accompanying the heat entering in reboiler and exiting condenser of the column.

$$E_{IN} - E_{OUT} + \sum E^Q = I \quad (3)$$

The rational efficiency defined by Kotas (1995) is shown in Eq. (4).

$$\psi = \frac{E_{IN} - E_{OUT}}{\sum E^Q} \quad (4)$$

Exergy analysis applied in bioethanol production processes, (Ojeda et al., 2011; Silva Ortiz and de Oliveira Jr, 2014) usually reports overall analyses to the complete processes. However, these studies do not include a stage-by-stage analysis for the EDC. The standard chemical exergy of the components present in the study are shown in Table 1.

Table 1 Standard Chemical Exergy (ϵ), MJ/kmol of the Main Components.

Component	Standard chemical exergy	Component	Standard chemical exergy
Water	3.12	Cellulose	3,404.40
Ethanol	1,364.56	Xylan	3,449.50
Glucose	2,793.20	Lignin	3,449.50
Xylose	1,835.30	Ash	0.00
Arabinose	2,328.08	Enzyme	145.60
CH ₃ COOH	908.00	CaSO ₄	4.30
H ₂ SO ₄	108.60	Ca(OH) ₂	62.50
DAP	220.98	Glycerol	1,999.27
Protein	145.60	<i>Z. mobilis</i>	540.47
CO ₂	19.09		

The standard chemical exergy of ethanol, water, CO₂, calcium sulphate (CaSO₄), calcium hydroxide (Ca(OH)₂), H₂SO₄ and CH₃COOH were obtained from Kotas (1995). For the components enzyme, glucose, cellulose, xylose and lignin the used values were the reported by Ojeda et al. (2011). The values of diammonium phosphate (DAP), arabinose, glycerol and *Zymomonas mobilis* were obtained by using Eq. (5), where, [C], [H], [O] and [N] are the atomic fractions for each element in the evaluated component.

$$\epsilon = 4.19 \left\{ \begin{array}{l} 8177.8[C] + 5.25[N] + 27892.6[H] - 3173.7[O] \\ + 0.15[O](7837.7[C] + 33888.9[H] - 4236.1[O]) \end{array} \right\} \quad (5)$$

3. Description of Bioethanol Production Process

The second-generation bioethanol production plant was simulated employing the Aspen Plus v 8.8 process simulator and divided into five stages: pretreatment, overliming, saccharification, fermentation and separation (Sánchez et al., 2013). The analysis was carried out taking wheat straw as raw material with a mass flowrate of 7,752.13 kg/h with composition in mole fraction of 0.47 of water, 0.34 of cellulose, 0.15 of xylan, 0.05 of lignin and traces of ash. In the saccharification section, the cellulose that cannot be dehydrated during the pretreatment section is converted into glucose with the help of enzymes that favor its reaction. During fermentation the fermentable sugars presents in the stream are converted into ethanol by *Z. mobilis*.

The ethanol purity obtained after fermentation must be raised up to 99.6 % to be utilized as a fuel. The latter is accomplished by setting a series of distillations columns as shown in Figure 1. The first column is called concentration column and it is used to increase the ethanol concentration in the product stream by eliminating the solids and low volatility compounds. The outlet stream of the concentration column contains ethanol at 80 % in mole base. Next, an EDC is used. In this, both, product and solvent streams are fed to the column. The solvent (in this case glycerol) breaks the azeotrope between ethanol and water by lowering the volatility of the water favoring the separations and high ethanol purity in the distillate stream. The molar based purity of the ethanol is 99.6%.

Figure 1. Separation Section on Bioethanol Production Plant.

The EDC was further analyzed through sensitivity analysis to obtain better operating conditions that allow lower energy consumption. Exergy analyses for comparing the exergy efficiency of base case and enhanced case were also performed.

4. Computer-Aided Tools Integration for Exergy Analysis

The simulator Aspen Plus v 8.8 has a shortcoming regarding exergy calculations, because it does not calculate chemical exergies of process streams. It only calculates physical exergies. In this work interconnections between the Aspen Plus and spreadsheets in Microsoft Excel were used for calculating chemical exergies of the material streams and irreversibilities in unit operations. The variables such as, H , S , x_i , mole flows (n), T and heat duty (Q) were imported to spreadsheets for further use in chemical exergy calculations. Figure 2 shows the six stages of the methodology used for exergy calculations inside the EDC. This methodology is used for the rest of the material streams and unit operations of the total bioethanol processes.

5. Results

The search range for the feed location of azeotropic mixture and solvent varied from stage 2 to stage 19, the molar reflux ratio (RR) from 0.10 to 10.00 and the solvent to feed molar ratio (S/F) from 0.10 to 5.00. Table 2 shows the results obtained in this study. Figure 3a and 3b shows the results of the sensitivity analysis. It is observed that feeding stages for the solvent and azeotropic mixture in stages 4 and 12, respectively, the energy rate is reduced from 1.81 MW to 1.75 MW in the reboiler. This energy rate is the lowest for a fixed RR of 0.5 and S/F ratio of 0.45, these ratios are obtained from sensitivity analysis showed in Fig 3b. Figures 3c and 3d show the physical and chemical exergy profiles, respectively.

Figure 2. Systematic Methodology to Integrate the Calculations of E^{ch} and I .

Table 2. Results of Exergy and Sensitivity Analysis in the Both Cases Studied.

Results	Base case	Enhanced case
Solvent feed location	2	4
Azeotropic mixture feed location	10	12
RR	0.50	0.50
S/F	1.00	0.45
Reboiler heat duty, MW	1.81	1.75
Irreversibility, MW	0.35	0.25
Rational efficiency, %	1.18	24.00

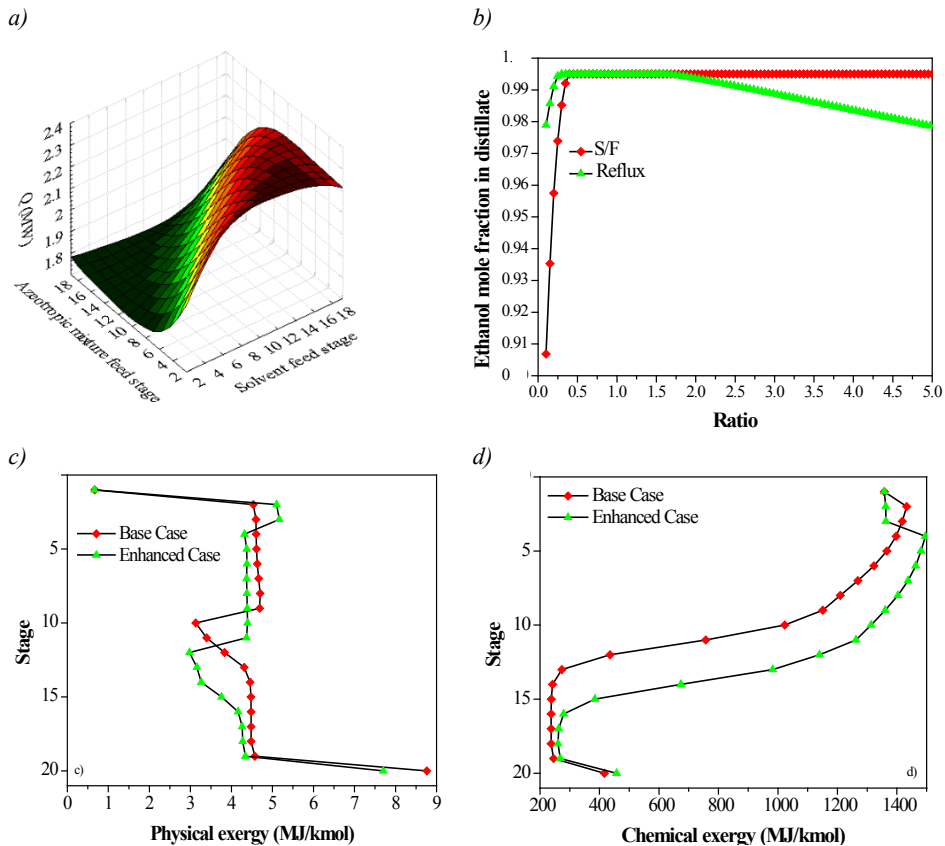

Figure 3. Results of the sensitivity analysis: a) feed location and b) reflux and S/F ratios. Exergy profiles: c) physical exergy profile and d) chemical exergy profile.

The chemical exergy profiles have a kink in the solvent feeding stage where the maximum chemical exergy is visible. Because of these stages, the greatest glycerol concentration is located, and the standard chemical exergy of this solvent is greater than that of ethanol and water. One can also note that in Figure 3c both curves start and end at

the same points, meaning that the chemical exergies of the top and bottoms are the same for ethanol and water/glycerol mixture standard chemical exergies, respectively.

The increase in total exergy in the enhanced case means that the capacity of obtain power of the product stream of the EDC increased after the sensitivity analysis increasing the efficiency of the column. This efficiency was calculated using Eq. (4), obtaining a value of 1.18 % and 24.01 % in the case base and enhanced case, respectively. The irreversibility was also calculated in both cases using Eq. (3) obtaining a reduction from 0.35 MW to 0.25 MW in the case base and enhanced case, respectively.

6. Conclusions

The extractive distillation column increases its efficiency in 22.82 % from the conditions reported by Gil et al. (2012) to the propose operating conditions by this work. This proposal does not increase the number of stages and decreases the energy consumption in the reboiler. Additionally, the incorporation of rigorous calculations of chemical exergies in Aspen Plus v 8.8 helped to perform the exergy analysis of the complete plant that will be shown in further publications.

Abstract

Most optimization problems with endogenous uncertainty can be modelled as multistage stochastic programs (MSSPs). The MSSPs grow exponentially with the increase in the numbers of scenarios and time periods, and quickly become computationally intractable for real-world sized problems. This paper presents a Relaxed Knapsack-problem based decomposition Algorithm (RKDA) to efficiently generate tight dual bounds for large-scale MSSPs. The algorithm builds upon the Knapsack-problem based Decomposition Algorithm (KDA) (Christian and Cremaschi, 2015), which generates feasible solutions for MSSPs with endogenous uncertainty by decomposing the original multi-period MSSP into a series of knapsack problems and by solving these problems at appropriate decision points of the planning horizon. The new approach, RKDA, employs KDA to solve a relaxed version of the original MSSP. The relaxed MSSP is obtained by removing its resource constraints. We applied KDA and RKDA to generate initial primal and dual bounds for the pharmaceutical clinical trial planning problem with two-, three-, four-, five-, six-, seven- and ten-products and three clinical trials with different planning horizon lengths. The results revealed that the initial relative gaps ranged from 2.10% to 4.66%, and KDA and RKDA yielded these gaps in 0.1 to 2377.0 CPU seconds.

Keywords: stochastic programming, endogenous uncertainty, knapsack-problem based decomposition heuristic, primal and dual bounds

1. Introduction

Optimization problems with decision-dependent, i.e., endogenous, uncertainty are commonly observed in process industry, e.g., R&D pipeline management (Colvin and Maravelias, 2010), synthesis of process networks with uncertain process yields (Tarhan and Grossman, 2008), and artificial lift infrastructure planning (Zeng and Cremaschi, 2017). In these problems, decisions may impact the resolution time (Type II) and/or the probability distributions of the uncertain parameters (Type I) (Apap and Grossmann, 2017). This paper restricts its scope to optimization problems with Type II uncertainty.

One approach to address these problems is multistage stochastic programming, which is a scenario-based method that considers decisions and recourse actions in multiple stages as uncertainty is realized. Each scenario defines a unique set of realizations for all uncertain parameters. In MSSP formulations of problems with endogenous uncertainty, decision variables are defined independently for each scenario. To prevent decision variable values that anticipate future outcomes of uncertain parameters, non-anticipativity constraints (NACs) are explicitly incorporated to MSSP formulations. Size of decision variables and

NACs grow exponentially as the number of uncertain parameters and the number of outcomes for each uncertain parameter increase. This growth results in both space and time complexities for solving MSSPs for real-world sized problems. In general, the solution approaches for large-scale MSSPs with endogenous uncertainty rely on heuristic, approximation, and decomposition methods, such as sample average approximation algorithm (Solak et al., 2010), improved Lagrangean decomposition framework (Gupta and Grossmann, 2014), sequential scenario decomposition approach (Apap and Grossmann, 2017), a branch and bound algorithm (Christian and Cremaschi, 2017) and a rolling-horizon heuristic approach (Colvin and Maravelias, 2009). It has been shown that moderate-size problems can be solved to optimality.

Here, we presents a Relaxed Knapsack-problem based Decomposition Algorithm (RKDA) to generate tight dual bounds for large-scale MSSPs with endogenous uncertainty. The algorithm builds upon the KDA (Christian and Cremaschi, 2014). Instead of enumerating all uncertain parameter space as scenarios, the KDA decomposes the original multi-period MSSP into a series of knapsack problems and solves these problems at appropriate decision points of the planning horizon. It provides tight primal bounds for the original problem, and generates these bounds several orders of magnitude faster than solving the original MSSP. The RKDA generates a tight dual bound by employing a relaxed version of the KDA to solve a relaxed version of the original MSSP. The relaxed MSSP is obtained by removing its resource constraints. The application of RKDA is demonstrated by solving instances of clinical trial planning problem, which is introduced in Section 2. Then, we describe KDA and RKDA (Section 3). In Section 4, we apply KDA and RKDA to different instances of the clinical trial planning problem with scenarios ranging from 64 up to 1,048,576. Finally, the concluding remarks are summarized in Section 5.

2. Clinical Trial Planning Problem and its MSSP formulation

The goal of the clinical trial planning problem is to identify the schedule of clinical trials for a set of candidate drugs, $i \in \mathbf{I} = \{1, 2, \dots, |\mathbf{I}|\}$, that maximizes the expected net present value (ENPV) of the clinical trial pipeline. The outcomes of the clinical trials for each drug are uncertain and decision-dependent, because the outcome of a clinical trial can only be realized once the trial is completed. A drug has to complete three clinical trials in order ($j \in \mathbf{J} = \{PI, PII, PIII\}$), and it can either pass (P) a clinical trial or fail (F) it. A drug that has failed a trial cannot continue to the subsequent clinical trial(s). Let θ_i be the uncertain parameter associated with this uncertainty for drug i . We then define the realizable values of this uncertain parameter with set $\Theta_i = \{PI(F), PII(F), PIII(F), PIII(P)\}$, where $PIII(P)$ corresponds to the outcome that drug i passes trials PI, PII , and $PIII$. The scenarios for the MSSP model are constructed as Cartesian product of uncertain parameter outcomes. Therefore, the total number of scenarios for a clinical trial planning problem with $|\mathbf{I}|$ drugs each of which should complete all three clinical trials is $|\mathbf{S}| = 4^{|\mathbf{I}|}$, where \mathbf{S} is the scenario set.

The planning horizon is defined as $t \in \mathbf{T} = \{1, 2, \dots, |\mathbf{T}|\}$ (period t starts at time $t-1$ and ends at time t). Each drug has a known cost C_{ij} , required resources ρ_{ijr} (where $r \in \mathbf{R} = \{1, 2, \dots, |\mathbf{R}|\}$), and fixed duration of τ_{ij} for each clinical trial. After successfully completing all clinical trials, the revenue from drug i is realized. Potential revenue is defined using the maximum revenue, rev_i^{max} , associated with drug i . Patent life of a drug is assumed to starts shrinking

once the drug enters the pipeline, and associated losses are represented by two penalty terms: γ_i^D (loss of market share) and γ_i^L (loss of patent life).

A slightly revised version of the MSSP formulation by Colvin and Maravelias (2010) is given in Figure 1. The decision variable $X_{i,j,t,s}$ is equal to one if clinical trial j of drug i is started at time t in scenario s . Equations 2-5 calculate the ENPV. Equations 6-8 are sequencing constraints. Per Colvin and Maravelias (2010), a clinical trial j' of drug i cannot be started at time t in scenario s , (1) if drug i fails a prerequisite trial ($j < j'$) in scenario s , and (2) if $t \leq \sum_{j=1}^{j'-1} \tau_{ij}$. We define set \mathbf{N} to include trial j' of drug i that cannot be started at time t in scenario s , and set decision variables associated with these (drug, clinical trial) pairs for these time periods and scenarios equal to zero by Eq. 8. Equation 9 enforces the resource limitations. The NACs are given in Eq. 10 for the first time period, and Eq. 11 for $t > 1$. For Eq. 11, we define the subset \mathbf{B} of $\mathbf{S} \times \mathbf{S}$ as scenarios s and s' , which are distinguishable in the outcome of one (drug, clinical trial) pair $(i^{s,s'}, j^{s,s'})$.

$$\max ENPV \tag{1}$$

$$\text{s.t. } ENPV = \sum_s p_s (Rev_s + FRev_s - Cst_s) \tag{2}$$

$$Rev_s = \sum_i \sum_t \left\{ rev_{i,j,t,s}^{max} X_{i,PIII,t,s} - \gamma_i^D \sum_{j=PII,PIII} (-X_{i,j,1,s} + \sum_{t' > \tau_{ij}-1} X_{i,j-1,t'-\tau_{ij}-1,s} - \sum_{t' \leq t} X_{i,j,t',s}) - \gamma_i^L (t + \tau_{i,PIII}) X_{i,PIII,t,s} \right\} \quad \forall s \tag{3}$$

$$FRev_s = \sum_i \sum_{j \neq PI} rev_{i,j}^{open} f_{i,j} (-X_{i,j,1,s} + \sum_{t' > \tau_{ij}-1} X_{i,j-1,t'-\tau_{ij}-1,s} - \sum_{t' \leq |T|} X_{i,j,t',s}) + \sum_i rev_{i,PI}^{open} f_{i,PI} (1 - \sum_{t' \leq |T|} X_{i,PI,t',s}) + \sum_i \sum_{j \in \{PI,PIII\}} \sum_{t > |T| - \tau_{ij}} rev_{i,j,t}^{run} f_{i,j+1} X_{i,j,t,s} \quad \forall s \tag{4}$$

$$Cst_s = \sum_{i,j,t} cd_t C_{i,j} X_{i,j,t,s} \quad \forall s \tag{5}$$

$$\sum_t X_{i,j,t,s} \leq 1 \quad \forall i, j, s \tag{6}$$

$$\sum_{t'} X_{i,j,t',s} \leq \sum_{t'} X_{i,j-1,t',s} \quad \forall i, j > 1, t', s \tag{7}$$

$$X_{i,j,t,s} = 0 \quad \forall (i, j, t, s) \in \mathbf{N} \tag{8}$$

$$\sum_i \sum_j \sum_{t' > t - \tau_{ij}} \sum_{t' \leq t} \rho_{i,j,t'} X_{i,j,t',s} \leq \rho_r^{max} \quad \forall r, t, s \tag{9}$$

$$X_{i,j,1,1} = X_{i,j,1,s} \quad \forall i, j, s \tag{10}$$

$$\left[\begin{array}{c} \sum_{t' \leq p - \tau_{i^s, s'}, j^s, s'} Y_{i^s, s', j^s, s', t', s} \\ X_{i,j,t,s} = X_{i,j,t,s'} \end{array} \right] \vee \left[\sum_{t' \leq t - \tau_{i^s, s'}, j^s, s'} Y_{i^s, s', j^s, s', t', s} \right] \quad \forall i, j, t \geq 1, (s, s') \in \mathbf{B} \tag{11}$$

Figure 1. An MSSP formulation for the clinical trial planning problem

3. Proposed Heuristic Algorithms

3.1. Knapsack-problem based decomposition algorithm (KDA)

The KDA generates and solves a series of $|\mathbf{R}|$ -dimensional 0-1 knapsack problems based on the realizations of uncertainty. The KDA uses the concept of eligible item set \mathbf{K} , where items $k \in \mathbf{K}$ are created by enumerating all allowable decisions associated with endogenous uncertain parameters at time period t according to the logic of the sequencing constraints. Each item has a value, V_k , and weight(s), W_k^r , associated with it. Item values and weight(s) are estimated using expected gains and resource requirements, respectively.

Suppose that a clinical trial planning problem only includes two drugs (A and B). The KDA starts by generating the eligible item set at $t=1$, the root node. The eligible items are (A, PI) and (B, PI) , and they are determined using the logic of sequencing constraints (Eqns. 6-8). Next, item values and weights are calculated. The value for (A, PI) is the expected value of its revenue assuming all remaining clinical trials are completed continuously, and it is calculated via Eqns. 12 and 13. Note that $t=1$ for Eq. 12. The item values approximate the impact of starting the drug, clinical trial pair at the current time period would have on objective function value of the original MSSP (Eqns. 2-5). Equation 12 reduces the potential revenue, rev_A , due to loss of active patent life for the total duration of the current and remaining clinical trials. The potential revenue is calculated by deducting the linearly depreciated clinical trial costs $C_{A,j'}$ from the maximum revenue rev_A^{max} (Eq. 13). Item weights for (A, PI) are equal to $\rho_{A,PI,r}$. The $|\mathbf{R}|$ -dimensional capacity vector $\{W_r^{max}\}$ contains the available resources for investment, ρ_r^{max} .

$$V_{(A,PI)} = E[rev_A - \gamma_A^L(t + \sum_{j' \geq PI} \tau_{A,j'} + 1)] \quad (12)$$

$$rev_A = rev_A^{max} - \sum_{j' \geq PI} C_{A,j'} \left(1 - 0.025 \sum_{j'' > PI} \tau_{A,j''} - 1\right) \quad (13)$$

The knapsack problems that are generated and solved are given in Eqns. 14-16. The objective is to maximize the total value (Eq. 14), and the weight constraints (Eq. 15) are equivalent to the resource constraints of the original MSSP (Eq. 9).

$$\max \sum_{k \in E} V_k y_k \quad (14)$$

$$\text{s.t. } W_{k,r} y_k \leq W_r^{max} \quad \forall r \in \mathbf{R} \quad (15)$$

$$y_k \in \{0, 1\} \quad \forall k \in \mathbf{K} \quad (16)$$

Once the root node knapsack problem is solved, the number of new knapsack problems generated and their generation times are based on the outcomes of the root node knapsack problem solution. For our example, if the solution selects (A, PI) and (B, PI) , time period is set to $\max(\tau_{A,PI}, \tau_{B,PI})$ and $2^2=4$ additional knapsack problems are generated. These problems correspond to the four possible outcomes: (1) drugs A and B pass clinical trial PI , (2) drug A fails PI while drug B passes it, (3) drug A passes trial PI while drug B fails it, and (4) both drugs fail trial PI . For each knapsack problem, the algorithm updates set \mathbf{K} and calculates corresponding item values and weights at the corresponding time period. The item values are updated based on the realizations of uncertainties that correspond to each individual knapsack problem. The algorithm continues to solve and generate new child knapsack problems until the end of the planning horizon or no eligible items remain. The KDA yields a feasible solution, and hence, generates a primal bound for the MSSP. Detailed discussions of KDA can be found in Christian and Cremaschi (2015, 2017).

3.2. Relaxed knapsack-problem based decomposition approach (RKDA)

The RKDA generates a valid dual bound for the original MSSP by solving a relaxed version of the original MSSP to optimality. The original MSSP is relaxed by removing the resource constraints (Eq. 9). We refer to this relaxed MSSP formulation as RMSSP. The optimal solution of RMSSP provides a dual bound for the original MSSP.

The weight constraints of the knapsack problems in the KDA are equivalent to the resource constraints of the MSSP. Therefore, to solve the RMSSP, the weight

constraints of the knapsack problems are removed yielding the relaxed knapsack problems given in Eqns. 17-18. The original KDA is modified to generate and solve the relaxed knapsack problems every time period at which the outcome of an uncertain parameter is realized. We refer to this modified KDA as relaxed KDA (RKDA). The solution obtained by RKDA to the RMSSP satisfies the sequencing constraints (Eqns. 6-8) and the NACs (Eqns. 10-11) of the RMSSP, and recommends starting all eligible clinical trials at the earliest time allowable. Therefore, the RKDA yields the optimal solution of the RMSSP, which is a tight dual bound for the original MSSP.

$$\max \sum_{k \in E} V_k y_k \quad (17)$$

$$\text{s.t. } y_k \in \{0, 1\} \quad \forall k \in \mathbf{K} \quad (18)$$

4. Results and Discussion

We applied KDA and RKDA to generate initial primal and dual bounds for the clinical trial planning problem with two-, three-, four-, five-, six-, seven- and ten-products and three clinical trials with different planning horizons. We also solved the original MSSPs of these problems to 0.1% optimality gap when possible. The models and algorithms were implemented in Pyomo and solved using CPLEX 12.6.3 on a standard node of Auburn University Hopper Cluster. Problem data are available upon request.

Number of trials, time periods, and scenarios for the problems are summarized in Table 1 along with the optimum ENPVs and the MSSP solution times for the problems that were solved to optimality. As expected, the MSSP solution times grow exponentially with the number scenarios. For example, CPLEX 12.6.3 required more than 30 hours to solve the six-product problem. The MSSP enumerates all scenarios, and quickly becomes computationally intractable due to its space and time complexity. Therefore, the MSSP formulations of seven- and ten-product problems cannot be generated in RAM and hence cannot be solved using CPLEX 12.6.3 due to their space complexities.

Table 1. Main characteristics and the MSSP solutions of the problems

Case Name	Number of Trials	Number of Time Periods	Number of Scenarios	ENPV (\$M)	MSSP Solution Time (CPUs)
2-prod	2	5	9	1104	0.1
3-prod	3	12	64	1189	4
4-prod	3	6	256	1696	7
5-prod	3	6	1,024	2082	185
6-prod	3	6	4,096	2450	29,357
7-prod	3	8	16,384	--	--
10-prod	3	10	1,048,576	--	--

Primal and dual bounds obtained for the problems using KDA and RKDA are compiled in Table 2. An initial relative gap for each problem is calculated using the primal and dual bounds. The gaps ranged between 2.10% and 4.66% (Table 2). The KDA and RKDA yielded these relative gaps very quickly, in 0.1 to 2377 CPU seconds. The Pearson correlation coefficient between the total solution time and number of scenarios is 1.00, revealing the strong linear relationship between them. It is worth noting that KDA and RKDA are able to generate a feasible solution and quantify its quality for even the ten-product problem under one CPU hour.

5. Conclusion

This paper discussed decomposition based heuristic algorithms, KDA and RKDA, to quickly obtain a feasible solution, a primal and a dual bound for large scale MSSP problems with endogenous uncertainty. Unlike the deterministic equivalent of MSSP formulations, the KDA and RKDA do not suffer from space complexity, and hence, can be used to generate a feasible solution and to obtain its solution quality for problems that are currently computationally intractable. Furthermore, the proposed algorithms is an initial step towards optimally solving large-scale MSSP for real-world sized problems.

Table 2. Primal and dual bounds, relative gap, and solution times for the KDA and RKDA

Case Name	KDA Primal Bound (\$M)	RKDA Dual Bound (\$M)	Relative Gap	Solution Time (CPUs)
2-prod	1097	1120	2.10%	0.1
3-prod	1178	1221	3.65%	2
4-prod	1677	1721	2.62%	3
5-prod	2052	2127	3.65%	7
6-prod	2407	2516	4.53%	18
7-prod	2874	3008	4.66%	69

Abstract

This work proposes a mixed-integer linear program approach to consider the uncertainty of input data in the optimal design of distributed multi-energy systems involving both conventional and renewable-based conversion technologies, as well as storage units. The design procedure determines the minimum-cost combination of technology selection, size and operation. Traditionally, distributed multi-energy systems are designed using deterministic optimization methods, implying that the input data are known when the system optimization is performed. However, such input data are commonly affected by significant uncertainty, making the deterministic solution possibly suboptimal or even unfeasible. Recently, both robust and stochastic optimization have been applied to the optimal design of multi-energy systems. Nevertheless, when including energy storage in the analysis, the traditional techniques are complicated by the short- and long-term evolution of the input data of the underlying optimization problem, as well as their complex interactions. Moreover, the analysis of the uncertainties characterizing such input data for the optimal design of multi-energy systems, as well as the evaluation of their impact on the system design, have been investigated in little details. The approach proposed in this work is based on the analysis of the historical time-series representing the input data of the mixed-integer linear program for different years. First, the most important input data in terms of optimality and robustness of the system design are identified. Moreover, the most relevant features of the corresponding time-series are determined and assessed. Then, this information is used to build a custom set of input data which translates into a system design able to guarantee both security of supply and cost optimality.

Keywords: Multi-energy systems, time-series analysis, MILP, stochastic optimization, energy storage

1. Introduction

The necessity of reducing the environmental impact of the current energy system has led to the development and deployment of conversion technologies based on renewable energy sources, storage systems to compensate for the resulting intermittent generation, as well as novel paradigms to design the future energy system, International Energy Agency (2016). Within this framework, distributed multi-energy systems (MES) integrating multiple energy carriers (e.g. electricity, heat,

natural gas, hydrogen) with high fractions of renewable energy and storage technologies, are promising options to cope with this challenge, Mancarella (2014). Within the analysis and optimization of MES, mixed integer linear program (MILP) has been particularly favored as optimization framework since it well catches the features of such systems with a reasonable computational complexity, Allegrini et al. (2015).

Traditional MILP approaches for the design of distributed multi-energy systems use deterministic optimization, implying that the boundary conditions of the optimization problem, i.e. weather conditions, energy prices and demands, are known with certainty when the optimization is performed, e.g. Weber and Shah (2011); Gabrielli et al. (2017a). However, the aforementioned input data are commonly affected by considerable uncertainty, making the deterministic solution possibly suboptimal or even infeasible, Ben-Tal et al. (2009). Recently, robust and stochastic MILP methods have been proposed to tackle the data uncertainty so as to guarantee the feasibility of the solution, which translates into security of energy supply under different operating conditions. In fact, both approaches have been investigated in literature. During his thesis, Mavromatidis (2017) investigated the optimal design of distributed urban energy systems under uncertainty. He compared a stochastic formulation, the traditional robust formulation by Soyster (1973), the robust optimization with uncertainty budget proposed by Bertsimas and Sim (2004), and the finely adjustable robust optimization introduced by Ben-Tal et al. (2004). Another approach was proposed by Majewski et al. (2017), who proposed a two-stage robust optimization considering at the same time the average and the worst-case scenarios and applied it to the optimal design of an industrial park. They found that robustness and optimality are not mutually exclusive, as the robust design itself is not more expensive, but the cost of the system increases only when worst-case operation occurs. Furthermore, Billionnet et al. (2016) have considered the design of a stand-alone energy system under uncertainty pertaining to both energy demands and solar and wind generation, whereas Zatti et al. (2017) proposed a three-stage stochastic integer programming model accounting for the uncertainty in the short-term forecast, the day-ahead electricity bidding, the day-ahead scheduling of large power plants and the possibility of real-time scheduling adjustment of flexible energy systems (through integer recourse). Despite these previous works, the analysis of the uncertainties characterizing the boundary conditions for the optimal design of distributed multi-energy systems, as well as the evaluation of their impact on the system design, have been investigated in little details. Moreover, when considering energy storage, traditional robust and stochastic optimization techniques are further complicated by the short- and long-term evolution of the input data, as well as their interactions. Indeed, large optimization problems can result from stochastic optimization due to the creation of a large number of scenarios, or from robust optimization due to the adoption of large uncertainty sets. Here, a three-stage procedure is developed based on the analysis of the historical time-series of the input data of a MILP problem aimed at determining the optimal combination of technology selection, size and operation in terms of total annual cost of the system. First, the optimal deterministic system design is determined for several sets of input data from different years. Next, each of the resulting designs, corresponding to a given year, is tested by operating it for all the other years. Within this phase, every design is evaluated in terms of cost optimality and robustness. Finally, the most relevant inputs, as well as the most important features of the time-series, are identified and assessed to build a custom year which ensures both cost optimality and robustness. A Swiss case-study is considered.

2. Problem formulation and system description

The multi-energy system (MES) considered in this study has the primary scope of supplying electricity and heat to a defined user. The MES is connected to the electrical grid and is composed of a set of conversion and storage technologies. A deterministic MILP is formulated to determine the

optimal system design. It can be written in the general form as

$$\begin{aligned}
 & \min_{\mathbf{x}, \mathbf{y}} (\mathbf{c}^T \mathbf{x} + \mathbf{d}^T \mathbf{y}) \\
 & \text{s.t.} \\
 & \mathbf{Ax} + \mathbf{By} = \mathbf{b} \\
 & \mathbf{x} \geq \mathbf{0} \in \mathbb{R}^{N_x}, \mathbf{y} \in \{0, 1\}^{N_y}.
 \end{aligned} \tag{1}$$

Inputs to the optimization problem are the (i) electricity price, (ii) end-users energy demands, (iii) weather conditions (ambient temperature and solar radiation), and (iv) set of available technologies with the corresponding performance and cost coefficients. Outputs of the optimization problem are the design and operation strategy which yield to the minimum total annual cost. In particular, the following decision variables are returned: (i) the size of the installed technologies, (ii) the scheduling (on/off) status of the conversion units, (iii) the input/output energy of both conversion and storage technologies, (iv) the amount of energy in the storage units, (v) the imported/exported energy from/to the electricity grid. The objective function of the optimization problem is the total annual cost of the system, given by the sum of capital, operation and maintenance contributions. The constraints of the optimization problem include the (i) energy balances within the multi-energy system, and (ii) performance of conversion and storage technologies. The former require that the sum of imported and generated power equals the sum of exported and used power for all the involved energy carriers. The latter describe the behavior of the conversion and storage units. Affine and piecewise affine descriptions of conversion and storage technologies are implemented to correlate the output power to the input power and to the unit size, as indicated in Gabrielli et al. (2018). The optimization framework implements the time-series aggregation method M2 introduced by Gabrielli et al. (2017b) to consider the entire year with hour resolution as the time horizon at reduced computation complexity. Overall, a detailed description of the optimization framework can be found in Gabrielli et al. (2017b).

2.1. Modeling the uncertainty

The input data (i)-(iii) are time-dependent profiles for one year with hourly resolution, based on historical realizations for a neighborhood in Zurich, Switzerland. Such input data are calculated and discussed by Murray et al. (2017). The proposed design approach is based on the following three-stage procedure:

- First, the MILP discussed above, given by Eq. 1, is applied to obtain the optimal deterministic design for the aforementioned multi-energy system for different sets of input data describing different years.
- Next, each of the resulting designs is tested by operating it on all the other years. At this stage, every design is evaluated in terms of cost optimality and robustness. In specific, an optimality index O is introduced for every year i :

$$O_i = \frac{1}{N} \left(\sum_{j=1}^N \frac{c_{jj}}{c_{ij}} \right) \tag{2}$$

where N is the number of considered years and $c_{i,j}$ the total annual cost (in /yr) obtained by operating on year j the design determined with year i . Similarly, a robustness index R is introduced for every year i :

$$R_i = 1 - \frac{1}{v_{\max} N} \left(\sum_{j=1}^N v_{ij} \right) \tag{3}$$

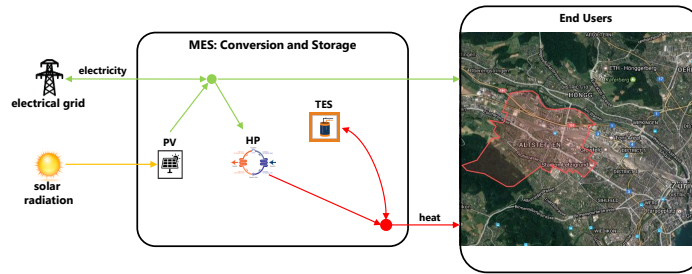

Figure 1: Schematic representation of the investigated multi-energy system.

where v_{ij} is the thermal demand not delivered (in kWh/yr) when operating on year j the design determined by using year i and v_{\max} is the maximum registered violation. Note that the decision of defining the robustness index based on the thermal demand (instead of the electrical or the total demand) stems from the consideration that, in this work, the electrical demand can always be satisfied by purchasing electricity from the grid.

- Finally, the most relevant inputs, as well the most important features of the time-series, are identified and assessed to build custom years ensuring both cost optimality and robustness at design level.

2.2. Case study

The proposed methodology is applied to the simple multi-energy system illustrated in Fig. 1, composed of photovoltaic (PV) panels, electricity-driven heat pump (HP), and hot water sensible thermal storage (TES). The system is connected to the electricity grid and provides electricity and heat to a neighborhood requiring a peak electrical and thermal demands of 0.42 MW and 2.01 MW, respectively. Here, we consider a single energy hub that satisfies the heat and electricity demands; therefore, the energy is converted and stored in a central node and then delivered to the buildings (see Gabrielli et al. (2017b)). Moreover, a constraint of 260 ton/yr is imposed on the maximum amount of CO₂ emissions. Such constraint corresponds to a 50% emission reduction with respect to the worst possible value for all the years. Such a limit is imposed to force the installation of PV panels, so to account for the solar radiation within the analysis.

3. Results

Some preliminary results are presented in this section, by using four different years including extreme high weather conditions (ambient temperature and solar radiation), extreme low weather conditions, and average weather conditions for two different years. Figure 2 shows the robustness-optimality Pareto front for the investigated years, where the color code indicates either the total electrical and thermal annual demand (left-hand side) or the 5-day peak thermal demand (right-hand side). The 5-day peak thermal demand is the largest thermal demand during a sequence of five days for all the considered years (integral value). For the considered pool of years, the analysis suggests that this is a good indicator of the robustness of the system design. Similarly, the total electrical and thermal annual demand is found to be a good indicator of the system optimality. Indeed, the left-hand side of Fig. 2 shows that an increase in optimality is observed when decreasing the total annual demand. Thus, the year 1 is the most optimal year, but the least robust one. Moreover, the right-hand side of the figure shows that an increase in robustness is observed when increasing the 5-day peak thermal demand. Therefore, the year 4 is the most robust year, but the

Figure 2: Robustness-optimality Pareto front for the four considered years. The color code indicates the total electrical and thermal annual demand (left) and the 5-day peak thermal demand (right).

least optimal one. The years 2 and 3 are located in the middle of the robustness-optimality plane, with year 2 being dominated by year 3.

Following these considerations, a custom year is built by replacing the five days of year 4 where the peak thermal demand occurs within the year 1, characterized by the lowest total demand. Such a custom year is reported on the robustness-optimality Pareto front in Fig. 3. One can note that the custom year improves the optimality by about 15% while reducing the robustness of only 0.7%. This suggests that starting from favorable conditions and adding an extreme event translates into an optimal and robust system design. Note that, in addition to providing a method to increase optimality and robustness at the same time, a quantitative evaluation of indicative extreme events can provide relevant insights (i) from a robust optimization perspective, e.g. indications for choosing suitable uncertainty sets; (ii) in terms of most suited clustering features for modeling the time horizon. Indeed, the investigated application highlights the necessity of detecting sequences of day, in this case a five-day sequence of high thermal demand, when applying clustering techniques

Figure 3: Robustness-optimality Pareto front for the four considered years and the custom year built by combining the total demand of year 1 and the 5-day peak thermal demand of year 4.

on the time horizon.

4. Conclusions

This work proposes a MILP approach to consider the uncertainty of the input data in the optimal design of distributed multi-energy systems involving both conventional and renewable-based conversion technologies, as well as storage units. A three-stage procedure is developed, based on the analysis of the historical time-series of the input data characterizing the underlying optimization problem. First, the optimal deterministic system design is determined for several sets of input data describing different years. Next, each of the resulting designs, corresponding to a given year, is tested by operating it on all the other years. Within this phase, every design is evaluated in terms of cost optimality and robustness. Finally, the most relevant inputs, as well the most important features of the time-series, are identified and assessed to build a custom year ensuring both cost optimality and robustness of the design. Findings show that the total electrical and thermal annual demand is an important indicator of the system optimality, whereas a five-day sequence of peak thermal demand is found to be a good indicator of the system robustness. A custom year built by accounting for both these features is found to ensure optimality and robustness at the same time.

Abstract

The complexity of optimization problems of optimization problems increases along with the dimensions, non-linearity, and/or the required accuracy of the model constraints and objective functions. Additionally, for mixed-integer multiparametric problems, the discreet and uncertain nature of the variables and parameters to be considered, affect the complexity further more. Recently, machine learning or data-driven techniques have been proposed as alternatives for the solution of complex multiparametric programming problems. However, those methods presents as a main limitation its very high prediction error in variables that show discrete behavior and on the limits of the critical/local regions. This work extends this investigation line via proposing a novel machine learning method for solving these kind of problems based on an iterative process that use Ordinary Kriging as supervised learning tool to classify and model data. Furthermore, Ordinary Kriging can be also used, as an unsupervised tool to cluster data. The proposed methodology is applied to a benchmark case-study and the numerical results exhibits a significant improvements, up to 65% based on the normalized root-mean-square error, compared with reported information that used other modeling techniques.

Keywords: Machine learning tool, classification, clustering, metamodeling.

1. Introduction

Given the fact that the complexity of today's optimization and simulation problems increases (Qiu, Xu, Gao, Li, & Chi, 2016), Metamodel Based Optimization (MBO) is one of the first-choice methodologies employed in the industrial sector. This can be seen as the most efficient technique for addressing complex optimization problems that cannot be managed using classical /mathematical optimization methods, due to the models high nonlinearity, complexity, dimensionality and/or complicated structure (Bartz-Beielstein & Zaefferer, 2017). The idea behind the MBO is to replace the complex and/or computationally-expensive algorithm with a simpler computationally-cheap data-driven model. These models, also called surrogates models or metamodels, can use different modelling techniques, such as Response Surface Methodology (RSM), Support Vector Machine, Radial Basis Function, Artificial Neural Network, and Gaussian Process Model or Kriging Model (Bartz-Beielstein & Zaefferer, 2017). Among the different metamodeling techniques RSM and Kriging are the most widely used given their prediction accuracy and tuning flexibility (Wang, Li, Li, & Zhong, 2008). Basically a Kriging model is composed of a polynomial term, $f(x)$ which

approximates the global trend of the system, plus a spatial deviation model, $Z(x)$. This model allows Kriging to represent non-linear behavior with high fidelity; Where Z is a stochastic Gaussian process, that represent the uncertainty of the mean of $y(x)$ with expected value zero $E(Z(x))=0$ and covariance for two points $(x_i, x_j) : cov(Z(x_i), Z(x_j)) = \sigma^2 R(x_i, x_j)$. Here σ^2 is a scale factor known as process variance that can be tuned to the data and $R(x_i, x_j)$ is the spatial correlation function (SCF). There are many choices for the SCF, but the most common used in kriging models is the exponential function Eq. (1) (Caballero & Grossmann, 2008).

$$R(x_i, x_j) = \exp\left(-\sum_{l=1}^d \Phi_l |x_{i,l} - x_{j,l}|^{P_l}\right), \quad \Phi_l \geq 0; \quad 0 \geq P_l \leq 2 \quad (1)$$

If $x_i = x_j$, then the SFC is one, and tends to zero as the difference between both points increases. In other words, the influence of the sampled data point on the point to be predicted becomes weaker as the distance among them increases. The value of Φ_l indicates how fast the correlation goes to zero as we move in the l^{th} coordinate direction. For large values of Φ_l , only the data points very close to each other are well correlated. Parameter P_l is a measure of the smoothness of the function. The response becomes smoother as the value for P_l increases. To estimate the values of μ , σ , Φ_l , P_l , the log-likelihood function Eq. (2) is maximized. The final predictor of the kriging method is given by equations (3).

$$\max_{\Phi_l, P_l} -\frac{n}{2} \ln(\sigma^2) - \frac{1}{2} \ln(|R|), \quad \sigma^2 = \frac{(y-1\mu)^T R^{-1} (y-1\mu)}{n} \quad (2)$$

$$\hat{y}(x^{\text{new}}) = \mu + r^T R^{-1} \cdot (y - 1\mu), \quad \mu = \frac{1^T R^{-1} y}{1^T R^{-1} 1} \quad (3)$$

In these equations r is the $n \times 1$ vector of correlations $R(x^{\text{new}}, x_i)$ between the point to be correlated and the sample design points. We are more confident in the prediction if the new point is near a sampled/training point, since then the error drops to zero in all sampled points. A detail of the development of the calculations can be found in (Sasena, 2002).

Recently, (Lupera Calahorrano, Shokry, Campaña, & Espuña, 2016) have successfully proposed a Meta-MultiParametric (M-MP) algorithm for the solution of multiparametric mixed-integer nonlinear problems, through the combination of metamodeling with clustering and classification techniques. However, these techniques are limited to consider continuous optimization problems/variables, because their approach showed a remarkable limitation associated to the very high prediction error of the metamodels at the limits of the critical/local uncertain regions and in the presence of variables with discrete behaviors. Therefore, the contributions to the discrete domain are still an open challenge.

In this work we show a methodology to solve multiparametric mixed-integer nonlinear problems. The methodology proposed is based on a machine-learning procedure, using Ordinary Kriging (OK) as a supervised learning tool to classify the data (e.g., feasible, unfeasible). Also, OK is used as an unsupervised learning tool to identify clusters. Lastly, OK is used for modelling the data of each cluster in order to specify the metamodel that would be used to evaluate the optimal solutions (Z^* , x^* and y^*) with continuous and discrete behavior as a function of the uncertain parameters (θ 's) (Eq. (4)).

$$Z_p^* = f_p(\theta), \quad x_{i,p}^* = f_{i,p}(\theta), \quad y_{j,p}^* = f_{j,p}(\theta) \quad (4)$$

$i = 1, 2, \dots, K_{\text{cnt}}, \quad j = 1, 2, \dots, K_{\text{int}}, \quad p = 1, 2, \dots, P, \quad \theta_{lb^p} < \theta_p < \theta_{ub^p}$

In Eq. (4) Z_p^* is the objective function, θ represents the bounded uncertainty, y is a vector of integer/binary variables, x is a vector of continuous variables.

The proposed methodology is evaluated by applying it to a benchmark case–study (Dua & Pistikopoulos, 1999), later used by Shokry et al., (Shokry, Medina-González, & España, 2017) applying neural networks and K-means techniques to classify and cluster data. Therefore, comparative results with Shokry’s investigation are reported.

2. Methodology

Figure 1, shows a flowchart of the proposed methodology which is briefly explained as follows:

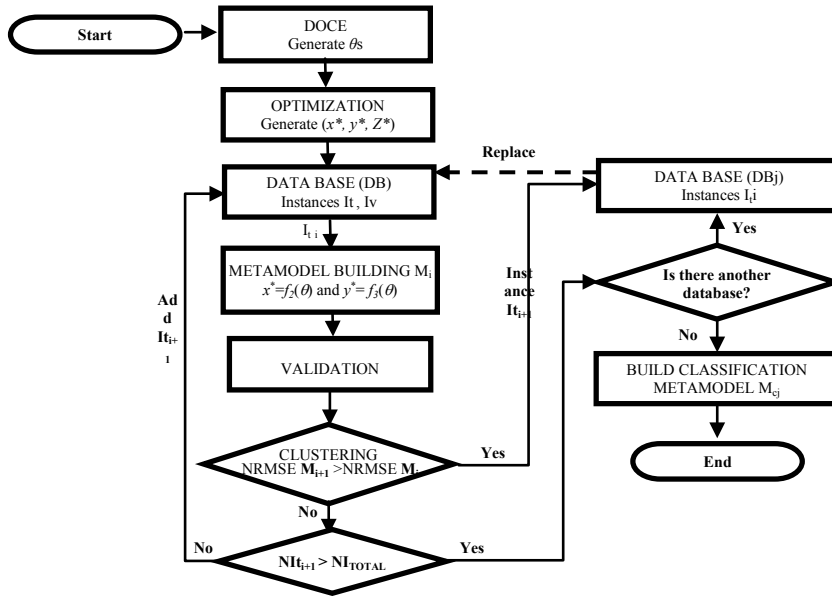

Figure 1. MBO Methodological Flowchart

Design of Computer Experiments (DOCE): Used for generate N combinations of the θ 's values. The design should provide information about all portions of the θ 's space. In the present work, a hybrid sampling technique of Hammersley sequence and full factorial design is used for selecting both the inputs of the training and validation data.

Optimization: Once the θ 's values were defined with DOCE, the mp-MINLP problem was solved to obtain a set of optimal solutions $(x^*, y^*$ and $Z^*)$.

Metamodel building: The metamodel based on OK was built. Since some variables could have a discrete or high nonlinearity behavior, the possibility of the P_l values to be between 0 and 2 during the maximization process of the log-likelihood was considered Eq. (2). This is done to have a wider representation of the smoothness of spatial correlation function.

Clustering: Considering the existence of discrete behaviors of some variables inside the optimization problem, the need to include a clustering technique was identified. Because

the proposed clustering algorithm is an iterative data process: two Data Bases (DB) are formed during the process being DB and DB_j. The starting DB consists of *N* instances (each instance is composed of the θ 's and their corresponding optimal values x^*, y^*, Z^*), both of the set of training instances (I_t) used to build the metamodel and a set of validation instances (I_v) used to validate it metamodel. DB_j is generated in the clustering process.

To begin the clustering process, a metamodel is built with a first set of instances (I_t ∈ DB), that was selected based on the proximity among them (Euclidean distance). Then, through an iterative process, the instances were added one by one to build a metamodel of each variable. After each metamodel is formed as the instances are added, a validation process is performed (base on NRMSE). The modeling and validation is made until completing the total amount of instances of the DB. The instances that produce a NRMSE smaller or equal to the previous one are sent to a primary cluster (DB_j with *j*=1 for the first iteration). Similarly, those that produce a greater NRMSE are sent to a secondary cluster (e.g. DB_j with *j*=2 in the first iteration). Once the original set of instances is completely analyzed, the process is repeated again with the instances not included in the first cluster (DB_j), and the process is repeated until no more clusters are detected.

Classification Metamodel building: The primary and secondary training clusters are used to construct a Classification Metamodel (M_c) based on OK. Where, the desired solutions are fed to the algorithm as labels (e.g.: primary cluster = 1, secondary cluster = 0). Once the M_c is trained, it is used to classify the original validation set I_v, and it will use to identify the cluster of a new instance. Those classified I_v, that belong the validation primary cluster are used to validate the corresponding cluster model. Those classified I_v, that belong the validation secondary cluster are used for next clustering analysis.

Validation: The validation data set is used for the metamodel assessment. The corresponding instances (I_v) were used in order to calculate the NRMSE for each built metamodel. Additionally, once classifying and integer variables models are built, the F₁-score, a measure of a test's accuracy in analysis of binary classification is evaluated to test of accuracy.

3. Case study and Results

With the objective to illustrate the proposed methodology capabilities, the case study proposed by (Dua & Pistikopoulos, 1999) has been used. The basic process scheme and model are illustrated in Figure 2.

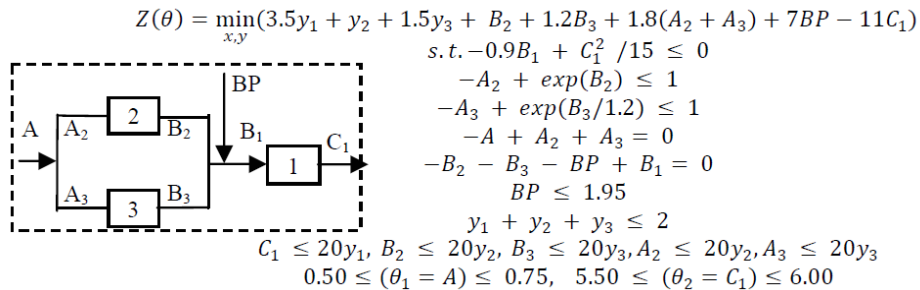

Figure 2. Case-study illustration and model

According to the methodology, a total of 650 samples for the first iteration (as shown in Table 1) has been generated in order to model the θ 's domain $[\theta_1, \theta_2]$. Those samples are used to solve the optimization problem N times and, ultimately, to obtain the optimal value of the main variables and objective function $[A^*, B^*, BP^*, C_1^*, A_2^*, A_3^*, B_2^*, B_3^*, Z^*, y_1^*, y_2^*, y_3^*]_n$. The optimization model has been written in GAMS 23.8.2 and solved using a CEPLEX11.0 on a PC (Intel (R) Core (TM) i7-4790 processor, 3.60 GHz, 16.0 GB RAM).

Table 1. Sample/iteration

No. Instances	Clustering		Metamodel's validation	Classification Metamodel
	I_c	I_v	I_v	I_c
DB	250	400	23	8
DB ₁	242	377	55	40
DB ₂	202	322	322	-

Once the proposed methodology based in OK is applied, the unfeasible region and 3 clusters have been identified in the feasible region (Figure 3). Therefore, 39 MBOs and 2 M_C have been built to resolve the case study. The results of 39 metamodels validation (based on NRMSE/ F_1 -score) together with the computational effort to build the models are summarized in Table 2. With the objective to compare techniques, the validation results of 13 MOBs based on OK and a single cluster per variable, are presented in Table 3. Finally, Table 4 show the results of MOBs' validation, which were based on Artificial Neural Network (ANN) to classification, K-means to clustering and OK to modelling, obtained in previous research realized by Shokry et al., (Shokry et al., 2017).

Figure 3. MOB clusters

Table 2. Results of MBO based on OK, (classification, clustering, metamodeling)

Cluster	NRMSE (%)									F ₁ -score (%)

Table 4. Results of MBO based on OK (modeling), ANN (classification), K-Means (clustering)

Cluster	NRMSE (%)									F ₁ -score (%)			
	A [*]	A ₂ [*]	A ₃ [*]	B ₁ [*]	B ₂ [*]	B ₃ [*]	BP [*]	C ₁ [*]	Z [*]	Y ₁ [*]	Y ₂ [*]	Y ₃ [*]	F [*]
1	1.2	0.4	0.4	1.1	0.0	0.0	4.8	0.1	0.5	100	98.5	97	99
2	-	21.5	20.7	-	17.0	20.1	-	-	-				

(Shokry, Medina-González, & Espuña, 2017)

These results show that the proposed MBO technique allows reductions from 15% and up to 65% in the worst NRMSE values (34% in the average worst case), compared with a MBO built with one cluster. On the other hand, when the results now proposed are compared with previous research using artificial neural network and k-mean as techniques for classification and clustering, the proposed MBO methodology allows significant reductions. In particular, the average worst NRMSE values was improved in 24% in the average worst case (from 1% and up to 64%) and a more comprehensive treatment of the information (same clusters for all variables).

4. Conclusions

The OK can be used as an effective machine learning tool for classifying, clustering and modelling based in data. The proposed MBO methodology allows addressing mp-MINL problems satisfactorily obtaining reduction up 65% of NRMSE values compared with previous research and when it is built with a MBO. The same clusters for each variable were identified in all domain of problem, evidencing with this result the interrelation between the variables in the system.

Abstract

In modern day sustainable development, it has become necessary to apply integrated approaches that aid in the understanding of the synergies and trade-offs between various systems and processes which co-exist and utilizing the resources in the energy, water and food nexus has become necessary. The research presented in this paper discusses a probabilistic risk-based approach to assess the diversification of the energy economy, which would particularly play an important role in the enhancement of food security in the State of Qatar. The modern portfolio theory was adopted for this purpose and was used to evaluate energy portfolios with enhanced economic and environmental performance, when compared to the constituent power generation assets. The results obtained thus far demonstrate that a symbiosis between the industries related to energy and biomass waste utilisation could simultaneously help tackle the problem of environmental deterioration and mitigate economic risks, primarily caused by the variabilities in the natural gas and CO₂ prices.

Keywords: Food Security, Portfolio Theory, Stochastic Processes.

1. Introduction

The growth in global population and rapid urbanization pose significant stresses on the Earth's natural resources. Recent research efforts focusing on sustainable development have increasingly placed an emphasis on the importance of assessing the energy, water and food (EWF) nexus to gain a deeper understanding of the intricate relationships that exist between the processes that utilize the EWF resources. There exists a significant body of literature that discusses the application of the Life Cycle Assessment (LCA) methodology which enables a holistic understanding of the interactions between industrial processes, product cycles, and value-chain accounting (e.g. Al-Ansari et al., 2014; 2015; 2016; 2017). Al-Ansari et al. (2014) presented a LCA modelling framework of the EWF system, implemented for a case study of domestic food production intensification set in the State of Qatar aiming to deliver a hypothetical pre-specified crop profile that represents 40% of the total food requirement. Multiple technological configurations were assessed, and their environmental impacts were

quantified within the EWF nexus. It was recognized that opportunities to reduce the net impact on the environment could be sought by focusing on the integration of technologies to capture CO₂ emissions and recycle biomass waste for energy production. However, such portfolios are exposed to potential risks and uncertainties, e.g. fluctuations in fuel prices; innovations in renewable energy technologies, which influence their capital and operating cost competitiveness against fossil fuel-based technologies; compliance requirements in the ever-changing national and international regulatory environments; and geopolitical risks. To the best of the authors' knowledge, the current literature does not include a robust approach for accounting the economic risks in technology portfolios which could be used to assess the sustainable development of energy sub-systems in the EWF nexus.

The objective of the work presented in this paper is to develop a methodology focusing on the techno-economic assessment of EWF sub-systems, including the probabilistic modelling of tangible risks that are associated with them. The individual levelized energy costs under uncertainty were estimated for the different power generation assets, namely conventional natural gas-fuelled combined cycle (CCGT) power plants; biomass integrated gasification combined cycle (BIGCC) power plants; CCGT and BIGCC power generation with the integration of post-combustion carbon capture (PCC) technology; and harnessing solar power using photovoltaic cells. The important risks considered in this study include the natural gas and CO₂ price variations that were modelled using some of the well-known stochastic processes, namely mean-reverting jump diffusion and geometric Brownian motion. Modern portfolio theory (MPT) was implemented for assessing the energy sub-systems under twelve EWF scenarios that serve a 40% food production increase for the State of Qatar. The aim is to develop an understanding of energy diversification that can be used to deliver food security in Qatar in an economically and environmentally sustainable manner.

2. Cost of electricity generation

2.1. Natural gas combined cycle power plant

Natural gas-fired plants have become a mainstay of the power generation industry, with a share of about 20% of the global electricity production and which is expected to rise owing to its low investment costs, high thermal efficiencies, high reliability and high flexibility (Italiana, 2012). The US Electric Power Research Institute (EPRI) has estimated that the expected value of capital costs would lie in the range of \$1,060 - \$1,150 per kW for CCGT plants without carbon dioxide capture, against a higher range of \$1,600 - \$1,900 per kW for CCGT plants with carbon dioxide capture (EPRI, 2011). The main problem, however, with natural gas-based power generation is the volatility of gas price, which could have a damaging effect on economic growth in countries that rely heavily on gas-fired power generation.

2.2. Biomass-based power generation

One of the solutions proposed in the literature is to utilize the carbon-neutral energy locked within biomass (from the syngas produced) for co-firing with natural gas. This can be controlled in providing reliable power following the variable load by means of a co-firing process called the Biomass Integrated Gasification Combined Cycle (BIGCC). A problem, however, is related to uncertainties in the economics of power generation

using biomass, and under most circumstances it is not very favourable due to the high capital costs incurred in the short-term, primarily owing to significant differences in the composition of natural gas and syngas. It is therefore recognized that the co-firing using the mixture of natural gas and biomass gas could reduce the costs of electricity from biomass by bringing about economies of scale (Faaij et al., 1998). An indicative capital cost requirement for retrofitting biomass co-firing to an existing coal-fired power plant is in the range of \$50 - \$500 per kW of biomass generating capacity in the United States depending on the type of boiler; the prices are likely to be similar in Europe (Breeze, 2014).

2.3. Solar power using photovoltaic cells

Solar energy is one of the vital resources that is freely available and sustains all forms of biomass on the Earth's surface. In many parts of the world where there is a good solar resource, high levels of sunlight can provide synchronized peak power with demand, particularly in the form of rooftop solar panels. Solar-generated electricity was generally considered as an expensive source of electricity, particularly from photovoltaic cells relative to electricity derived from fossil fuels. However, there now exists a noticeable fall in the costs owing to technological advances and economies of scale due to the rise in production volumes (Breeze, 2014). Moreover, there has been fierce competition from the photovoltaic manufacturers in China by undercutting the prices of traditional manufacturers in the United States and Europe. The cost of a crystalline silicon solar cell in Europe in 2009 was \$2,620 per kW, but by the beginning of 2013 the cost had fallen to \$790 per kW (Breeze, 2014). A similar price trend is also true for other solar cell types, such as the cadmium-telluride thin films. This is beginning to make solar photovoltaics competitive with fossil fuel-based power generation technologies today, even without government subsidies, depending on location.

3. Methodology

The Levelized Cost of Electricity (LCOE) in Eq. (1) was adopted in the current work since it allows for the direct comparison of the costs of electricity generation projects with unequal economic life, capital costs, risks and returns, capacity factor, efficiencies, and fuel costs. It is defined as:

$$LCOE = \frac{\text{Capital Investment} + \sum_{n=1}^N \frac{O \& M \text{ Costs}}{(1 + DR)^n}}{\sum_{n=1}^N \frac{\text{Net Annual Energy Generated} (1 - DF)^n}{(1 + DR)^n}} \quad (1)$$

where DF is the degradation factor, which considers the deterioration of performance of CCGT; and DR is the discount rate, which allows the consideration of the time value of money and O&M stand for operating and maintenance costs. Some of the key economic risks were modelled by simulating the stochastic paths for both natural gas and CO₂ prices using market parameters available in the literature that were calibrated using historical price movements (Lucheroni and Mari, 2017). The stochastic behaviour of price paths for fossil fuels, such as natural gas, is described using the mean-reverting jump diffusion process, given by:

$$dX_t = (\alpha - \kappa X_{t-1}) dt + \sigma dW_t + J_t(\mu_J, \sigma_J) d\pi_t(\lambda_J) \quad (2)$$

where X is the (log) price value; α and κ are mean reversion parameters; σ is the price volatility; W is a standard Brownian motion (or Weiner process); J is the jump amplitude, with normally distributed mean μ_j and standard deviation σ_j ; and π is a Poisson process with constant intensity λ_j . This scheme captures the economic logic of considering large variations in price owing to unexpected events/shocks or abnormal arrival of news and information. An additional source of risk for power generation using fossil fuels also comes from the fluctuations in nominal carbon prices. The carbon price path evolution is usually represented with a simpler model, such as the geometric Brownian motion, given by:

$$dX_t = \mu X_{t-1} dt + \sigma X_{t-1} dW_t \quad (3)$$

where X is the (log) price value; μ is the percentage drift expected per annum, normally assumed to be associated with the inflation rate; σ is the daily volatility expected in the prices; and W is a Weiner process. In the case of BIGCC, BECCS (BIGCC integrated with carbon capture) and PV technologies, however, only systematic risks or volatilities were assumed, and thus explicit modelling of other potential risk factors was not considered in this study. Finally, the estimated values were used to implement the MPT theory (Markovitz, 1952) to assess the economic performance of different energy portfolios that cater for the resource requirements in the EWF nexus to meet the stated target of 40% in the annual domestic food production in the State of Qatar (see Table 1).

Table 1. Power generation portfolios considered in this study.

Scenario	a	b	c
1 Conventional mode	CCGT is used to power the water and food sub-systems.	PV is integrated with the water sub-system.	PV is integrated with the water and food sub-systems.
2 Integration of BIGCC	<i>BIGCC power is distributed amongst the water and food sub-systems.</i>		
	CCGT is used to power the water and food sub-systems.	PV is integrated with the water sub-system. The food sub-system is powered by the CCGT.	PV is integrated with the water and food sub-systems.
3 Integration of PCC	Same as scenario 1(a).	PCC is integrated with the CCGT powering the water sub-system.	PCC is integrated with the CCGT powering the water and food sub-systems.
4 Integration of PV and BECCS (BIGCC + PCC)	<i>BIGCC power is distributed amongst the water and food sub-systems.</i>		
	Same as scenario 2(a).	PV is integrated to power the water sub-system. The food sub-system is powered with the CCGT integrated with PCC.	PV is integrated to power the water and food sub-systems. The BIGCC is integrated with PCC.

4. Results and discussion

Fig 1(a) illustrates selected examples of histograms of the LOCE for the cases 1a and 3a, using CCGT based power generation in the conventional mode and one that includes CO₂ capture respectively. For both the cases, in general, Monte Carlo simulations were performed by drawing 10,000 price paths for both natural gas and CO₂ prices, and computing the corresponding LCOE distributions. Whilst the contributions from the volatilities of the natural gas and CO₂ prices towards the O&M costs are represented in 1a, only that of natural gas is represented in 3a. Meanwhile, a noticeable increase in the average LCOE exists owing to the capital cost of PCC integration. It was also estimated that there is an increase of 7-8% in levelized energy cost with a 10% increase in the cost of natural gas. Fig 1(b) illustrates the results obtained for the estimated LCOE generated by a given portfolio against the corresponding risk level that the costs are subjected to under uncertainty. It was assumed that there exists no correlation between the assets in terms of their capital and operating costs. Interestingly, four distinct clusters arise in the cost and risk structure based on the MPT evaluation, as follows:

- low levelized costs and intermediate risks (2a and 4a) - these portfolios are predominantly driven by power generation using BIGCC;
- intermediate levelized costs and high risks (1a, 3a, 3b and 3c) - these portfolios are purely driven by power generation using CCGT; albeit the increased environmental performance, it is noted that the integration of PCC technology further increases the economic risk owing to the increase in natural gas utilization;
- high levelized costs and low risks (1b and 1c) - these portfolios are predominantly driven by power generation using PV; and
- intermediate levelized costs and intermediate risks (2b, 2c, 4b and 4c) - these portfolios represent the trade-off between the costs and associated risks for power generation using CCGT, BIGCC and photovoltaics, including the integration of PCC technology; based on the current assumptions used in the calculations and scenarios assessed thus far, 4b represents an optimal portfolio, both in terms of its economic and environmental performance.

Fig 1. (a) Histograms of the stochastic LCOE values for conventional CCGT and CCGT with CO₂ capture technology integration; (b) Expected LCOE values and associated risk levels for the different portfolios considered in this study.

5. Conclusions

This paper presents a portfolio assessment methodology used to assess the economic risks for a variety of power generation technology portfolios that serve the same food security target within a EWF nexus framework developed for the State of Qatar. Whilst the current results indicate that energy mixes involving conventional CCGT exhibit variability in terms of economic risks, this is readily minimized by the introduction of BIGCC/BECCS technologies, as indicated by the cluster representing the intermediate levelized costs and risks. In addition, the inclusion of photovoltaics further diversifies the mix and hedges against the potential risks owing to the fluctuations in natural gas prices and carbon tax. Moreover, in accordance with the principles of economy of scale and learning curves, a general tendency now exists for the lowering of capital costs, which is expected to make photovoltaics a more competitive form of power generation in the future.

With regards to the drawbacks identified in the proposed methodology, there is a need for an extension to include a detailed consideration of other potential risk factors that have been assumed to be absent in the current assessment, particularly in the cases of renewable energy sources. Moreover, the authors acknowledge that a more rigorous time-dependent stochastic optimization framework with predictive capabilities could be implemented by including the levelized costs of other technologies that participate in the sustenance of the nexus, namely those related to the water and food sectors, and the associated value chains.

Abstract

Multi-objective optimization algorithms are employed in chemical process engineering to simultaneously model objectives related to profit, emissions, and safety. The challenge in generating trade-off curves for these problems comes from the nonlinearity and complexity of plant design models, so stochastic optimization techniques are considered in this work to compute Pareto-optimal surfaces. The purpose of this research is to investigate the efficacy and capabilities of the Tabu search algorithm for multi-objective optimization, specifically for plant design models. Traditional Tabu search algorithms have three key characteristics: local intensification, diversification, and the utilization of a Tabu list to apply adaptive memory to guide the search. Local intensification serves to ensure that search areas with several good solutions are searched thoroughly. Diversification allows access to wider regions of the search space.

In this work, a Tabu Search algorithm is developed to solve plant design models for multiple objectives. An alkylation process was investigated in order to maximize the profit while simultaneously minimizing the byproduct formation. This is significant as energy requirements decrease with decreasing byproduct formation. Pareto-optimality curves were generated, and results show how tuning the parameters of the algorithm leads to more efficient determination of the Pareto surface, for highly nonlinear plant design models. While the Tabu search algorithm allows for the generation of Pareto-optimality curves, it is limited for larger problems by its lack of directionality in search. Therefore, the implemented multivariable Tabu search algorithm utilizes a greedy heuristic in determining the next region of the search space to investigate. A bounding component was introduced which progressively tightens of bounds, leading to smaller search regions and improving computational efficiency of the algorithm. Results show the efficacy of the novel approach.

Keywords: Multi-objective Optimization, Tabu Search, Plant Design

1. Introduction

Optimization within plant design enables the determination of operating conditions which produce the most profit, minimize environmental impact, or reduce safety concerns (Kalyanmoy, 2013). Often it is desirable to simultaneously optimize multiple objectives including profit, and environmental impact (Acevedo & Pistikopoulos, 1997). Realistic plant design models are normally formulated as mixed-integer nonlinear programs (MINLPs). When these models are solved while optimizing multiple objectives, the goal becomes the determination of a Pareto-optimal set of solutions. A solution can be classified as Pareto-optimal if one of the objectives cannot be improved without worsening another objective (Rangiah, 2017) The value of the

Pareto-optimal solution set lies in the fact that a process designer can use it to consider trade-offs. For example, a process can be design to operate with lower risk, but at a higher cost. Due to the nonlinearities in the problem formulations, deterministic algorithms often fail to find Pareto-optimal points; therefore, stochastic algorithms are utilized. While other stochastic methods such as genetic algorithms have been used for multi-objective optimization (Fonseca 1995), Tabu search has many advantages which allow an efficient determination of the Pareto-optimal solution set.

Tabu search is a stochastic algorithm developed in 1989 that uses the search history to guide the algorithm (Glover, 1989). Tabu search has been used for job-shop scheduling (Dell'Amico & Trubian, 1993), plant layout problems (Kaku & Mazzola, 1997), and molecular design (McLeese *et al*, 2010). Traditional Tabu search for single variable optimization exhibits three key characteristics: local intensification diversification, and the use of a Tabu list (Glover, 1989).

2. Methods: Multi-objective Tabu Search

To simultaneously optimize two objectives via Tabu search, the first objective is optimized, then the second objective is optimized while holding the first objective within a variable tolerance of the maximum value. Both loops utilize Tabu search with local intensification, diversification, and bound strengthening. Local intensification is a technique applied to promising regions of the feasibility space to ensure that they are more thoroughly searched. A region of the search space may be classified as promising if it contains a solution set for which the objective value exceeds a user-defined benchmark or is within a certain tolerance of a current Pareto-optimal solution. Local intensification reduces the step size of changes to independent variables, ensuring a finer search is conducted in regions containing good solution sets.

A search space is deemed promising if the successive addition of a directional step change, h_1 , to one of the independent variables increases the investigated objective function. Local intensification occurs after the objective function no longer increases with the addition of the step change to the independent variable. Subsequently, the directionality of the step change is reversed and divided by a positive integer, η , such that: $h_2 = -\frac{h_1}{\eta}$, where h_2 is an integer. This increases the efficacy of the algorithm as only promising search areas are tested with small sequential step changes to the independent variables. This process is repeated until the objective function no longer increases, at which point diversification is enabled.

After local intensification, the candidate solution set of the investigated search space is evaluated against other local optima. If the objective value of the candidate solution vector is greater than the objective value of the previously determined 'best' solution vector, then the candidate solution vector becomes the 'best' solution vector and is added to the Tabu list. Figure 1 shows the details of local intensification and the tuning of the step size within the developed multi-objective Tabu search algorithm.

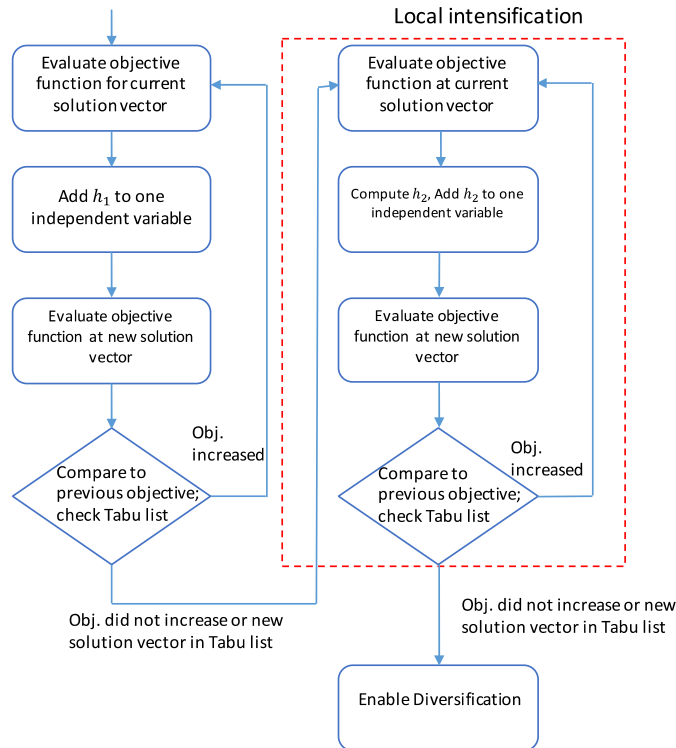

Figure 1: Flowchart showing the structure for varying an independent variable with the addition of a step to find a locally Pareto-optimal solution, $h_1 = \text{step change}$, $h_2 = -\frac{h_1}{\eta}$ where η is an integer.

Diversification is a technique that is employed after the algorithm has completed local intensification, determined that the solution vector is Pareto-optimum, or has encountered a solution vector on the Tabu list. Modifications are made to the solution set to move the next candidate solution set to a new area of the search space. For this algorithm, after a candidate solution set is evaluated against the best candidate solution set, the next candidate solution set is filled from the possible values of the independent variables. This enables a shallow search of many regions quickly to determine which ones are promising and should be investigated with more rigor.

A greedy heuristic is utilized in the determination of the candidate solution set by selecting the neighbor, in the investigated direction, of the current candidate solution vector that has the greatest objective value. Note that if the next candidate solution vector is on the Tabu list, then the next candidate solution set is determined through diversification. To reduce the search space that must be investigated, the bounds of the independent variables are tightened. The bounds of the independent variables are: the modified upper bound is a fixed value greater than the respective variable value within the ‘best’ solution vector, the modified lower bound is another fixed value less than the respective variable value with the ‘best’ solution set. The modified lower and upper bounds cannot be greater or lesser, respectively, than the original constraints on the independent variables.

In order to optimize two variables simultaneously, an inner and outer loop structure was utilized. Within the inner loop the first objective function was optimized using single variable Tabu search. The optimized value of the first objective, and the corresponding ‘best’ solution set are subsequently utilized as the starting point for the outer loop. Within the outer loop, the second objective is optimized using Tabu search, while the first objective is maintained within a tolerance of the optimized value of the inner loop. This is treated as a constraint that must be satisfied in order to replace the outer ‘best’ solution vector for that iteration. This process is repeated while the tolerance increases with each iteration. As can be seen in Figure 2, at the end of each iteration, the outer ‘best’ solution vector should correspond to a value of the first objective that is within the tolerance of the inner loop valve, while the second objective is maximized with respect to the constraints.

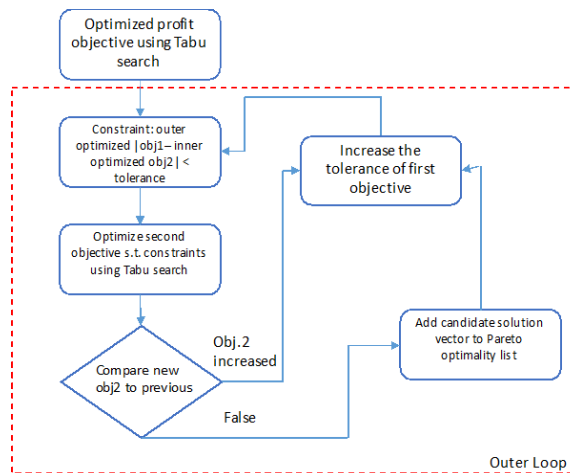

Figure 2: Flowchart showing the structure of the inner and the outer loop of the multi-objective Tabu search algorithm

3. Problem Formulation

To evaluate the effectiveness of the novel algorithm, the following example was obtained from Rangiah (2016). This example shows the capacity of the algorithm to determine Pareto-optimal points for highly nonlinear problem formulations with multiple degrees of freedom, and objectives. The formulation is sufficiently generic as to be applicable to specific industrial settings without requiring large modifications.

Table 1: Variables in the example formulation and their physical meaning

Variables:	Physical Representation:	Units:
x_1	Olefin Feed Flowrate	Barrels/day
x_2	Isobutane Recycle Flowrate	Barrels/day
x_3	Acid Addition Rate	Thousand pounds/day
x_4	Alkylate Production Rate	Barrels/day
x_5	Isobutane Feed Flowrate	Barrels/day
x_6	Spent Acid Strength	Weight Percent
x_7	Octane Number	N/A

x_8	Isobutane to Olefin Ratio	N/A
x_9	Acid Dilution Factor	N/A
x_{10}	F-4 Performance Number	N/A

Objectives:

$$\text{Max Profit} = 0.063x_4x_7 - 5.04x_1 - 0.035x_2$$

$$\text{Max isobutane: olefin ratio} = x_8$$

Bounds on Variables:

$$0 \leq x_1 \leq 2,000$$

$$90 \leq x_7 \leq 95$$

$$3 \leq x_8 \leq 12$$

$$0 \leq x_4 \leq 5,000$$

$$0 \leq x_5 \leq 2,000$$

$$0 \leq x_2 \leq 16,000$$

$$85 \leq x_6 \leq 93$$

$$145 \leq x_7 \leq 162$$

$$1.2 \leq x_9 \leq 4$$

$$0 \leq x_3 \leq 120$$

Constraints:

$$x_4 = x_1(1.12 + 0.13167x_8 - 0.006667x_8^2)$$

$$x_5 = 1.22x_4 - x_1$$

$$x_2 = x_1x_8 - x_5$$

$$x_{10} = -133 + 3x_7$$

$$x_9 = 35.82 - 0.222x_{10}$$

$$x_3 = 0.001 \frac{(x_4x_6x_9)}{98 - x_6}$$

4. Results

The example problem formulation is solved with our multi-objective Tabu search algorithm, and the Pareto-optimal points shown in Figure 4 were generated. A modified Tabu search which includes an additional bounding technique which reduces the search region, by constricting the bounds of the manipulated variables was utilized to generate Figure 3.

Figure 3: Pareto-optimality curve for the alkylation problem, the profit is on the x-axis, while the isobutane:olefin ratio is on the y-axis

It was determined that the utilization of the designed Tabu search algorithm is successful in determining Pareto-optimality points. The points classified as Pareto-optimal are those for which the profit cannot be improved without worsening the isobutane to olefin ratio, or vice versa. The points were shown to be locally Pareto-optimal via comparison with the solution vector's corresponding neighboring points. The maximum profit was determined by conducting a single variable optimization with profit serving as the sole objective and the maximum isobutane to olefin ratio was determined via the constraints. For the example presented, the novel method finds the Pareto-optimality frontier efficiently and the Pareto-optimal points generated are in agreement with those presented in Rangiah 2017.

5. Conclusions

In this work, a novel multi-objective Tabu search optimization technique is presented. Additionally, a bounding technique was applied which increases the efficacy of the algorithm by reducing the search space, through tightening of constraints. It was determined that it is feasible to generate a Pareto-optimality curve for plant design problems utilizing multi-objective Tabu search. The advantage of utilizing Tabu search for multivariable optimization stems from its ability to be easily modified for various problem formulations and its ability to be solved in parallel. For the implemented algorithm, and Tabu search holistically, the structure of the search technique allows it to be easily modified to solve different problem formulations. As the algorithm can search different regions of the feasibility space independently, the search space can be partitioned, allowing for the problem to be solved in parallel. The use of the Tabu list also prevents cycling issues between near Pareto-optimal solutions. Most importantly, because of local intensification ensuring a thorough search, diversification ensuring a broad search, and the Tabu list with bound modification driving the direction of search, the algorithm is able to converge on Pareto-optimal solutions efficiently.

milos.bogataj@um.si

Abstract

In this work, we propose an alternative mixed-integer (MI) reformulation of Generalized Disjunctive Programs (GDP) and compare its efficiency against the Big-M and hull reformulation (HR). We show that the reformulation yields a continuous relaxation equal to the HR for linear GDPs and comparable to the one obtained by HR for nonlinear GDPs. A particular advantage of the proposed reformulation is that the usage of the perspective function can be avoided when reformulating nonlinear GDPs. The reformulation is validated on a set of numerical examples using Branch and Bound algorithm. Results obtained thus far indicate that the proposed reformulation represents a promising alternative to the established ones.

Keywords: Disjunctive Programming, Mixed-Integer Programming, Big-M Relaxation, Hull Relaxation.

1. Introduction

A common approach to process synthesis is usually based on a superstructure representation of competitive/plausible alternatives. The most intuitive way for representing it in a mathematical language is the one in the form of GDP (Raman and Grossmann, 1994; Türkay and Grossmann, 1996). While, among other advantages, the GDP framework facilitates the modelling stage, solving these problems is not a straightforward task. In most cases, a GDP problem is reformulated to an MI problem and then solved using the established solvers.

The GDP problems can be formulated as mixed-integer (non)linear problems (MI(N)LP) in different ways. This, however, leads to models of different sizes (in a number of variables and constraints) and of different tightness (i.e. relation of the feasible region of a problem to the feasible region of its continuous relaxation). Therefore, the efficiency of the solvers to solve these problems depends on the type of the reformulation.

Several procedures can be utilized to achieve the MI formulation - the most instinctual being the Big-M relaxation (Nemhauser and Wolsey, 1988). While it produces small-sized models, its relaxation strongly depends on the selection of Big-M parameters. Often, even when the smallest Big-M parameters are selected, the Big-M reformulation results in a weak continuous relaxation. Recently, an improved Big-M reformulation for GDP has been presented by Trespalacios and Grossmann (2015). In contrast to the traditional one, the latter uses multiple Big-M parameters for each constraint. Consequently, it produces tighter continuous relaxations and reduces the computational effort needed to solve discrete-continuous optimization problems.

To obtain tighter relaxations, Lee and Grossmann (2003) proposed an HR for (non)linear convex GDPs. It produces at least as tight relaxation as the Big-M reformulation, however, it requires additional variables and constraints. It has been shown that HR, although it produces larger-sized models, dominates the Big-M reformulation in the majority of cases, primarily because of the tight relaxation it produces. The concept of HR in process synthesis problems was utilized and further developed by Ropotar and Kravanja (2009). The authors presented an HR based on MI translation of variables. The reformulation tends to exploit the benefits of the fact that the variables in engineering problems are often bounded by nonzero positive lower and upper bounds. For additional insights into a hierarchy and advances in relaxations and reformulations for GDPs, the reader is referred to Sawaya and Grossmann (2012), and Ruiz and Grossmann (2012).

The remainder of the manuscript is organized as follows. In section 2 we present an overview of a GDP model and present the alternative MI reformulation. In section 3 we present an illustrative example. Section 4 is dedicated to testing of the proposed reformulation on a set of process synthesis examples and presentation of the results.

2. Alternative MI reformulation of GDP

Consider the general GDP presented as follows:

$$\begin{aligned}
 \min Z &= \sum_{ik} c_{ik} + f(x) \\
 \text{s.t.} \quad & h^g(x) \leq 0 \\
 & \bigvee_{i \in D_k} \begin{bmatrix} Y_{ik} \\ g_{ik}(x) \leq 0 \\ c_{ik} = \gamma_{ik} \end{bmatrix} \quad k \in K \quad (\text{GDP}) \\
 & \bigvee_{i \in D_k} Y_{ik} \quad k \in K \\
 & \Omega(Y) = \text{True} \\
 & x \in \square^n, c_{ik} \in \square, Y_{ik} \in \{\text{True}, \text{False}\}
 \end{aligned}$$

In (GDP) the objective is a function of continuous variables, $h^g(x) \leq 0$ are global (non)linear constraints, which must hold true regardless of the discrete decision. Each of the disjunctions $k \in K$ contains disjunctive terms D_k , linked by an OR operator (\vee). A Boolean variable Y_{ik} is assigned to each of the disjunctive terms, which contain a set of local (non)linear constraints ($g_{ik}(x) \leq 0$) describing the alternatives. The local constraints within a given term are only enforced when a corresponding Boolean variable takes a value of *True*. On the other hand, if the Boolean variable equals *False*, the local constraints are ignored. $\Omega(Y) = \text{True}$ represents a set of logical propositions.

The proposed MI reformulation of (GDP) based on MI translation of variables is given by (AMI). Similar to the HR presented by Lee and Grossman (2003), the Boolean variables in (AMI) are transformed into 0-1 variables y_{ik} , the continuous variables x disaggregated into variables x_{ik}^D and the logical propositions reformulated into a set of linear constraints $Ey \leq e$. The main difference between the reformulations is that the disaggregated variables x_{ik}^D are not required to be forced to 0 when $y_{ik} = 0$.

$$\begin{aligned}
\min Z &= \sum_{ik} y_{ik} \gamma_{ik} + f(x) \\
\text{s.t.} \quad & h^g(x) \leq 0 \\
x &= \sum_{i \in D_k} x_{ik}^D - (1 - y_{ik}) x_{ik}^F & k \in K \\
g_{ik}(x_{ik}^D) - (1 - y_{ik}) g_{ik}(x_{ik}^F) &\leq 0 & i \in D_k, k \in K \\
x_{ik}^D &\geq x_{ik}^{D,LO} y_{ik} + (1 - y_{ik}) x_{ik}^F & i \in D_k, k \in K \quad (\text{AMI}) \\
x_{ik}^D &\leq x_{ik}^{D,UP} y_{ik} + (1 - y_{ik}) x_{ik}^F & i \in D_k, k \in K \\
Ey &\leq e \\
\sum_{i \in D_k} y_{ik} &= 1 & k \in K \\
x^{LO} &\leq x \leq x^{UP}, y_{ik} \in \{0, 1\}
\end{aligned}$$

Instead, they are forced to arbitrary fixed values x_{ik}^F (vanishing points -VPs), which are usually chosen between nonzero lower and upper bounds of variables x_{ik}^D . For additional explanation of the reformulation based on MI translation of variables, the reader is referred to Ropotar and Kravanja (2009). In their work, the authors have shown that if local constraints ($g_{ik}(x) \leq 0$) are reformulated using the perspective function i.e.

$y_{ik} (g_{ik}((x_{ik}^D - (1 - y_{ik}) x_{ik}^F) / y_{ik})) \leq 0$, the above reformulation produces relaxation identical to HR. If local constraints in (GDP) are linear, it can be easily shown that $y_{ik} (g_{ik}((x_{ik}^D - (1 - y_{ik}) x_{ik}^F) / y_{ik})) = g_{ik}(x_{ik}^D) - (1 - y_{ik}) g_{ik}(x_{ik}^F)$. Therefore, the reformulation as given by (AMI) is a hull relaxation for GDPs containing linearly constrained disjunctive feasible regions. If the local constraints are nonlinear or combination of linear and nonlinear constraints, the relaxation of (GDP) as given by (AMI) is generally weaker as the one produced by the HR. However, using an initialization procedure, described in section 2, the relaxation obtained by (AMI) is expected to be considerably tighter than the one obtained by the Big-M reformulation.

3. Illustrative example

We illustrate the proposed reformulation on an example taken from Trespalacios and Grossmann (2015). The example deals with optimization of linear objective function over a set of disjoint circles. Its GDP representation is given by (1). The optimal solution of the example is $Z = -9.472$, $Y = (\text{False}, \text{False}, \text{True})$, $x = (5.789, 2.106)$. If we apply the (AMI) model to (1) we obtain the MINLP reformulation (2). The solution of the relaxed MINLP, assuming the VPs are the centers of the circles (i.e. (0,0), (1,5) and (4,3)), is $Z^R = -9.816$, $y = (0.027, 0.038, 0.935)$ and $x = (5.859, 1.902)$. The continuous relaxation is stronger as the one obtained by the Big-M reformulation ($Z^R = -10.493$) and slightly weaker than the one obtained by the improved Big-M reformulation ($Z^R = -9.735$). However, if we select the VPs as (0.680, 1.934), (1.372, 4.431) and (5.788, 2.015), the relaxation is identical to the one obtained by the HR and relaxed MINLP problem produces integer solution: $Z^R = Z = -9.472$, $y = (0, 0, 1)$, $x = (5.789, 2.106)$. It is evident that the selection of VPs in (AMI) plays an important role in providing tight continuous relaxations when the constraints in the disjunctions are nonlinear.

$$\begin{aligned}
\min \quad & Z = \sum_{v \in V} c_v x_v \\
& \bigvee_{i \in D_k} \left[(x_1 - a_i)^2 + (x_2 - b_i)^2 - r_i \leq 0 \right] \\
& \bigvee_{i \in D_k} Y_i = \text{True} \\
& -1 \leq x_1 \leq 6, -1 \leq x_2 \leq 7; \\
& c = (-2, 1), a = (0, 1, 4), b = (0, 5, 3), r = (1, 2, 4)
\end{aligned} \tag{1}$$

$$\begin{aligned}
\min \quad & Z = \sum_{v \in V} c_v x_v \\
x_v &= \sum_{i \in D_k} x_{v,i}^D - (1 - y_i) x_{v,i}^F \quad v \in V \\
& (x_{1,i}^D - a_i)^2 + (x_{2,i}^D - b_i)^2 - r_i - (1 - y_i)((x_{1,i}^F - a_i)^2 + (x_{2,i}^F - b_i)^2 - r_i) \leq 0 \quad i \in D_k \\
& x_{v,i}^D \geq x_{v,i}^{D,LO} y_i + (1 - y_i) x_{1,i}^F \quad v \in V, i \in D_k \\
& x_{v,i}^D \leq x_{v,i}^{D,UP} y_i + (1 - y_i) x_{1,i}^F \quad v \in V, i \in D_k \\
& \sum_{i \in D_k} y_i = 1 \\
& x_{v,i}^{D,LO} = (-1, -1), x_{v,i}^{D,UP} = (6, 7) \quad v \in V, i \in D_k \\
& c = (-2, 1), a = (0, 1, 4), b = (0, 5, 3), r = (1, 2, 4)
\end{aligned} \tag{2}$$

3.1. Algorithm for selection of VPs

To study the effect of how the selection of VPs affects the continuous relaxation of (2), we have generated 500 random VPs within each of the disjoint feasible regions. The results show the average value of $Z^R = -10.542 \pm 0.764$ to be approximately 10 % weaker than the one obtained by the HR. Nevertheless, we have observed that the relaxed problem does produce relaxation identical to the HR in several instances. Currently, the theoretical background for whether there always exists a set of VPs that guarantees as tight continuous relaxation as the one obtained by the HR and, if it does, how to determine such VPs is still under investigation. However, what has shown to be a promising path is to first solve a reduced version of (AMI) and set the optimal values of disaggregated variables as VPs for (AMI). The reduced model (redAMI) is given as follows:

$$\begin{aligned}
\min \quad & Z = \sum_{i,k} f(x_{ik}^D) \\
\text{s.t.} \quad & g_{ik}(x_{ik}^D) \leq 0 \quad i \in D_k, k \in K \\
& x_{ik}^{D,LO} \leq x_{ik}^D \leq x_{ik}^{D,UP}
\end{aligned} \tag{redAMI}$$

By solving (redAMI), we optimize the continuous part of the objective function over the feasible region constrained solely by local constraints. Note that the only type of variables present in the model is the disaggregated continuous variables. Testing the procedure on the 500 randomly generated VPs has revealed that in all the instances (redAMI) produces VPs that lead to the tightest possible continuous relaxation. We must note that solving (redAMI) introduces another step into the optimization

procedure; however, since the model is significantly smaller, the impact of solving (redAMI) on the solution time is expected to be low. As a final note, the effect of VPs on the tightness of the continuous relaxation is only present if the disjunctions contain nonlinear or combination of linear and nonlinear constraints.

4. Process Synthesis Examples

In this section, we compare the efficiency of the proposed reformulation against Big-M and HR reformulation. The process network synthesis is a classical optimization problem in which the goal is to select a process network that maximizes profit while considering the costs of raw materials and the cost of the process units. The numerical examples Proc8, Proc10 and Proc12 are variations of the example introduced by Turkey and Grossmann (1996). A general GDP model is described by (3). The examples were solved using SBB solver. The results for the three instances are given in Tables 1-2.

$$\begin{aligned}
 \min Z &= \sum_i c_i + \sum_j p_j x_j + \gamma \\
 \text{s.t. } &\sum_j r_{j,n} x_j \leq 0 \quad \forall n \in N \\
 &\left[\begin{array}{c} Y_i \\ \sum_j d_{i,j} (e^{x_j/t_{i,j}} - 1) - \sum_j s_{i,j} x_j \leq 0 \\ c_i = \gamma_i \end{array} \right] \vee \left[\begin{array}{c} -Y_i \\ x_j = 0, j \in J^i \\ c_i = \gamma_i \end{array} \right] \quad (3) \\
 \Omega(Y) &= True \\
 x_j, c_i &\geq 0, Y_i \in \{True, False\}
 \end{aligned}$$

Table 1: Comparison of relaxations and total computational times.

Ex./N _{bins}	Opt.	Big-M ^a		HR ^b		redAMI + AMI	
		LB	t _{CPU} /s	LB	t _{CPU} /s	LB	t _{CPU} /s
Proc8/8	68.01	-829.88	0.23	67.7334	0.13	67.7334	0.11
Proc10/10	-27.93	-1146.88	0.84	-40.1313	0.16	-40.1314	0.14
Proc12/12	-69.21	-894.52	2.01	-73.8895	0.14	-73.8895	0.09

a – Value of 50 was used for all the Big-M parameters. | b – In the HR reformulation, value of 1e-6 was used for ε.

Table 2: SBB solver statistics.

Ex.	Big-M			HR			redAMI + AMI		
	Iter	Nds	t _{NLP} /s	Iter	Nds	t _{NLP} /s	Iter	Nds	t _{NLP} /s
Proc8	801	34	0.23	117	1	0.12	53	1	0.09
Proc10	2820	205	0.84	236	4	0.15	78	5	0.05
Proc12	7347	463	1.97	174	3	0.14	99	3	0.08

As can be seen in Table 1, the HR and the proposed approach (redAMI +AMI) produce significantly tighter relaxations than the Big-M reformulation in all the instances. Both the HR and the proposed reformulation exhibit faster computational times. The proposed approach produces equally tight continuous relaxations as HR in two instances (Proc8 and Proc12), while the relaxation of Proc10 is slightly weaker, consequently causing an increase in the number of nodes searched to find the optimal solution. Interestingly, the proposed approach requires the least computational time to find optimal solutions and the least solver iterations (Table 2).

5. Conclusions

Over the last decades, a number of reformulation strategies for obtaining tighter continuous relaxations of discrete-continuous problems have been proposed. In this work, we present a reformulation that utilizes MI translation of variables and avoids the usage of the perspective function. When dealing with nonlinear GSPs and their MINLP representations, the first property, as suggested by Ropotar and Kravanja (2009), tends to reduce the search space of nonlinear subproblems. The second property might be important for producing more robust nonlinear subproblems as the proposed reformulation does not introduce additional nonlinearities to the model. Based on the results presented in this work, we can conclude that the proposed reformulation provides results comparable to those obtained by the HR, both in terms of tightness of continuous relaxation as well as of the computational effort needed to obtain optimal solutions. Future work will focus on research dedicated to providing the answers regarding the procedures for obtaining VPs, and testing of the proposed reformulation on large-scale synthesis problems. We believe that the findings of the future work will enable us to fully evaluate the benefits as well as drawbacks of the proposed reformulation.

LES of particle collision and agglomeration in vertical channel flows

T. Ogholaja*, D.O. Njobuenwu, M. Fairweather

School of Chemical and Process Engineering, University of Leeds, Leeds LS2 9JT, UK

Abstract

Large eddy simulation in a four-way coupled system is used to simulate particle collisions and agglomeration in turbulent vertical channel flows. The particle phase is modelled using Lagrangian particle tracking, ensuring that individual particle behaviour is effectively monitored by solving the particle equation of motion. Particle collisions are described using the hard-sphere collision model, with agglomeration tested based on the pre-collision kinetic energy, restitution coefficient and the van der Waals interactions between particles. The conditions influencing collision and agglomeration are studied for a fluid of $Re_\tau = 300$ with $125 \mu\text{m}$ spherical particles at volume fraction $\phi_v \sim O(10^{-3})$. Comparing flows in upward and downward directions reveals the influence of the various forces acting on the particles, with the drag and lift forces being dominant in both flows, although the latter is found to govern particle behaviour in downflow, driving the particles towards the wall regions where increased collisions and agglomeration occur. The particle distribution in upflow is more symmetric, with fewer collisions and agglomerations, due to the increased effects of drag. The fluid flow is also slightly modified by the presence of the particles.

Keywords: Eulerian-Lagrangian, particles, collision, agglomeration, vertical channel

1. Introduction

Particle collision and agglomeration can occur in a wide range of industrial applications where particle-laden flows are being transported. Instances of such behaviour are found in the nuclear industry during the mobilisation and transport of waste materials, in the pharmaceutical industry where fine chemicals are continuously being processed, and in the oil and gas industry during the exploration and processing of crude oil. In these applications, as well as in many others, it is important to gain an understanding of the rheological behaviour of such flows, particularly in terms of the impact of particle agglomeration which can lead to particle deposition and ultimately flow blockage. Numerical models are frequently used in evaluating particle-laden flows since they can generate understanding that is often impossible to gain through experimental means. The Reynolds-averaged Navier-Stokes (RANS) computational fluid dynamic approach is most commonly used in industry due to its relatively modest computational requirements, although large eddy simulation (LES) and direct numerical simulation (DNS) provide far more accurate turbulent flow predictions, and do not require the case-by-case adjustments necessary when using RANS techniques. LES is preferred in this study given that it is a compromise between the more accurate but computationally expensive DNS, and the relatively low computational cost but lower precision RANS approach.

The current study combines LES with a Lagrangian particle tracking (LPT) approach to improve the accuracy of turbulent two-phase flow predictions over those based on RANS techniques through the time and spatial resolution of the motion of large turbulent eddies, with individual particle motion tracked. Only a few studies of particle agglomeration in wall-bounded flows exist, with most investigations focussing on the dynamics of particles within a flow and their resulting effect on the flow structure. Relevant studies include those of Afkhami et al. (2015) and Njobuenwu et al. (2017) who both used LES as the basis for predicting particle agglomeration, although particle behaviour was modelled using the discrete element method and Lagrangian particle tracking, respectively. Almohammed et al. (2016) compared energy-based and momentum-based agglomeration models, whilst Sommerfeld et al. (2017) introduced a novel agglomerate structure model. Overall, however, our understanding of particle agglomeration remains poor, particularly for the case of wall-bounded flows. Building on previous work (Ogholaja et al., 2017), this study aims at improving our understanding of these flows by extending the investigation to vertical channels, where fluid flow with and against the direction of gravity is expected to lead to contrasting collision and agglomerate formation processes. In particular, the type and number of agglomerates formed in these flows, their local concentrations and their impact on the flow are considered. The understanding gained is of value in improving our ability to predict particle deposition that may lead to flow restrictions.

2. Numerical Simulation

Fluid flow predictions were derived based on solutions of the time-dependent Navier-Stokes equations for an incompressible Newtonian fluid. The BOFFIN-LES simulation code was employed (Bini et al., 2008), which uses a top-hat technique to filter the governing equations of motion. A dynamically calibrated version of the Smagorinsky model was used in computing the resulting sub-grid scale tensor, while the influence of the unresolved velocity fluctuations on particle motion was modelled using a stochastic Markov technique. The code is based on a finite-volume approach, having a co-located grid arrangement and using an implicit low-Mach number formulation. A two-step approximate factorisation pressure correction method is applied to ensure mass conservation, with the time step chosen to ensure the maximum Courant number lies between 0.1 and 0.3. More details of the mathematical model and numerical solution method can be found in Bini et al. (2008) and Ogholaja et al. (2017).

Integration of the particle equation of motion was performed within the LPT code, with the particle velocity and location computed using a fourth-order Runge-Kutta integration method, given initially random particle positions and velocities set equal to those of the fluid. The study considered all the significant forces acting on the particles, namely drag, gravity/buoyancy, added mass, shear lift and pressure gradient forces. The simulation was four-way coupled, ensuring particle-particle and particle-fluid interactions. The deterministic hard-sphere collision model (Breuer and Alletto, 2012) was employed in the prediction of particle interactions, with agglomeration modelled using the approach proposed by Breuer and Almohammed (2015).

The number of grid nodes used in the x , y and z directions of the channel was $129 \times 128 \times 128$, respectively, corresponding to the wall normal, spanwise and streamwise

directions. For both fluid and particles, periodic boundary conditions were imposed in the y and z directions, whilst in the x direction, fixed boundaries with no-slip conditions for the fluid velocity and elastic particle collisions were assumed. The flow considered was of shear Reynolds number $Re_\tau = u_\tau h/\nu = 300$, based on the channel half height, h , the shear velocity, u_τ , and the kinematic viscosity, $\nu = 10^{-6} \text{ m}^2 \text{ s}^{-1}$. The continuous phase density was that of water, $\rho = 10^3 \text{ kg m}^{-3}$. The particles were assumed spherical and of equal diameter, $d_p = 125 \text{ }\mu\text{m}$, and density, $\rho = 2710 \text{ kg m}^{-3}$, with a particle volume fraction $\phi_v \sim O(10^{-3})$. The minimum particle contact distance δ_0 was $3.36 \times 10^{-10} \text{ m}$, the mean yield stress σ was $3.0 \times 10^8 \text{ Pa}$, and the Hamaker constant H set to $3.8 \times 10^{-20} \text{ J}$, with the normal restitution coefficient $e_n = 0.4$ being representative of calcite (a frequently used simulant in nuclear waste studies). Simulations were performed for flows in both upward and downward directions, given the anticipated differences in particle behaviour. In order to isolate these effects, a number of assumptions were made: particle-particle collisions are binary; no agglomerate break-up due to turbulence; minimal particle deformation post-collision; and particle agglomeration based on the pre-collision particle energy, restitution coefficient and van der Waals interactions.

3. Results and Discussion

Results from both single- and two-phase channel flow simulations were first validated against direct numerical simulation-based predictions, see Ogholaja et al. (2017), with good agreement found.

For the upward and downward channel flows, Fig. 1(a) compares the total number of particle collisions, N_{col} , and agglomerations, N_{agg} , for both flows up to a simulation time of $t^+ = 1000$. Both flows show increases in N_{col} and N_{agg} with time, and it is clear that not all collisions result in agglomeration. Both flows initially show a sharp increase in the number of collisions and agglomerations, although with time the rate of increase of both reduces. Unlike for the upflow, however, N_{col} and N_{agg} continue to increase with time in the downflow, and do not asymptote to an approximate steady state. This is as a result of the lift effect which enhances particle migration into regions of high turbulence near the channel walls, consequently increasing particle interactions. This is confirmed by the particle concentration profiles in Fig. 1 which clearly indicate particle migration towards the wall regions in the downflow, whilst the bulk of the particle concentration for the upflow remains evenly distributed across the channel, although depleted in the near-wall regions. Also shown in Fig. 1(b) is the rate of depletion of the primary single particles with time, and the corresponding evolution of multi-sized particle agglomerates, for the two flow cases. In both flows, two-particle agglomerates form fairly rapidly early in the simulation, after which larger agglomerates form through collisions between single primary particles and larger agglomerates, and also between the agglomerates themselves. These results also show that the formation of agglomerates is more prevalent in downflow, with agglomerates consisting of up to five primary particles forming over the time period considered, which contrasts with the upflow case which has a maximum of three particle agglomerates. Again, the increased number of multi-sized particle agglomerates in downflow is a result of more collision events occurring in near-wall regions within the flow where particle concentrations are high due to effect of the lift force on the particles.

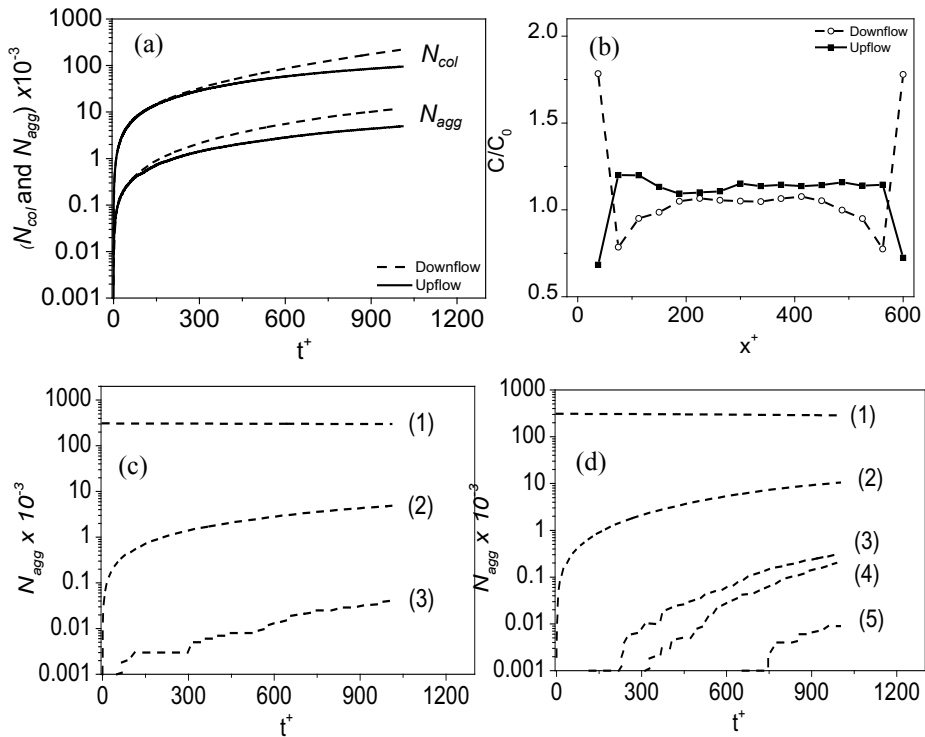

Figure 1. (a) Total number of collisions and agglomerates with time, (b) particle concentration profiles across the channel, and (c, d) agglomerate formation with time for upflow and downflow, respectively. Line numbers: single particle (1), double particle (2), etc.

Figure 2 provides more detail on the collision and agglomeration distribution across the channel width. Results are shown for the cross-stream domain divided into 16 regions in the wall-normal direction at $t^+ = 1000$, although results are averaged over $t^+ \pm 500$ about this time to provide a sufficiently large statistical sample. In upflow, the number of collisions and agglomerations are roughly constant, although there are slightly more collisions in the near-wall regions of the flow where turbulence levels are high. In downflow, the trends are noticeably different, with collision and agglomeration reaching maximum levels in the two wall regions due to the migration of particles from the bulk flow towards the walls. As already noted, the lift force is responsible for the continuous increase in particle concentration in the wall regions where turbulence levels are high, consequently promoting more collisions and agglomerations. This is confirmed in the plots that give the forces acting on the particles in the wall-normal direction in the same figure. In these plots, only one half of the channel is shown as the results show identical behaviour in both halves. The lift and drag forces are clearly dominant, and act on the particles in opposite directions, whilst all other forces are insignificant. In upflow, these two forces are almost balanced, explaining why collision and agglomeration events across the channel are nearly symmetric, although there is a slight migration of particles towards the wall owing to the more dominant lift force. In downflow, this imbalance is more pronounced, with the more dominant lift force pushing the particles at a faster rate towards the two wall regions.

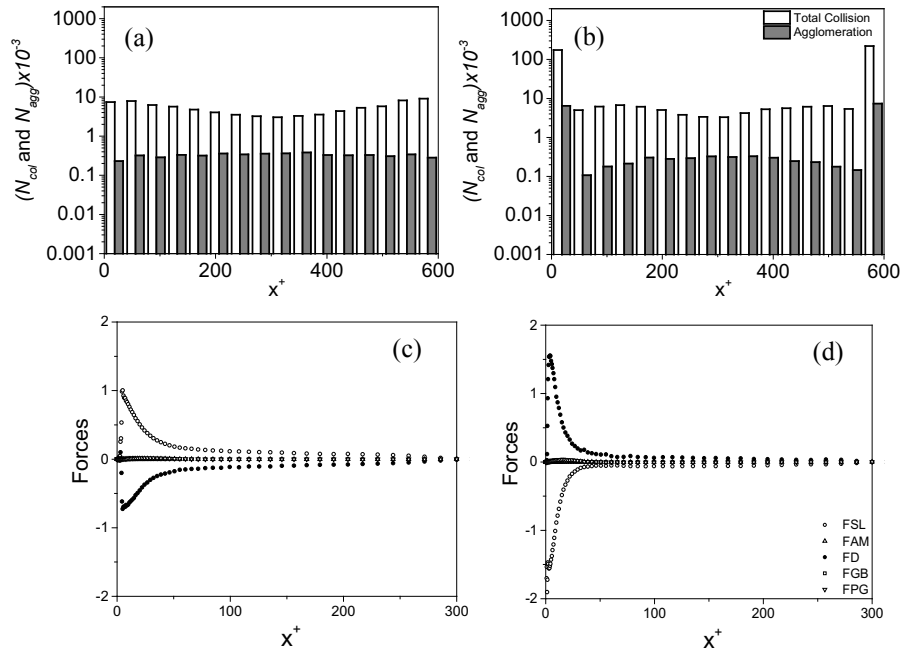

Figure 2. Distribution of particle collisions and agglomerations across the channel for (a) upflow and (b) downflow, and (c, d) forces in $(N \text{ kg}^{-1})$ acting on the particles at $t^+ = 1000$ for upflow and downflow, respectively (FSL = shear lift, FAM = added mass, FD = drag, FGB = gravity/buoyancy, FPG = pressure gradient).

Figure 3. Continuous phase streamwise mean velocity in (a) upflow and (b) downflow.

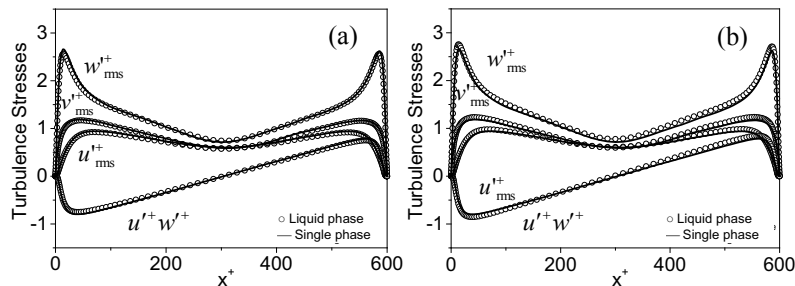

Figure 4. Continuous phase normal and shear stresses in (a) upflow and (b) downflow.

Lastly, the effect of particles on the fluid flow is considered in Figs. 3 and 4, again at $t^+ = 1000$, where single-phase flow predictions are compared with liquid phase results for flows including particles. In upflow, the fluid mean streamwise velocity is suppressed due to the increased drag on the fluid, and enhanced in downflow where drag forces are less influential. Additionally, in Fig. 4 a very slight decrease in the upflow stresses is apparent, whilst the opposite is the case in downflow. These differences are, however, almost negligible.

4. Conclusions

LES coupled with a Lagrangian particle tracking technique has been employed to predict particle collision and agglomeration in turbulent vertical channel flows. Collision and agglomeration increase with time, although at a much higher rate for a downward flow where particles are observed to migrate towards the wall regions, where turbulence levels are high, owing to the dominant lift force effect on the particles. The particle distribution in upflow is more symmetric, with fewer collisions and agglomerations, due to the increased effect of drag. Only slight changes to the velocity field of the continuous phase are predicted due to the presence of the particles, although some slight enhancement is evident in downflow, with the opposite the case in upflow.

Improved modeling of membrane separation in integrated hybrid processes

Bettina Scharzec^a, Mirko Skiborowski^a

Abstract

Membrane processes reportedly provide a tremendous potential for improving separation performance and energy efficiency compared to thermal separation processes (Sholl and Lively, 2016). However, the benefits of membrane processes, as e.g. the ability to overcome limitations of other separation techniques introduced by azeotropes or eutectic points, are exploited best when integrated in hybrid processes (Skiborowski et al., 2013). Nevertheless, industrial applications are still limited due to a lack of reliable models that allow for an accurate description of the separation performance of the membrane. Process design approaches oftentimes neglect limiting effects, such as pressure drop, or concentration and temperature polarization. However, the impact of ignoring these limitations was recently demonstrated by Micovic et al. (Micovic et al., 2014) for modeling organic solvent nanofiltration. Additionally, the correct consideration of the flow pattern, such as co- and counter-current as well as cross flow, can have an equally significant impact on the accuracy of the model. However, the consideration of cross flow requires a two dimensional discretization resulting in a more complicated model compared to co- or counter-current flow.

In order to consider all these complex effects in a simultaneous process optimization an efficient model reduction without sacrificing model accuracy has to be performed. In this respect, Skiborowski et al. (Skiborowski, 2014) proposed to model a pervaporation-assisted distillation process, using an orthogonal collocation on finite elements (OCFE) for accurately modeling a co-currently operated membrane module, while applying external functions for computing thermodynamic properties. However, only temperature polarization was considered.

The current work extends this approach by implementing concentration polarization and pressure drop computations. Furthermore, modifications of the OCFE approach towards the alternative flow patterns are investigated and comparisons with simple discretization schemes are presented. The results indicate the benefits of the efficient model reduction by OCFE in order to allow for the consideration of more accurate modeling of the membrane process.

Ontology engineering approach to support process of model integration

Linsey Koo^a, Edlira Kalemi^a, Nikolaos Trokanas^a, Franjo Cecelja^a

Abstract

Process modelling and simulation is a vital tool to plan, evaluate, assess, and develop different alternatives for the design of products and processes. The complexity of problems as well as heterogeneity of modelling methods make process modelling and simulation challenging, time consuming and often tedious process requiring a wide range of expertise. Inconsistencies in model development are the main cause for redundant work. Models remain implicit to the engineers who have built them, which further limits the potential of reusability. The only model integration framework in use, the CAPE-OPEN, addresses the issue of standardisation of interfaces to enable interoperability between simulator software components from different sources. It is the framework built around a middleware, the Common Object Request Broker Architecture (CORBA) that hosts communication between unit operations defined for a specific function and the process modelling environments. The standard specification is defined as a property package which is needed for a thermodynamic or physical property calculation. The interoperability of models, such as model selection, parameter identification, and experimental work is enabled through the connection related to the unit operations and physical properties. It is not necessary to match all parameters in order to facilitate Input-Output (I-O) matching. However, the shortcoming of the CAPE-OPEN is in the need for identifying key variables for each unit operation.

In this paper a new approach for model integration is proposed which builds upon the CAPE-OPEN framework and proposes the use of ontology and replaces the object bus with more flexible semantic repository (Koo, Trokanas and Cecelja, 2017). Models are described by Semantic Web Services (SWS) using Ontology Web Service Description (OWL-S) as an enabler of web services through service discovery, selection, composition, and execution stages (Figure 1). The discovery stage allows formation of an integrated model through matching requests from a public repository(ies). The best match that satisfy the requestor's functionality is selected in the model selection stage. The model composition stage then formulates the chain of integrated models and execution of integrated model takes place during the execution stage. This paper focuses on the matching parameters related to the domain of process system engineering, with emphasis placed on the role of physical properties and unit operation. Each model representing a device (e.g. unit operations, flowsheets, subflowsheets etc.) is semantically described in domain ontology including domain assumptions and descriptions of the functionality of the model. The domain ontology guides the process of registering models and instantiation of ontology through ontology parsing, which makes the model and data explicit and sharing terminology in domain ontology

improves consistency. The devices in a process are connected via streams that transmit information through multiple inlets and outlets from one unit to the other. The connection between devices are described in ontology by introducing the concept of 'ports' and 'connections'. The 'ports' generally describe inlets and outlets of devices and three different types of streams are distinguished: material, energy, and information, which are further described by objective properties. The 'connections' are the object that is responsible for establishing a link between two ports, which contains information regarding methods, types, quantities, and units of streams.

Approximation Algorithms for Process Systems Engineering

Abstract

Approximation algorithms offer heuristics with performance guarantees for difficult mixed integer linear optimization problems. In this presentation, we consider two major problems in process systems engineering, heat exchanger network synthesis and re-optimization after an unexpected system fail.

Heat exchanger network synthesis exploits excess heat by integrating process hot and cold streams and improves energy efficiency by reducing utility usage. Determining provably good solutions to the minimum number of matches is a bottleneck of designing a heat recovery network using the sequential method. This subproblem is an NP-hard mixed-integer linear program exhibiting combinatorial explosion in the possible hot and cold stream configurations. We explore this challenging optimization problem from a graph theoretic perspective and correlate it with other special optimization problems such as cost flow network and packing problems. In the case of a single temperature interval, we develop a new optimization formulation without problematic big-M parameters. Numerical results from a collection of 51 instances substantiate the method.

Unexpected system failures may confront a decision-maker. For example, a machine in an industrial system may unexpectedly fail, a client may suddenly cancel a job, or a machine may complete a job significantly earlier than expected. In these circumstances, re-optimization is essential.

Our work studies a fundamental parallel machine-scheduling problem, which is part of several complex problems, e.g. manufacturing production planning. We show that the recovery problem is strongly NP-hard, at least as hard as the planning problem. Thus, combining planning and recovery does not mitigate the problem's computational complexity. But, if the initially planned solution is produced using lexicographic optimization, we prove a positive performance guarantee of the recovered solution for every input realization. Lexicographic optimization becomes a powerful tool towards efficient re-optimization under uncertainty. In addition to its significance in scheduling problems, our contribution can be extended to uncertain min-max partitioning problems with more general cost functions and other major applications, e.g. facility location and network communications. The novel lexicographic optimization method strengthens solutions obtained with our approach. This method and its underlying components are also of independent interest to other fields in the scope of lexicographic optimization including multi-objective optimization and fairness.

We close with an outlook on the possible applications of approximation algorithms to process systems engineering.

Abstract

In this work we have developed and analyzed two alternative $\text{Si}_{(\text{SG})}$ production processes using a stochastic optimization scheme within ASPEN PLUS. The first one is an intensified Fluidized Bed Reactor (FBR) process using a reactive distillation column. The second process is a hybrid process combining both the Siemens and the conventional FBR processes. The base case is the optimized Siemens process. The optimized processes show savings in the TAC of 53.28%, 67.65% and 62.58% for Siemens, Intensified FBR and Hybrid process, respectively. Siemens process is the one with the lowest TAC. However, it has the lowest silicon production rate, 0.47 kt/y. The Intensified FBR Union Carbide Process turns out to be the most expensive of the three, but with a large production of $\text{Si}_{(\text{SG})}$, 1.49 kt/y. However, it is the hybrid process which shows the larger yield by far, with a production of 1.89 kt/y of $\text{Si}_{(\text{SG})}$ and TAC of 1.95 M\$/y, showing the highest profit from sales of the three, 40.47 M\$/y. From the environmental point of view, the Siemens process shows the lowest environmental impact based on the eco-indicator 99, while the Hybrid process is the second best.

Keywords: Silicon, Alternative processes, Optimization, TAC

1. Introduction

For years, microelectronic industry has been an important source of polysilicon. In that industry, ultrapure Si, 9N or $\text{Si}_{(\text{EG})}$, is required. The waste of Si remaining in the melting units as well as the pieces of waffles that do not reach the proper purity are typical sources of solar grade Si (Braga et al., 2008). However, the development of the solar sector has increased the demand for solar grade Silicon and the scraps from microelectronic industry are no longer enough to meet the needs of PV industry. Therefore, there is a need to improve the production processes from polysilicon to reduce their cost. The cost shares per Watt Peak of polysilicon solar systems are roughly as follows: Solar grade silicon ($\text{Si}_{(\text{SG})}$): 20%; ingot and wafer production: 28%; solar cell processing: 13%; solar module processing: 9%; installation of the PV-system including converter costs: 30% (Sadique, 2010). There are two main opportunities to reduce the

panels cost since approximately half of it is due to the materials, bulk silicon production and wafer manufacturing (Müller et al., 2006). Thus, the development of optimized processes for production of cheap $\text{Si}_{(\text{SG})}$ feedstock material can help reduce PV power production costs

Solar grade silicon can be produced from quartz following a two-stage process consisting of the production of metallurgic silicon and its further purification up to solar grade quality. The two most used processes are Siemens and Fluidized Bed Reactor, FBR, from Union Carbide. Siemens process was patented by Siemens Corporation in the 1950's. Its main feature is the Siemens or Bell reactor where 6N silicon is produced by Si deposition on a silicon pole (Payo, 2009). However, this alternative shows a large energy consumption and a number of waste streams. On the other hand, Union Carbide's process uses silane as a raw material for the production of Si. It was developed in the 1970s (Erickson and Wagner, 1952). Even though the yield of this alternative is larger than the one provided by Siemens process, the conversion from silane is larger than that from trichlorosilane and the operating conditions are more difficult to achieve.

Due to the high production cost of PV panels, the aim of this work is to reduce the production costs of $\text{Si}_{(\text{SG})}$ by developing more efficient processes. In particular two novel processes have been developed in this paper. The first one corresponds with an intensified FBR's process by substituting the conventional reactors and separation stage with a reactive distillation column (RD) intensifying the process. Furthermore, this configuration improves the yield, because products alone are withdrawn from the reactive zone while reactants remain inside the reactive zone for further reaction. This reactive distillation section has been reported previously in the work of Ramírez-Márquez et al. (2016). The second alternative process is a novel process that is based on both, the Siemens and the FBR attempting to reduce the use of raw material (Vidal and Martín, 2014). The three simulated processes were optimized for a consistent comparison of their in their Total Annual Cost (TAC) and in their production capacity of solar grade silicon.

2. Methodology

We first simulate the all three processes rigorously in Aspen Plus V8.4. To predict the thermodynamic of the system, we used the thermodynamic package Peng-Robinson, and 'Solids' property method for solids components. To meet the typical production capacity of around 2000 t/y, the processes are fed with the components and quantities with 532.32 kg/h of SiO_2 and 369.84 kg/h of Carbon. The simulation was carried out through the use of various Aspen modules. In the case of reactors, the stoichiometric module was mainly used, in the chlorosilanes synthesis reactors, the combination of two reactors had to be considered, because the software did not allow the sequential reaction of the components in a single reactor. Something similar happened with the carboreduction and deposition of silicon, where the reactor is essentially an oven, where the reactor was used with an oven to achieve the simulation. The 'RadFac' module was used for rigorous conventional distillation columns and for reactive distillation. A conventional set of modules was also used to implement the separators, pumps, compressors and exchangers, always trying to take care of each of the processes. Note that implementing solid compounds in Aspen is an arduous task. Next, we perform a

stochastic based optimization to decide on the column design and the operating conditions for each process.

Furthermore in this work we have added the calculation of the environmental impact which is measured through the Eco-indicator 99, a cradle to gate methodology, which reflects the advances in the damage-oriented method recently developed for Life Cycle Impact Assessment (LCA), as show Guillén-Gosálbez et al., (2008). The Eco-indicator 99 was chosen, since it is one of the most widely used impact assessment methods in LCA, and for the purposes of this work it is indicated, because allows the environmental load of a product to be expressed in a single score. Three different processes are proposed for obtaining the $Si_{(SG)}$, such is the case of the a) Siemens Process, b) the Enhanced FRB Process and c) the Hybrid Process (See Figure 1).

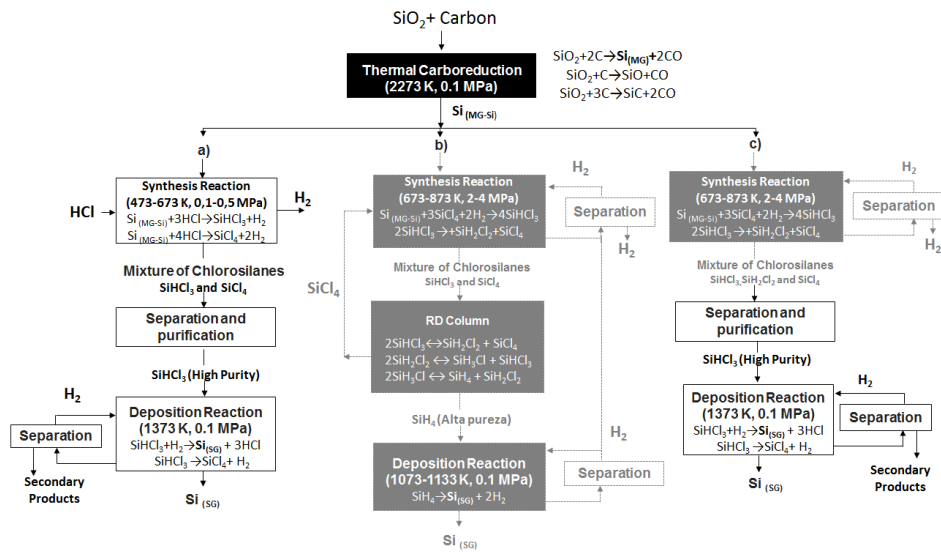

Figure 1. Scheme of the $Si_{(SG)}$ production processes. a) Siemens process, b) FBR Union Carbide with RD column process, c) Hybrid process.

The first case is the Siemens Process, which consists of a carboreduction section, followed by a chlorosilanes synthesis reactor using HCl as a precursor. Next, the mixture is separated in a conventional distillation column, to finish with the Siemens deposition reaction to produce solar grade silicon. The second process called intensified FRB, begins also with quartz carboreduction. Next, chlorosilanes are produced using $SiCl_4$ as a precursor. Subsequently, the separation process consists of two conventional separation columns, and two reactive distillation columns to obtain silane before moving on to the silicon deposition reaction. The last process is the one named as the Hybrid Process. It consists basically of the combination of the two previous ones. The first part of the process, until the separation, corresponds to the FRB Process. Then in the separation, two conventional columns are used, and the part of the deposition reaction, similar to the Siemens Process. Each process is optimized separately. Note that the design and the optimization of the processes are highly nonlinear problems involving continuous and discrete design variables. Furthermore, the objective function is potentially non-convex, with the possibility of finding local optimum and being subject to constraints.

In order to optimize the three processes, we used a stochastic hybrid optimization method due to the model is highly non-linear, potentially non-convex and with a large amount of local minimums, also the model is not explicitly stated. The use of stochastic optimization methods is a good alternative; several reports have proved the successful application in cases of study with those already mentioned characteristics. The stochastic hybrid optimization is called differential evolution with tabu list (DETL) (Srinivas and Rangaiah, 2007). The implementation of this optimization approach was made using a hybrid platform including Microsoft Excel, Aspen Plus and Matlab. The vector of decision variables (i.e., the design variables) are sent to Microsoft Excel to Aspen Plus using DDE (Dynamic Data Exchange) through a COM technology. In Microsoft Excel, these values are attributed to the process variables that Aspen Plus needs. After the simulation, Aspen Plus returns to Microsoft Excel the resulting vector. Those values are sent from Microsoft Excel to Matlab where the objective functions are calculated. Finally Microsoft Excel suggests new values of decision variables according to the used stochastic optimization method.

For this study, the following parameters have been used for the DETL method: 200 generations, 200 individuals, a tabu list size of 100 individuals, a tabu radius of $2.5 \cdot 10^{-6}$, Crossover fractions (Cr): 0.8, Mutation fractions (F): 0.6, respectively. The parameters were obtained via preliminary calculations, as shown in the methodology of Srinivas and Rangaiah, (2007a). The objective function used is shown in equation (1).

$$TAC = \frac{\text{Capital Cost}}{\text{Payback time}} + \text{Operating cost} \quad (1)$$

The payback time of the plant is considered to be five years, and 8400 hours of annual operation for each process are assumed. In each of the iterations we calculate the TAC of units such as the vessel of the reactor, furnaces, separators, mixers, heat exchangers, pumps and compressors. The units cost depend on their size and operating cost.

3. Results

In this section we present the results of the optimization of each of the processes including the iteration results to show that a plateau is reached and the operating and design variables. Thus, we first show a Figure of the iterations vs TAC obtained for each case will be shown. The TAC decreases over the iterations and a good value is achieved for 40,000 iterations. This is taken to be a valid solution since there is not a significant decrease in the last evaluations. This demonstrates the robustness of the DETL method, showing the convergence and results corresponding to good solutions.

All the runs to carry out the optimization were performed on an Intel (R) Core TM i7-4790 CPU @ 3.6 GHz, 16 GB computer, the computing time for obtaining the optimal solutions was different according to the complexity of each process: The Siemens process required 28.2 hours, the FBR Union Carbide Process required 125.6 hours, and the Hybrid process required 127.2 hours. In the case of the Siemens configuration, it is possible to observe that only the optimization of a single conventional column and the fresh feed of HCl to initiate the reaction of the reactor producing the silanes are performed. These parameters represent substantial economic savings in the process, since the separation section always represents a high cost in any chemical process, and that the right amount of reactant represent large savings in the actual operation of the

process. In the optimization of the Siemens Process, the initial configuration has a TAC of 1.08 M\$/y, ending with a TAC of 0.50 M\$/y, representing savings of 53.28%.

The Intensified FBR Union Carbide Process has the highest number of decision variables to optimize. For the Siemens Process infers the manipulation of 7 decision variables among continuous and discrete variables for each route process. The Intensified FBR Union Carbide Process implies the manipulation of 29 variables among continuous and discrete variables for each route process. And for the Hybrid Process infers the manipulation of 13 continuous and discrete variables for each route process. The optimization was carried out in two conventional columns, two reactive distillation columns, and the fresh feed stream of SiCl_4 . The TAC of the initial configuration of the Intensified FBR Union Carbide is 7.95 M\$/y and ending with 2.57 M\$/y, saving 67.65%. The Hybrid Process shows the optimization of two conventional columns, and the fresh SiCl_4 feed. The initial configuration has a TAC of 5.21 M\$/y, ending with 1.95 M\$/y, saving 62.58%. Table 1 shows, for all sequences, the capital cost, the TAC, the energy required and the products. Note the comparison between the TAC and the amount of products, mainly with the produced $\text{Si}_{(\text{SG})}$.

Figure 2. Results of TAC, ECO-99, amount of solar grade silicon, and profit per sale of all configurations.

Table 1. Comparative results for all process.

	Q [kW]	TAC [\$/y]	$\text{Si}_{\text{S-G}}$ [ton/y]	H_2 [ton/y]	SiH_2Cl_2 [ton/y]	SiCl_4 [ton/y]	HCl [ton/y]
Siemens	58,963	506,790	477.4	185.2	N/A	7807.9	N/A
FBR	63,042	2,573,400	1,495.9	221.0	1,237.2	N/A	N/A
Hybrid	64,344	1,951,075	1,899.0	260.1	1,335.1	5762.9	1643.5

The least expensive process is the Siemens one. However, it also shows the minimum annual production of $\text{Si}_{(\text{SG})}$. The Intensified FBR Union Carbide Process turns out to be the most expensive of the three proposed, with a large production of $\text{Si}_{(\text{SG})}$, but it is not

the best in this way. The Hybrid Process shows the highest production of $\text{Si}_{(\text{SG})}$, at a higher cost compared to the Siemens process, but lower than the Intensified FBR Union Carbide process. Figure 2 shows the potential of the hybrid process with the most important items. Performing the analysis of the results the potential of the Hybrid Process could be observed, which could represent an incentive for the silicon industry. It is known that the processes Siemens and FBR Union Carbide, are technologies that have matured over time and are the ones usually used in the production of $\text{Si}_{(\text{SG})}$, but the $\text{Si}_{(\text{SG})}$ industry could benefit from novel alternatives such as the Hybrid Process.

4. Conclusions

In this work, we have developed intensified and optimized processes for the production of $\text{Si}_{(\text{SG})}$. The results show that the Siemens process presented the smallest TAC, but with the lowest production of $\text{Si}_{(\text{SG})}$. The Intensified FBR Union Carbide Process, showed the largest TAC due to the capital cost of the equipment and the heat duty for $\text{Si}_{(\text{SG})}$ purification. Finally, the Hybrid Process exhibited a large production of $\text{Si}_{(\text{SG})}$, with a TAC between the one of the Siemens process and that of the Intensified FBR Union Carbide. However, evaluating the TAC vs production of $\text{Si}_{(\text{SG})}$, it turned out that the Hybrid Process was the best of the three. In addition to the above, the Hybrid Process shows the largest gains from the sale of the multiple products resulting, with earnings of 40.47 M\$/y. It is expected that with this type of research can be made more competitive the technology based on $\text{Si}_{(\text{SG})}$, lowering the costs for the industry of solar panels.

Abstract

Biorefineries are the most promising route for the sustainable exploitation of lignocellulosic biomass sources into a wide range of fuels and materials. Value chains include all potential processing routes from raw materials to intermediate and end-chemicals that are possible to enter the biorefinery site. In this scope, process integration techniques are required to evaluate all potential biorefinery structures and reveal promising multiple-product biorefinery solutions with high efficiencies in use of energy and materials. Provided that biorefinery operations subject to seasonal availability of biomass varieties, the design problem additionally requires screening and planning of appropriate biorenewable feedstocks. This work introduces new concepts and representations that incorporate processes and feedstocks as additional degrees of freedom in integration. The proposed methodology investigates synergies among candidate processes, which benefit the biorefinery instead of operating individually, as well as schedules multiple-feedstock operations. A biomass representation maps all process synthesis options along value chains, while a cascade representation is proposed to simultaneously model direct (heat source-to-sink) and indirect (via steam generation-reuse) integration among involved processes of under-construction site. The proposed model (MILP) is explained through real-life biorefinery cases, which involve 15 candidate biorefinery paths and 6 candidate biomass varieties. The model reveals high efficiency biorefining routes and examines preferences on the use of multiple feedstocks minimizing the annual energy cost of under-construction biorefineries.

1. Introduction

Biorefineries are mainly related with the use of cheap and abundant lignocellulosic material that consists of sugars and lignin. Lignocellulosic sources are met in agricultural and forestry residues as well as in pulp industry wastes. A range of novel chemistries have been revealed over the recent years that upgrade lignocellulosic biomass into commodity and chemical specialties like polymers, solvents, lubricants, pharmaceuticals, nutraceuticals, cosmetics, surfactants, animal feed and fuels (Hughes et al., 2013). Figure 1 shows a typical lignocellulosic value chain with multiple choices for biomass feedstocks and chemical products that may enter upcoming biorefineries. Since there are not clear technical, commercial and environmental evidences for the selection of biomass varieties and chemistries, engineering tools are required to systematically screen benefits from integration of different processes across same site and detect biomass mixtures that maximize efficiencies in use of energy and materials.

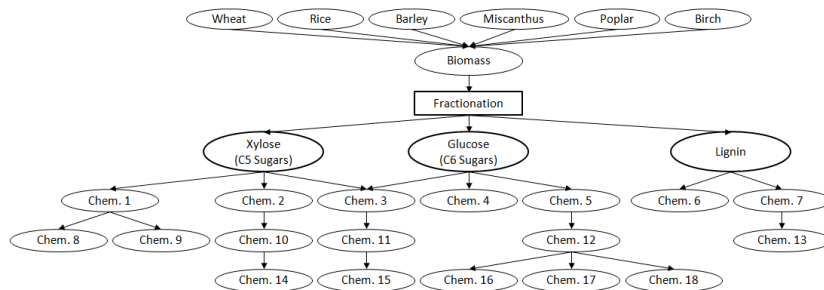

Figure 1. Illustrative biorefinery value chain.

2. Problem description

Process integration techniques are used to estimate cost savings by exchanging materials and energy among processes instead of operating individually. Energy integration searches for heat source-to-sink matches maximizing heat recovery within each process. At a next level, Total Site Analysis (TSA) applies for the integration of different processes and estimates steam targets by means of graphical and numerical tools based on the concept of Site Sources and Sinks Profiles (SSSPs). Though there is extensive literature for steam targeting in sites, the conventional concepts appear inefficient to apply for the design of biorefineries, since processes and operations are not fixed and known beforehand; namely, SSSPs cannot directly apply for the infinite candidate sites that emerge through value chains. Beyond selection of processes to integrate, the problem also brings questions about operations and capacities of involved processes, which subject to seasonal availability and variability of biomass. There are several literature studies focusing on the optimization of biomass supply chains (Yue et al., 2014) and planning energy systems (Varbanov and Klemeš, 2011); however the approaches are limited by the use of graphical tools that exclusively address particular synthesis applications and scenarios. The design of sustainable biorefineries requires for multiple processes and products that properly integrate within sites as well as planning of multiple-feedstock operations over the year. Therefore, integration thermodynamics should be combined with mathematical programming to systematically assess energy targets of all potential process combinations so as to maximize benefits from process-to-process integration. Fundamentals of this concept has been recently presented by Kokossis et al. (2015). This work further presents systems representations that map value chain synthesis options and integration thermodynamics to develop a comprehensive optimization model that can be widely used as a engineering tool for synthesis, integration and planning problems in existing or upcoming industries.

3. Methodology

The conventional Total Site integration tools assume given processes that exchange energy via steam production and reuse. When the case includes candidate processes and infinite combinations to integrate, the graphical tool appears inefficient to estimate steam targets; steam sources and sink profiles would actually behave as variable curves that vary according to process selections and capacities along value chains each time. Kokossis et al. (2015) originally introduced an integration concept that addresses processes as additional variables in integration generating value chain paths combinations assuming paths as binary options. This paper further establishes a cascade

representation that lets processes and their capacities get combined in any way; namely, competitive processes may exist in the design for sake of improved energy targets. Synthesis options for storing and biomass pre-treatment (drying) are also introduced in the process synthesis representation to enable switching and combining biomass feedstocks as well as to plan multiple-feedstock operations over the year.

Process portfolios are developed by means of a Biomass Bipartite graph Representation (BBR) that enables the development of mass balances along value chains considering seasonal changes in biomass feedstocks. Heat contents of sources (hot streams) and sinks (cold streams) vary according to selections made by BBR. A Total Site Representation (TSR) that is based on common sense of heat cascading but formulated by means of an extended transshipment model enables recording energy balances among candidate process hot/cold streams and utility levels. The proposed Total Site Cascade is configured by combining temperature intervals of all individual heat cascades - each related with a candidate process - along a super-interval cascade that is used for direct and indirect integration purposes of variable processes. Heat contribution to cascade intervals is adjusted by decisions made by BBR. Direct heat source-to-sink integration (within each process) is described quite similarly to conventional integration at each interval of the proposed cascade that is configured according to minimum temperature difference (ΔT_{min}). Indirect integration refers to heat exchange among processes via steam production-reuse and is described by translating excess heat of intervals into generated steam and transferring that energy, through cross-interval heat flows, to lower temperature intervals according to minimum temperature difference of the site, $\Delta T_{min}^{site} = 2 \cdot \Delta T_{min}$, where $1 \cdot \Delta T_{min}$ accounts for steam generation and $1 \cdot \Delta T_{min}$ for steam reuse. Hot streams and utilities residuals of the proposed Total Site Cascade can be used to reproduce the sources and sinks profiles of regular SSSPs.

Synthesis of paths also copes with matching steam-source with steam-sink processes improving steam savings due to overlap of generated and demanded steam. Processes may act as steam source or sink or both according to processes portfolio in which they are integrated with. While Total Site cascade evaluates steam savings under steady-state biorefinery operations, biomass seasonality imposes changes on process capacities and energy efficiencies in time, since each variety features with different organic content and yields in sugars and lignin capacities; these constitute the main intermediates in lignocellulosic biorefineries (Figure 1) and rule all downstream process capacities.

Biomass seasonality and the use of multiple feedstocks are incorporated by letting input chemicals flows related with chemicals stored in previous seasons. Storage and drying facilities have been employed (i) to store biomass feedstocks for seasons with biomass shortage as well as to compose biomass mixtures that improve biorefinery efficiencies and (ii) to dry woody biomass before entering the biomass fractionation process, which constitutes the core process in lignocellulosic biorefineries (Figure 1). Changes in biomass feedstocks naturally result in changes of intermediates yields, downstream process capacities and process streams heat contents. As a result, selections on biomass varieties have an apparent impact on energy savings and the selection of steam-source/sink-process portfolios. Steam savings are also affected by the number and the temperature levels of applied utilities along the cascade. The size and complexity of the combined process synthesis and integration problem require the use of mathematical programming to optimize multiple-product biorefinery structures and plan multiple-feedstock operations. Portfolios made by BBR are integrated and evaluated by TSR. Mass (BBR) and energy (TSR) balances are constructed as an optimization model

(MILP) that makes selections on processes, biomass mixtures and utilities and plans the annual biorefinery operation to minimize the energy cost of the under-construction site.

4. Systems representations

BBRs (Figure 2.a) employ product nodes, units and interconnections to translate unclear value chains into superstructure-like representations for optimization purposes. So, let $P=\{p|p=1,NP\}$ and $PR=\{pr|pr=1,NPR\}$ be the process units and product nodes assigned to each path and chemical of the value chain; $T=\{t|t=1,NT\}$ be the interconnections that make connections among nodes (pr) and units (p); $B=\{b|b=1,NB\}$ be the biomass varieties and $SE=\{se|se=se1,\dots,se4\}$ be the seasons of the year for biorefinery operation. Also, let variable F_t be the chemical flowrate of interconnection t . Storing in BBRs is dedicated to interconnections that transfer chemicals from one season to next one. Storing in facilities protected from environmental conditions is also capable to secure drying of woody biomass (50% w/w moisture content) at the rate of 5% w/w per season. For this reason, storages $p1-p4$ denote (Figure 2.a) free of energy cost drying in storage facilities for seasons $se1-se4$, respectively; drying in storages cannot reduce moisture lower than 30% w/w. Drying units $p6-p9$ are next applied to further dry biomass exiting units $p1-p4$ down to the limit of 15% w/w that is required for operation of the core biomass fractionation process; drying is not required for non-woody biomass, whose moisture content is below this limit. Mass balances are recorded using flowrates, F_t , of input-output interconnections at each product node and process unit. Logical constraints are also required to limit intense and impractical fluctuations of process capacities over the year due to equipment sizing and instrumental design limitations. The heat contents of contributed process streams are linearly estimated by the selected operation capacities (flowrates of process input interconnections) and the known (estimated by process simulations) heat contents of streams per product flowrate.

For the development of TSR (Figure 2.b), let C_p be the cascade of each candidate process p . Also, let $QS_m^{C_p}$, $QW_n^{C_p}$ and QS_m^{TS} , QW_n^{TS} be the heat loads of hot, cold utilities of cascade C_p and the Total Site. The Total Site Cascade (TSC) is formulated by the temperature intervals of all candidate cascades. Energy balances are formulated using an extended transshipment model that uses detailed heat exchange options among hot-cold streams and utilities at each interval. Heat flows referring to direct integration of streams of different processes are fixed to zero. Thus, the TSC incorporates all debottleneck problems of candidate processes without affecting each other; accordingly, the utility demands of the TSC correspond to the demands of all individual cascades. A Utility Storages System (USS) has been also set-up to supervise the utilities demands of the TSC. Excess heat from the TSC is extracted by cold utilities and next sent to lower-temperature intervals replacing external steam demands. The excess heat is transferred via energy bridges that pass through the USS, which estimates the energy overlap between generated-demanded steam and thus, minimizes the external utilities needs.

5. Case studies

5.1. Case 1

The biorefinery value chain of Figure 3 involves 6 candidate biomass varieties (wheat straw, rice, barley, miscanthus, softwood and hardwood) and 17 chemical products that need to be examined in order to reveal energy promising biorefinery solutions. Each

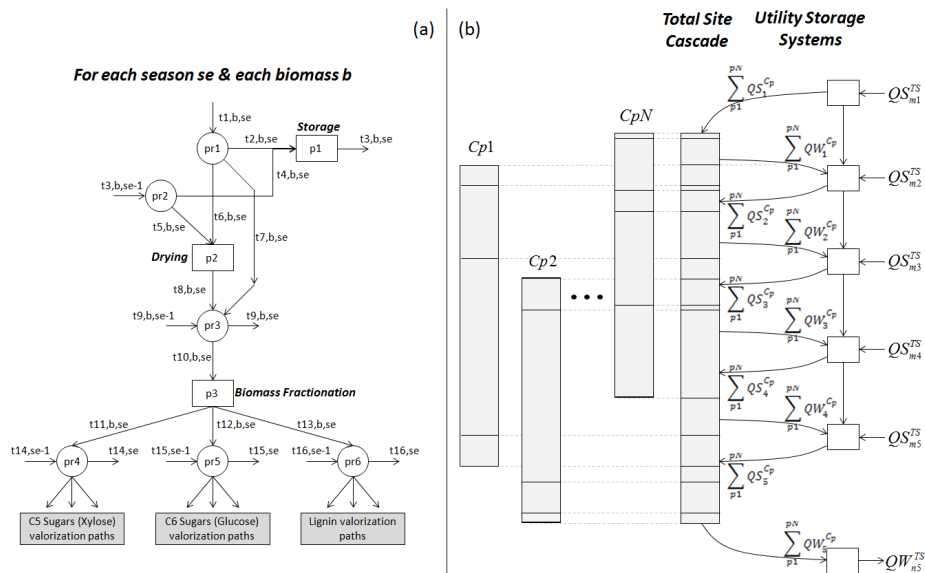

Figure 2. Systems Representations of BBR (a) and TSR (b).

path from one chemical to another denotes a chemical process. The paths have been optimized in the course of a biorefinery study in Hungary based on real-life seasonality data. Hungary offers options for wheat, barley and hardwood. The biorefinery size is bounded by the installation capacity of the biomass fractionation process at 22.500 kg/hr of dry matter. Wheat straw was preferred instead of barley and hardwood due to its low sugars content, which result in lower operation capacities and energy cost for the energy intensive sugar-based paths compared to the lower energy intensive lignin-based paths. Barley is used at wheat depletion completing the annual biomass needs, while hardwood is excluded. The biorefinery includes the biomass fractionation process as well as the xylitol, isoprop./butanol and poly-urethanes production processes. The utilities are estimated to 58 MW (hot) and 40 MW (cold), while the generated steam replaces 6.5% of external steam demands. In Case 2, the proposed model was applied to examine preferences on biomass varieties in building biorefinery efficiencies.

5.2. Case 2

The model was applied for multiple times by additionally using inter-cut equations to constrain selections about biomass varieties by excluding each time the varieties that selected in previous runs. Table 1 presents the results according to the preferences obtained for the varieties. Miscanthus has been selected as the prime biomass variety for minimizing energy cost, while softwood holds the last position. High trends have been obtained for xylitol, isoprop./butanol and poly-urethanes production processes, while itaconic acid enters the biorefinery site sharing the xylose (C6 sugars) intermediate with isoprop./butanol process at the use of rice or barley. The percentages reflect to the selected process operation capacities on the basis of their maximum capacities. The maximum capacities account for operations, when processes do not share upstream (input) chemicals with other competitive processes. Drying facilities are also included at the use of woody biomass. The results of Table 1 could play a significant role in making quick decisions on selecting and planning production lines and multiple-feedstock operations according to biomass availability at each season.

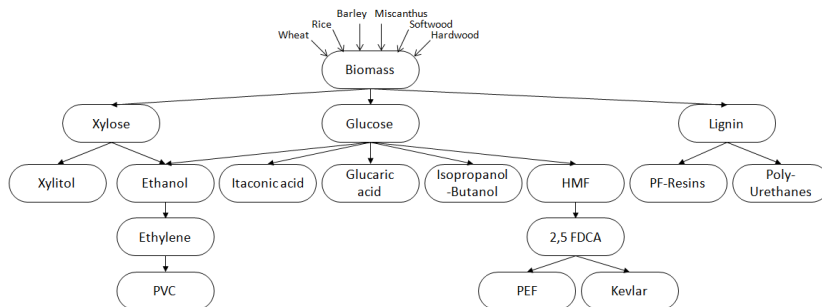

Figure 3. Understudied biorefinery value chain.

Table 1: Ranking of biomass varieties with respect to energy cost

Ranking biomass varieties	Dryers	Splitting intermediates among competitive products			
		Biomass to Fractionation process	Xylose to Xylitol	Glucose to Itaconic acid	Lignin to Poly-Urethanes
(1)Miscanthus	-	100%	100%	100%	100%
(2)Rice	-	100%	100%	13%	100%
(3)Wheat	-	100%	100%	100%	100%
(4)Barley	-	100%	100%	13%	100%
(5)Hardwood	100%	100%	100%	100%	100%
(6)Softwood	100%	100%	100%	100%	100%

6. Conclusions

This paper presents systems representations to model process-to-process integration and select biorefinery portfolios that subject to seasonal availability of biomass varieties. Total Site integration is re-stated as a process synthesis tool that addresses processes and biomass feedstocks as additional degrees of freedom in integration procedure. A biomass representation maps all value chain process synthesis options and the use of multiple feedstocks, while an extended transshipment model is used to evaluate energy savings from process-to-process integration. The proposed methodology was used to reveal high energy efficient process portfolios, assess preferences on biomass varieties and plan multiple-feedstock operations minimizing the annual biorefinery energy cost.

Abstract

In this work is presented the simultaneous design and optimization of three alternatives of azeotropic distillation processes to purify Furfural by the mathematical technique called Differential Evolution with Tabu List (DETL), having as objective functions economic, environmental and safety criteria to the processes were evaluated. The schemes here studied are: conventional Quaker Oats process to purification of Furfural (CQO), an azeotropic distillation process with heat integration through vapour recompression (DHI) and dividing wall azeotropic distillation column (DWC). The results of the simultaneous optimization show that the intensification processes DHI and DWC have important reduction on the cost and environmental impact, with respect to conventional process (CQO). However, the increase in operative pressures in the case of DHI process and the increase of internal flows and the size of equipment in DWC process cause an increment of the risk, despite of the risk increment in DWC it is considered the best option to furfural purification due reductions mainly on TAC and Eco99 that mean important savings in a long-term.

Keywords: Furfural, Optimization Process, Multi- Objective Optimization, Process Intensification, Bio-Refinery.

1. Introduction

The depletion of sources energy, greenhouse effect and the high environmental impact, are some problems of using petroleum. Thus the efforts in recent years have been focused on developing of alternative renewable resources that can replace to derivate petroleum products like fuels, plastics among others. The biomass is considered the most important among the renewable resources due to is the most abundant feedstock in the planet (Long et al. 2016). The US National Renewable Energy Laboratory (NREL) gave himself to the task to identify the chemicals from biomass and listed 30 potential chemical from biomass that could compete and replace the chemical from petroleum. Furfural stands out in this list with a wide range of applications that go from extracting for the refinement of lubricating oils, as a fungicide, nematocide and as a raw material (up to 65% of all furfural produced), to furfural alcohol production and other important products like levulinic acid (Long et al. 2016).

The furfural is produced from biomass rich in pentoses like corn cobs, oat hulls, sugar cane bagasse to name a few. The first process production of furfural was Quaker Oats process established in 1921 and it remains as the most used today. This process has had few changes since 1921, the Quaker Oats consists mainly of two steps, which are a reaction and distillation steps respectively. At the reaction step, the biomass is pretreated and subsequently it is introduced in a reactor with diluted sulphuric acid where the biomass is degraded in a hydrolysis reaction into furfural, methanol and acetic acid. The stream from the reactor has a composition in mass fraction of 6% furfural, 4% of methanol and acetic acid and 90% of water (Zeitsch; 2000). As almost all bio-refinery process, the low composition of the main product (in this case furfural) conditions us to high separation costs, in the case of furfural purification these costs are even higher due the formation of azeotropes between the organic components with the water. For this reason in this work are studied three different azeotropic distillation process to purify Furfural; conventional Quaker Oats process purification of Furfural (CQO) and two intensified processes, an azeotropic distillation process with heat integration through vapour recompression (DHI) and dividing wall azeotropic distillation column (DWC). Due the bio-refineries need to be the most profitable and cheap, with less environmental impact and with the safest operating conditions, the design and optimization of the three distillation process were realized in order to minimize these aspects.

2. Methodology

The three different schemes studied in this work are showed on the Figure 1, compositions and flows were taken by Long et al. 2016. The CQO and DHI processes consist in an azeotropic column (C1) that breaks the azeotrope furfural-water, a mixture rich in water and acetic-acid leaves the bottom of this column, whereas from the top of the azeotropic column a stream rich in water and methanol leaves the column, which is then separated in a conventional distillation column (C2), also a side stream is withdrawn between the top and bottom of C1, this stream contains a mixture rich in water and furfural which is sent to a decanter where the organic phase rich in furfural is purified in a third column (C3). On the other hand the DWC process, the C1 and C2 have been integrated in only one column with a dividing wall.

The three distillation schemes were designed and simulated using ASPEN PLUS™ to obtain purities of 99.2% and 99.5% mass fraction of methanol and furfural respectively. The vapor-liquid equilibrium can be predicted by NRTL-HOC model, which includes the Hayden- O'Connell equation, which can predict reliably the solvation of polar compounds and dimerization in the vapor phase, which occurs with mixtures containing carboxylic acids (Long et al. 2016).

The total annual cost (TAC), Eco-indicator 99 (Eco99) and individual risk (IR) were chosen as the objective function to be minimized. TAC was calculated through the Guthrie method, all the parameters for the equipments were taken from Turton et al. 2008, carbon steel was the assumed as the construction material for all the equipments, and the time of investment was considered ten years. The trays selected to the columns were the type Sieve with spacing between trays of 2 ft. The operating costs included cooling utilities, heating utilities, and 8500 hours of yearly operation for each configuration were defined. The operating costs were taken of Turton et al. 2008.

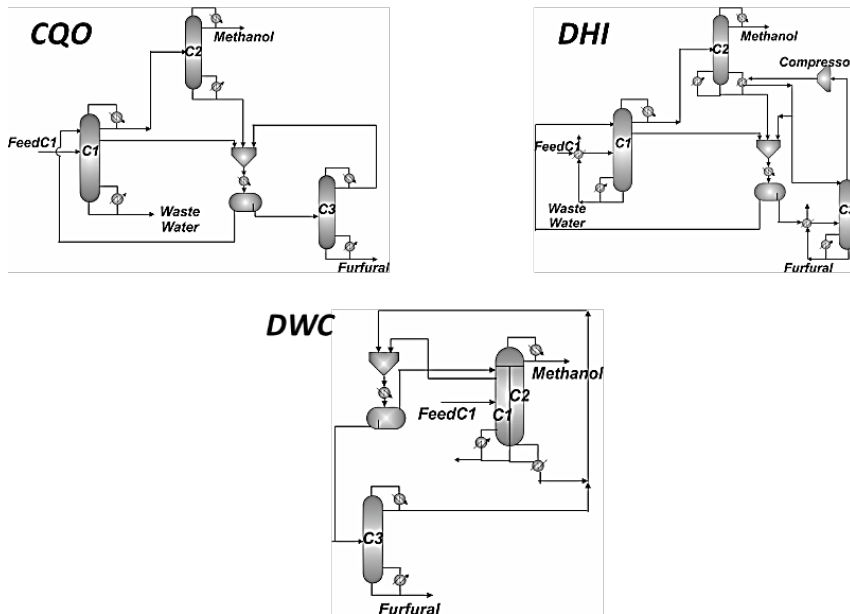

Figure 1. Azeotropic Distillation schemes to furfural purification

The Eco99 was used to evaluate the sustainability of the processes, this methodology is based on lifecycle analysis of different categories where individual scores are assigned depending on the categories, three impact categories (steel, electricity, and vapor) were considered according to work presented by Errico et al. 2016 where this indicator has been utilized to quantify the environmental impact in some chemical processes. In the case of the safety, the individual risk was calculated through quantitative risk analysis technique, which is a methodology of inherent safety where the main objective is to evaluate the frequency and probability of death or injury due to accidents like explosions or toxic release. This methodology has been successfully used to evaluate the risk on chemical process (American Institute of Chemical Engineers 2000), the equations and procedure was realized to a distance of 50 m from the equipments according to reported by American Institute of Chemical Engineers, 2000.

In this work, it has been used the Differential Evolution with Tabu List Algorithm which is a multi-objective optimization method proposed by Sharma and Rangaiah 2010. The DETL has four basic steps: generation of initial population, mutation, crossover, a selection of the best solutions, each one of these steps require of some parameters that need to be determined by a tuning process where is evaluate the ability of the algorithm the algorithm's ability to find solutions that meet all constraints. The value of required parameters to the DETL algorithm determine by tuning process are the following: Population size (NP): 120 individuals, Generations Number (GenMax): 834, Tabu List size (TLS): 60 individuals, Tabu Radius (TR): 0.01, Crossover fractions (Cr): 0.8, Mutation fractions (F): 0.3. The implementation of the multi-objective optimization strategy involved a hybrid platform, which linked Aspen Plus™, Microsoft Excel™. The decision variables for each reactive distillation configuration are reported in Table 1. Finally, the multi-objective optimization problem can be expressed mathematically as in Eq. (1) and Eq. (2):

$$\min Z = \{TAC; Eco99; IR\} \quad (1)$$

$$\text{Subject to: } \begin{aligned} y_{i,PC} &\geq x_{i,PC} \\ w_{i,FC} &\geq u_{i,FC} \end{aligned} \quad (2)$$

Table 1. Decision variables of the reactive distillation configurations.

Decision Variables	Continuous	Discrete
Number of stages, C1		X
Number of stages, C2		X
Number of stages, C3		X
Feed stage recycle of C1		X
Feed stage, C1		X
Stage of side stream C1		X
Feed stage C2		X
Feed stage C3		X
Reflux ratio of C1	X	
Reflux ratio of C2	X	
Reflux ratio of C2		
Heat duty of C1, kW	X	
Heat duty of C2, kW	X	
Heat duty of C3, kW		
Diameter of C1, m	X	
Diameter of C2, m	X	
Diameter of C2, m	X	
Discharge pressure of compressor(Comp), atm	X	
Interlinking flow, Kg h ⁻¹	X	

The objective function is restricted to the accomplishment of the purity vectors, and the mass flowrate vectors for the components in the mixture. For example, the values of the purities for the components obtained during the optimization process $y_{i,PC}$ must be either greater or equal to the specified values of purities for the component $x_{i,PC}$. Furthermore, the mass flowrates obtained $w_{i,PC}$ must also be either greater or equal to the specified values of the mass flowrate $u_{i,PC}$.

3. Results

The optimal design parameters, design specifications, and values for the objective functions for all the studied sequences are offered in Table 2. Figure 2 shows the Pareto charts of the DWC process, the DHI and CQO keep the same tendency.

The results show that the DHI process does not provide a big saving of TAC and the values of Eco99 and IR are bigger than the values of the CQO process. The reason of these results is because the energy savings in DHI are very low compared to conventional process, the addition of more equipment such as heat exchangers and compressors directly affects steel category on Eco99 and the probability of an accident to occur increases due IR value is bigger than CQO.

Table 2. Optimal design parameters for the sequences.

Design Variables	CQO	DHI	DWC
Number of stages, C1	50	51	70
Number of stages, C2	9	33	72
Number of stages, C3	6	8	12
Feed stage recycle of C1	14	19	5
Feed stage, C1	30	29	37
Stage of side stream C1	12	13	30
Feed stage C2	8	20	-----
Feed stage C3	4	7	6
Reflux ratio of C1	22.95	2.93	-----
Reflux ratio of C2	0.203	1.25	25.09
Reflux ratio of C3	1.564	0.28	0.273
Heat duty of C1, kW	20018	19519	19131
Heat duty of C2, kW	773	882	320
Heat duty of C3, kW	604	566.246	715
Diameter of C1, m	1.396	0.86	-----
Diameter of C2, m	0.524	0.80	1.535
Diameter of C3, m	0.380	1.13	0.321
Discharge pressure of compressor(Comp), atm	-----	1.29	-----
Interlinking flow, kg h ⁻¹	-----	-----	25887
TAC (\$/yr)	9,383,987	9,318,611	9,179,222
Eco99 (Eco-points)	4,344,805	4,546,195	4,299,778
IR (1/yr)	2.734x10 ⁻⁴	2.850x10 ⁻⁴	5.371 x10 ⁻⁴

In the case of DWC this process has savings of TAC and low Eco99 value with respect to CQO process due there are less equipment because of the thermally coupling. This process presented an important reduction in the side of the divided wall column that corresponding to column C2 in the conventional process, however the column C3 has an increment in the energy consumption of around 100 KW with respect to the C3 column of CQO process. The azeotropic column is the equipment that contributes with the greatest amount of energy in the CQO process, the DWC has a reduction near 900 KW it indicates that TAC and Eco99 reductions are due the lessening of steel category because of the integration of C1 and C2 columns in only one equipment and it is not for energy savings. The IR presents increment in DWC process with respect to CQO, the increment of risk is mainly due the increment of the size and the amount of material of dividing wall column. The IR is dependent of the size of equipment, bigger distillation columns imply that there is more mass inside the columns from which like explosions can derivate in a greater range of damage , and due DWC is used to purify methanol, a big column represents more flammable material inside it, then the potential of a more destructive accident increases. It has traditionally been thought that dividing wall columns provide more secure process due to the reduction of equipment reduce the probability of accident, nevertheless, the results obtained in this work indicate that this affirmation may not be met in all cases.

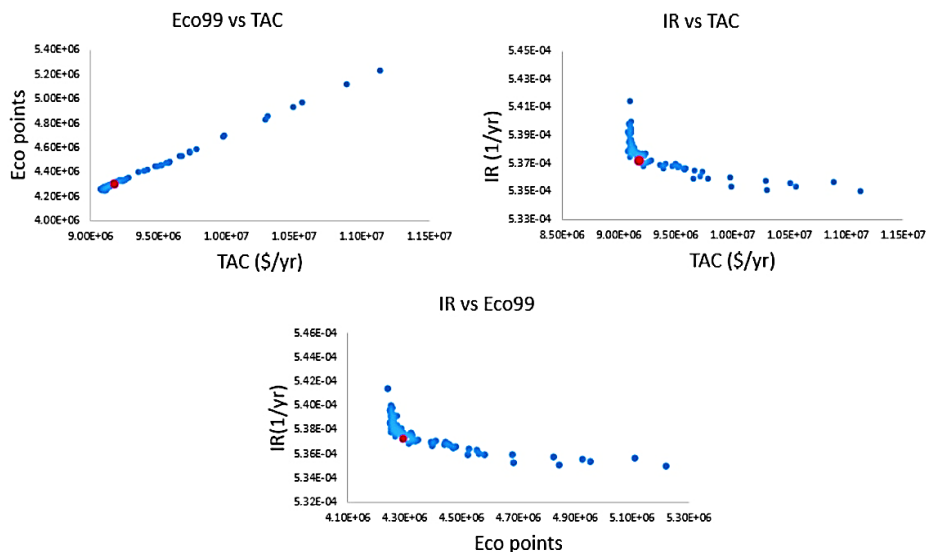

Figure 2. Pareto Fronts to DWC process

4. Conclusions

In this work was realized the simultaneous design and optimization of three alternatives to purification of furfural, the application of the quantitative risk analysis represents an additional selection criterion that can help to take measures to a safe operation of these processes. The results indicate that the DHI does not provide reductions on TAC, Eco99 and IR compared to CQO processes thus DHI is not considered a good option to purify furfural. The DWC processes has an increment in the value of IR compared with CQO mainly to increase in size of dividing wall column, we considered that IR of DWC process is not enough large to a dangerous. Therefore, DWC is considered the best option to furfural purification due reductions mainly on TAC and Eco99 that significates important savings in a long-term.

Abstract

The economic sustainability of lignocellulosic biorefineries can be significantly improved by co-producing added value chemicals together with common biofuels like ethanol. In this work a techno-economic analysis of a multiproduct biorefinery was carried out by means of process simulations, cost and profitability analysis. Alternative process flowsheets including the co-production of xylitol or furfural from C₅ sugars deriving from biomass hydrolysis were assessed and compared with the ethanol base case. A comparison between the purchase of enzymes and the on-site production of enzymes was also addressed. The lowest Payback Selling Price of ethanol was obtained for the case of xylitol co-production thanks to its higher added value.

Keywords: lignocellulosic biorefinery, multi-product, xylitol, ethanol, furfural.

1. Introduction

The strong dependence of modern society on fossil fuels derives from the intensive use and consumption of petroleum products. To reduce the dependence on oil and to limit simultaneously the effects on climate change, it is necessary to make changes in transport and in chemical sector, where new production processes are needed (Conde-Mejía et al., 2016). The National Renewable Energy Laboratory of US listed the 12 chemical compounds more easily obtainable from lignocellulosic biomass by industrial biorefineries (Bozell and Petersen, 2010). They are value-added chemicals or precursors of other chemicals in common use. However, the commercialization of conversion technologies has been hindered by several factors including the unavailability of reliable feedstock supply systems (Galanopoulos et al., 2017), the seasonality of biomass production (Giuliano et al., 2016b) and conversion systems non-fully mature. Besides these, integrated process layouts enabling the optimized exploitation of the feedstock are necessary to make the biorefinery sustainable. For the latter issue, the optimization by process synthesis and integration methods can help to identify the optimal pathways to increase the biobased products profitability. Few studies reported in the literature addressed the optimization of the biomass allocation among alternative pathways for a biorefinery co-producing several compounds (Giuliano et al., 2014) such as alcohols like ethanol or/and butanol (Ségolène et al., 2016), high-value chemicals like succinic acid and levulinic acid (Giuliano et al., 2016a). Significant improvements in the techno-

economic feasibility can be also obtained by applying the biorefinery cascade approach in which the process by-products/secondary streams can be thermally valorised to bioenergy (da Silva et al., 2017).

The aim of this paper is to analyze the technical-economic feasibility of a lignocellulosic biorefinery converting the cellulose into ethanol and the hemicellulose into xylitol or furfural. This analysis is performed by process simulation tools. Material and energy balances were solved. Reactors and separation units were sized. The profitability of alternative process flowsheets was assessed by calculating the cumulated cash flows and by computing the payback selling price of ethanol provided the price of by-products.

2. Biorefinery process description

The process simulation of the biorefinery was carried out through the implementation of a process flowsheet in Aspen Plus (version 8.6). Figure 1 reports the general simplified biorefinery Block Flow Diagram (BFD) including all the possible process pathways. Each block corresponds to an Aspen Plus *hierarchy*, containing a specific process section of the plant. Solid line streams and blocks refer to the base case process (E and E_s), while dashed line streams and blocks refer to optional pathways considered for alternative cases (EX and EF).

The wet biomass is first processed in the steam explosion section where it is pretreated by the steam explosion technology. Steam pretreated pulp can be further fractionated into its main components or sent directly to the enzymatic hydrolysis. (De Bari et al., 2014). Pretreated biomass is sent to the enzymatic hydrolysis section, where the polysaccharides, namely cellulose and hemicellulose, are converted into C6 and C5 sugars. Two scenarios were analysed: 1) cellulase enzymes are purchased (case E), they are produced on site by using part of the pretreated feedstock (case E_s). C6 and C5 sugars are then fermented to ethanol. Ethanol separation and purification is performed by distillation and molecular sieves. The exhausted hydrolysis cake containing lignin and residual cellulose and hemicellulose is sent to the thermal section where is burnt to produce heat and electricity. Biogas generated through the anaerobic digestion of liquid waste streams is also converted to energy.

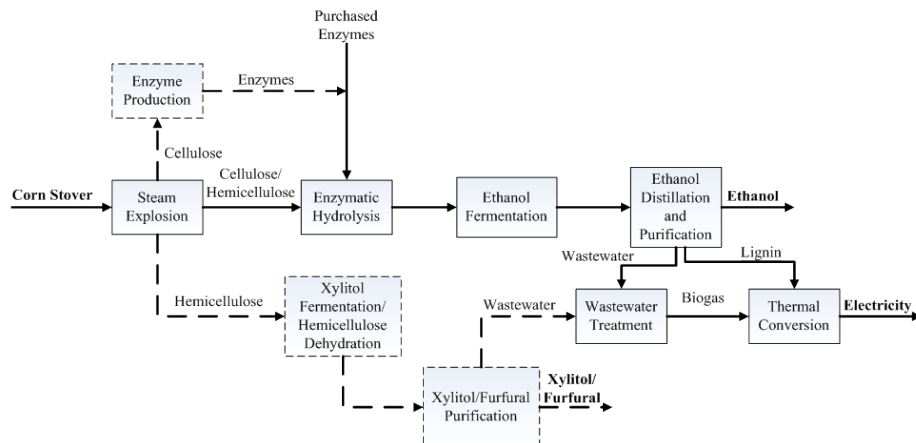

Figure 1: General Flowsheet of the multi-product lignocellulosic biorefinery.

Table 1: Corn stover data, conversion data and economic parameters of process simulations.

Feedstock data		
Feedstock flowrate (t_{WET}/h)	33	
Water ($\%_{WET}$)	17.0	
Cellulose ($\%_{DRY}$)	42.8	
Hemicellulose ($\%_{DRY}$)	17.7	
Lignin ($\%_{DRY}$)	31.5	
Other compounds ($\%_{DRY}$)	8.0	
Reactors data	conversion (%)	residence time (h)
Xylose to ethanol	70	18
Glucose to ethanol	93	18
Xylose to xylitol	69	30
Xylose to furfural	70	1
Economic data		
Plant Life (y)	20	
Xylitol Price (€/kg)	3.50	
Furfural Price (€/kg)	1.10	
Biomass Price (€/t)	60	
Discount Rate (%)	5	
Enzyme cost (€/kg)	3	
Electricity cost (€/MWh)	94	
Electricity selling price (€/MWh)	150	

In two alternative cases the hemicellulose leaving the Steam Explosion section is separated and sent to dedicated conversion units to produce xylitol (case EX) *via* fermentation or furfural (case EF) *via* sugars dehydration. The production of xylitol (case EX) occurs in a bioreactor where xylose is transformed to xylitol. The broth is sent to a purification section where 99% pure xylitol is recovered by a sequence of a flash, an activated coal adsorption unit and a crystallizer. In the case of furfural production (case EF), dehydration of the hemicellulose takes place and xylose is transformed to furfural in a reactor. Reaction products are sent to the purification section consisting in sequence of distillation, column, decanter and distillation column to obtain a 99% pure furfural product.

Table 1 reports the data of the biomass feedstock, corn stover, main economic data and reactor data assumed from previous simulation results on enzymatic hydrolysis and ethanol fermentation (Giuliano et al., 2015) and from literature data. Unit sizing was carried by shortcut methods based on the residence time. More accurate evaluations were performed for the sizing of distillation columns by means of rigorous stage-to-stage methods.

3. Economic Analysis

Economic analysis of the several cases was performed by estimating capital and operating costs. Capital cost were estimated by power law correlations based on unit capacity. Data relevant to biorefinery sections were taken from the literature (Hamelinck et al., 2005). The factorial method was applied to obtain the total investment cost. Operating costs are mainly given by raw materials. In particular, a 60 €/t purchase cost for corn stover and 3 €/kg purchase cost for enzymes were assumed. Moreover, the costs of inoculum, NaOH, SO₂ and water required for pretreatment and hydrolysis were also accounted for. In addition, the costs of salaries, maintenance, and insurance were assessed by the factorial method.

Revenues consists in the sales of the products (ethanol, xylitol and furfural) and of electricity. Linear depreciation was assumed. A discounted cash flow analysis was carried out to obtain the Payback Selling Price (PSP) of ethanol provided the price of the other possible by-products. The PSP was calculated as the value that makes the Net Present Value equal to zero after a 20 years plant life.

4. Results

Results reported in Figure 2 show that the total mass yield to products was almost equal for all the case studies and it was about 25%. In fact, ethanol yield was 25% for the case E and 18% for cases EX and EF. Xylitol and furfural yield was about 8% for the EX and the EF cases, respectively. The ethanol yield for the case E_s was slightly lower (24%) than for the case E due to the partial consumption of cellulose for the enzymes production on site.

The electricity produced by the plant was significantly higher for the production of ethanol only (cases E and E_s) than for the multiproduct cases (case EX and EF), as shown in Figure 2. This is due to two reasons: 1) the inlet stream to the thermal treatment section for the cases EX and EF has a lower organic content, and thus a lower heating value, which reduces the energy yield; 2) the co-production of xylitol or furfural requires more steam. In particular, the higher energy demand is for the xylitol crystallizer and for the distillation columns of furfural.

Table 2 reports the economic analysis results for all the cases in terms of investment costs for each plant section, operating costs and Payback Selling Price (PSP) of ethanol. For the production of ethanol only, as expected, the Total Investment Cost for the plant with the on site enzymes production (case E_s) is higher than that for the plant with the purchased enzymes (case E). On the other hand, lower operating costs are necessary for the case E_s than for the case E due to the avoided purchase cost of the enzymes. On the whole, the two opposite effects tend to counterbalance each other and result in similar PSP values.

The multiproduct cases require on the one hand additional investment cost for the process section transforming the C5 sugars into xylitol or furfural, but on the other hand lower cost for a smaller size section for the enzymatic and the ethanol fermentation.

Figure 2. *a*: Product yields for 4 biorefineries. Black bar is the ethanol yield, dark grey bar is the xylitol yield, blank bar is the furfural yield. *b*: net power for 4 biorefineries.

Table 2: Economic results for 4 biorefinery cases.

	E _s	E	EX	EF
<i>Total Investment Cost (M€)</i>	184.4	153.1	144.9	130.9
Steam Explosion	11.4	11.4	11.4	11.4
Enzymatic Hydrolysis & Ethanol Fermentation	23.7	24.1	19.6	19.6
Xylitol Fermentation	-	-	6.7	-
Hemicellulose Dehydration	-	-	-	3.7
Ethanol Distillation & Purification	11.9	12.0	11.3	11.3
Xylitol Purification	-	-	2.2	-
Furfural Purification	-	-	-	1.3
Wastewater Treatment	20.7	20.7	22.1	19.0
Thermal Conversion	82.6	84.5	71.6	64.4
Enzyme Production	34.1	-	-	-
<i>Operating costs (M€/y)</i>	85.3	89.5	89.9	90.0
<i>Revenues (M€/y)</i>	94.6	97.6	97.3	96.9
Ethanol	85.6	88.3	31.0	72.8
By-product (Xylitol or Furfural)	-	-	60.1	18.2
Electricity	9.0	9.3	6.2	5.8
<i>Payback Selling Price of Ethanol (€/kg)</i>	1.62	1.61	0.79	1.85

Significantly lower cost is necessary for the thermal conversion due to the lower production of electricity. On the whole, the Total Investment Cost for the case EX and the case EF is lower than for case E by 5% and 14%, respectively. Instead, operating costs are equivalent for the three cases E, EX and EF. As mentioned above, the yield values to ethanol and the yield values to the other by-product (xylitol or furfural) are very similar for the cases EX and EF. As a result, since the xylitol price is three times the furfural price, the by-product revenues for the case EX is about three times those for the case EF. Consequently, since also the ethanol production is comparable, the PSP of ethanol for the case EF is about twice the PSP of ethanol for the case EX. Furthermore, the PSP for the case EX is slightly higher than the PSP for the case E.

5. Conclusions

A techno-economic analysis on a biorefinery processing corn stover to obtain ethanol as main product was carried out. Similar mass yield and Payback Selling Price of ethanol were obtained for the case with purchased enzymes and for the case with enzymes produced on site. We are aware that this result might be significantly affected by the plant size or the production rate of the biorefinery and deserves a sensitivity analysis, which will be addressed in future works.

Alternative process flowsheets including the co-production of xylitol or furfural from C₅ sugars deriving from biomass hydrolysis were assessed and compared with the ethanol base case. A constant total mass yield to products of the biorefinery, about 25%, was obtained for all the cases with different biomass yield values to single products in

multiproduct cases. The electricity produced by the plant decreases by about 30% if xylitol or furfural is produced together with ethanol.

From the profitability point of view, xylitol coproduction appears more convenient than both the co-production of furfural and the production of ethanol alone. This result is due to the significantly higher selling price of xylitol which prevails by means of higher revenues, despite the 10% higher total investment cost than that for the co-production of furfural.

Endpoint-oriented Life Cycle Optimization Models for Sustainable Design and Operations of Shale Gas Supply Chains with Modular Manufacturing

Jiyao Gao, Fengqi You

Cornell University, Ithaca, New York, 14853, USA

Abstract

Modular manufacturing is identified with great potential in the exploitation of shale gas resource. In this work, we propose a novel mixed-integer nonlinear fractional programming model, where design and operational decisions regarding both the conventional processing plants and modular manufacturing devices are considered. The allocation, capacity selection, installment, moving, and salvage decisions of modular manufacturing devices are modeled with corresponding integer variables and logic constraints. To systematically evaluate the full spectrum of environmental impacts, an endpoint-oriented life cycle optimization framework is applied that accounts for up to 18 midpoint impact categories and three endpoint impact categories. Total environmental impact scores are obtained to evaluate the comprehensive life cycle environmental impacts of shale gas supply chains. A tailored global optimization algorithm is also presented to efficiently solve the resulting computationally challenging problem. To illustrate the applicability of proposed modeling framework and tailored global optimization algorithm, a case study of a well-to-wire shale gas supply chain based on Marcellus Shale is considered. Based on the optimization results, the application of modular manufacturing helps achieve the lowest LCOE of \$59.4/MWh and the smallest ReCiPe endpoint environmental impact score per MWh electricity generation as 64.5 points/MWh.

Keywords: Endpoint, life cycle optimization, modular manufacturing, shale gas

1. Introduction

In recent years, the rapid expansion of shale gas industry leads to continuing growth in shale gas production (Cafaro and Grossmann, 2014). However, the lack of midstream infrastructure impedes the exploitation of shale gas resources (Gao and You, 2017). Modular manufacturing has been proposed as a viable approach to address this issue (Tan and Barton, 2015). Modular manufacturing devices are small-scale, highly mobile process units that are produced as individual modules and shipped to the sites of interest for quick assembling (Stewart, 2015). Compared with the conventional shale gas processing plants, the modular manufacturing devices have the potential of reducing the capital expenditures, improving the accessibility of shale gas energy resource, and mitigating the life cycle environmental impacts through process intensification (Gong et al., 2017). To systematically investigate the economic and environmental implications of shale gas modular manufacturing, it is imperative to account for and optimize relevant modular manufacturing options in shale gas supply chain design and operations for better economic and environmental sustainability (Gao and You, 2015).

In this work, we propose a novel mixed-integer nonlinear fractional programming (MINLFP) model. Moreover, a general endpoint-oriented LCO framework is developed that can quantify the full spectrum of environmental impacts in the optimal design and operations of shale gas supply chains. An endpoint-oriented LCIA method ReCiPe is adopted, which comprises of 18 midpoint impact categories and three endpoint impact categories (Goedkoop et al., 2009). This endpoint-oriented LCIA approach is further integrated into a functional-unit-based multiobjective LCO framework to connect the optimization decisions with their environmental impact scores. To illustrate the applicability of proposed modeling framework, a case study of a well-to-wire shale gas supply chain based on Marcellus Shale is considered.

2. Problem Statement

This LCO framework accounts for the well-to-wire life cycle of shale gas, which starts with the well drilling at shale sites and ends with the electricity generation at NGCC power plants (Laurenzi and Jersey, 2013). Corresponding to the well-to-wire life cycle of shale gas, we employ a functional unit of generating one MWh of electricity (DOE/NETL, 2011). Accordingly, both the economic and environmental performances are evaluated based this functional unit. The main data sources of this basic LCI are the most up-to-date LCA studies on shale gas and the Ecoinvent database v3.3 (Laurenzi and Jersey, 2013; Stamford and Azapagic, 2014; "Ecoinvent database v3.3," 2017). We choose the endpoint-oriented LCIA approach ReCiPe to quantify the full spectrum of life cycle environmental impacts (Goedkoop et al., 2009).

We consider a planning horizon consisting of a set of time periods with identical intervals. There are a set of shale sites. Each shale site allows multiple wells to be drilled. The raw shale gas produced at shale sites is either sent to conventional processing plants or transported to modular LNG plants for processing (He and You, 2014, 2016). Once a modular LNG plant is constructed, it can be disassembled and moved to another location at any time. The sales gas from the conventional processing plants is sent to a set of NGCC power plants with known electricity generation efficiency. LNG produced at modular plants, on the other hand, can be sent to a set of storage facilities for temporary storage or transported to a NGCC power plant directly for electricity generation. Based on the given information, the objective of this LCO problem is to simultaneously optimize the economic and comprehensive environmental performances of the shale gas supply chain with modular manufacturing devices by optimizing the following decisions: (1) Drilling schedule, production profile, and water management strategy at each shale site; (2) Construction and capacity choices of conventional processing plants, locations and specs of modular manufacturing devices, moving schedule of modular manufacturing devices, and production planning; (3) Installment and capacity selection of gathering pipeline networks, planning of transportation activities, and storage inventory management;

In accordance with the predefined well-to-wire system boundary and the functional unit of one MWh of electricity generation, we consider the following objective functions:

- Minimizing the LCOE generated from shale gas, which is formulated as the total net present cost divided by the total amount of electricity generated.
- Minimizing the endpoint environmental impact score associated with producing one MWh of electricity.

3. Model Formulation and Solution Algorithm

According to the problem statement in the previous section, a multiobjective MINLFP model is proposed to address the endpoint-oriented LCO of shale gas supply chains with modular manufacturing devices. The economic objective is to minimize the LCOE generated from shale gas, denoted as $LCOE$ and formulated as the total net present cost (TC) divided by the total amount of electricity generation (TGE). The environmental objective is to minimize the endpoint environmental impact score per MWh electricity generation, denoted as UE and formulated as the total environmental impact score (TE) divided by the total amount of electricity generation (TGE). The total environmental impact score accounts for the full spectrum of environmental impacts associated with water management (E_{water}), shale well drilling, stimulation, and completion (E_{drill}), shale gas production (E_{prod}), shale gas processing (E_{proc}), transportation (E_{trans}), LNG storage (E_{stor}), and electric power generation (E_{power}).

$$\min LCOE = \frac{C_{proc}^{CAPEX} + C_{trans}^{CAPEX} + \sum_{t \in T} \left[\frac{C_{water,t}^{OPEX} + C_{drill,t}^{OPEX} + C_{prod,t}^{OPEX} + C_{proc,t}^{OPEX} + C_{trans,t}^{OPEX} + C_{stor,t}^{OPEX} + C_{power,t}^{OPEX}}{(1+dr)^t} \right]}{\sum_{g \in G} \sum_{t \in T} GE_{g,t}} \quad (1)$$

$$\min UE = \frac{TE}{TGE} = \frac{E_{water} + E_{drill} + E_{prod} + E_{proc} + E_{trans} + E_{stor} + E_{power}}{\sum_{g \in G} \sum_{t \in T} GE_{g,t}} \quad (2)$$

- s.t. Economic Constraints (3)
- Environmental Constraints (4)
- Mass Balance Constraints (5)
- Capacity Constraints (6)
- Bounding Constraints (7)
- Logic Constraints (8)

The resulting multiobjective MINLFP problem is computationally challenging to be optimized globally. Based on the problem structure, we apply a tailored global optimization algorithm integrating the parametric algorithm (Zhong and You, 2014) with a branch-and-refine algorithm to tackle this computational challenge.

4. Application to a Well-to-Wire Shale Gas Supply Chain

To illustrate the applicability of the proposed endpoint-oriented LCO model of shale gas supply chains with modular manufacturing devices, we consider a case study of a well-to-wire shale gas supply chain based on Marcellus Shale. A total of 12 shale sites are considered, among which six shale sites are existing ones with active wells and six shale sites are potential ones to be developed. Each shale site allows for drilling of up to four to eight shale wells. There are two existing and one potential conventional shale gas processing plants. Up to six locations are considered for the modular LNG plants. There are three capacity levels for the modular LNG plants, corresponding to 25 kgal, 50 kgal, and 100 kgal maximum LNG production per day, respectively. Relevant process-level data are taken from recent literature (Stewart, 2015; Tan and Barton, 2015; Yang and You, 2018; Gong and You, 2018). There are two LNG storage facilities where LNG products can be temporarily stored before being sent to the market. In this well-to-wire shale gas supply chain, there are three NGCC power plants with combined cycle gas turbines, and the average efficiency is 50% on a lower heating value (LHV) basis. A 10-year planning horizon is considered. The planning horizon is divided into 20 time

periods, and each time period represents half a year. The resulting MINLFP problem has 4,012 integer variables, 13,767 continuous variables, and 9,556 constraints. All the models and solution procedures are coded in GAMS 24.7.3 on a PC with an Intel® Core™ i7-6700 CPU and 32GB RAM.

The resulting MIBLFP problem is solved using the presented tailored global optimization algorithm and a Pareto-optimal curve consisting of 13 Pareto-optimal solutions is shown in Figure 1. The x -axis represents the ReCiPe endpoint environmental impact score per MWh electricity generation from shale gas. The y -axis represents the LCOE in the shale gas supply chain.

Figure 1. Pareto-optimal curve illustrating the trade-offs between LCOE and ReCiPe endpoint environmental impact score per MWh electricity generation with breakdowns.

Along this Pareto-optimal curve, we choose 3 solution points from point A to point C for comparison. Their corresponding LCOE breakdowns are presented with pie charts above the curve, and the breakdowns of environmental impact score per MWh electricity generation are demonstrated with the donut charts below the curve. The sizes of these charts are proportional to the absolute values of total net present cost and total environmental impact score. From point A to point C, the portion of environmental impact score associated with processing activities increases, and the portion associated with transportation activities decreases accordingly for the similar reason as discussed above on the LCOE breakdowns.

In Figure 2 we present the detailed design and planning decisions for modular LNG plants in different Pareto-optimal solutions. As can be seen, there are four modular LNG plants in the optimal solution of point A. In addition to the existing modular plants, a capacity of 25 kgal LNG/day is installed at location 1 in the beginning. Relocation of modular LNG plants is observed in the optimal solutions of point C. Specifically, for point C, the modular plant at location 5 with a capacity of 25 kgal LNG/day is moved to location 6 three years later, and the modular plant at location 6 with a capacity of 50 kgal LNG/day is moved to location 5 half a year later. Such an exchange of modular LNG plants matches the varying demand of processing capacity at different regions. The moving option of modular LNG plants offers more flexibility in the operations of a shale gas supply chain, and the overall economic performance can be improved. Nevertheless, the moving activities of modular plants incur extra environmental

impacts, such as land use change, energy consumption, and emissions. Thus, the relocation of modular plants may not be preferred when minimizing the comprehensive environmental impacts is the main objective.

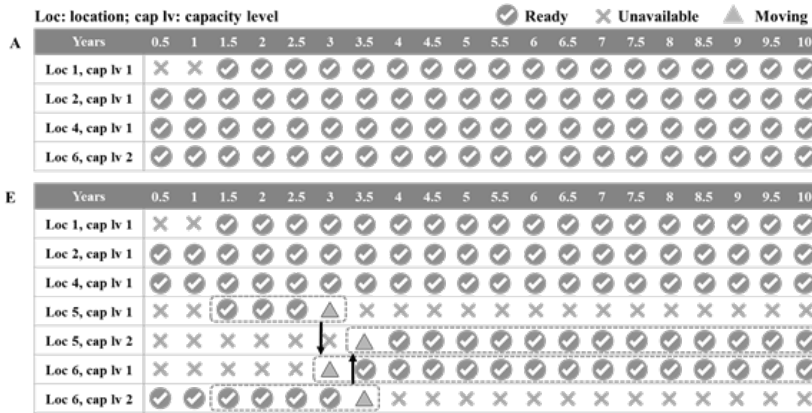

Figure 2. Design and planning decisions for modular LNG plants.

The detailed midpoint environmental impact score breakdowns associated with Pareto-optimal solutions A and E are presented in Figure 3. The impacts of climate change to human health and climate change to ecosystems stand out as two major contributors especially in the life cycle stages of shale gas production, LNG storage, and power generation. Fossil depletion is one of the major midpoint impact categories in water management, drilling, shale gas processing, and transportation, which are all energy-intensive processes. The human toxicity is another key midpoint impact category especially in water management and drilling phases, when large amounts of chemicals and additives are used in drilling and fracturing fluids. The different wastewater treatment strategies also result in disparate environmental performance. We identify RO technology for onsite treatment as the optimal wastewater treatment technology in point A. Nevertheless, in point C, all the wastewater is treated by remote CWT facilities.

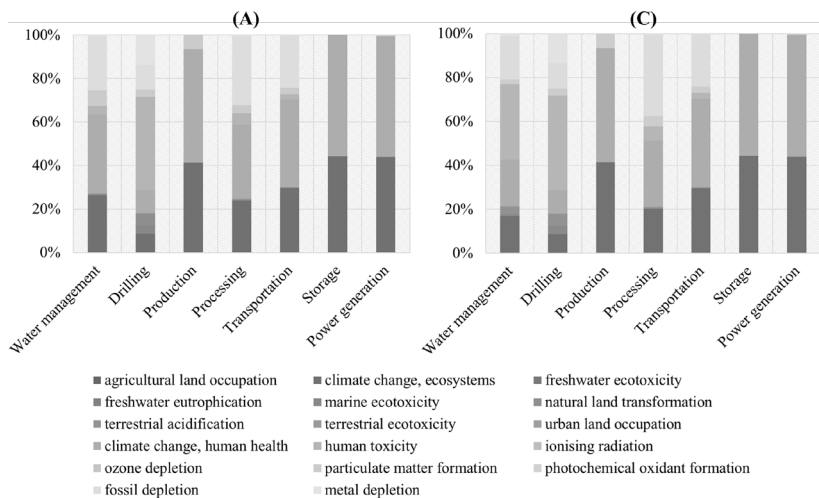

Figure 3. Midpoint environmental impact score breakdowns.

5. Conclusions

A novel endpoint-oriented LCO model was proposed to investigate the economic and environmental implications of incorporating modular manufacturing devices in the optimal design and operations of shale gas supply chains. The applicability of proposed endpoint-oriented LCO framework was illustrated by a well-to-wire shale gas supply chain based on Marcellus Shale. Through a detailed analysis and discussion, we conclude that the application of modular manufacturing devices could improve the economic performance of a shale gas supply chain.

Abstract

This paper is concerned with the synthesis of membranes networks for gas separation using a surrogate-based optimization approach. The developed methodology accounts for the main sources of non-ideality in membrane processes based on a mechanistic model. These non-idealities are typically neglected in membrane network synthesis formulations, which often results in inaccurate predictions. The optimization proceeds by a trust-region algorithm and relies on grey-box surrogates that combine a shortcut model with response surface models. The methodology is applied to a case study in natural gas sweetening, where it is shown that the surrogate predictions are within 0.1% of the mechanistic model upon convergence of the trust-region algorithm. Comparisons with classical, constant-permeability surrogates confirm the benefits of the proposed approach.

Keywords: membrane network, process synthesis, surrogate-based optimization, natural gas sweetening

1. Introduction

Over the last few decades, membranes have proved to be a viable technology for the separation of gas mixtures. Due to lack of selectivity however, single-stage membrane modules are often not able to meet high purity targets in terms of contaminant concentrations and meanwhile achieve a large enough product recovery. Instead, a gas mixture can be processed using multiple modules and passes, namely a membrane network or cascade arrangement (Agrawal, 1996).

The problem of determining the optimal design and operation of a membrane network in terms of capital and operating costs, subject to a given purity target, as received attention in the literature. Qi and Henson (2000) formulated a mixed-integer nonlinear programming (MINLP) model for the synthesis of membranes cascades with applications to natural gas (NG) sweetening, whereby the differential equations describing a membrane module are discretized into a set of algebraic equations using a Runge-Kutta scheme. Uppaluri et al. (2004) used a discretized membrane model within a superstructure optimization problem for membrane network synthesis. Alshehri et al. (2013) modelled a membranes permeator in a sequential modular process simulator, where a numerical solution of the differential equations is computed using Gears method, while the membrane network is designed based on a simplified superstructure optimization problem. A common trait among the abovementioned studies is the use of simplified models to describe the performance of individual membrane modules, namely the assumption of a constant permeability for the various gas species through the membrane. The recent review Khalilpour et al. (2015)

emphasizes the need for more accurate models, which can account for the main sources of non-ideality for more reliable membrane network synthesis and design.

It is noteworthy that high-fidelity, mechanistic models for predicting the behavior of membrane permeators have become available in recent years (Bounaceur et al. (2017); Scholz et al. (2013)), and they can be interfaced with commercial process simulators, e.g., via the CAPE-OPEN standard. Such models may be embedded into systematic optimization procedures based on mathematical programming for the design and optimization of a given membrane network. However, they remain too complex for use in a generic superstructure optimization approach in order to determine an optimal network configuration using state-of-the-art MINLP methods.

The main contribution in this paper is the development and application of a surrogate-based modelling approach to enable a more rigorous optimization of membrane networks in gas separation. The surrogates are constructed from data generated using the mechanistic model by Scholz et al. (2013), which accounts for a number of non-ideal effects, in a given trust-region. The mechanistic model is implemented using Aspen Custom Modeler (ACM), while the surrogate-based superstructure model is implemented in GAMS, and the update/refinement of the surrogates is performed using Matlab. Using a case study in NG sweetening, we show that the surrogate models enable the solution of the superstructure optimization subproblems to optimality as part of the trust-region algorithm. The benefits of the proposed methodology are also illustrated by comparing the optimized membrane network with networks designed using constant-permeability membrane models.

2. Superstructure Modelling of Gas Membrane Network

The optimization methodology developed herein relies on a superstructure model, which accounts for all the equipment in the membrane network system and describes the mass and energy balances thereof. It is inspired from the model described in Qi and Henson (2000), where the binary variables describing the existence of interconnections and other logical decisions have been removed, converting the original MINLP into an NLP. The basic set of equipment comprises of the permeators, compressors, stream mixers and stream splitters. In order to enable non-isothermal process operations, heaters are included in every retentate recycle stream. The role of such heaters is to compensate for the Joule-Thomson effect (described in the mechanistic permeator model) by providing sufficient energy to maintain the feed temperatures of the permeator modules at their optimal levels.

Both a mechanistic membrane model (Sec. 2.1) and a grey-box surrogate membrane model (Sec. 2.2) are used to describe the membrane permeators with different accuracies within the superstructure optimization methodology. The surrogates are embedded in the superstructure NLP problem for computational tractability, whereas the mechanistic model is used to generate data points in order to train and refine the surrogates.

2.1. Mechanistic Membrane Model

The mechanistic model of a hollow fiber membrane module developed by Scholz et al. (2013) has been used in this work. The sources of non-ideality captured by this model include: concentration polarization, Joule-Thomson effect, pressure drops (on both sides of the membrane module), and real gas behavior. This model has been implemented in ACM in order to take advantage of the thermo-physical property packages and the numerical integration schemes available therein (a detailed description this model can be found in the original work). Furthermore, the model has been adapted to a NG sweetening application by considering a gas mixture comprised of five species: CH_4 , CO_2 , C_2H_6 , C_3H_8 and H_2S . The permeabilities for CO_2 and CH_4 are computed for a polyimide membrane in function of the pressure and temperature based on the equations proposed

by Safari et al. (2009), and fitted with experimental data provided by Chung et al. (2004). The permeabilities of the other three species are calculated by assuming a constant selectivity of each component with respect to CH_4 , equal to 16, 0.4 and 0.1 for H_2S , C_2H_6 , C_3H_8 , respectively.

Overall, the numerical simulation of this mechanistic membrane model requires the specification of 9 inputs or parameters (flow rate, temperature, pressure and composition of the feed; pressure of the permeate stream; and membrane area), denoted collectively by v_{in} thereafter. The differential equations are discretized using a 2nd-order orthogonal collocation method, resulting in a system of 13,602 algebraic equations that are solved using a Newton-like iterative approach.

2.2. Grey-Box Surrogate Membrane Model

The use of grey-box surrogate models is advantageous compared to completely black-box models, as it often offers a reduction in the number of nonlinear terms needed to accurately fit a set of experimental or in-silico data. The grey-box surrogate in Eqs. (1) to (6) combines a shortcut model with several response surface models:

$$F_i^f = F_i^r + F_i^p \quad (1)$$

$$F_i^p = K_i A p_i \quad (2)$$

$$\Delta p_i^{0.3275} = 0.5(p_i^f - p_i^p)^{0.3275} + 0.5(p_i^r)^{0.3275} \quad (3)$$

$$K_i = a_i + 0.5b_i(T^f + T^r) + c_i p^f \quad (4)$$

$$T^r = T^r(v_{in}) \quad (5)$$

$$T^p = T^p(v_{in}) \quad (6)$$

The shortcut model in Eqs. (1) and (2) is based on an analogy with counter-current heat exchangers as developed by Pettersen and Lien (1994). Here, F_i denotes the molar flow rate for species i , in the feed (f), retentate (r) and permeate (p), K_i the permeability for species i , Δp_i the driving force for species i , and A the membrane area. Note that in the original shortcut model the driving force Δp_i is represented by the logarithmic mean of the partial pressures p_i , whereas this term has been replaced by Chens approximation in Eq. (3), in order to avoid numerical difficulties. The permeabilities K_i in Eq. (4) consist of a 1st-order approximation in terms of the feed and retentate temperatures (T^f , T^r) and the total pressure (p^f), with a_i , b_i and c_i as adjustable parameters (see Step 3 of Algorithm in Sec. 3). An important physical mechanism in the NG sweetening process is the Joule-Thomson effect, mainly due to the presence of CO_2 and the large pressure drop across the membrane. To account for this effect, the retentate and permeate temperatures were approximated by 2nd-order polynomials in terms of all nine inputs / parameters v_{in} in Eqs. (5) and (6).

3. Surrogate-based Superstructure Optimization Algorithm

The proposed superstructure optimization algorithm is inspired by the trust-region (TR) method developed by Eason and Biegler (2016). It comprises the following steps:

Step 1 Initialization

1.1 - Solve the superstructure NLP model using the grey-box model in Eqs. (1) to (6) with fixed values for the permeabilities (K_i) and temperatures (T^r and T^f).

1.2 - Initialize the TR around the initial superstructure given by Step 1.1, e.g. by incorporating a priori knowledge about the problem in order for grey-surrogate to provide a good fit of the mechanistic membrane model predictions within the TR.

Step 2 Generate data from the mechanistic model

2.1 - Obtain a sample set within the current TR, and then simulate the mechanistic model of Sec. 2.1 at each sampling point.

Step 3 Train the surrogate model in Eqs. (1) to (6)

3.1 - Update the quadratic approximations for T^r and T^f in Eqs. (5) and (6) using data at the input values v_{in} for the sample set of Step 2. Here, we apply a model reduction and parameter estimation algorithm based on partial least squares (PLS) regression as proposed by Graciano et al. (2018).

3.2 - Update the linear approximations for the permeabilities K_i in Eq. (4) using the updated surrogates for T^r and T^f in Step 3.1. Here, the parameters a_i , b_i and c_i are determined using least-squares error minimization between Eq. (4) and the mechanistic model predictions on the sample set of Step 2.

Step 4 Solve the superstructure optimization model to optimality

4.1 - Solve the superstructure NLP model, by minimizing the economic objective function, within the current TR and using the updated grey-box surrogate in Step 3.

4.2 - If the NLP problem is infeasible, interpolate a point in-between the last to feasible solutions, and return to Step 2.

Step 5 Termination

5.1 - If the solution in Step 4.1 is on the boundary of the current TR, check the surrogate accuracy against the mechanistic model at this point. If the error between the surrogate and mechanistic model predictions is less than 2%, increase the TR by 30%, and center the TR at the new point. If the error is greater than 5%, reduce the TR by 30%, and then center the TR at the new point. Return to Step 3.

5.2 - If the solution in Step 4.1 is in the interior of the current TR, also check the surrogate accuracy against the mechanistic model at this point. If the error between the surrogate and mechanistic model predictions is less than 0.1%, terminate the search. Otherwise, reduce the TR by 30%, and return to Step 3.

Upon termination, the algorithm will normally reach a neighborhood of a local optimum of the superstructure optimization problem. A formal analysis of the convergence conditions is currently under investigation.

4. Case Study in Natural Gas Sweetening

The superstructure optimization problem consist of minimizing the total annualized cost of a gas membrane network subject to a maximum CO_2 concentration of 2%vol in the NG product stream; refer to Qi and Henson (2000) for more details about the formulation of the economic objective function. Two membrane modules are considered next in this case study.

The results of the surrogate-based superstructure optimization algorithm are shown in Figure 1 (top). This approach determines a simple network structure, where the first module is responsible for the main separation, so that the NG stream meets the 2%vol specification; whereas the second module enable methane recovery for the permeate of the first module. In the convergence, the grey-box surrogate presents a maximum error of 0.058% with respect to the mechanistic model. It is important to reiterate that the synthesis problem accounts for the main process non-idealities; for instance, the feed temperature is reduced to its lower bound so as to increase the selectivity between CO_2 and CH_4 (Safari et al., 2009).

Next, the results obtained by the surrogate modelling approach are compared with the synthesis of a membrane cascade using simplified models, which do not account for the non-idealities observed in the process. Specifically, the superstructure is optimized using the simplified model in Eqs. (1) to (6), now with fixed permeabilities and temperatures (step 1, section 3). For validation purposes, the mechanistic model is simulated using the specifications determined by the simplified model. The results are shown in Figure 1 (bottom).

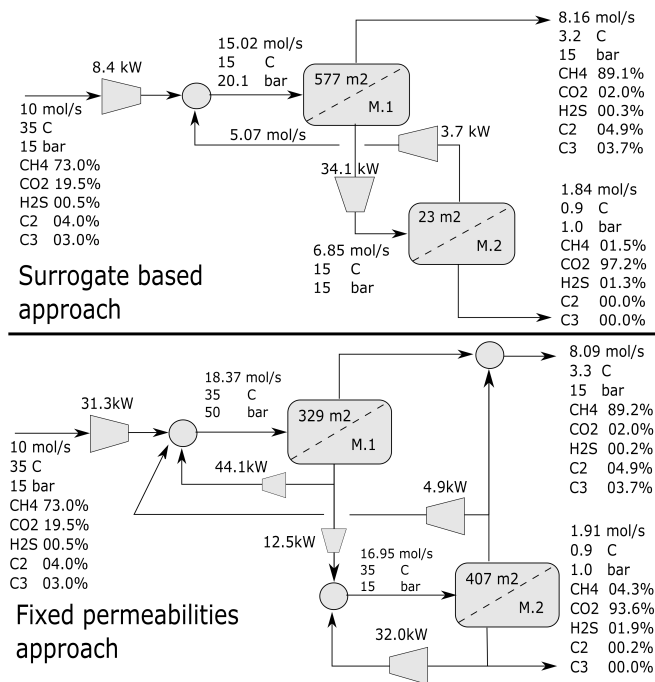

Figure 1: Comparison between the results obtained by the surrogate modeling approach and the fixed permeabilities model.

Large discrepancies are observed between the surrogate model using fixed permeabilities and the mechanistic model (maximum error of 200% for the predicted CO_2 concentration in retentate

stream). In order to compensate for the model mismatch and satisfy the 2%vol CO_2 specification in the product stream, the optimized membrane network presents a large number of recycle streams, which results in extra capital and operational costs.

5. Conclusion

This paper has presented a strategy for the synthesis of membrane networks using a surrogate modeling-based approach. The main objective is to design reliable membrane cascades taking into account the main sources of non-ideality present in this process. A mechanistic model is used to train a surrogate, which is embedded into a superstructure optimization problem and updated using a trust-region like approach. The results show that the algorithm can obtain a reliable cascade structure with errors smaller than 0.1%, whilst the network synthesis based on simplified models (with fixed permeabilities) can result in suboptimal networks to compensate for the mismatch between the simplified and mechanistic models.

Abstract

In this work, a novel strategy for the design of a hydrogen supply chain (HSC) network for Germany is presented for minimum daily supply costs, minimum mitigation costs of CO₂ and maximum network safety. The proposed model is a mixed integer linear program that is solved with the Advanced Integrated Multidimensional Modeling System (AIMMS). The model is solved as a multi-criterion decision making problem, where three objectives (costs, safety and environmental impact) are balanced. The results show that hydrogen as type of fuel has potential to replace carbon-based fuels in the near future. Implementation of decentralized hydrogen production plant based on water electrolysis may compete with coal-based dominant technology.

Keywords: Hydrogen supply chain design, Mixed integer linear programming, fuel infrastructures, Multi-objective optimization, AIMMS.

1. Introduction

The transportation sector plays a crucial economic role in the world. The main transportation fuels currently in use come from non-renewable fossil sources. Moreover, being the main fossil fuel consumer, the transportation sector is the second largest contributor of CO₂ emissions worldwide, which is one of the causes of global warming. The vehicle industry has been working on the improvement of fuel efficiency and the reduction of greenhouse gas emissions. The use of different types of fuel such as biodiesel, methanol, hydrogen, is considered a promising alternative. Being the most abundant element in the universe, hydrogen is regarded as a suitable energy carrier for mobility and stationary fuel cell systems applications. The challenge of developing a successful hydrogen infrastructure stands behind the development of a hydrogen supply chain (HSC) considering safety, economic and environmental impact issues.

In this work, a model of the HSC network is developed for the transport sector in Germany considering a significant fuel cell electrical vehicles penetration into customer market. The model is solved using a deterministic Mixed Integer Linear Programming

(MILP) approach and implemented in AIMMS/CPLEX for multiple objectives: costs, safety and environmental impact are balanced via the epsilon constraint method to generate the Pareto front. The sampling grid of this three-dimensional window is created by a surface response methodology. The aim of the current work is to identify the best hydrogen infrastructure pathways while taking into account local factors such as the location of the hydrogen supply and demand, and distribution between the hydrogen production location and hydrogen demand points. Two types of technologies to produce hydrogen are evaluated, namely coal gasification and water electrolysis.

2. Methodology

2.1. Problem Description

Given are the location and capacity of energy source suppliers, capital and operating costs for a large-scale hydrogen production plants, transportation modes and storage facilities of the network, under the conditions that:

1. locations of storage facilities are fixed;
2. the relative risk of production plants, storage facilities and transportation modes are expected not to change under the various demand scenarios;
3. electricity is the main energy source to power rail freight transport;
4. electricity price is based on industrial electricity price for Germany.

Each facility of the HSC includes: a technological option, a capacity, a location. The problem is concerned with finding the number and locations of the production facilities for a given demand, considering the minimum total operating cost, the minimum safety risk and the minimum environmental impact of HSC network.

2.2. Formulation of the HSC

The model consists of a set of grid points g (each grid point represents a German state), energy sources e , different transportation modes t , different hydrogen production p and storage facilities s . As hydrogen might be generated by different production technologies p (i.e. coal gasification, water electrolysis), it may be transported into two forms f (i.e. liquid or gaseous), which determines the transportation mode that will be used. In the following subsections, each component of the HSC model will be described in more detail.

2.2.1. Grid

In this study, the landscape of Germany is divided into 16 grid points, each of these grid points represents a German region. Moreover, the region's largest city is taken as the potential centre for a hydrogen production facility and for a storage facility to satisfy the local demand and further product distribution to another region. The total hydrogen demand was estimated based on the fuel cell electric vehicles (FCEVs) penetration rate of 10% of the total number of passenger transports (public buses, light motor vehicle) available by 2030. 2015 was used as the reference year for the calculations.

2.2.2. Primary energy sources

The primary energy resource availability at each grid point plays an important role in defining the type and location of production technologies. Moreover, the main problem of a domestic production facility is concerned with finding an appropriate energy source supplier. There are three opportunities related with the energy source consumption from i) a domestic grid point or ii) supply from neighbouring grid points or iii) import from abroad.

2.2.3. Hydrogen production

Two types of technologies to produce hydrogen were included in model: coal gasification and water electrolysis. Each facility has fixed capital and operational costs. The main decisions to be made are: the type, location and number of production facilities. Each facility carries out large-scale hydrogen production (960 ton per day).

2.2.4. Hydrogen physical form

Hydrogen can be carried in two physical forms: liquid and gaseous. The hydrogen form plays an important role in defining which transportation mode and storage facilities should be used. These decisions affect the final costs of the HSC network.

2.2.5. Transportation mode

The transportation mode is related to the hydrogen form. The main decision is to define the transportation mode and its number of vehicles used to deliver the final product from production point to storage point. Each transportation mode has a specific capacity, capital cost, operating cost and delivery distance. It is noted that the operating cost is associated with the delivery distance (including fuel, labour, maintenance and general expenses).

2.2.6. Storage facility

The storage facility, just like the transportation mode, is linked to the hydrogen form. Each type has a specific capacity, capital and operating cost. Storage facilities are installed at each grid point to satisfy the local hydrogen demand. Storage facilities could be located next to production plant or away from it.

2.3. Mathematical formulation

This proposed model must meet three target requirements:

- Minimize the total cost of the HSC network
- Minimize environmental impact
- Minimize the total relative risk of the network.

2.3.1. Total daily cost

The first objective function is the total daily cost (*Total*) of HSC network. It consists of the production, storage and transportation capital and operating costs and expenses of energy sources as follows:

$$\text{Total} = \text{PC} + \text{SC} + \text{TS} + \text{ESC} \quad (1)$$

$$\text{PC} = \sum_{p,f,g} \left(\frac{\text{PCC}_{p,f} \text{NPF}_{p,f,g} \text{AF}_p}{\text{OP}} + \text{HP}_{p,g,f} \text{POC}_{p,f} \right) \quad (2)$$

$$\text{SC} = \sum_{f,s,g} \left(\frac{\text{SCC}_{s,f} \text{NSF}_{s,f,g} \text{AF}_s}{\text{OP}} + \text{SOC}_{p,f} \left(\text{HP}_{g,f} + \sum_{t,g'} \text{HI}_{g',g,t,f} \right) \right) \quad (3)$$

$$\text{TC} = \sum_{f,t,g,g'} \left(\frac{\text{TCC}_{t,f} \text{NTF}_{f,t,g,g'} \text{AF}_t}{\text{OP}} + \text{FC} + \text{LC} + \text{MC} + \text{GC} \right) \quad (4)$$

$$\text{ESC} = \sum_{g'',g,p,e} \left(\text{PESN}_{g'',g,p,e} \text{ESDis}_e \text{Dis}_{g'',g} + \text{PESAv}_{g'',g,p,e} \text{ESCost}_e + \text{PESIm}_{g,p,e} \text{ESICost}_e \right) \quad (5)$$

where PC (production cost), SC (storage cost), TC (transportation cost), ESC (energy sources cost), PCC (production capital cost), SCC (storage capital cost), TCC (transport capital cost), POC (production operating cost), SOC (storage operating cost), NPF(number of production facilities), NSF(number of storage facilities), NTF (number of transportation mode), AF (annual capital charge factor), OP (operating period) HP (domestic produced hydrogen), HI (imported hydrogen from neighbouring grid points), FC (fuel cost), LC (labour cost), MC (maintenance cost), GC (general cost), PESAv (the amount of available domestic energy sources), PESN (the amount of energy source supplied from neighbouring grid points), PESIm (the amount of imported energy sources), ESDis (the delivery price for energy source), ESCost (energy source price), ESICost (energy source import price), Dis (distance between grid points).

2.3.2. Total environmental impact

Based on the work of Almaraz (De-León Almaraz et al., 2013), the total daily greenhouse gas (GHG) emission is associated with GHG in production, storage sites and transportation of HSC network as indicated by:

$$\text{TotalCO}_2 = \text{PCO}_2 + \text{SCO}_2 + \text{TCO}_2 \quad (6)$$

$$\text{PCO}_2 = \sum_{p,g,f} \text{HP}_{p,g,f} \text{GEP}_{p,f} \quad (7)$$

$$\text{SCO}_2 = \sum_{p,g,f} \text{HP}_{p,g,f} \text{GES}_f \quad (8)$$

$$\text{TCO}_2 = \sum_{g,g',t,f} 2\text{Dis}_{t,f,g,g'} \text{NTF}_{g,g',t,f} \text{GET}_t \quad (9)$$

where TotalCO₂ (total daily amount of realized GHG in HSC network), PCO₂ (daily GHG emissions from production sites), SCO₂ (daily GHG emissions from storage sites), TCO₂ (daily GHG emissions during hydrogen delivery), GEP (kg GHG emissions per kg H₂ produced), GES (kg GHG emissions per kg H₂ in storage side), GET (kg GHG emissions per km).

2.3.3. Total relative risk

Based on the work of Kim (Kim and Moon, 2008), the total relative risk consists of total relative risk of production, storage sites and total relative risk of transportation as given by:

$$\text{TotalRisk} = \text{TotalPRisk} + \text{TotalSRisk} + \text{TotalTRisk} \quad (10)$$

$$\text{TotalPRisk} = \sum_{p,f,g} \text{NPF}_{p,f,g} \text{PRisk}_p \text{PW}_g \quad (11)$$

$$\text{TotalSRisk} = \sum_{s,f,g} \text{NSF}_{s,f,g} \text{SRisk}_s \text{PW}_g \quad (12)$$

$$\text{TotalTRisk} = \sum_{g,g',f,t} \text{NTF}_{g,g',f,t} \text{DRisk}_{t,f,g,g'} \text{TRisk}_t \quad (13)$$

where: TotalRisk (total relative risk), TotalPRisk (total risk of production facilities), TotalSRisk (total risk of storage facilities), TotalTRisk (total risk associated with hydrogen distribution between grid points), PRisk (risk level of the production facility), SRisk (risk level of the storage facility), TRisk (risk level of the transportation mode), DRisk (road risk level between grids), PW (population weight factor).

2.4. Multi-objective problem

The tri-objective optimization problem is solved by implementing epsilon constraint method. The HSC design problem in this work is given as follows:

$$\min\{\text{Total}, \text{TotalCO}_2, \text{TotalRisk}\} \quad (14)$$

3. Results and Discussion

The model is formulated as a mixed integer linear programming model and has 2508 constraints, 5498 continuous variables and 2177 integer variables. AIMMS is used as optimization platform and CPLEX 12.6.3 is selected as the preferred solver. A three dimensional pareto front is created using the epsilon constraint method. The sampling grid of this three-dimensional window is created by a surface response methodology. The German government targets to reduce GHG emissions up to 20% by 2050, this work considers two types of hydrogen production technologies: water electrolysis and coal gasification. A case study of Germany threatened by Almansoori (Almansoori and Betancourt-Torcat, 2016) shows the benefit of coal gasification based HSC as compared to the network based on other types of hydrogen production technologies such as steam methane reforming, biomass gasification. This result has also been considered to illustrate capabilities of the proposed work.

In our work there are 4 cases, which will be analysed and compared to each other. Each case consists of a minimization target. Three objectives were optimized separately to analyse how their optimal values decrease when making a multi-objective optimization. The results of each optimization cases can be seen in Table 1.

Table 1 – Results of optimization among treated cases

	Total cost (M\$ d ⁻¹)	Relative risk (units)	CO ₂ gas emission (10 ³ t CO ₂ d ⁻¹)
Min Total Cost (case 1)	9.6 (59.1%)	5072 (-36.4%)	102.9 (27.7%)
Min Total CO ₂ (case 2)	148.9 (-84.2%)	1993 (41.5%)	83.3 (38.2%)
Min risk (case 3)	29.8 (-21.3%)	5058 (-38.2%)	15.6 (89%)
Multi-objective optimization (case 4)	23.5	3225	142.4

The results obtained for Case 1 are in agreement with the base case Almansoori (Almansoori and Betancourt-Torcat, 2016) and reasonable with the average hydrogen cost expected for Europe in the 2030 (i.e. around 3.2). A minimum number of 3 production plants is obtained with coal gasification technology. The number of storage facilities is 62 adopting for projected hydrogen demand and storage period of 10 days. The total cost of the HSC is 9.6 M\$ involving 201 transportation vehicles to cover the demand between grids. Case 2 minimizes the total relative risk. In this case, there is environmental benefit of 20% as compared to case 1. The total cost of the HSC is 148.9 M\$ involving 115 transportation vehicles. As in Case 1, the number of storage facilities adopted for a storage period of 10 days. In Case 3, there is a high risk of accidents, but reduced costs for HSC network as compared to Case 2. The total cost of the HSC is 29.8 M\$ involving 228 transportation vehicles. For cases 2 and 3 hydrogen is produced in liquid form via water electrolysis, this explains a high price of the HSC network for both cases. The optimal configuration of the HSC for Case 4 involves 6 production plants with coal gasification technology. The total HSC network costs are 23.5 M\$ per day and 308.1 kt CO₂-equiv per day involving 169 transportation vehicles. The analysis of the network is quite different from other cases. Table 2 shows that the best value obtained for the total costs in Case 4 is higher (by 59.1%) than Case 1. Moreover, the CO₂ emissions increased by 27.7%, but the risk improved by 36.4%. The total costs decrease by 84.2 % in Case 4 as compared to Case 2 while the CO₂ emissions increase by 41.5% and risk by 38.2%. The HSC network costs decrease by 21.1% in Case 4 and risk by 36.2% but CO₂ emissions are increased by 89% as compared with Case 3. Finally, the hydrogen production costs vary between 3.4 and 8.43 \$ per kg for cases 1

and 4. It can be concluded that the costs of the HSC are still high, and technological improvements are needed: the modification of conventional methods or development of innovative technologies are necessary for reduction of conversion losses and capital costs investment. The model consider centralized hydrogen production. Due to centralized production guarantees more financial benefits with less safe and environmental friendly construction, decentralized production needs to take into account in future work (Han et al., 2013).

Figure 1 – Contour plot of three dimensional pareto front (Cost vs Emissions, Risk)

4. Outlook and Conclusions

In this work, multi-criterion optimization for development of sustainable HSC network is done. Main objectives are cost, safety and environmental impact. This study shows that coal gasification is the most economic method, but it emits considerable amounts of CO₂. Otherwise, for safety and environmental purposes, water electrolysis technology is more suitable. To develop a sustainable HSC network based on water electrolysis, considering supply cost, safety and mitigation cost, decentralized H₂ production configuration needs to be taken into account, due to the reason it may guarantees a safer and more environment friendly HSC.

Abstract

In this paper, the process integration of a conventional oil refinery hydrotreatment unit and renewable hydrogen production is proposed. This might lead to reductions in the need for energy and greenhouse gas emissions. First a conventional hydrotreating process is modeled and simulated with the flowsheeting package Unisim Design R450 (Honeywell). Secondly an exergy analysis for identification and quantification of thermodynamic inefficiencies is accomplished with Aspen Plus V10. To complement the exergy analysis, the evaluation of environmental impact is with a life cycle assessment (LCA) tool (Eco-indicator 99) is done.

Keywords: Oil refinery, hydrotreating unit, renewable hydrogen, exergy analysis, life cycle assessment

1. Introduction

An atmospheric residue desulphurization (ARDS) hydrotreater is applied in oil refineries for the purpose of residue upgrading. This highly exothermic process unit allows a purification from sulfur, nitrogen, oxygen, chlorine and metal impurities as well as the cracking of heavy hydrocarbons, prior to downstream processing.

This catalytic pretreatment step is basically implemented by application of hydrogen at high temperature and pressure. Currently, the hydrogen used for hydrotreatment in a refinery is obtained from light hydrocarbons through the conversion stages of synthesized gas in steam methane reforming or pressure swing adsorption to produce a final product with purity ranges between 70 to 80 %. The consumption of hydrogen during this treatment process ranges from 0.6 kg hydrogen per ton of light distillates to 10 kg hydrogen per ton for vacuum distillates (Fahim et al. 2010a).

Renewable hydrogen production via electrolysis from a hybrid system that combines wind and solar energy has become attractive due to installation flexibility, increasing performance efficiency and large scale production capability. In this study we propose the possibility to integrate the renewable hydrogen with the modified ARDS system.

2. Theory & definitions

A sustainable refinery needs to be energy efficient and environmentally friendly. An exergy analysis according to second law thermodynamics provides measures in quantifying the actual energy consumption, energy destruction rate, location of losses

and real efficiency that considers the energy losses in the system. Additionally, an environmental impact assessment is an essential indicator to operational sustainability.

2.1 Exergy, exergy destruction and exergy efficiency

Exergy is defined as the maximum amount of work obtained as the process changes reversibly from the given state to a state of equilibrium with the environment. Alternatively exergy can be defined as the maximum work that can be obtained from any quantity of energy (Kotas, 1995). Physical exergy is the work obtainable by taking the substance through a reversible process from its initial state (T, P) to the state of the environment (T_0, P_0). The specific physical exergy is written as:

$$ex_j^{phy} = ex_i - ex_o = (h_i - h_o) - T_0(s_i - s_o) \quad (1)$$

here the enthalpy, h_i and entropy, s_i are the independent thermodynamic state functions. h_o and s_o denote the variables at a reference condition. Unless otherwise, the reference temperature and pressure are 298.15 K and 1.013 kPa respectively.

Chemical exergy is the maximum extractable work when a substance is brought from the reference environment state to the dead state (T_0, P_0, μ_0) by a process including heat transfer and the exchange of substances only with the reference environment (Dincer and Rosen, 2013a). The chemical exergy in the process stream can be determined from the standard molar chemical exergy of all components in the stream as given by Moran (1999):

$$ex_j^{chem} = \sum_{i=1}^j y_i \bar{e}_i^{ch} + RT_0 \sum_{m=1}^j y_m \ln y_m \quad (2)$$

y_i is the component fraction, R is universal gas constant and \bar{e}_i^{ch} is the standard molar chemical exergy of the components. The specific total exergy is the summation of physical and chemical exergy neglecting the potential and kinetic exergy terms.

$$ex_j^{total} = ex_j^{phy} + ex_j^{chem} \quad (3)$$

The exergy rate of a stream is calculated as the product of the mass flow of material j and the total exergy:

$$\dot{E}x_j = \dot{m}_j ex_j^{total} \quad (4)$$

Exergy destruction or irreversibility is the magnitude of exergy loss as a result of the entropy generated in the system. The losses can occur internally due to irreversibility within the system or externally due to wastes to environment. Exergy destruction is determined by the Gouy-Stodola theorem:

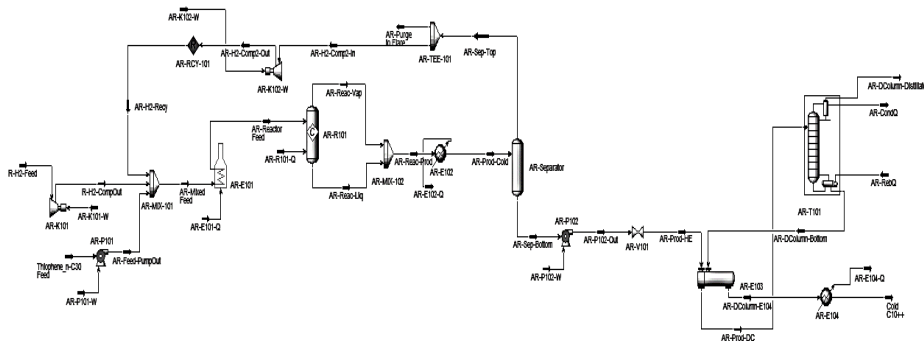

$$E_d = \sum E_{x_{input}} - \sum E_{x_{output}} \quad (5)$$

Exergy efficiency of the unit and system are calculated respectively (Dincer and Rosen 2013b):

$$\psi_{unit} = \frac{\sum \dot{E}x_{product}}{\sum \dot{E}x_{source}} \quad (6)$$

$$\psi_{overall} = \frac{\sum \dot{E}x_{outlet}}{\sum \dot{E}x_{inlet}} \quad (7)$$

Figure 1 : The ARDS hydrotreating modelled and simulated in UniSim Design R450

2.2 Environmental impact analysis

As defined in the ISO Standard 2006, LCA refers to the evaluation of the total energy and material used and the waste released to the environment throughout the full life cycle of the products and processes (Elzakker et al. 2017). A quantitative aggregated indicator LCA tool, the Eco-indicator 99 is chosen as method for this purpose because the outcome can be translated into a singular accumulated metric point. The damage oriented approach is used to determine the environmental impact based on the damage to human health, resource and ecosystem (Pré Consultants, 2000).

3. Modelling and Simulation

3.1 ARDS process description

The process flow diagram of the ARDS hydrotreating is shown in Figure 1. Data input and process flow are adapted from Fahim et al. (2010b) and Parkash & Parkash (2003). This process is required to remove undesired sulphur in the form of thiophene and at the same time cracks the heavy hydrocarbon component *n*-C30 into lighter components *n*-C20, *n*-C10 and *n*-C4. Operation are assumed at the steady state condition. The feed stream contains the mixed components of *n*-C30 and thiophene and are pumped at 455 kg mole/h at 38 °C and 820 kPa. The thiophene fraction is 1 % of the feed. This feed stream is then mixed with the (renewable) hydrogen at a flowrate of 560 kg mole/h at 65 °C and 1,380 kPa. Subsequently, the stream is heated to 370 °C and 10.35×10^3 kPa in the fired heater and enter the conversion reactor. The sequential reactions involved in the reactor are shown in Table 1. Products from reactor are then cooled to 92 °C by the cooler and conveyed to the gas-liquid separator. An amount of 126.5 kg mole/h of hydrogen with small trace of hydrogen sulphide H₂S is splits from the gas stream from the top separator stream and recycled to reactor to maintain the partial pressure and compensate the amount consumed. The remaining amount of top product is purged in a flaring system. Liquid products at bottom are then transferred and expanded by a valve to reduce the pressure to 1,780 kPa. The stream is then heated to 105°C in a shell and tube heat exchanger using the hot product stream from bottom of the distillation column. In the distillation column, the stream is distilled to produce top distillates and bottom products. The top distillates contain mostly light hydrocarbon gas, hydrogen and trace amounts of other components are sent to the next processing unit. At the bottom, the cracked hydrocarbons are cooled to 38 °C and 400 kPa. It is noted that the process also simulated in Aspen Plus V10 to compare the results and calculate the exergy efficiencies.

Table 1 Reaction in the hydrotreating reactor

No	Reactions	Reactor type	Percent Conversion
1	$C_4H_4S + 4H_2 \rightarrow C_4H_{10} + H_2S$	Conversion	100
2	$C_{30}H_{62} + H_2 \rightarrow C_{20}H_{42} + C_{10}H_{22}$	Conversion	70

3.2 LCA analysis using Eco-indicator 99

The input and output streams for the environmental impact analysis is based on the process flow diagram of Figure 1. The input streams include the feed and the utilities such as hydrogen, heat, electricity and the fuel gas combusted for the heater and reboiler. The output products are the CO₂ and SO₂ emissions during the operation.

In this study, the goal of analysis is to evaluate the environmental impacts of ARDS hydrotreating process and products. The impacts includes two components, the utilities consumed and the emissions by the products burning. Three damage categories are considered as specified in the Eco-indicator 99 manual; the ecosystem, human health and resources. Each of the categories are determined by a total of ten respective impacts categories such as ecotoxicity, carcinogens and respiratory effects. In the analysis, the relevant input and outputs mass and energy associated with the process are used to calculate the environmental impacts. The life cycle inventory (LCI) of utilities and pollutants impact factor values are gained from the Eco-indicator 99 database (Pré Consultants, 2000). The damage in each of the impact categories is calculated from the life cycle impact categories as:

$$IMP_{j,u} = \sum_i m_u LCI_{i,u} \quad \forall_j \quad (8)$$

where $IMP_{j,u}$ is the impact factor in Pt /kg or Pt /kWh, j and i represent the damage category and impact category respectively, m_u denotes the consumption or emission of utilities or pollutants in kg /h or kW /h and $LCI_{i,u}$ is the impact factor of utilities and pollutants, in Pt /kg or Pt /kWh. The impact categories are then aggregated into three damage categories and integrated into a single environmental metric: the environmental impact of process and products as in the following equations:

$$DAM_u = \sum_j IMP_{j,u} \quad (9)$$

$$EI = \left(\sum_u DAM_u \right) \cdot t \quad (10)$$

where DAM_u denotes the damage factor of utilities and pollutants, in Pt /kg or Pt /kWh and EI is the environmental impact in Pt /year. The t is annual operating time in hours which is assumed equivalent to 8,400 hours a year in this study.

The data and calculation for fuel gas consumption, m_{fg} for furnace and boiler are taken from Wu & Liu (2016). The furnace and boiler have 6,485 kW and 24,462 kW power ratings respectively with similar efficiencies, 93.8 %. The high calorific value of the fuel gas from the diesel oil used is 44,800 kJ /kg. The calculated m_{fg} is 2,651.19 kg /h. The (renewable) hydrogen consumption, in kg /h, the heat flows and electricity to drive pumps and compressors, in kWh are taken from simulation results.

CO₂ and SO₂ are two important output parameters released by the burning fuel gas. The emission of CO₂ is determined from

$$m_{CO_2} = \frac{44}{12} \times m_{fg} w_{fg,c} \quad (11)$$

where m_{CO_2} is the mass of CO₂ emitted in kg /h, 44 and 12 are the molecular weights of CO₂ and carbon, in kg /kmol, m_{fg} is the fuel gas consumption, in kg /h and $w_{fg,c}$ is the carbon content in fuel gas, in %. The m_{fg} is 2,651.19 kg /h from the previous calculation and the carbon content is 66.3% (Wu and Liu 2016). Therefore, m_{CO_2} is 6,445.03 kg /h. The SO₂ emission in fuel gas and flaring system is determined as:

$$m_{SO_2} = \frac{64}{32} \times (m_{fg} w_{fg,s} + m_{H_2S} w_{H_2S,s}) \quad (12)$$

where $w_{fg,s}$ and $w_{H_2S,s}$ are the sulphur contents which both are assumed as 18.8 ppm referred to Parkash & Parkash (2003) and $w_{H_2S,s}$ is the purge gas flow rate to the flaring system obtained from the simulation. The calculated m_{SO_2} from the fuel gas is 0.05 kg /h and from burning H₂S is 0.004 kg /h.

4. Results and Discussion

In the reactor, thiophene is totally removed from the mixed feed stream in the conversion reactor. There are no traces of thiophene found in the subsequent streams. Approximately, 41.5 % of the top product from the separator which mostly contains hydrogen and a small trace of H₂S is purged from the system to maintain the partial pressure in the reactor. The balance is compressed and recycled with the new *n*-C30 and hydrogen feed to the reactor. In the distillation column, 460 kg mole/h and 451 kg mole/h distillates and bottom products are produced respectively. The distillate consists of 314.1 kg mole/h of *n*-C10, 137.2 kg mole/h of hydrogen and small amounts of *n*-C4 and H₂S. The bottom distillation product contains the cracked amount of *n*-C30 at 135.13 kg mole/h, *n*-C20 at 315.31 kg mole/h and at *n*-C4 at 1.17 kg mole/h. Approximately 3.64 kg renewable hydrogen is used to produce a ton of distillation product in this simulation. This equivalent to 63.3 percent reduction as only hydrodesulphurization and cracking reactions involved.

The input and results from Unisim Design R450 are further processed with Aspen Plus V10 and Microsoft Excel to determine the exergy destruction rate, E_d and exergy efficiency for each equipment in the ARDS hydrotreating unit. The highest exergy loss rates occur in the reactor at 1,100 MW, followed by the distillation column at 599 MW and the separator at 334 MW. For the other equipment, the exergy losses are less than 14 MW. The exergy destruction rates are proportionally related to the changes in chemical exergy of the streams. For example, in the reactor AR-R101, the chemical exergy changed from 1703 MW to 603 MW due to reactions in desulphurisation of thiophene and crackings *n*-C30 to *n*-C20 and *n*-C10. In the distillation column, these chemical exergy transformed from 909 MW at the inlet to the 473 MW and 1047 MW at the distillates and bottom products. The lower exergy efficiencies occur in pumps at less than 20 %, coolers and heaters between 21- 42.2 % and for the reactor and distillation column at 36.4 % and 36.6 % respectively. Compressors, separator and valve retains efficiencies above 64 %. Coolers and heater efficiencies are depending on the amount of heat used for the cooling and heating requirements of process streams. In the distillation column a large amount of heat at 12,106 kW is removed via the condenser to obtain the distillates while at the bottom reboiler uses a huge amount of heat at 84,025 kW for reboiling the bottom liquid products.

The input utilities consumed have a greater damage impact than output products i.e. the emissions of gas CO₂ and SO₂. The damage impact to human health are high as compared to ecosystem quality and resources. Input utilities of heat consumed gives the highest points for all damage categories at 2.9897 x10⁹, 3 x10¹⁰ and 2.491 x10⁷ point per year respectively. Electricity and fuel gas have approximately equivalent impacts while there is only a minor effect from the use of make-up hydrogen. The damage impact in the output to human health, ecosystem quality and resources are at 9.5301 x10⁵, 1.5745 x10⁵ and 9.5301 x10⁵ point per year respectively. Most of the impact can be attributed to the emission of CO₂ and SO₂ due to the burning of fuel gas for fired heater and reboiler. The calculated impact of SO₂ emission from the top purged gas in the flaring system is very limited due to small fraction of H₂S in the purging amount.

5. Outlook and Conclusions

Integration of renewable hydrogen in the hydrotreating process yields potential reductions in the energy consumption and environmental impact. Approximately 3.64 kg of hydrogen is used to produce a ton of distillate products in this simulation considering the thiophene desulphurization and *n*-C30 cracking.

The exergy analysis shows that reactor, distillation column and separator have large energy losses between 334 -1,100 MW. The lower exergy efficiency occurs in pumps, heat exchangers, reactor and distillation column in the range of 10.9 - 42.4 %. Life cycle analysis through Eco indicator-99 method reveals the apparent damage effects to human health of greenhouse gases emission from burning fuel gas for fired heater and reboiler. This is corresponding to 9.5301 x10⁵ point per year. The impact of SO₂ emission from burning excess H₂S in the flaring system to atmosphere is minor and can be neglected.

Experimental Study of a Biomass Downdraft Gasifier with Multi-tube Gas Outlets to Improve Synthesis Gases Quality

Ajaree Suwattthikul and Paisan Kittisupakorn*

Department of Chemical Engineering, Chulalongkorn University, Bangkok 10330, Thailand

paisan.k@chula.ac.th

Abstract

A downdraft gasifier is favored due to its easy fabrication and due to low tar content in the synthesis gas. This work presents a designed and experimental results of downdraft gasifier. The throat, the smallest cross-sectional area, is approximately 175 millimeters. The gasifier is divided into 2 pieces (top and bottom) for easy fabrication and cleaning of the internal parts. The top is a fuel chamber while the bottom is a reaction and ash chamber. This gasifier was made of carbon steel inserting multi-tube (12) carbon steel of 1 inch diameter to be outlets of synthesis gas. These tubes were returned back to drying and pyrolysis zones of the top chamber as a heat source to wood pellets. The gasification was carried out under atmospheric pressure with ambient air as gasifying agent. Experimental results showed that average volumetric percentage in the synthesis gas were 39.71 % CO, 16.48 % CO₂, 36.26 % H₂ and 7.55 % CH₄. The gasification efficiency of this work of 40.47 % can be achieved.

Keywords: Design, Experiment, Biomass, Downdraft, Gasifier

1. Introduction

Gasification is a thermo-chemical process which converses organic material with partial oxidation to generate synthesis gas (mixture of CO, CO₂, CH₄ and H₂). The synthesis gas can be used as fuel in the internal combustion engine in order to produce electricity. A 25 kWe downdraft gasifier was presented by Ladpala et al. 2007. The fuel consumption rate was 50 kg/h and the heating value of synthesis gas was 4.5 MJ/ m³. The gasification efficiency of 66 % was achieved. Ma et al. 2012 designed a 190 kWe biomass fixed bed gasification. The overall height and effective inner diameter were 6205 mm and 1154 mm, respectively. The gasifier was made from steel (A105, ASTM) that was lined by refractory and insulated by ceramic fibers. The upper part was an air jacket for preheating the air agent. The lower part was a water jacket with an aim to reduce the charcoal's temperature as much as possible. This gasifier was a double air stage to reduce the tar level considerably and increase the heating value of the synthesis gas. A primary air supply located at the top section and a secondary air supply located at the middle section. Wood chips were used as feedstock with the consumption rate 250 kg/h. The heating value of 5.25 MJ/Nm³ and the gasification efficiency of 53 % were achieved. A small downdraft gasifier was presented by Chawdhury and Mhkamov 2011. The main body of the gasifier was divided into 3 sections. These three sections were top cylinder (fuel chamber), middle cylinder (reaction chamber) and bottom cylinder (ash

chamber). The top cylinder (pyrolysis zone) was made of 6.3 mm thick, 219 mm outer diameter and 272 mm length stainless pipe. Middle part (the oxidation zone and the throat section) was made of 6.3 mm thick, 219.1 mm outer diameter and 320 mm long stainless steel pipe. Inside this chamber there was a slab of thermal resistant concrete to provide insulation around hot zone. There were 4 holes in middle of the slab for the air supply nozzles. The bottom chamber (ash zone) was made of 219.1 mm diameter and 325 mm long cylinder. The consumption rate of wood chips and wood pellets were 3.1 and 2.9 kg/h, respectively. The heating value of synthesis gas was 4424 - 5007 kJ/m³ and the gasification efficiency was 62.5- 69.4 %.

The objective of this work is to experimentally study a downdraft gasifier with multi-tube gas outlets using wood pellets as feedstock. The performance of the downdraft gasifier is evaluated in terms of the synthesis gas composition, the heating value (LHV) and the gasification efficiency.

2. Design of downdraft gasifier

In this work, the gasifier is divided into 2 pieces (top and bottom) for easy fabrication and cleaning of the internal parts. The top is a fuel chamber while the bottom is a reaction and ash chamber as shown in Figure 1. The total height of the gasifier is 1.8 m with the inside diameter 700 mm. The throat, the smallest cross-sectional area, is approximately 175 mm. This gasifier was made of carbon steel and lined by refractory. The inserting multi-tube (12) were made of carbon steel of 1 inch diameter to be outlets of synthesis gas. These tubes were returned back to drying and pyrolysis zones of the top chamber as a heat source to wood pellets.

Figure 1 The schematic of the downdraft gasifier with multi-tube gas outlets.

3. Experimental setup

The experimental setup is shown in Figure 2. To control the gasification, air supply is designed to be adjusted by a damper. Air is fed into the gasifier from the center air distribution nozzle which then is allocated throughout the chamber via seven air nozzles. An air blower of 1 Hp motor with variable air flow rates is used to provide sufficient quantity of air for combustion. The wood pellets in the reduction zone are supported by a fixed grate at the bottom of the gasifier. The remaining ash is collected in the bottom. To measure the temperature of various zones in the gasifier, thermocouples are placed inside the gasifier at different locations. Temperatures along the gasifier are monitored every 10 minutes by type K thermocouples located at 0.11, 0.50, 0.73, 0.88 and 1.30 m above of the grate and another at the synthesis gas exit.

Figure 2 The experimental setup of the downdraft gasifier

4. Experimental procedure

The wood pellets of 100 kg were fed into the gasifier, afterwards, the gasifier was ignited at the ignition starting hole, which was installed at the combustion zone. After ignition, the hole was closed and air was supplied by the blower through the air inlet pipe. A gas analyser was used to measure the composition of the gas. The temperatures in the gasifier were measured using six thermocouples and recorded using a data logger and computer. The gasification was carried out under atmospheric pressure with ambient air as a gasifying agent.

5. Experimental results

5.1. Effect of air flow rate on the synthesis gas composition

The effect of air flow rate on synthesis gas consumption rate is shown in Figure 3. In this experimental study, air flow rate is varied from 95 to 120 m³/h and biomass consumption rate is then varied correspondingly from 20 to 22 kg/h. It was found that an increase in the air flow rate lead to the increase in biomass consumption rate. This is because the increase in the air flow rate will provide more oxygen to oxidize and higher amount of biomass will get combusted.

Figure 3 Effect of air flow rate on the synthesis gas composition

Figure 4 shows the temperature readings from T1 to T6 located as described above during the 3 h experimental run. T1 and T2 represent the temperatures at reduction and combustion zones, respectively. It can be seen that the highest T1 of 350 °C can be achieved at 50 minute, then it slightly decreases to 280 °C at the end. T2 reaches 280 °C at 20 minute, then it increases to the maximum of 760 °C at 170 minute and decreases to 600 °C at the end.

Figure 4 The temperature profiles of T1 to T6 at air flow rate 105 m³/h

5.2. Effect of air flow rate on LHV and gasification efficiency

The gasification efficiency is defined as the ratio between the energy content of the synthesis gas (in terms of LHV) and the energy content of the biomass (in terms of HHV) (Azzone et al. 2012). The gasification efficiency is calculated as below:

$$\eta = \frac{LHV_g \times Q_g}{HHV_b \times M_b} \times 100\% \quad (1)$$

Q_g is volumetric flow rate of the synthesis gas (Nm^3/h). M_b is biomass consumption rate (kg/h). LHV_g is heating value of the synthesis gas (MJ/Nm^3). HHV_b is the heating value of the biomass (kJ/kg). The heating values of typical gases are obtained from the standard gas tables as $10.1 \text{ MJ}/\text{Nm}^3$ for hydrogen, $12.64 \text{ MJ}/\text{Nm}^3$ for carbon monoxide and $38 \text{ MJ}/\text{Nm}^3$ for methane (Keche et al. 2015). The following equation is used to calculate the gas heating value:

$$LHV_g = \frac{10.1V_{H_2} + 12.64V_{CO} + 38V_{CH_4}}{100} \quad (2)$$

The effect of air flow rate on the heating value (LHV) of the synthesis gas is illustrated in Figure 5. When the air flow rate increases from 95 to $120 \text{ m}^3/\text{h}$, the LHV of the synthesis gas decreases. This is because the content of CH_4 is relatively low at high air flow rate. According to Eq. (2), the LHV of CH_4 is $35.814 \text{ MJ}/\text{Nm}^3$, which is more than three times as the LHV of H_2 ($10.788 \text{ MJ}/\text{Nm}^3$). Therefore, a small change of the CH_4 content will lead to large decrease in the LHV of the synthesis gas.

Figure 5 Effect of air flow rate on the LHV of the synthesis gas

Figure 6 shows the effect of air flow rate on the gasification efficiency. It was found that the increase in the air flow rate lead to the increase in gasification efficiency. The maximum gasification efficiency take place at the air flow rate of $120 \text{ m}^3/\text{h}$. Eq. (2) shows that the gasification efficiency is determined by the LHV, biomass consumption rate and the volumetric flow rate of synthesis gas. The results show that the gasification efficiency of the gasifier is directly proportional to the volumetric flow rate of synthesis gas; the change in the volumetric flow rate of synthesis gas has more impact on the gasification efficiency than the heating value and the biomass consumption rate.

Figure 6 Effect of air flow rate on the gasification efficiency

6. Conclusions

This work presents a designed and experimental results of a downdraft gasifier with multi-tube gas outlets. When the air flow rate increases from range 95 to 120 m³/h, the heating value decreases (from 1212.86 to 1155.06 MJ/Nm³) while the gasification efficiency increases (from 38.30 to 40.47 %). The maximum gasification efficiency, 40.47 %, take place at the air flow rate of 120 m³/h. The volumetric percentage of the synthesis gas composition of 39.71 % CO, 16.48 % CO₂, 36.26 % H₂ and 7.55 % CH₄ can be achieved.

Design and Optimisation of Novel Cascade Refrigeration Cycles for LNG Production

Fernando Almeida-Trasvina and Robin Smith*

Centre for Process Integration, School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, UK.

robin.smith@manchester.ac.uk

Abstract

LNG production involves the use of large, complex and energy-intensive refrigeration cycles. The costs associated with the energy for refrigerant compression (shaft work energy) dominates the overall operating costs of the refrigeration cycles. In this work, a novel cascade refrigeration cycle is presented, as an alternative option for large scale LNG production, which is competitive in terms of energy-efficiency with the commercial cascade cycles: propane precooled mixed refrigerant (C₃MR) cycle, dual mixed refrigerant (DMR) cycle and Phillips Cascade cycle. In a case study, the novel and the commercial cascade cycles are optimised to minimise shaft work consumption for a given liquefaction duty. A stochastic search optimisation (Genetic Algorithm) is firstly applied in order to avoid local optima, and the best solution found with the Genetic Algorithm is used as the starting point for a deterministic optimisation (SQP). The optimised novel cascade cycle ('CryoMan Cascade' cycle) is able to achieve energy savings of around 5 % when compared to the optimised DMR cycle, which is the most energy-efficient commercial cascade cycle.

Keywords: LNG production, cascade refrigeration cycle, design and optimisation.

1. Introduction

Complex cascade refrigeration cycles are usually employed for the large-scale production of liquefied natural gas (LNG), i.e. for production rates above 2.5 million t per annum (MTPA). The multistage compressors used for refrigerant compression heavily influence the capital cost of the refrigeration cycle. The corresponding shaft work energy demand for refrigerant compression strongly dominates the operating costs of these cascade refrigeration cycles. Thus, minimising the total shaft work demand in a given refrigeration cycle configuration leads to minimise operating costs. Intercooling after each compression stage reduces the volumetric flow rate of the refrigerant stream fed into the next compression stage, hence reducing the overall shaft work energy demand. Therefore, the number of compression stages and associated intercoolers significantly affects the performance of the refrigeration cycles.

The commercially-established refrigeration cycles are the propane precooled mixed refrigerant (C₃MR) cycle, dual mixed refrigerant (DMR) cycle and Phillips Cascade cycle. Previous work studied the energy efficiency (in terms of shaft work demand) of the commercial cascade cycles for the production of LNG. However, the resulting performance indicators are difficult to use for comparisons because i) the configuration of the cascade cycles (number of compression stages) are often different across the

literature; ii) the natural gas feed flow rates and compositions also vary; iii) different modelling assumptions are made (minimum temperature approach in heat exchangers, compression efficiencies, etc.) across the publications; and iv) some of the reported energy efficiencies of the cascade cycles are values from simulations rather than values from optimised scenarios. Furthermore, from the open research literature it is evident that the development of novel cascade refrigeration cycles for large-scale LNG production is not a research focus.

In this work, a novel cascade cycle is developed – The CryoMan Cascade cycle – which is competitive in terms of energy efficiency with those commercially-established. The commercial cascade cycles are firstly modelled and fully optimised so as to have relevant benchmarks for comparing the novel cascade cycle. The cascade cycles are evaluated for the same basis of natural gas liquefaction duty and under the same modelling assumptions (e.g. minimum temperature approach in heat exchangers, compression isentropic efficiencies, etc.). Additionally, an effort is made in order to keep a similar configuration in terms of the number of compression stages across the cascade cycles. The novel cascade cycle is based on the CryoMan process (Figure 1), which is a single mixed refrigerant cycle for small scale production of LNG (Kim and Zheng, 2011).

Figure 1. The CryoMan process (Kim and Zheng, 2011).

2. Configuration of the commercial cascade refrigeration cycles

An effort is made to define the configuration of the commercial cascade cycles to have a similar number of compression stages. The cascade refrigeration cycles are modelled using Aspen HYSYS v8.2 (Aspen Technology Inc., 2013). The models of the commercial cascade cycles have been verified after simulating various examples from the open literature (since real operational data is not available for model validation).

The configuration of the C_3MR cycle (Figure 2a) consists of three cooling stages in the (propane) precooling cycle and so three refrigerant compression stages. Propane is the refrigerant and kettle-type heat exchangers are used in the precooling cycle. In the liquefaction cycle, the mixed refrigerant is composed of $C_1 - C_3$ and N_2 , and multi-stream heat exchangers (MSHEs) are employed. Refrigerant compression is carried out in three compression stages. Overall, the C_3MR cycle has six compression stages. The model of the C_3MR cycle has been verified by simulating examples published by Fahmy et al. (2016a) and by Wang et al. (2012) for the propane cycle and the mixed refrigerant cycle, respectively.

The configuration of the DMR cycle (Figure 2b) consists of a precooling cycle in which cooling is provided at two pressure levels, and MSHEs are employed. The heavy mixed refrigerant comprises C_2 to C_4 . Refrigerant compression is carried out in three compression stages. In the liquefaction cycle, the light mixed refrigerant consists of C_1 to C_3 and N_2 . Cooling is provided in MSHEs and refrigerant compression takes place in three compression stages. Overall, the DMR cycle has six compression stages. The model of the DMR cycle has been verified after simulating the example published by Hwang et al. (2013).

In the Phillips Cascade cycle (Figure 2c), the propane precooling cycle provides cooling in three stages and the refrigerant is compressed in three compression stages. In the ethylene cycle, refrigerant compression is performed in two compression stages. In the ‘methane’ open-loop cycle, the natural gas stream is flashed at three expansion pressure levels and cooled in two MSHEs. Compression of the ‘methane’ refrigerant is carried out in three compression stages. Overall, the Phillips Cascade cycle has eight compression stages, which is due to the nature of the process – having three refrigeration cycles. The model of the Phillips Cascade cycles has been verified by simulating the example presented by Fahmy et al. (2016b).

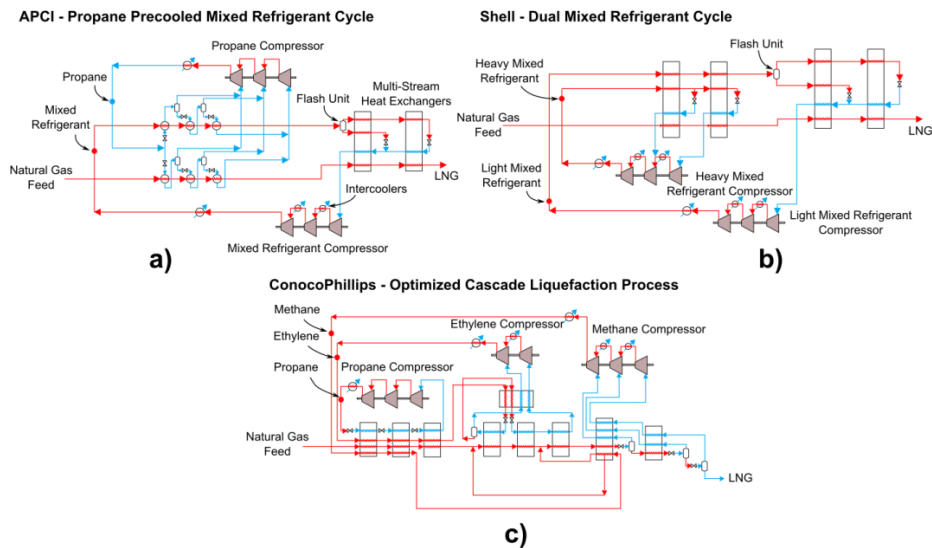

Figure 2. Configuration of the commercial cascade refrigeration cycles: a) C_3 MR cycle; b) DMR cycle; c) Phillips Cascade cycle.

3. Configuration of the novel CryoMan Cascade cycle

For the configuration of the novel cascade cycle, the CryoMan process is used as the liquefaction cycle within the cascade, since the liquefaction cycle usually has a larger cooling duty than the precooling cycle, and so the potential energy savings would be more evident. For the precooling cycle, a mixed refrigerant cycle is employed.

So, in the configuration of the novel CryoMan Cascade cycle (see Figure 3) the heavy mixed refrigerant in the precooling cycle consists of C_2 to C_4 . Cooling is provided at two pressure levels using MSHEs. Refrigerant compression is performed with three compression stages. In the liquefaction cycle, the light mixed refrigerant is comprised of

C₁ to C₃ and N₂. Cooling is provided in MSHEs at two pressure levels. Refrigerant compression is carried out in three compression stages. Overall, the novel CryoMan Cascade cycle has six compression stages.

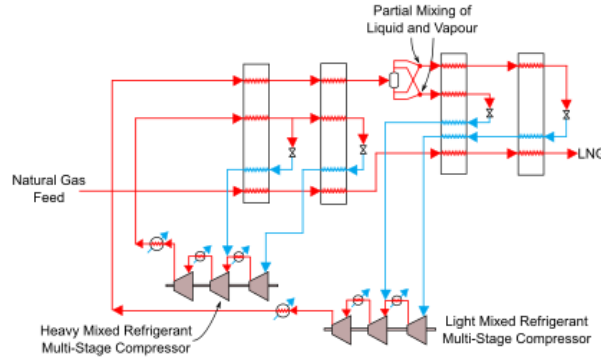

Figure 3. The novel CryoMan Cascade cycle.

4. Optimisation strategy and case study

All the commercial cycles (C₃MR, DMR and Phillips) and the novel CryoMan Cascade cycle are evaluated using the same optimisation strategy, and for the same liquefaction case study. The case study consists in fully liquefying a natural gas stream (see Table 1) for producing 5.6 MTPA of LNG – data based on that from (Fahmy et al., 2016a) – while minimising the total shaft power demand for refrigerant compression. The minimum temperature approach is assumed as 2 °C for the MSHEs and 5 °C for the kettle-type heat exchangers. Intercooling is available after each compression stage to cool down the refrigerant stream to 30 °C. Compression isentropic efficiency is assumed as 80 %. The maximum compression ratio (outlet to inlet pressures) in any compression stage is defined as 3.5. Peng–Robinson equation is used for calculating thermodynamic and physical properties (e.g. enthalpies, temperatures, etc.) of the refrigerant streams.

The cascade refrigeration cycles are modelled in Aspen HYSYS and the optimisation is performed using MATLAB (The MathWorks Inc., 2013). The objective function of the optimisation is to minimise the specific shaft work demand for refrigerant compression in each cascade refrigeration cycle, i.e. the total shaft work demand per unit production of LNG, according to Eq.(1).

$$\frac{W^{Total}}{\dot{m}_{LNG}} = \sum_{i=1}^n \frac{W_i^{Stg}(\phi)}{\dot{m}_{LNG}} \quad (1)$$

A stochastic search algorithm (Genetic Algorithm) is applied in order to avoid local optima. The set of random initial conditions is generated in MATLAB and each vector of random conditions is simulated in HYSYS. The performance of the simulations is continuously evaluated in MATLAB as the optimisation progresses. Once the stochastic optimisation terminates, the best solution found is used as the starting point for a deterministic optimisation (using *fmincon*) to refine further the final solution.

For each cascade cycle, the degrees of freedom to be optimised include the refrigerant flow rates, refrigerant compositions, expansion pressure levels, outlet temperatures of each stream in each MSHE, compression ratio of relevant compression stages, and refrigerant split fractions (where applicable), for both precooling and liquefaction cycle within a cascade cycle. During the optimisation process, penalties are applied if practical constraints are not met, such as having infeasible heat transfer in any MSHE, a compression ratio above 3.5 in any compression stage, or wetness at the inlet of any compression stage.

Table 1. Natural gas data for the case study.

Flow rate [$\text{kg}\cdot\text{s}^{-1}$]	177.59
Inlet pressure [bar]	63.0
Inlet temperature [$^{\circ}\text{C}$]	25.0
Outlet temperature [$^{\circ}\text{C}$]	-161.0
Composition [mole fraction]	
Methane	0.98385
Ethane	0.01070
Propane	0.00090
<i>n</i> -Butane	0.00020
CO ₂	0.00005

The optimised shaft work demand value for each cascade cycle is shown in Table 2. Energy and associated operating cost savings of each cascade cycle, also shown in Table 2, are relative to the C₃MR cycle which is the commercially dominant cascade cycle. The unit shaft work energy cost is taken as £0.0976 per kWh (U.K. Department of Energy & Climate Change, 2017).

Table 2. Optimised performances and comparison between cascade refrigeration cycles.

	C ₃ MR Cycle	DMR Cycle	Phillips Cascade	CryoMan Cascade Cycle
Compression stages	6	6	8	6
Initial specific shaft work [MW/MTPA LNG]	38.48	33.48	38.52	29.01
Optimised specific shaft work [MW/MTPA LNG]	30.09	27.32	34.80	25.97
Energy savings [%]	—	+ 9.20 %	-15.65 %	+ 13.71 %
Annual operating cost savings	—	+ £13.26 million	- £2.98 million	+ £19.75 million

The DMR cycle is the most energy-efficient amongst the commercial cascade cycles (27.32 MW/MTPA LNG), achieving 9.2 % savings in shaft work compared to the C₃MR cycle (30.09 MW/MTPA LNG). The Phillips Cascade resulted as the cascade cycle with the lowest energy-efficiency (34.80 MW/MTPA LNG) despite having two additional compression stages compared to the rest of the cascade cycles.

The optimised CryoMan Cascade cycle yielded 25.97 MW/MTPA LNG, which means shaft work savings of around 13.7 % when compared to the C₃MR cycle. Moreover, the

specific shaft work demand achieved with the CryoMan Cascade cycle is also equivalent to shaft work savings of around 5 % when compared to the DMR cycle, which is the most energy-efficient commercial cascade cycle.

In terms of the operating variables, the light mixed refrigerant flow rate (in liquefaction cycle) of the CryoMan Cascade cycle increases from 334.4 kg/s to 407.1 kg/s when compared to that in the DMR cycle. However, the composition of the light mixed refrigerant in the CryoMan Cascade cycle is heavier (ethane mole fraction increases from 0.3189 to 0.3513, and propane mole fraction from 0.2012 to 0.2213). A refrigerant stream with a relatively heavy composition requires less shaft work energy for compression than a refrigerant stream with a lighter composition. Thus, partial mixing the flash outlet streams of the liquefaction cycle allows manipulating the composition of the refrigerant streams, and so the CryoMan Cascade cycle is able to work with a heavier refrigerant stream, which helps reducing the overall shaft work demand, while still meeting the cooling demand. Furthermore, the operating cost savings achieved by the CryoMan Cascade cycle come as the expense of relatively minor increase in complexity and associated capital costs when compared to the DMR cycle.

5. Conclusions

A novel cascade refrigeration cycle is presented, which is competitive in terms of energy efficiency with the commercial cascade cycles. The novel cascade cycle and the commercial cycles are optimised to liquefy a given natural gas stream while minimising the specific shaft power demand. The models of the commercial cascade cycles have been verified by simulating examples published in the open research literature. From the case study presented, around 5 % savings in shaft work energy are achieved by the CryoMan Cascade cycle when compared to the DMR cycle, which is the most energy-efficient commercial cycle.

Abstract

The present predominant resource of acrylic acid is formed partial oxidation of propene, produced as a by-product from industrial production of ethylene and gasoline. This process depends on the processing of petrochemicals as raw material, resulting in resource depletions and many environmental problems. Therefore, biomass technology has been introduced to reduce the disadvantages of existing conventional process. The proposed process is composed of a bio-fermentation reactor, a catalytic dehydration reactor, a quencher, and an acrylic acid purification unit. Among them, it focuses on the quencher process. Recently, most of the research is currently focused on microorganisms in fermentation reaction and developing catalysts in dehydration reaction. However, this technology also remains a problem that a large quantity of water is required in the bio-fermentation and dehydration reactors. In this paper, we focus on the after the dehydration of 3-hydroxypropionic acid to produce acrylic acid about the method of efficient removal of water. To solve this problem, we introduced a quencher using solvent to remove water and improve the efficiency of the process. It is essential to remove water in order to obtain high purity of the acrylic acid.

We designed the process using Aspen Plus v8.8 simulator. Approximately 76.0 wt% of water, 22.6 wt% of acrylic acid, 1.4wt% 3-hydroxypropionic acid were fed to quencher. The results from the simulation show that 64.2 wt% of water was removed and 47.5 wt% of total flow was saved. The elimination of water reduces the overall flow rate, resulting in reduced equipment size of the process. Therefore, we expect that the use of this method will reduce the capital cost and operating cost of the acrylic acid purification process.

Keywords: Biomass. Acrylic acid. Quencher. 3-Hydroxypropionic acid. Removal of water.

1. Introduction

Acrylic acid is an important polymer as raw material for many industrial and consumer products. It can numerous to apply for surface coatings, textiles, adhesives, paper treatment, baby diapers, feminine hygiene products detergents and super absorbent polymers as known (Danner et al., 1998). Currently, most acrylic acid is obtained from the catalytic partial oxidation of propene which is a by-product of ethylene and gasoline production. In this two-step oxidation reaction via acrolein is usually preferred, achieving about 90 % overall yield (Lin, 2001; Straathof et al., 2005). However, this conventional process affects global CO₂ emissions: 175 kg/ton of CO₂ has been released in converting propene to acrylic acid (Segawa, 2014) and petrochemical carbons sources are limited and not renewable. The global acrylic acid market sizes is growing. Because acrylic acid demands for super absorbent polymers is expected the growth (Research, 2016). This process feedstock, propene, is related to volatile crude oil prices. Therefore, alternative methods have been studied such as biomass resources. It is encouraging to find renewable alternatives to produce acrylic acid in more environmentally friendly and economical way. Most of the feedstock for producing the acrylic acid, the quantitative conversion to lactic acid would open a new market for renewable resources (Danner et al., 1998). There are recent advances in the research and development of acrylic acid via the fermentation of renewable sources using microorganisms that ferment the 3-hydroxypropionic acid that is then dehydrated to from acrylic acid. In this paper, we focus on the process after the dehydration of 3-hydroxypropionic acid to produce acrylic acid. We conducted simulations and designed proposed model using commercial simulators that referred as the patent product components. This process introduced a quencher using solvent to cool the main stream in order to separate water in extractor unit and to avoid acrylic acid polymerization. It remove water from fermentation reaction of biomass and catalytic dehydration reaction of 3-HP. By first removing water from the quencher through solvent, the initial investment cost and the operating cost of the separation process can be reduced.

2. Process description

2.1. Propene based conventional process

Acrylic acid is used a precursor to a wide variety of chemicals in the polymer and textile industries. There are several chemical pathways to produce acrylic acid but the most common one is via the partial oxidation of propene. The usual mechanism for producing acrylic acid utilizes a two-step process in which propene is first oxidized to acrolein (1) and the further oxidized to acrylic acid (2). Each reaction step usually takes place over a separate catalyst and at different operating conditions (Turton et al., 2013).

Figure 1 Propene based conventional process flow diagram

The conventional process based on propene overall flow diagram is shown in Figure 1. First, propene flows to the oxidation reactor. In this reactor, a proprietary catalyst is used to eliminate the production of intermediates such as acrolein and acetic acid. After the reaction, it is essential to cool the products to avoid further oxidation reactions and to achieve rapid quenching of the reactor effluent with a cool recycle. This is combined with the liquid phase to form the feed to the extractor unit. In the liquid-liquid extraction step, the acid fraction is preferentially removed from the water prior to purification. There are many possible solvents that can be used as the organic phase in the separation: high solubility for acrylic acid and low solubility for water are desirable. Some examples include ethyl acetate, isopropyl acetate, ethyl acrylate, methyl isobutyl ketone, toluene, and xylene, which are used in the extraction unit (Alvarez et al., 2007). The organic phase is sent to a solvent recovery column where the solvent is recovered overhead and returned to the extractor. The bottom stream of the extractor product is sent to the purification column. Thereafter, acrylic acid is obtained as a product of high purity. However, the conventional process depends heavily on the processing of petrochemicals as the base raw material. Also, it includes problems with limited fossil fuel resources and environmental issues related to CO₂ emissions.

2.2. Biomass based proposed process

The pathway from biomass procedure is provided below. Beginning with a source of glycerol, a special strain of *Escherichia coli* produces 3-hydroxypropionic acid via a biosynthetic pathway (3). It can be dehydrated with a phosphoric acid catalyst to form acrylic acid (4).

The Figure 2 is acrylic acid manufacturing proposed process based on glycerol overall flow diagram. This process has been divided into a fermentation reactor, a dehydration reactor, a quencher, an extraction, a distillation, and a purification unit. In order to successfully produce acrylic acid from glycerol, first glycerol is converted to 3-hydroxypropionic acid via the aerobic fermentation of *E. coli*. This concentrated 3-hydroxypropionic acid stream flows through a reactor with phosphoric acid. This acid acts as a catalyst in the dehydration reaction, converting 3-hydroxypropionic acid to acrylic acid in roughly 30% yield. Through the bio-fermentation reaction, a large quantity of water and acrylic acid are produced through a gaseous phase dehydration reaction. It requires high energy to separate the generated water and acrylic acid (Bebensee et al.,

n.d.). Therefore, we focus on quencher, the between dehydration of 3-hydroxypropionic acid and distillation, to produce acrylic acid about the method of efficient removal of water using solvent.

Figure 2 Glycerol based proposed process flow diagram

3. Proposed process modeling methodology

The simulated proposed process is shown Figure 3. We applied a NRTL-HOC thermodynamic package model for this model, in order to select the proper physical property methods of the simulation (Carlson, 1996). The effluent through dehydration is based on the experimental data provided in a BASF patent (Bebensee et al., n.d.). In this model, the products of the dehydration reaction stream (1000) and solvent (2000) is entered into a quencher column. The preceding dehydration is a 350 °C high temperature dehydrating reaction, and the temperature should be lowered to 40 °C for the extraction process of water and acrylic acid. However, the heat exchanger should be minimized considering that the acrylic acid is easily polymerized. This is because it should not take longer to stay in high temperature at 90°C. Hence, 170 °C of stream generated through a single heat exchanger is sent into the quencher. The gaseous phase stream (1000) and solvent (2000) is formed azeotropic conditions. The vapor stream (1001) withdrawn from the top is condensed and fed to a decanter (1002) in which organic and aqueous phases are formed. The organic phase (1003) is recycled to a quencher column while part of the aqueous phase is separated (1005). The solvent selection is important to this process. Toluene is ultimately selected as the most appropriate solvent. Because toluene can form azeotrope composition 52.3 mol% with water and have stable azeotropic temperature at 85 °C in order to avoid acrylic acid polymerization (Gmehling et al., 1996). The azeotrope properties of toluene are shown in Table 1. Also, the toluene used in this process should be the same as the solvent used for the extractor unit.

Table 1 Characteristics of toluene used as a solvent (Horsley, 1962)

Component, <i>i</i>	Normal B.P., (°C)	Azeotropic Temp, (°C)	Azeotropic Comp, (mol %)
Toluene	110.6	85.0	52.3

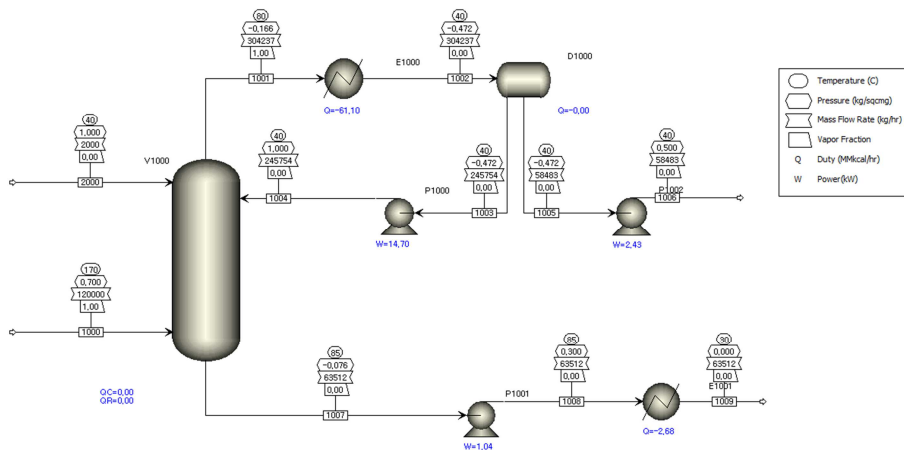

Figure 3 Flow diagram of the quencher

Table 2 Simulation results

	Inlet	2000	Outlet
Stream name	1000	2000	1009

Toluene	25.5	0	25.5
	0	21.7	21.2

4. Results and conclusion

The manufacturing process of biomass based acrylic acid occurred to overcome the environmental limitations of the existing propene based process. There is a problem with the amount of water droplets in bio-fermentation and dehydration reaction. It is necessary to undergo and extraction process to separate water and acrylic acid and that is decreased to the proper temperature using quencher. In this research, we designed

through the quenching from 3-hydroxypropionic acid of dehydration reaction product. It has the effect of removing the amount of water with additional solvent. We conducted commercial simulation using 3-hydroxypropionic acid dehydration reaction data onto patent. As a result, the total flow rate can be reduced from 120 ton/hr to 63 ton/hr, 47.5 wt% decreased. And water flow rate reduced from 91 ton/hr to 32.6 ton/hr, 64.2 wt% decreased without loss of acrylic acid. As the overall flow rate reduce after an extractor, a distillation and a purification unit size will be decreasing. This proposed process as using biomass can solve the environmental and price volatility of conventional. This process, which has been limited to a large quantity of water, can increase efficiency using quencher with toluene. Furthermore, the study will complete the post purification acrylic acid model and apply it to overall process to evaluate the economy.

Abstract

Techniques to address the process plant layout problem have gone from an engineering judgement-based approach prior to the late 90s, to a more systematic means - through mathematical programming, simulated annealing and a range of other techniques. Over the past 20 years, factors such as the connectivity costs, pumping costs, cost of safety device installations, pipe routing, multi-floor arrangements, etc., have all been included as constraints in a mathematical programming model to determine predominantly, the most cost effective and safe means for plant layouts.

This work proposes a mixed integer linear programming (MILP) model to include more realistic considerations for the multi-floor process plant layout problem - specifically tall process plant units with heights well above the typical floor height - which are common in most process plants but have not been given considerable attention in previous works. The model accounts for floor construction costs, area-dependent land use costs, pumping costs (upwards and within the same floor), connection costs by pipes as well as variable connection points along the heights of process units. The proposed optimisation approach has been applied successfully to an industry-relevant examples of 17 processing units with satisfactory computational results.

Keywords: multi-floor plant layout; optimisation; MILP

1. Introduction

The practice of process plant layout dates as early as process plant design, but systematic approaches were not employed until the late 90s. The layout design of a process finds the spatial arrangement of process equipment with interconnections in order to achieve a balance in safety requirements within and without the plant, economics, construction, maintenance, operation as well as the need for future expansions (Moran, 2016). In chemical process plants, these interconnections are mostly by pipes.

Earlier works in the area of mathematical programming techniques applied to process plant layout predominantly sort to minimise a cost function, and have remained so till date with slight variations. Penteado and Ciric (1996) proposed a mixed integer non-linear programming (MINLP) model to minimise the total layout cost - piping, land allocation, as well as financial risk and safety costs. Georgiadis and Macchietto (1997) included pumping and floor construction costs, but excluded financial risk and safety in a discretized spatial domain in a mixed integer linear programming (MILP) model. Papageorgiou and Rotstein (1998) solved the layout problem over a continuous spatial domain preventing equipment overlap for a single floor case with production

sections and then a multi-floor case (Patsiatzis and Papageorgiou, 2003). Scenarios with different inputs and outputs for each equipment, irregularly shaped equipment, safety and operability factors and a 3D representation was modelled by Barbosa-Póvoa et al. (2002). In each of these formulations, case studies with more than 11 units could not be handled in reasonable computational time to a global optimum. Patsiatzis and Papageorgiou (2003); Xu and Papageorgiou (2009) proposed successful algorithms for larger case studies, but global optima could not be guaranteed in all cases. Apart from a cost minimisation objective, other factors such as safety and risk assessment (Jung, 2016), area minimisation (Ku et al., 2013), routing and layout of pipes (Guirardello and Swaney, 2005), etc., have also been researched; with varying solution techniques (Xin et al., 2016). The work seeks to build upon previous research whilst addressing two key deficiencies: the scalability of exact model solutions, and the modelling of more realistic considerations within process plants. It extends the work of Patsiatzis and Papageorgiou (2003), proposing an model to address the multi-floor process plant layout problem with additional considerations for long-length equipment - equipment that exceed the typical height of a floor. Ku et al. (2013) previously proposed an MINLP model with a hybrid solution technique to handle this consideration, but a more efficient MILP will be proposed to handle larger case studies. Varying connection points between equipment will also be considered for a more realistic consideration.

In the rest of the paper, a process plant layout problem is described in detail in section 2. The mathematical programming model is proposed in section 3, and its computational performance is shown with a relevant case study in section 4. Final remarks and areas for future considerations are then given in section 5.

2. Problem Description

A description of the multi-floor process plant layout problem and the underlying assumptions made in the mathematical formulation are given in this section. In the mathematical formulation, equipment items are approximated as having a rectangular geometry, with rectilinear distances taken between equipment geometrical centres in the x-y plane. Vertical distances/connections are taken from a predefined point along the equipment height based on conditions unique to the problem being solved. Each equipment is allowed to rotate in 90° angles in the x-y plane, and must start from the base of each available floor. The floor height is fixed across all floors and if an equipment exceeds such height, it is allowed to extend through successive available floors.

The problem description is as follows:

Given:

- a set of N process plant equipment items, i, j , and their dimensions (length, α_i , breadth, β_i , and height, γ_i);
- the connections amongst each equipment;
- a set of K available floors for layout with floor height, FH ;
- connection, C_{ij}^c , pumping (horizontal, C_{ij}^h , and vertical, C_{ij}^v), land purchase (LC) and construction ($FC1$, $FC2$) cost data;
- space and equipment allocation limitations; and the minimum safe distances between equipment items;

determine

- the total number of required floors for layout;
- spatial equipment allocation to floors; and

- floor area;

so as to minimise the total plant layout cost.

3. Mathematical Formulation

The mathematical formulation to address the multi-floor process plant layout problem is outlined in this section. It constitutes an extension of the model initially proposed by Patsiatzis and Papageorgiou (2003).

First, every equipment is assigned to an equivalent number of floors based on its height, M_i :

$$\sum_k V_{ik} = M_i \quad \forall i \quad (1)$$

where V_{ik} is binary variable that determines if an equipment i is assigned to floor k . A binary variable, N_{ij} , is introduced to determine if two equipment i and j are assigned to the same floor k :

$$n_{ijk} \geq V_{ik} + V_{jk} - 1 \quad \forall i = 1, \dots, N-1, j \neq i, k = 1, \dots, K \quad (2)$$

$$N_{ij} \geq n_{ijk} \quad \forall i = 1, \dots, N-1, j \neq i, k = 1, \dots, K \quad (3)$$

Multi-floor equipment are assigned successive floors, starting from any available floor:

$$\sum_{\theta=1}^{M_i-1} v_{i,k+\theta} \geq (M_i - 1) \cdot (V_{ik} - V_{i,k-1}) \quad \forall i, k \quad (4)$$

Each of these available floors should only be considered for construction ($W_k = 1$) if an equipment starts on it, and not just passes through it.

$$S_{ik}^s \leq W_k \quad \forall i, k \quad (5)$$

where S_{ik}^s , the starting floor k of an equipment i , is defined by eq. 6 and must only occur on one floor (eq. 7), with each floor existing only if the preceding floor is occupied (eq. 8):

$$-V_{ik} + V_{i,k-1} + S_{ik}^s \geq 0 \quad \forall i, k \quad (6)$$

$$\sum_k S_{ik}^s = 1 \quad \forall i \quad (7)$$

$$W_k \leq W_{k-1} \quad \forall k = 2, \dots, K \quad (8)$$

The total number of floors (NF) required is then determined by eq. 9:

$$NF \geq \sum_k W_k \quad (9)$$

Every equipment is allowed a 90° rotation only in the x-y plane, as otherwise is unrealistic. Connections between equipment are assumed to originate from the mid point of equipment (x_i, y_i) , and these equipment are placed within the boundaries ($[0, 0]$ and $[X^{max}, Y^{max}]$) of the floor area. Each of these constraints is as defined in Patsiatzis and Papageorgiou (2003). Each equipment is placed at the base of each floor assigned (eq. 10).

$$\gamma_i = h_i \quad \forall i \quad (10)$$

The horizontal, vertical and total distances between connected equipment is defined by eqs. 11 - 13, and is taken from the mid-points of equipment in the x-y plane, and from pre-specified heights,

OP_{ij} and IP_{ij} , from equipment i to equipment j , in the z plane respectively:

$$R_{ij} - L_{ij} = x_i - x_j \quad \forall(i, j) : f_{ij} = 1 \quad (11)$$

$$A_{ij} - B_{ij} = y_i - y_j \quad \forall(i, j) : f_{ij} = 1 \quad (12)$$

$$U_{ij} - D_{ij} = FH \sum_k (k-1) (S_{ik}^s - S_{jk}^s) + OP_{ij} - IP_{ij} \quad \forall(i, j) : f_{ij} = 1 \quad (13)$$

$$TD_{ij} = R_{ij} + L_{ij} + A_{ij} + B_{ij} + U_{ij} + D_{ij} \quad \forall(i, j) : f_{ij} = 1 \quad (14)$$

where R_{ij} , L_{ij} , A_{ij} , and B_{ij} are the relative distances between equipment i and j , if i is to the right, left in x coordinates; above, below in y coordinates; higher, lower in z coordinates; of j , respectively, and are connected ($f_{ij} = 1$). These equipment, connected or not, are prevented from overlapping if they are on the same floor as described in Patsiatzis and Papageorgiou (2003). The total area FA is defined from a set of predefined sizes, s , by a binary variable Q_s and is determined by eqs. 15 - 18:

$$FA = \sum_s AR_s Q_s \quad (15)$$

$$\sum_s Q_s = 1 \quad (16)$$

$$X^{max} = \sum_s \bar{X}_s Q_s \quad (17)$$

$$Y^{max} = \sum_s \bar{Y}_s Q_s \quad (18)$$

A new term NQ_s is introduced in order to linearise the cost term associated with the area of floors ($FC2 \cdot FA \cdot NF$) in the objective function.

$$NQ_s \leq K Q_s \quad \forall s \quad (19)$$

$$NF = \sum_s NQ_s \quad (20)$$

The objective function which minimises the total floor construction (fixed and area dependent), land area, pumping and connection cost is given by:

$$\begin{aligned} \min \sum_i \sum_{j \neq i: f_{ij}=1} [C_{ij}^c TD_{ij} + C_{ij}^v D_{ij} + C_{ij}^h (R_{ij} + L_{ij} + A_{ij} + B_{ij})] \\ + FC1.NF + FC2 \sum_s AR_s.NQ_s + LC.FA \end{aligned} \quad (21)$$

The multi-floor process plant layout model can then be summarized as the minimisation of the total layout cost (eq. 21), *subject to* floor constraints (eqs. 1 - 3, 5 - 9), multi-floor equipment constraint (eq. 4), distance constraints (eqs. 10 - 14), area constraints (eqs. 15 - 20), equipment orientation, non-overlapping and layout constraints (Patsiatzis and Papageorgiou, 2003).

4. Case study

For the case study, a Crude Distillation plant with preheating train (CDU plant) was simulated with Aspen HYSYS® v8.0. It consisted of a total of 17 units, 5 of which - pre-flash drum (unit 5), atmospheric distillation tower (unit 7), fired heaters 1 and 2 (unit 6 and 12), and debutaniser (unit 15) - exceeded the floor height of 5m. The process flow diagram of the plant is shown in Figure 1 and data on the equipment dimensions, connectivity and construction costs were evaluated from results from the simulation. 7 floors (K) were made available for layout, with land cost LC , fixed

floor construction cost $FC1$ and area dependent cost $FC2$ as 666rmu^1 , $3,330\text{rmu}$ and 33.3rmu respectively. All multi-floor equipment were made to start from the ground floor as such represents a realistic representation from a construction point of view. The summary of the model statistics and computational performance is shown in Table 1 and the optimal layout in Figure 2.

Figure 1: Flow diagram of Crude Distillation Plant with Preheating train

Table 1: Summary of model statistics and computational performance

CDU Plant (17 units)	
Total cost (rmu)	749,690
CPU (s)	105.0
Number of binary variables	568
Number of continuous variables	1,388
Number of equations	2,993

Figure 2: Optimal layout results

The results obtained gave a total of 4 floors, out of an available 7, with each measuring $20\text{m} \times 20\text{m}$ (Figure 2). A total cost of $749,690\text{rmu}$ was obtained (Table 1) - 6% attributed to connection costs, 50% pumping costs and 44% construction costs - consistent with previous observations (Patsiatzis and Papageorgiou, 2003). As all the multi-floor equipment (5, 6, 7, 12 and 15) starting floors were predefined, they all started from the first floor through the number of floors required based on their height. It is worthy of noting that although equipment 14 required 5 floors based on

¹relative monetary units

its height, a total of 4 floors was decided. This is because the construction of a fifth floor was deemed unnecessary as no other equipment other than equipment 14 was to be located on such floor in order to obtain an optimal solution, and the additional construction cost for a fifth floor was eliminated. So, although a multi-floor equipment can span a specified number of floors based on its height, not every one of those floors need to be constructed. Practical examples include multi-floor layouts about fired heaters with long stacks, distillation columns and flare stacks.

5. Concluding remarks

The process plant layout MILP model by Patsiatzis and Papageorgiou (2003) was extended to address a larger problem scale with multi-floor equipment in chemical process plants having varying connection points along their height. The new model proposed allowed multi-floor equipment start on a floor to be determined and span successive floors equivalent to the height of the equipment. Connection points on each equipment were at heights unique to the problem being solved. The model was validated with a CDU plant case study and model performance noted. The CDU plant had a total of 17 major equipment with 5 multi-floor units, and 7 floors made available for layout. A global optimum was achieved in 105s selecting 4 out of 7 floors with a floor area of 20mx20m. The model successfully handled multi-floor equipment, allowing their placement in successive floors equivalent to their height. Each floor was constructed on the basis of its use by non-multi-floor equipment, as such is obtainable in practice. Further work will entail model validation with larger case studies and the development of decomposition techniques.

claugtez@gmail.com

Abstract

The forecast indicates that aviation sector will grow 4.8% each year, until 2036; which means that more fuel will be required and more carbon dioxide will be released. Therefore, the International Air Transport Association has identified the renewable aviation fuel as the most promissory alternative for the sustainable development of the sector. The renewable aviation fuel can be obtained by triglycerides hydroprocessing, which consists on deoxygenation, cracking/isomerization and purification. Regarding this process, researchers have been focused on the determination of the yield to biojet fuel of different raw materials, the development of more selective and multifunctional catalysts, and the proposal of strategies to reduce energy consumption. In particular, the decreasing in energy consumption has been addressed through energy integration and thermally coupled distillation sequences. However, one alternative that remains as an opportunity area is the use of reactive distillation. Therefore, in this work the feasibility of using this intensified strategy in the hydrotreating process is presented. The design of the reactive distillation column is performed through recursive simulation, since the reactive system is multicomponent and multireaction. The conventional hydrotreating process is compared with the intensified one, in terms of total annual costs, CO₂ emissions and biojet fuel price. Results show that renewable aviation fuel can be produced through reactive distillation, with a slightly increasing of 1% in the yield and a decreasing of 87% in the operation pressure, in comparison with the conventional process. Also, the profitability of the process can be increased in 7,188 USD/year, due to the electricity required in the process is generated along with an excess.

Keywords: reactive distillation, biojet fuel, hydroprocessing.

1. Introduction

Aviation sector is forecasted to grow up at 4.8% per year until 2036 (Gutiérrez-Antonio et al., 2016a); this will mean at least doubling the fuel requirements in 2036, and also an increasing in CO₂ emissions. In this context, the International Air Transport Association has identified the renewable aviation fuel as the best alternative to significantly reduce the CO₂ emissions of aviation sector (IATA, 2009). Renewable aviation fuel, or biojet fuel, consists of hydrocarbons in the boiling point range of C₈-C₁₆, including paraffinic and naphthenic compounds. It can contain aromatic compounds, depending of the

production process; the absence of these compounds does not affect the properties of the fuel, but may cause leaks from the fuel tanks. Thus, the standard ASTM D7566 (2016) establishes the use of biojet fuel in mixtures until 50% in volume. Biojet fuel can be obtained from any type of biomass for different processing routes (Gutiérrez-Antonio et al., 2017). One of the most advanced and mature technologies is the hydroprocessing of triglyceride feedstock, which consists on hydrodeoxygenation, followed by hydroisomerization and hydrocracking (McCall et al., 2009). As result, light gases, naphtha, biojet fuel and green diesel are obtained. These renewable hydrocarbons are separated through distillation. Several works have studied the reduction in energy consumption of hydroprocessing. Thermally coupled distillation columns with energy integration have been proposed considering *jatropha curcas*, castor and microalgae oils (Gutiérrez-Antonio et al., 2013; 2015, 2016a, 2016b). Recently, reactive distillation for green diesel production has been reported (Perez-Cisneros et al., 2017); however, the use of reactive distillation columns for biojet fuel production remains as an opportunity area. Therefore, in this work the use of reactive distillation is proposed to intensify the hydrotreating process; *jatropha curcas* oil is used as renewable raw material. Conventional and intensified biojet fuel production processes are compared in terms of total annual costs, CO₂ emissions and biojet fuel price.

2. Modelling of conventional hydrotreating processes

The conventional hydroprocessing consists of hydrodeoxygenation reactor, hydroisomerization/hydrocracking reactor and purification train. The modelling of this process was presented by Gutiérrez-Antonio et al. (2016a), and the reported results are taken as baseline for comparison. A brief description of the modelling is presented. A flow stream of 100 kg/h of *jatropha curcas* oil is considered, which composition in %wt is: triolein (42), trilinolein (44), tripalmitin (11) and tristearine (3%) (Herrera, 2007). Moreover, a hydrogen flow of 1500 mL NPT H₂/mL of vegetable oil is used, in order to avoid coke formation (McCall et al., 2009). The hydrodeoxygenation reactions are described with the kinetic model reported by Sharma et al. (2012), at 320 °C and 80 bar:

$$C_L = \frac{-k_1}{k'} C_{tg0} (e^{-k't} - 1) \rightarrow \frac{dC_L}{dt} = -k_1 C_{tg} \quad (1)$$

$$C_J = \frac{-k_2}{k'} C_{tg0} (e^{-k't} - 1) \rightarrow \frac{dC_J}{dt} = -k_2 C_{tg} \quad (2)$$

$$C_H = \frac{-k_3}{k'} C_{tg0} (e^{-k't} - 1) \rightarrow \frac{dC_H}{dt} = -k_3 C_{tg} \quad (3)$$

$$C_P = \frac{-k_4}{k'} C_{tg0} (e^{-k't} - 1) \rightarrow \frac{dC_P}{dt} = -k_4 C_{tg} \quad (4)$$

Where C_{tg} , C_{tg0} , C_L , C_J , C_H and C_P are the concentration of triglycerides, initial triglycerides, light compounds (C5–C8), intermediate compounds (C9–C14), heavy compounds (C15–C18), and oligomerized compounds (>C18), respectively; the values of the kinetic constants are k' (14.35), k_1 (0.04), k_2 (0.11), k_3 (1.24) and k_4 (13.25). The effluent of the first reactor is hydrocracked and hydroisomerized at 480 °C and 80 bar. For the hydrocracking we used the kinetic model developed by Shayegh et al. (2012):

$$\frac{dC_{VGO}}{dt} = -k_{12}C_{VGO}^2 - k_{13}C_{VGO}^2 \quad (5)$$

$$\frac{dC_{gasoline}}{dt} = -k_{12}C_{VGO}^2 - k_{23}C_{gasoline} \quad (6)$$

$$\frac{dC_{GL}}{dt} = -k_{13}C_{VGO}^2 - k_{23}C_{gasoline} \quad (7)$$

Where C_{VGO} , $C_{gasoline}$ and C_{GL} are the concentration of vacuum gas oil (C19–C21), n and iso-paraffins (C5–C11), and light gases (C1–C4), respectively; k_{12} (16,401,205,675), k_{13} (33,040,947,364), and k_{23} (74.13) are the values of the kinetic constants. For the hydroisomerization, the kinetic modeling of Calemma et al. (2000) is considered:

$$\frac{dC_{isoparaffins}}{dt} = k_2 C_{paraffins} \quad (8)$$

Where $C_{isoparaffins}$ and $C_{paraffins}$ are the concentrations of isoparaffins and paraffins, respectively; and k_2 (0.00239 min^{-1}) is the kinetic constant. Both reactors are modeled in the RPlug module of Aspen Plus. The kinetic constants values are reported at a fixed temperature, where the maximum yield to biojet fuel is obtained; also, kinetic models are used in the form reported by their authors (Sharma et al., 2012; Shayeg et al., 2012, Calemma et al., 2000). From the reactive zone, light gases, naphtha, biojet fuel and green diesel are obtained, which are separated through a direct conventional distillation sequence, since it presented the lower energy consumption (Gutiérrez-Antonio et al., 2016a). The design is performed with DSTW module, with recoveries of 99% of the key components. The distillation scheme is simulated in Radfrac module assuming equilibrium stages. Additionally, the conditioning of both reactants is performed through pump, compressor and heat exchangers in order to be fed to the first reactor; the effluent of the second reactor is conditioning with a turbine to generate electricity in the process. Figure 1 shows the conventional hydrotreating process.

3. Modelling of intensified hydrotreating process

As mentioned before, the intensification between the isomerization/cracking reactor is proposed in this work, and the kinetic models described in section 2 are used. Since we have a multicomponent system with multiple reactions, recursive simulations are used. Manipulated variables were operation pressure, number of reactive stages, number of separation stages, reflux ratio, feed stage of reactants, condenser type and temperature of feed flow streams. Figure 2 shows the intensified hydrotreating process. Both hydrotreating processes are compared in terms of three parameters. The first one is the total annual cost, where capital costs are calculated with the Guthrie method (Turton et al., 2008):

$$\text{Total annual cost (TAC)} = \text{Annual operating cost} + \text{Annual capital cost} \quad (9)$$

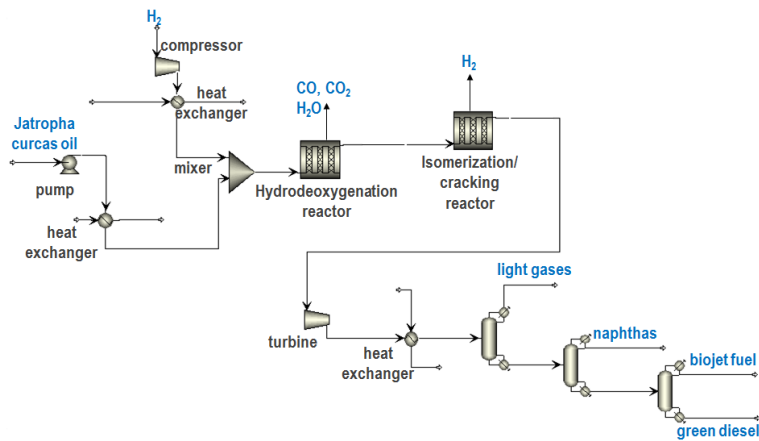

Figure 1. Conventional hydrotreating process to produce biojet fuel

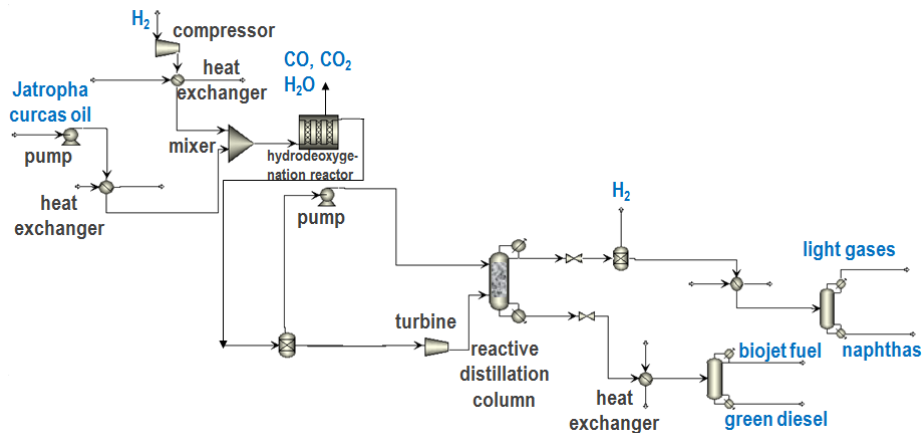

Figure 2. Intensified hydrotreating process to produce biojet fuel

The second parameter is given by the CO₂ emissions due to steam and electricity generation, which are calculated with emission factors and the amount of used fuel. The emission factor for steam production is 2.15 kg CO₂/kg burned fuel, while for electricity generation is 0.166 kg CO₂/kWh (Gutiérrez-Antonio et al. 2016a). Finally, the estimation of the price of the products is realized with the methodology proposed by Gutiérrez-Antonio et al. (2016b), where the mass fraction of each product along with its price and density are employed.

4. Analysis of results

In this section the analysis of the results is presented. Table 1 shows the total annual costs, and biojet fuel prices, while Table 2 presents the CO₂ emissions for both conventional (CHP) and intensified (IHP) hydrotreating processes. The raw material cost is 4,470,116.82 USD/year for both hydrotreating processes.

Table 1. Equipment, services, electricity and total annual costs (TAC), USD/year, and biojet fuel price (BJ price), USD/L, for both hydrotreating processes.

Process	Equipment	Services	Electricity	Excess energy	TAC	BJ price
CHP	234,017.41	27,670.93	2,087.39	0	4,751,742.59	0.689
IHP	191,115.13	359,712.31	0	5,101.03	5,020,944.16	0.728

Table 2. CO₂ emissions (kg/year) in hydrotreating processes.

Process	Emissions due to vapour generation	Emission due to electricity	Total generated emissions	Saved emissions
CHP	286,458,714.13	8,692.48	286,467,406.6	0
IHP	295,031,520.66	0	295,031,520.66	6,037.73

According to Table 1 we can observe that the total annual cost of the conventional processes is 5.3% lower than the one of the intensified process; as consequence, a similar difference can be found in the biojet fuel price. However, an interesting finding is that the intensified process is self-sufficient with respect to the electricity required. Indeed, an excess of energy is produced, which can be sold generating a potential gain of 5,101.03 USD/year. Also, it can be noted that CO₂ emissions are lower in the conventional process, in spite that the excess energy allows avoiding the emission of 6,037.73 kg CO₂/year. Nevertheless, according to the simulation data the reactive distillation column operates at 10 atm, which means a significantly decreasing with respect to the pressure in the second reactor of the conventional process. Other authors have reported processes in which reactive distillation schemes are integrated operate at lower pressures compared to conventional processes (Rosales-Quintero et al., 2008). However, this result is obtained in a simulation environment; therefore, experimental validation is required. Also, an increase of 1% in the yield to biojet fuel was observed when the reactive distillation column is used. The reactive distillation column includes a total condenser, 13 total stages with a reactive section of 7 stages.

5. Conclusions

A feasibility study for the intensification of the hydrotreating process between the isomerization/cracking reactor and the first distillation column of the separation train has been presented. The intensified process is compared with the conventional one. Results shows that is feasible to perform the intensification of the hydroprocessing through reactive distillation; however, from the economic and environmental point of view the conventional hydroprocessing is slightly better, in spite of excess electricity is generated.

Extended Value Chain Synthesis towards the Design of Multi-Feedstock Algae Biorefineries

Melina Psycha, Maria Kapnisi, Antonis C. Kokossis

School of Chemical Engineering, National Technical University of Athens, Zografou Campus, 9, Iroon Polytechniou Str., GR-15780 Athens, Greece

akokossis@mail.ntua.gr

Abstract

The work focuses on broadening the scope beyond the state-of-the-art and deals with more complicated concepts in the field of algae biorefineries. A general methodology is analyzed targeting the design of multi-feedstock biorefineries, thus providing flexibility in terms of feedstock and products. For this purpose, three microalgae are introduced as potential feedstock (Dunaliella, Nannochloropsis and Haematococcus), which individually are commercialized for the unique high-value compounds they have to offer (β -carotene, ω -3 fatty acids and astaxanthin respectively). The integration of their value chain identifies the similarities and differences between these microalgae in terms of prospective compounds rendering the formulation of the product portfolio an important degree of freedom.

Keywords: flexible biorefineries, value chain, synthesis, algae, design.

1. Introduction

The merits of microalgae as an alternative source of biomass are well established over the years, especially because of their versatility in terms of products. This potential in addition to the utilization of carbon dioxide, which microalgae need for their growth, render the development of a large-scale application extremely promising either as a standalone venture or in integration with other plants. Specifically, the co-production of specialty chemicals from microalgae is gaining ground as the related markets expand and profit margins grow (García Prieto et al., 2017; Psycha et al., 2014)). A plethora of microalgae has been studied and researched, especially for applications in the pharmaceutical, nutraceutical and cosmetic sector (Chua and Schenk, 2017; Panis and Rosales Carreon, 2016).

The challenges related to the design of algae-based systems are numerous which are enhanced by the lack of industrial applications in this field. The present work focuses on broadening the scope beyond the state-of-the-art and addresses the challenges of designing multi-feedstock microalgae biorefineries by capitalizing on previous research on single-feedstock microalgae biorefineries (Psycha and Kokossis, 2016, 2017). This paper proposes a flexible microalga biorefinery to deal with more complicated concepts in this field (competitive chemistries between microalgal species, seasonality for cultivation, advanced technologies, volatile markets for specialty chemicals).

2. Methodology

2.1. Formulation of value chains

The selection of suitable algae strains is a challenging task that requires extensive knowledge and/or research regarding the respective value chains. The different strains must share characteristics and properties in terms of treatment and group of products. For instance, the production of biodiesel from algae requires fundamentally unlike processing than the recovery of chemicals (commodity and specialty). Specifically, the recovery of specialty chemicals of high market value has already been highlighted in this paper and constitutes a significant criterion for the presented methodology. Figure 1a illustrates two value chains of microalgae A and B as a generic approach to the problem.

Figure 1: Graphical representation of general methodology

2.2. Identification of common fractions

The fractions are directly extracted from the cells and each fraction represents a group of products and/or a single product. For instance, the fraction of carotenoids can be further divided into carotenes and xanthophylls, while the fraction of glycerol is a product by itself. Depending on the synthesis of the product portfolio, one can set as

end-product any intermediate of the value chain. These intermediates are considered mixtures of chemicals which are further separated into pure end-products.

The main fractions are proteins, lipids, carbohydrates and carotenoids. A plethora of components can be found in each fraction and they vary depending on the algal strain. Thus, different products can be recovered from the same fraction among different strains. Figure 1b shows the identification of the common fractions among algae A and B and demonstrates the variety of end-products from the same fraction.

2.3. Product portfolio customization

The finalization of the product portfolios requires knowledge regarding yields and market prices of the potential end-products. The product portfolios are formulated for each strain separately, since the need for mutual products among the strains is not important, which is not the case for the fractions as explained in the previous section. Thus, the product selection has to be carried out with respect to every single strain and the number of products is a matter of synthesis decision. Figure 1c shows the selection of the final products for each value chain with three of these products deriving from the indicated common fraction (A_4 , B_5 and B_6).

2.4. Integrated value chain

The final step is the combination of the different value chains into one integrated value chain. As depicted in Figure 1d, only the selected fractions and products are incorporated into the final value chain. For instance, the product A_3 is not included, since it was not selected; the fraction A_2 is part of the integrated value chain, even though it was not characterized as a common fraction because product A_5 (deriving from fraction A_2) is part of strain A product portfolio as shown in Figure 1c. Consequently, suitable technologies need to be used for the extraction of fractions from the algal cells and for further separating these fractions into the desired products.

3. Comparison study

3.1. Biorefineries of single strains

Three algae strains have been selected in the context of this study, *Dunaliella*, *Haematococcus* and *Nannochloropsis*. All are characterized by a target product and include high-value specialty chemicals in the value chain. Specifically, *Dunaliella* is well established for its β -carotene production, *Haematococcus* for the production of astaxanthin and *Nannochloropsis* for the accumulation of large amounts of lipids. Additional products are taken into account for each case and the corresponding flowsheets of the three biorefineries are shown in Figure 2.

Table 1 lists the costs (capital and operating) as well as the revenue for each plant. The costing estimations derive from a combination of known costing equations (Lang, 1947) and the commercial software Aspen Process Economic Analyzer v8.4, which offers valuable information regarding the sizing of equipment. The target products play the leading role in the revenue of the biorefinery; β -carotene corresponds to 94% of the revenue, astaxanthin to 80%, whereas in the case of *Nannochloropsis*, proteins and violaxanthin correspond to 90% in total. It is worth mentioning that lipids from *Nannochloropsis* do not yield high revenue and render that biorefinery less promising as observed by the numbers in Table 1.

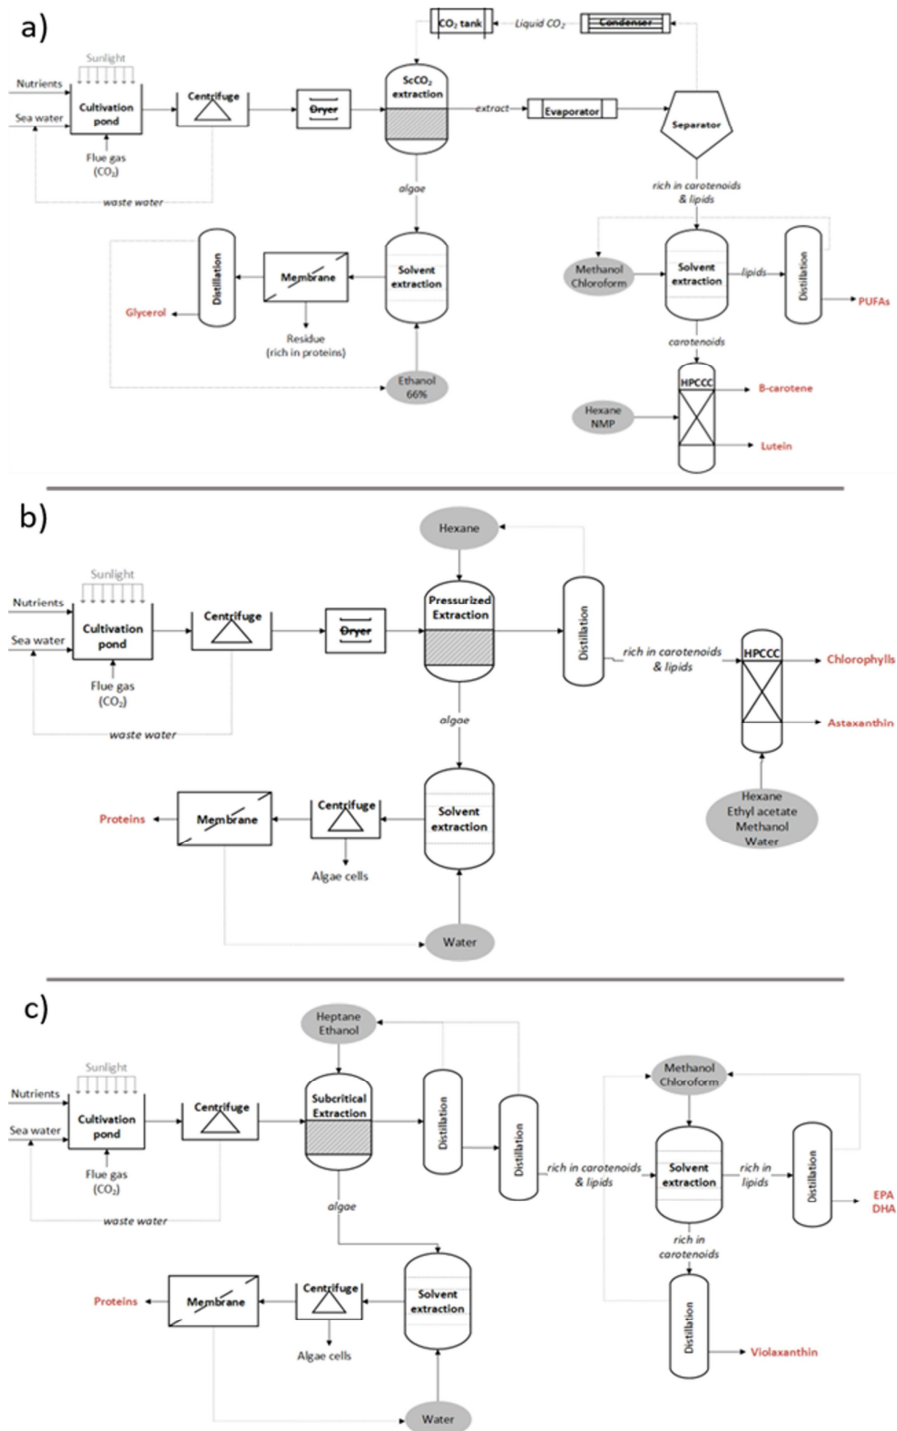

Figure 2: Conceptual flowsheets of three plants – a) *Dunaliella* biorefinery; b) *Haematococcus* biorefinery; c) *Nannochloropsis* biorefinery

Table 1: Economics of the three biorefinery plants

	Dunaliella biorefinery	Haematococcus biorefinery	Nannochloropsis biorefinery
Capital cost (M\$)	89	80	96.7
Operating cost (M\$/y)	31.2	25.7	35.1
Revenue (M\$/y)	126.6	108	44.2
Number of products	4	3	3

3.2. Flexible biorefinery of multiple strains

Following the methodology presented in this paper, the integrated value chain of Figure 3 is constructed, which relates to the three algal strains studied in the previous section (Dunaliella, Haematococcus, Nannochloropsis). The final products are indicated and derive from the common fractions of the different strains. As shown in Figure 3, proteins are produced by both Haematococcus and Nannochloropsis and it is considered the only mutual product in this case.

The biorefinery presented in Figure 4 is characterized by flexibility in terms of feedstock and products, thus attempting to overcome difficulties related to market uncertainties. The proposed flexible biorefinery has the potential of minimum 10 products and the employed technologies overlap by 83% compared to the single-feedstock biorefineries. The capital investment of such a venture is estimated at 128 M\$, a small increase considering the enhancement of the biorefinery potential. Especially in the case of microalgae biorefineries, CAPEX holds a predominant place, as reported by Psycha and Kokossis (2017). By integrating three candidate plants, the proposed biorefinery copes with high CAPEX demands and introduces the concept of flexibility in the field of microalgae biorefineries.

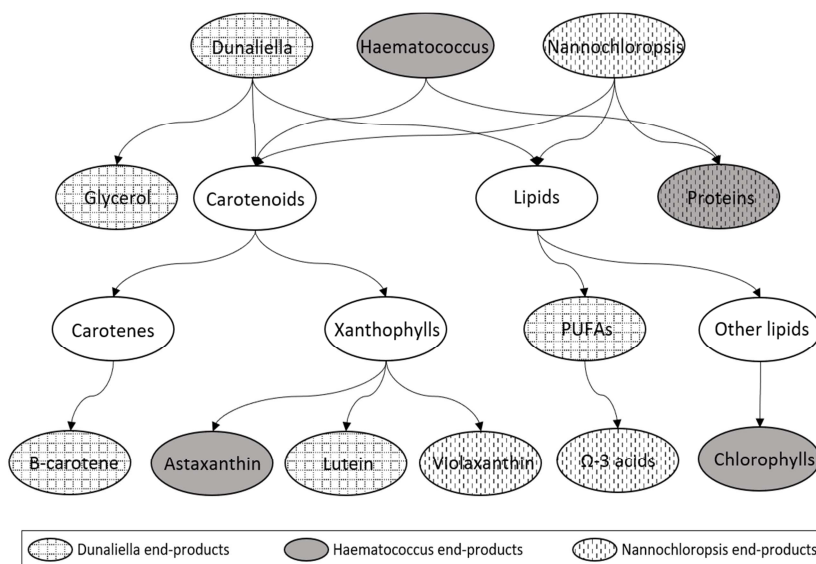

Figure 3: Integrated value chain of a multi-feedstock biorefinery

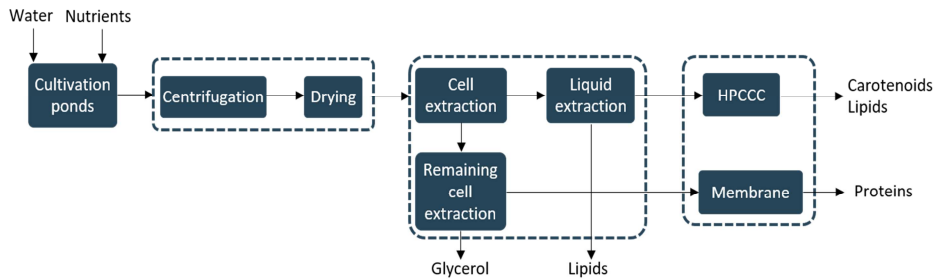

Figure 4: Processing stages of the flexible algal biorefinery

4. Conclusions

The present work attempts to address challenges related to the design of algae biorefineries by introducing the novel concept of the flexible alga biorefinery. A generic methodology for the development of integrated value chains is analysed, and three algae strains are used as a case study. With a process overlap of 83%, the resulting biorefinery is flexible in terms of feedstock and products and overcomes difficulties related to market uncertainties. Furthermore, the biorefinery potential enhances with a small increase in total investment. More research is required focusing on the predictability of operation and the study of different strains and potential products.

Abstract

Mixed consumer products, such as cosmetics and foods, normally consist of a mixture of intermediates. Most of these intermediates are currently produced by fractionation, a rather complex process where multiple intermediates are obtained from a single raw material, often focused on high purity. These intermediates can subsequently be combined to satisfy demand and quality requirements. The chemical purity of intermediates is, however, not always necessary, and mild fractionation of raw materials is often sufficient. Therefore, we propose an optimization-based decision support framework to select cost-efficient fractionation pathways and intermediates. We illustrate our approach for the processing of lupin seeds and yellow peas, and investigate mild fractionation as a more resource-efficient way of producing intermediates for mixed consumer products. The results show that, if only few intermediates are used, high purity is needed to comply with the quality requirements of a broad range of final applications. If more intermediates can be used, mildly refined intermediates can be selected to cover the demand of a part of the products with resource savings. In our illustrative case, using eight instead of four intermediates leads to water and energy reduction of about 29 % and 28 %, respectively. In general, our results indicate that using fractionation pathways leading to intermediates with lower purity provides opportunities for more resource-efficient production, and similar opportunities are expected to exist in integrated product and process design for other mixed consumer products.

Keywords: optimization, product selection, mild fractionation, process selection

1. Problem description

Consumer products such as cosmetics and foods are often a blend of intermediates. The production of these intermediates can be resource intensive due to a focus on purity, with the aim to guarantee a standard quality and broad applicability (van der Goot et al., 2016). Generally, there is a reduction in yield and an increase in the resources required to refine a raw material into intermediates with a higher degree of purity (Tamayo Tenorio et al., 2017). However, the purity of intermediates is often not required for application in mixed products. The functionality of products does not only depend on a single pure component, but is expressed in the complex composition of different

components with their native functionality (Geerts et al., 2017). Therefore, applying mild fractionation and using less-refined intermediates could improve resource efficiency (Berghout et al., 2015).

However, for an intermediate producer, the selection of the set of intermediates is not straightforward. Intermediates to produce a variety of mixed products, need to be selected in such a way that these products could be made while minimising costs and resource consumption. Additionally, the divergent nature of fractionation pathways inherently leads to the production of multiple intermediates that all have to be valorized (Jonkman et al., 2015).

This paper provides an optimization-based decision support framework for the selection of raw materials, fractionation pathways, as well as its associated intermediates. Producers of intermediates can use this framework to improve their integrated product and process design.

2. Decision support framework

A producer of intermediates has to decide how to meet customer demands based on product specifications resulting from the final application in which the intermediate is used. The intermediate producer must select the materials and the fractionation pathways required to produce intermediates that can be used to make products according to customer requirements. Intermediates can be used directly in the fulfillment of customer requirements, but can also be blended. Figure 1 illustrates the producer's decision problem.

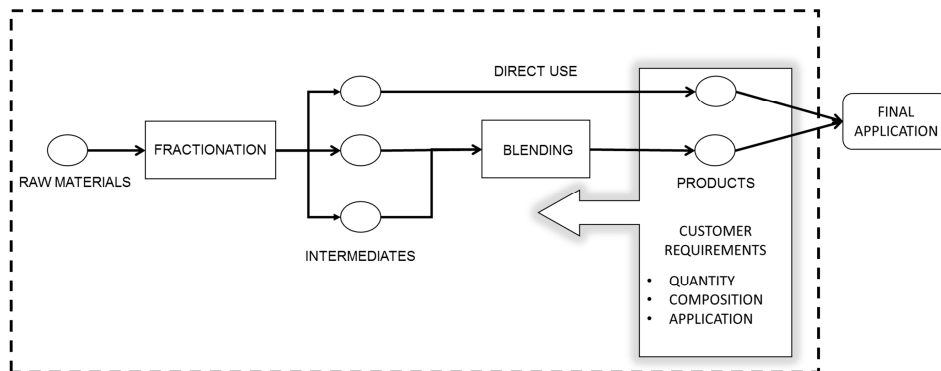

Figure 1. Fractionation system with boundaries for the intermediates producer

Figure 2. Decision support framework

To support this decision, we propose the approach as presented in Figure 2. The first stage of the approach is focussed on determining the needs of the different customers and should lead to insight in the final application of the intermediate, the required functionality, and a description of the properties the intermediate should have. In the second stage, the intermediate producer has to create an inventory of the possible raw materials and fractionation pathways to use, and identify the properties of these materials and pathways. This information is combined in the third stage, leading to a set of potential intermediates with associated properties, co-production relationships, and fractionation costs. In the fourth stage, an optimization model is used to select the combination of raw materials, fractionation pathways, and intermediates that satisfies the demand of the customers, while minimizing the total raw material and production (i.e. fractionation and blending) costs.

The formulation of the optimization model used in the fourth stage is based on the work of Akkerman et al. (2010). Due to space limitations, we do not include our complete model, but limit ourselves to a brief discussion of the changes we made to the original model. Their model is extended to allow for (i) the selection of different fractionation pathways; (ii) the consideration of co-production of intermediates in intermediate portfolios, including related material balance relationships; and (iii) the consideration of the resource consumption of water and energy.

3. Case study

In this section, we illustrate our decision support framework with an example from the food industry. We use the illustration to investigate the potential benefits of selecting mild-refined intermediates. Our case considers an intermediate producer conventionally focused on producing protein-rich intermediates for its customers, using yellow peas (*Pisum sativum*) and lupin seeds (*Lupinus angustifolius*) as raw materials.

3.1. Description and data

The customers demand protein-rich intermediates for applications in products that can be grouped into categories, such as solid and liquid foods, nutraceuticals and supplements, and non-food applications. Although the conventional high-purity intermediates meet the customers' demand, the first stage of the decision support framework leads to the insight that the different product categories do not strictly need high-purity protein intermediates. For example, in the category of solid foods are pasta or pasta-like products. Pasta enriched with vegetable protein targets the need for protein supplement in vegan or similar diets (Duranti, 2000), while also containing other components. In liquid foods, protein-rich drinks require the addition of protein without negatively affecting the viscosity of the drink by adding too much fibre. Supplements like protein powders for athletes, on the other hand, do require a higher degree of protein purity. Non-food applications, such as livestock feed, do not have strict targets on the presence of other components besides protein. The quality requirements for the product categories are summarized in Table 1.

For the second and third stages of the framework, the intermediate producer knows that conventional and mild fractionation pathways can be used to produce a variety of intermediates with different degrees of purity from yellow peas (Pelgrom *et al.*, 2014) and lupins (Berghout *et al.*, 2015). Yellow peas are pulses rich in starch and protein, whereas lupins are oilseed legumes with a protein content similar to soy but with a

lower oil content. They are two types of potential raw materials to obtain intermediates suitable for the applications described above.

Table 1. Quality bounds for the product according to the final applications

Product description	Quality requirement
Pasta enriched with veg-protein	Min 55 % protein content.
Protein-rich drink	Max 5 % fibre content and low viscosity.
Nutraceuticals (e.g. protein powders)	High purity and low moisture.
Non-food application	Flexible, no restrictions.

Four fractionation pathways are considered: conventional, aqueous, dry, and a combination of dry and aqueous. However, only aqueous and dry are applicable to fractioning yellow peas. Each fractionation pathway leads to a specific portfolio of intermediates, i.e. producing one intermediate from the portfolio implies co-producing the other intermediates, for a total of eighteen intermediates in the case study. The yield of each intermediate and its composition are given in Table 2. Moreover, the use of each fractionation pathway implies a certain resource consumption, in terms of water and energy usage, and production costs.

3.2. Optimizing the selection of fractionation pathways and intermediates

The problem is optimized subject to a set of constraints in the fourth stage. The quality constraints, such as a minimum percentage of protein are defined as in Akkerman *et al.* (2010), with upper and lower bounds for each quality parameter of the product, defined according to the final application requirements. Balance constraints are used to ensure that demand of the customers was met according to the product formulation. Operational constraints are added to regulate the maximum number of intermediates that could be selected, the maximum number of intermediates allowed to blend to satisfy a customer's demand, and the possibility to use an intermediate to cover demand for a product. Demand for products is fixed and blending capacity is set at a non-binding value.

Table 2. Intermediate portfolios produced per raw material and fractionation pathway. Yields and composition are reported as 'x(a:b:c:d)', where x is the intermediate yield per kg of processed raw material, and (a:b:c:d) represents the ratio of fibre, protein, sugars, and fat, respectively (w/w%), multiplied by ten for readability. Water use (kg) and energy use (MJ) are reported per kg of processed raw materials (Berghout et al., 2015; Geerts et al., 2017; Pelgrom et al., 2014).

	Conventional	Aqueous	Dry	Combined
Lupin	0.27 (0:8.3:1:0)	0.29 (0:8:0:0.7)	0.33 (0:4.9:3.5:0.7)	0.14 (0:8:0:0.7)
	0.37 (6.8:2.3:0:0)	0.46 (6.5:1.2:0:1.6)	0.67 (3.7:3.2:1.4:0.6)	0.11 (4.7:2:0:2.6)
	0.27 (0:2.8:5.9:0)	0.20 (0:3.7:5:0)		0.07 (0:6.4:2.2:0)
	0.07 (0:0:0:10)			0.67 (3.7:3.2:1.4:0.6)
Pea		0.66 (2.5:0.4:6.6:0)	0.32 (3.8:3.9:0.2:0.3)	
		0.24 (3:5.3:0.3:0.9)	0.68 (1.9:0.7:6:0.1)	
		0.10 (2.9:5.1:0.2:1)		
Water	51.00	51.00	0.00	35.40
Energy	9.99	10.50	0.52	3.88

3.3. Selected case results: Resource efficiency

The number of intermediates used affects the resource efficiency and operational complexity for the intermediate producer. Using more intermediates leads to an increase in operational complexity, while allowing for application specific intermediates that could improve resource efficiency. Therefore, we investigate the trade-off between operational complexity and resource savings. By varying the maximum number of selected intermediates, we obtain an overview of the raw material, water, and energy use, defined as the total kg of raw materials, the kg of water, and the MJ of energy required to produce all the needed intermediates (Figure 3).

If 4 or 5 intermediates are allowed, conventional fractionation is selected because it leads to more purified intermediates that can cover demand for all products. It is possible to cover demand using the 3 intermediates from the aqueous fractionation pathway, however the lower yield of the pure protein intermediate in the process requires more materials to be processed, and consequently leads to higher resource use. When the number of selected intermediates is equal to or above 6, the mild fractionation pathways dry and combined are selected to process part of the raw materials. However, the production of conventional intermediates remains necessary for those applications that require high-purity protein intermediates. When the maximum number of intermediates is equal to 8, there is a water use reduction of about 29 % and energy savings of about 28 %. Selecting more than 8 intermediates does not lead to additional cost and resource savings in the illustrative case.

Figure 3. Water and energy use for different maximum numbers of intermediates. Conventional is set to 100%. L=Lupin; Aq=Aqueous; Conv=Conventional; Comb=Combined dry and aqueous.

4. Discussion and conclusions

This paper presents an optimization-based decision support framework for the selection of raw materials, fractionation pathways, as well as intermediates, which can be used to support integrated product and process design for mixed consumer products. The application in a case study illustrated the applicability of the proposed framework. The results also indicate that mild fractioned intermediates could lead to more resource-efficient production of mixed consumer products. However, there is an added complexity in handling the number of intermediates by the intermediate producer, and there has to be more collaboration between the intermediate producer and its customers producing the final mixed consumer products. Additionally, certain customer requirements are not translatable to chemical composition only (Bongers, 2009; Dubbelboer et al., 2015). Therefore, extending the scope of the approach to include functionality on top of chemical composition will lead to additional value.

Abstract

In this work, we introduce a non-convex MINLP optimization model for water management in shale gas production. The superstructure includes: reuse/recycle in the same or neighboring wellpad, treatment in mobile units or in centralized water treatment (CWT) facility, or transport to Class II disposal wells. We consider four different water qualities: flowback water, impaired water, desalinated water and freshwater. Additionally, water blending ratios are unrestricted and friction reducers expenses are calculated accounting for impaired water contamination. The objective is to optimize the fracturing schedule, the number of tanks needed in each time period, flowback destination (reuse, treated or disposal), and fracturing fluid composition by maximizing the “sustainability profit” (Zore et al., 2017). The problem is tackled in two steps. First, we solve an MILP model based on McCormick relaxations. Second, a smaller MINLP is solved in which some binary variables are fixed. The capabilities of the proposed mathematical model are validated against long-time horizon scenario from historical data of the Marcellus Shale play.

Keywords: shale gas, water management, sustainability profit, optimization, mixed-integer nonlinear programming

1. Introduction

The development of new additives in the shale gas industry, which tolerate the use of high Total Dissolved Solids (TDS) base fluid, has allowed reusing the wastewater in the drilling of subsequent wells (U.S. Environmental Protection Agency, 2016). This practice is currently the most popular and cost-effective option for shale gas water management. Although it minimizes freshwater consumption, producers should take into consideration possible long-term issues and challenges. For instance, the TDS concentration will increase significantly, around 2-3 times, which can represent a cost barrier to reuse the water for fracturing operations. Besides, as the number of drilled wells decrease this practice becomes less attractive. Specifically, the volume of fracturing fluid required to fracture new wells may be less than the volume of water generated by producing wells in the area.

Currently, several works have been reported on the optimization of shale gas water management (Gao and You, 2015; Yang et al., 2015; Lira-Barragán et al., 2016). However, most of the works published in the literature consider that the water blending

ratio is restricted or the return to pad operations are not allowed. Drouven and Grossmann (2017) assume that the water-blending ratio is unrestricted, they over-estimate the friction reducers expenses. The MILP model that they proposed does not account the salt concentration of impaired water. Moreover, they only distinguish between two types of water: impaired water and freshwater. Hence, the model cannot handle any water management option when drilling operation decrease.

In this work, we propose a mixed-integer non-linear programming (MINLP) model considering the TDS concentration of wastewater and different water treatment solutions. We estimate the friction reducers expenses as a function of TDS concentration to determine if the level of TDS in impaired water is an impediment to reusing it in fracturing operations. Moreover, the model distinguishes between four types of water: impaired water, flowback water, desalinated water and freshwater. The objective is to maximize the “sustainability profit” in order to obtain a compromise solution between economic, environmental and social aspects. Only a single objective function is necessary since all the indicators are expressed in monetary terms (Zore et al., 2017).

2. Problem statement

The superstructure proposed for water management in shale gas operations is shown in Figure 1. The water management system comprises wellpads p , shale gas wells in each wellpad w , centralized water treatment technologies (CWT) k , freshwater sources f , fracturing crews c , and disposals wells d .

After hydraulic fracturing, a portion of water called flowback water returns to the wellhead. The flowback water is stored in fracturing tanks (FT) onsite before basic treatment (pre-treatment) in mobile units or transport to CWT facility, Class II disposal or neighboring wellpad. Pre-treatment includes technologies to remove suspended solids, oil and grease, and bacteria, certain ions that can cause the scale to form on equipment and interfere with fracturing chemical additives. After pre-treatment, the water can be used as a fracturing fluid in the same wellpad, or can be desalinated in the onsite TDS removal technologies. The flowback water reused for fracturing operations is called impaired water. Several desalination technologies can be selected such as multi-stage membrane distillation (MSMD), multi-effect evaporation with mechanical vapor recompression (MEE-MVR) or forward-reverse osmosis (FO-RO) hybrid. We consider that the outflow brine salinity in the onsite treatment is close to salt saturation conditions to achieve zero liquid discharge (ZLD) operation. Cost and salinity levels restrict the type of desalination unit that can be used for TDS removal. The onsite desalinated water can also be used as a fracturing fluid in the same wellpad, transported to the next wellpad or discharge for other usages. The flowback water can also be transported and treated in CWT plants. Desalinated water from CWT plants can select the same routes as the desalinated water in onsite technologies. Natural freshwater is obtained from an uninterrupted fresh water source. Desalinated water and freshwater are stored in freshwater tanks (FWT) and/or water impoundment. Transportation of freshwater, impaired water, flowback water and desalinated water can only be through trucks. Storage tanks and mobile treatment are assumed to be leased.

The problem is to determine: (1) wellpad fracturing start date (fracturing schedule), (2) number of tanks leased at each time period, (3) number of trucks needed in each time period, (4) flowback destination, reuse (impaired water), treatment (onsite or offsite) or disposal, and (5) quality of water used to fracture each well.

Figure 1. General superstructure of shale gas water management operations

3. Problem formulation

The optimization problem is formulated as an MINLP model that includes: assignment constraints, material balance in storage tanks, mixer and splitters, logic constraints and an objective function. Salt material balances are modeled using total flows and salt composition as variables (bilinear terms). An advantage of using this representation is that the variables involved in the bilinear terms are well bounded, allowing us to define tight under and over estimators. A brief outline of some of these equations is next given.

3.1. Assignment constraints

Eq. (1) ensures that in each time period only one well can be fractured by one of the available fracturing c. $y_{t,p,w,c}^{hf}$ indicates the beginning of stimulating each well.

$$\sum_{t \in T} \sum_{c \in C} y_{t,p,w,c}^{hf} \leq 1 \quad \forall w \in W, p \in RPW \quad (1)$$

Eq. (2) guarantees there is no overlap in the hydraulic fracturing operations between different wells. τ_w^{hf} is the time required to fracture well w with fracturing crew c.

$$\sum_{p \in RPW} \sum_{w \in W} \sum_{t=t-\tau_w^{hf}+1}^t y_{t,p,w,c}^{hf} \leq 1 \quad \forall t \in T, c \in C \quad (2)$$

3.2. Storage balance

Flowback water, impaired water and freshwater is storage in portable leased tanks at a wellpad. Eq. (3) describes the storage balance of tank s in wellpad p in time period t.

$$n_{t,p,s} = n_{t-1,p,s} + n_{t,p,s}^{ins} - n_{t,p,s}^{unins} \quad \forall t \in T, p \in P, s \in S, \quad (3)$$

where $n_{t,p,s}$ is a total number of tanks, $n_{t,p,s}^{ins}$ and $n_{t,p,s}^{unins}$ represents the number of tanks installed or uninstalled in a specific time period.

The amount of water stored $ST_{t,p,s}$ is bounded by the capacity of one tank CST_s and the number of tanks installed. As time is discretized into weeks, the storage tank should

handle the inlet water that comes from one day. Therefore, $\theta_{t,p,s}$ represents the inlet water in the storage tank divided by the number of days in a week.

$$ST_{t,p,s} + \theta_{t,p,s} \leq CST_s \cdot n_{t,p,s} \quad \forall t \in T, p \in P, s \in S \quad (4)$$

$$y_{t,p,s}^{st} \cdot N_s^{LO} \leq n_{t,p,s}^{ins} \leq N_s^{UP} \cdot y_{t,p,s}^{st} \quad \forall t \in T, p \in P, s \in S \quad (5)$$

N_s^{LO} and N_s^{UP} are lower and upper bounds of a number of tanks installed. $y_{t,p,s}^{st}$ indicates the occurrence of installation tanks for each tank s at each time period t .

3.3. Objective function

The objective function to be maximized is defined as the sum of economic profit ($P^{Economic}$), eco-profit (P^{Eco}) and social profit (P^{Social}).

$$\max SP = P^{Economic} + P^{Eco} + P^{Social} \quad (6)$$

Economic profit includes revenues from natural gas minus the sum of the following expenses: wastewater disposal cost, storage tank cost, freshwater cost, friction reducer cost, wastewater and freshwater transport cost and onsite and offsite treatment cost.

Eco-profit distinguishes between eco-benefit (raw material and products that unburden the environment) and eco-cost (raw material and products that burden the environment). Both terms are calculated by using eco-cost coefficients (Delft University of Technology, 2017). In our problem, impaired water and desalinated water used to fracture a neighboring well exhibit unburdening effect on the environment. However, natural gas, freshwater withdrawal, disposal and transportation burden the environment.

Social profit includes social security contributions paid for the employed people to fracture a well, plus the social transfer by hiring people, minus social cost. We only take into account the numbers of jobs on a fracturing crew and the time that they are working to fracture a specific well. Once the well is completed, the number of jobs generated by truck drivers or maintenance team are not considered.

4. Case study

The proposed model is applied to a case study in Marcellus Play with 3 wellpads and 20 wells, one year discretized at one week per time period, four interruptible sources of fresh water, three class II disposal wells, two CWT plants and one fracturing crew.

The MINLP problem consists of 3,117 binary variables, 13,463 continuous variables and 10,297 constraints. In order to treat the presence of bilinear terms, which are non-convex, we apply the following decomposition strategy:

- The original MINLP is relaxed using under and over estimators (McCormick convex envelopes), obtaining an MILP. The solution of this problem yields an upper bound (UB) to the MINLP.
- The binary variables which determine the fracture schedule ($y_{t,p,w,c}^{hf}$) are fixed into the original MINLP, resulting in a smaller MINLP.

The model is implemented in GAMS 25.0.1. The relaxed MILP problem is solved with Gurobi 7.5.2 and the MINLP problem with DICOPT 2 using CONOPT 4 to solve the

NLP sub-problems. Although DICOPT cannot guarantee a global solution, we calculate the optimality gap to obtain the deviation of this solution with respect to the global optimum. The decomposition strategy applied for bilinear non-convex MINLP models solves the problem within 0.1% optimality gap in 1904 CPUs.

The sustainable profit of the optimal solution is equal to k\$ 767, where the economic profit and social profit are equal to k\$ 16,910, and k\$ 1,469 million, respectively. However, the eco-profit component is negative equal to k\$ -17,611.

The solution of the model shows that the capabilities to reuse impaired water to fracture other wells is the best economic and environmental practice for shale gas water management. Figure 2 displays the fracturing schedule for each wellpad. The producer would spend k\$171 on tolerant additives. Overestimating the price of the friction reducers this cost would rise to k\$270, decreasing the total profit to k\$668. It is important to highlight that in Marcellus play, only 10-40% of the water injected is recovered. For that reason, although 92,700 m³ are recirculated, 124,300 m³ of fresh water are still necessary to complete all candidate wellpads.

The solution also provides an effective storage water management strategy to minimize the total storage cost and maximize the impaired water. We consider that operators lease fracturing tanks with 60 m³ of capacity. The total cost of storage is equal to \$363,000. Figure 3 (a) shows the number of tanks required in each wellpad along time horizon. Figure 3 (b) displays the blending ratio - impaired water used compared to water demand required to fracture each well - over the time.

Figure 2. Fracturing schedule.

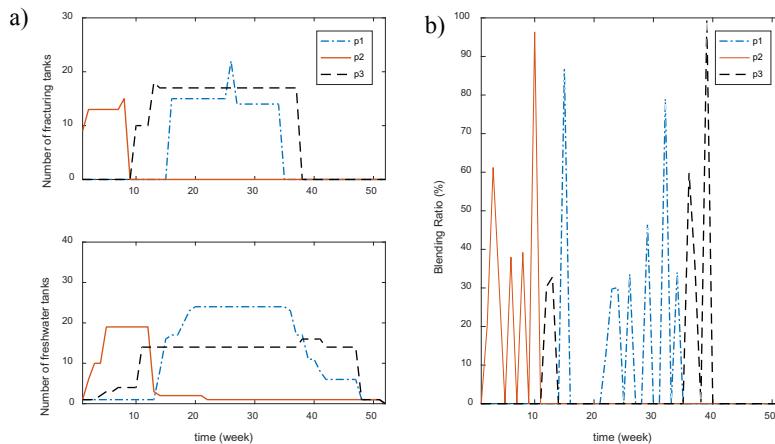

Figure 3. Results for the case study: a) Number of fracturing tanks (FT) and freshwater tanks (FWT) and b) Blending ratio over time for each wellpad.

As commented in the introduction section, it is important to figure out the water management option when all candidates wells are completed. The practice selected by the model is desalinate the water onsite using membrane distillation treatment. Finally, although transportation cost decreases reusing the wastewater, it still represents a high contribution to the final water management cost equal to \$806,000.

5. Conclusion

An MINLP model has been proposed for economic and environmental decisions in shale gas water management. The new measure expressed in monetary value helps the producers to make sustainable, viable and economic decisions. The model, which can be effectively solved with the proposed decomposition technique, reveals that the level of TDS in impaired water is not an obstacle to reusing it for fracturing purposes. Also, it has been shown that onsite desalination treatment can be cost-effective for operators once no more wells to fracture are available. Further development of this work includes the analysis of different sources of uncertainty of some inlet parameters as gas and wastewater production.

Abstract

Energy recovery has been playing a major role in most of chemical industries and related fields. A conventional heat recovery system or heat exchanger network (HEN) is usually composed of lots of exchangers. This may lead to extra costs in operation and construction. Thus, this work focuses on designing, optimizing, and applying multi-stream plate-fin heat exchangers (PFHEs) into a HEN to reduce a number of exchangers and costs. The process of doing so starts with synthesis of a conventional HEN. The process stream data used as the case study in this work is taken from a gas separation plant in Thailand. Such network is recognized as the based case which will be improved by replacing some exchangers with PFHEs. The improved network is recognized as the improved case which provides less annual cost than the conventional one around 3 times.

Keywords: multi-stream, plate-fin, heat exchanger, design, techno-economic study

1. Introduction

Heat exchanger networks (HENs) are imperative for utility saving because they help recovering heat from hot streams to others leading to a reduction in utility requirement. A common type of exchanger used worldwide is shell-and-tube heat exchanger (STHE) which has a limit to facilitate exchange of heat from two streams, one hot and one cold. Thus, Most of HENs must contain lots of STHEs leading to high expenses. A STHE requires a large area for installation and a great robust supporter for holding it, thus it is not suitable for application where the area is limited like vehicles and offshore platforms. Compact heat exchangers are considered to resolve such problems. A PFHE is classified as one type of compact heat exchangers having area density more than 700 m²/m³ which is extremely greater than A STHE. At the beginning, Kays and London (1984) published their work concerning compact heat exchangers. They presented the basic fundamental principles, correlations, and behaviours of frictional and thermal performances of many secondary surfaces of a PFHE from experiment. Then, Picón-Núñez (2002) proposed a thermal design of a multi-stream plate-fin heat exchanger by using the pinch technology, thermo-hydraulic model. Their methodology considers a maximum pressure drop of a critical stream as the design objective. Recently, Nassim and Samira (2013) developed some parts of Picon's work to make it more accurate and reliable. They introduced the temperature correction factor parameter (ζ) to correct the value of physical properties of fluids changed across a heat exchanger.

2. Intensification process of a heat exchanger network (HEN)

A heat exchanger network normally consists of a large number of exchangers leading to many consequences. A possible way to reduce a number of exchangers is to applying multi-stream heat exchanger into a HEN. The process starts off the following steps.

2.1. Generation of a conventional shell-and-tube heat exchanger network (HEN)

A conventional HEN is generated by using the grassroots technique or stage-model presented by Grossmann et al. (1990). The exchanger minimum approach temperature (EMAT) used to generate the network is assumed to 1 °C. After finishing generating the HEN, heat load, utility consumption, inlet and outlet temperatures, area, volume, and cost of each exchanger are determined and recognized as the base case.

2.2. Design of a multi-stream plate-fin heat exchange (PFHE)

The network generated from the previous step is redesigned by removing all exchangers that have small approach temperature difference, around 5 °C, and all groups of exchangers performing exchange of heat from split streams and then replacing with PFHEs. The design process of a PFHE starts with collecting inlet and outlet temperatures of streams of such exchangers and then constructing composite curves to calculate heat load per interval, stream population, and inlet and outlet temperatures. After that, dimensions (length, height), heat transfer coefficient, and pressure drop of each exchanger is calculated by guessing fin type, width, and number of passages. Heat transfer coefficient of each stream is calculated by the equation (1) below

$$h = \frac{am^{1-b}\mu^b c_p}{d_h^b Pr^{2/3}} \times \left(\frac{1}{A_c}\right)^{1-b} \quad (1)$$

where h is the heat transfer coefficient, a and b are constants in the correlation between Colburn factor and Reynolds number provided by Kay and London (1984), m is the mass flow rate per passage, μ is the fluid's viscosity, C_p is the specific heat capacity, d_h in the hydraulic diameter of the secondary surface, Pr is the Prandtl number, A_c is the cross sectional free flow area. Then, volume of two passages that are adjacent is calculated by the equation (2)

$$V_i = \frac{Q}{\Delta T_{lm}} \left[\frac{1}{\eta_1 \alpha_1} \left(\frac{1}{h_1} + R_{f,1} \right) + \frac{1}{\eta_2 \alpha_2} \left(\frac{1}{h_2} + R_{f,2} \right) + R_w V_i \right] \quad (2)$$

Where Q is the heat load per passage, ΔT_{lm} is the logarithmic mean temperature difference, η is the surface efficiency which is assumed to one, α is area density faction calculated by equation (3), R_f is the fouling factor that is negligible in this design step, and R_w is the thermal resistance which is normally close to zero if the wall thickness is really thin. For the total volume of a PFHE can be estimated by equation (4)

$$\alpha_1 = \frac{\beta_1}{\beta_1 + \beta_2} \quad (3)$$

$$V_T = \sum_i V_i \quad (4)$$

After that, length of a PFHE is easily estimated by the equation (5). For pressure drop can be calculated by the equation (6)

$$L = \frac{V_T}{A_{fr}} \quad (5)$$

$$\Delta P = \frac{2xm^{2-y}\mu^y}{d_h^{1+y}\rho} L \left(\frac{1}{A_c}\right)^{2-y} \quad (6)$$

Where A_{fr} is the frontal area of a PFHE estimated by the equation (7), and β is the area density between plates, x and y are the constants in the correlation between friction factor and Reynolds number, ρ is the fluid density.

$$A_{fr} = \sum \frac{4A_c}{\beta d_h} \quad (7)$$

The height (H) of a PFHE is estimated by the equation (8) and the heat transfer area is calculated by the equation (9)

$$H = \frac{v_T}{L \times W} \quad (8)$$

$$A = \sum_{i=1}^n [W \times L \times \delta \times N \times \beta]_i \quad (9)$$

Where W is the width which is guessed, δ is the plate spacing, N is the number of passages.

2.3. Cost estimation

Costs of a heat exchanger whether they are operation or construction are necessary to estimate because they are a useful economic factor for investment decision. The capital expenditure of an exchanger in this work is known as CAPEX while OPEX is referred to operating expenditure of an exchanger. CAPEX and OPEX are estimated from equations (10) and (11).

$$CAPEX = C_1 \frac{I_2}{I_1} \frac{Q}{\Delta T_{min}} \quad (10)$$

Where C_1 is the cost per unit of $Q/\Delta T_{lm}$ of a certain year in the past, and I_2 is the cost index of the same year as C_1 while I_1 is of the current year. Value of C_1 of different type of exchanger will be different and can be found in several literature such as Hewitt et al. (2007) and Hesselgreaves et al. (2017)'s work. The unit of equations (10) is Baht but the unit of OPEX is Baht/y, thus equation (10) has to be multiplied by the capital recovery factor $\left(\frac{i(1+i)^n}{(1+i)^n - 1}\right)$, where i and n are the interest rate and operating period assumed to 10 % a year and 10 years, respectively.

$$OPEX = \text{pumping or compressing cost} + \text{maintenance cost} \quad (11)$$

$$\text{Pumping cost} = \frac{1}{\varepsilon} \dot{V} \Delta P \times AH \times f_e \quad (12)$$

$$\text{Compressing cost} = \frac{n_c}{n_c - 1} \frac{P_{in} \dot{V}_{in}}{\eta_p} \left[1 - \frac{P_{out}}{P_{in}} \frac{n_c - 1}{n_c} \right] \times AH \times f_e \quad (13)$$

Where ε is the pump's efficiency assumed to 80 %, \dot{V} is the volumetric flow rate, ΔP is the pressure drop, AH is the annual hour of operation assumed to 7200 h/y, f_e is the electrical cost that is 1.666 Baht/kWh, η_p is the polytropic efficiency and n_c is the polytropic coefficient.

$$n_p = 0.017 \ln(\dot{V}) + 0.7 \quad (14)$$

$$n_c = \frac{\gamma n_p}{\gamma n_p - \gamma + 1} \quad (15)$$

$$\frac{P_{out}}{P_{in}} = \frac{P_{in} + \Delta P}{P_{in}} \quad (16)$$

Maintenance cost of each exchanger is assumed to 10 % of its annualized CAPEX. Total annual cost (TAC) is the summation of annualized CAPEX and OPEX.

2.4. Optimization process of a PFHE

The objective function for optimizing a PFHE is TAC of itself. The optimization process is performed by minimizing TAC by varying a number of passages and width under following constrains: a number of passages are integers and range between 1 and 200, width ranges from 0.5 to 2 meters, height is not exceed 3 meters, and length is set to 0.2 meter at least.

3. Case study

Stream data used as a case study in this work is from a gas separation plant in Thailand. Such process stream data is taken to generate a conventional HEN by grassroots technique and shown as a grid diagram in the Figure 1(a). The number of exchangers in the network is 19. Calculated area, EMAT, volume, and cost of each individual are

shown in Table 1. From the grid diagram of a conventional HEN, exchanger no. 2, 3, 5, 8, and 9 facilitate exchange of heat from split streams leading to the more number of exchangers exists in the network which is undesirable. Thus, exchanger no. 2, 3, and 5 will be replaced with a single unit of PFHE, exchanger no. 8 and 9 are also replaced with a PFHE. Moreover, exchanger no. 1, 4, 7, 12, 13, 17, and 19 have small EMAT which is impractical for STHE, thus such exchangers are replaced with PFHEs as well. The total number of PFHEs to be designed for this network is 9. Detailed design of each PFHE is shown in Table 2. For the fin type of all PFHE is plain-fin 15.08. The improved network is shown in Figure 1(b). The cost analysis of the improved case, shown in Table 3, shows that TAC is lower than up to 3 times a conventional HEN.

4. Conclusions

PFHEs are an alternative for HEN because PFHEs have enough potential to handle exchange of heat from process streams at small EMAT. From the results, area of the improved case is more than the base case about 13,381.42 m² (8.34 % increase) while its total volume is less about 1610.56 m³ (899.05 % reduction). This means a PFHE provides a large heat transfer area with small volume compared to a STHE. Moreover, the number of exchangers of the improved case is reduced and TAC is much less around 3 times. Anyway, cost, pressure drop, and heat transfer coefficient of a PFHE are directly affected from changes of values of width, length, height, and fin type. This work does not cover the fin selection, thus the optimum fin is not presented here.

Abstract

The current work addresses a methodology for the optimal design of biogas supply chains based on anaerobic digestion of animal manure. The problem formulation allows the utilization of optimized processing plants that have been previously designed within a generic superstructure-based optimization problem. The definition of the plant capacity is performed based on the raw biomass availability as well as the demand profiles. Thus, these plants, carrying information on their capacity, investment and operating costs as well as their energetic input and outputs can be used as building blocks within an MILP optimization framework that aims to optimally place the plants with respect to total cost minimization. The latter is subject to constraints related to the application domain, biomass availability and end products demand. The spatial identification of the processing plants is performed taking into account the potential synergies between them, in the form of energy exchanges between the units as well as the consideration of storage locations.

Keywords: supply chain design, biogas, biomass conversion, animal manure

1. Introduction

Recent fluctuations in the prices of fossil fuels as well as the overall shift towards renewable energy have led to the intensification in the design and employment of biomass-based conversion technologies. Animal waste in the form of manure is a great source of biogenic carbon, exploitable for the production of biofuels as well heat and power cogeneration. Especially in agricultural countries such as Switzerland where the sustainable potential of animal manure amounts to 9.9 PJ per year out of which only 9.6 % is currently exploited (Thees et al., 2017), there appears to be a promising potential to enhance the role of biomass in the modern energy mix.

The swift introduction of such technologies in the market, however, necessitates not only the robust design of the conversion process itself but also the consideration of the entire supply chain that introduces the link between raw materials, conversion technologies and end services. To this end, the integration of process design with the supply chain will highlight the benefits and reveal potential synergies between the various steps of the path from raw materials to services. Further, it will bridge the current design methodologies and set the transition from process design level to national design level, while considering the economies of scale.

Numerous studies regarding the design of biomass supply chains based on manure and bio-SNG exist in the recent literature. Balaman and Selim (2014) used a fuzzy multi-objective optimization to design the supply chain of anaerobic digestion based

bioenergy. Recently, Calderón et al. (2017) present an optimization framework for bio-SNG supply chain design. Their work encompasses a generic spatially explicit multi-period MILP optimization scheme that is able to investigate different design scenarios. Svanberg et al. (2017) analyzed the potential of horse manure in waste to energy supply chains exploring the parameters that affect their efficient design. Ghaderi et al. (2016) provide a comprehensive review of the design of biomass supply chains. Their work compares the approaches of a large number of published works revealing a large diversity in the modeling approaches and at the same time providing a good insight on the current state-of-the-art.

Although most works focus on the design of the supply chain itself, aiming at the minimization of the transportation costs and the identification of the facility locations, few address the problem of integrating the factors affecting the design of the conversion plants themselves. To this end, this work proposes a methodology for the optimal design of a supply chain addressing the conversion of cow manure into biogas through anaerobic digestion, upgrading into bio-SNG and subsequent conversion to heat and power. The design of the conversion plants on the process level is performed using a generic framework that utilizes a process superstructure approach to represent the possible pathways as well as their synthesis from a list of available conversion and intermediate processes that act as building blocks. The combination of these optimally designed plants in a similar optimization framework that addresses the possible spatial correlations and connectivity patterns between the various raw material supply points, conversion plants, as well as the end use locations will determine the optimal allocation strategy in the form of spatial identification of the supply chain components. The efficient design of the supply and conversion chain is achieved using a MILP optimization approach that aims to minimize the total cost. By using the above formulation, not only the spatial allocation is possible, but also the potential synergies between neighboring facilities can be identified, allowing for an integrated approach that considers the minimization of energy losses and the effective utilization and distribution of the end products.

2. Methodology

2.1. Biomass conversion to fuels, heat and power

Animal manure, as most wet biomass types can be converted to biogas through anaerobic digestion, a biochemical process that is used to break the biogenic carbon and transform it to a mixture of methane and carbon dioxide through a complex series of chemical reactions. In practice, anaerobic digestion is often preceded by a pre-treatment step that aims to increase the rates of the chemical reactions through mechanical, thermal, chemical or biochemical processing. On the other hand, biogas, consisting of approximately 55-65 % CH₄ and 35-45 % CO₂ as well as traces of other impurities like H₂S, NH₃, siloxanes etc., can either be utilized as it is or undergo an upgrading process to increase its methane content, thus creating a stream of bio-SNG. The latter is achieved either by CO₂ separation or conversion of the contained CO₂ to additional CH₄. Lastly, the upgraded or non-upgraded biogas can be used to produce heat, power or fed to cogeneration units for CHP production. Bio-SNG can be directly injected to the gas grid, provided that it fulfills the corresponding criteria. Particular care also has to be given to the treatment of digested manure. Indeed, when the digested matter is

removed from the reactor (generally around 70% of the initial manure), it can either be transported back to the farms to be used as a fertilizer, or go through additional processes, such as hydrothermal gasification, for carbon acquisition. The latter is a high pressure catalytic treatment that allows the transformation of organic matter into methane in the presence of moisture, resulting in an extra methane stream as well as the reclaiming of useful concentrated nutrients. Obviously, the large number of possible options when considering manure-to-services leads to structural and operational decisions that have to be taken *a priori*, during the process design stage. The multiple design paths arising from this complexity are depicted in Figure 1 in the form of a generalized process superstructure that accounts for the different possible conversion and treatment pathways.

Figure1. Generalized plant design superstructure.

2.2. Formulation of the biomass supply chain

The definition of the supply chain is based on the identification and spatial placement of the biomass processing units based on a set of pre-defined criteria. In this case, an economic criterion is used, encompassing both the investment and operating costs of the conversion plants (CAPEX and OPEX) and the transportation costs between the sources, plants and end users as well as the net revenues from the sales of the end products. Thus, the economic objective becomes the basis of multi-parametric optimization problem, the solution of which will define the optimal locations of the biomass conversion facilities.

As previously described, the conversion of manure to services requires four main steps: pre-treatment, biomass conversion, biogas upgrading and conversion to services that can be either electricity, heat, or bio-SNG meeting the grid requirements. A generic formulation of the supply chain problem should account for the disconnection of the above conversion chains, leading to the consideration of biomass processing at different spatial locations (e.g. pre-treatment at different locations but digestion in a large centralized plant). The latter results in the formulation of sub-chains including biomass processing plants that account for the spatial diversity. Some of the arising possibilities are schematically depicted in Figure 2. Suitable intermediate storage facilities should also be considered to account for the potential centralized distribution.

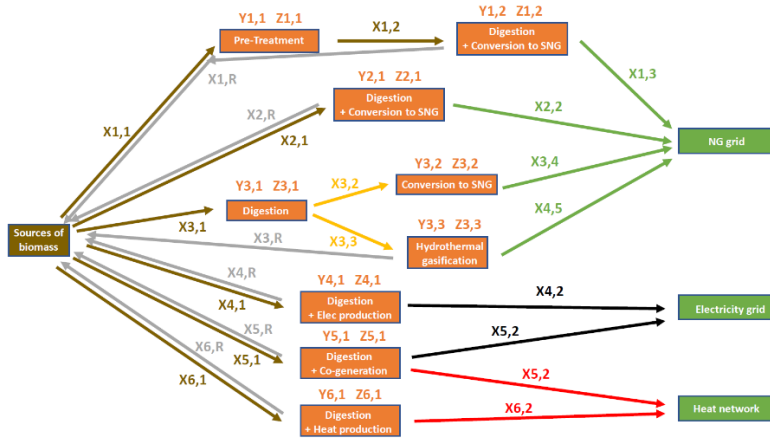

Figure 2. Schematic representation of indicative biomass supply chains

On the other hand, a crucial parameter in the design of biomass the supply chains is the identification of the plant sizes. The classification of the various plants based on their capacity is performed by the assessment of the regional supply and demand profiles so that sensible size selections are used. To this end, the process design problem illustrated in Figure 1 is used to generate solutions based on known biomass supply and demand that will be used during the determination of the plant locations. This results in a catalogue of pre-optimized plants of known size and functionality that are used as building blocks in a mixed integer linear (MILP) optimization problem. Each of these solutions carries the information of plant capacity as well as associated total annualized cost, together with the energetic demands and output. The latter is the necessary link between the various plants, enabling the accounting of energy exchanges that will help explore potential plant synergies during the design of the supply chains.

3. Mathematical approach

3.1. Objective function formulation

The mathematical formulation of the problem is based on a linearized objective function that aims to minimize the expenses throughout the supply chain. It is composed of four main terms namely the revenues from the sales of the end products, the investment and operating costs of the plants as well as the transportation costs within the design space as seen in Eq. 1:

$$\min J = -\sum P + \sum_{i=1}^{np} C_{CAPEX} + \sum_{i=1}^{np} C_{OPEX} + \sum tc \quad (1)$$

3.2. Linearization of the transportation costs

For large scale problems like the one addressed here, mathematical simplifications that ensure the acquisition of fast and reliable solutions are imperative. Although the nature

of the three first terms in Eq. (1) is linear based on the original process design problem (Gassner and Maréchal, 2009), the transportation costs are essentially non-linear. The last term can be linearized over a spatial domain (x,y) containing n_L+1 and n_H+1 discretization points for the x and y directions respectively. The linearized transportation cost between a plant of type l (e.g. pre-treatment, conversion etc.) and another plant of random type m , is given by an expression of the form:

$$\sum_{i=1}^{n_s} \sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} \sum_{l=1}^{n_1} \sum_{\substack{m=1 \\ m \neq l}}^{n_1} tc_{l,m} X_{i,j,k,l} \sqrt{(sx_i - dx(j-1))^2 + (sy_i - dy(k-1))^2} \quad (2)$$

where sx_i and sy_i denote the spatial coordinates of the supply point of biomass type i that has to be transported to a location defined by (dx, dy) . $tc_{l,m}$ expresses the transport cost between a plant of type l and a plant of type m , while $X_{i,j,k,l}$ stands for the transported biomass quantity.

Similarly, the transport costs between all combinations of adjacent units including the initial supply positions as well as the end use locations are discretized in a fashion similar to Eq. 2. The objective function (Eq. 1) is solved with respect to constraints describing the continuity of biomass flows through a plant m , as well as inequalities that ensure that the transported flows remain within the bounds set by the end products demand (sq_i) and also remain below the pre-defined capacity limit (cap_i) of each processing unit (Eqs. 3, 4 and 5 respectively):

$$\sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} \sum_{l=1}^{n_1} \sum_{\substack{m=1 \\ m \neq l}}^{n_m} X_{i,j,k,l,m} = \sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} \sum_{\substack{m=1 \\ m \neq l}}^{n_m} \sum_{\substack{p=1 \\ p \neq l,m}}^{n_p} X_{i,j,k,m,p} \quad (3)$$

$$\sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} \sum_{l=1}^{n_1} \sum_{\substack{m=1 \\ m \neq l}}^{n_1} X_{i,j,k,l,m} \leq sq_m \quad (4)$$

$$\sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} \sum_{l=1}^{n_1} \sum_{\substack{m=1 \\ m \neq l}}^{n_1} X_{i,j,k,l,m} \leq cap_m \quad (5)$$

Furthermore, binary variables Y and Z associated with the existence of each unit in the design problem as well as along the spatial coordinates, respectively, are used. For the binary variables, Y , the following constraint holds, expressing the permissibility of the link between the mass streams in plant locations l and m :

$$\sum_{i=1}^{n_s} \sum_{j=1}^{n_L+1} \sum_{k=1}^{n_H+1} X_{i,j,k,l,m} - M_l Y_{l,m} \leq 0, \quad \forall l, m = 1 \dots, n_1, \quad l \neq m \quad (6)$$

with M_l representing the maximum biomass capacity that can be transferred between locations l and m , while the Z binary variables are subject to:

$$\sum_{j=1}^{n_l+1} \sum_{k=1}^{n_{ll}+1} Z_{j,k,l} \leq 0, \quad \forall l = 1 \dots, n_l \quad (7)$$

The mathematical system of Eqs. (1-7) can be solved using conventional MILP solvers, provided that the biomass availability and end products demand profiles as well as the plant sizes and spatial application domain are known.

4. Conclusions

A comprehensive methodology for the design of biogas supply chains was presented here. The approach involves the use of pre-designed processing plants representing the main steps of the biomass-to-services conversion chain. Such plants of assigned capacity, configuration and operation are then used within a MILP optimization framework that identifies their spatial locations accounting for the raw biomass availability, end products demand, as well as the possible energetic exchanges between the plants in an effort to minimize the total supply chain expenses. The latter are defined as the sum of the plants' investment and operating costs and the linearized transportation costs between the supply chain's components, also considering the annualized total revenues from the satisfaction of the energetic demands within the applied domain.

Retrofit of mass exchange networks using a reduced superstructure synthesis approach

Adeniyi J. Isafiade

^aDepartment of Chemical Engineering, University of Cape Town, 7701, South Africa

Aj.isafiade@uct.ac.za

Abstract

This paper presents a new methodology for the retrofit of mass exchanger networks using the reduced superstructure synthesis approach. The new method entails two steps. In the first step, the retrofit problem specification is first solved for a grass-root scenario using the mass exchange network synthesis equivalent of the stage-wise superstructure synthesis method. The mass exchange units selected in the solution of the first step are then used to generate a reduced superstructure in the second step. This reduced superstructure is initialised using a combination of the matches selected in the first step and the existing matches of the original network. This ensures that much of the existing units in the original network are utilized in the retrofitted network so as to reduce additional capital investment. The reduced superstructure is then solved as a mixed integer non-linear model so as to obtain an optimal retrofitted network. One of the major benefits of this synthesis approach is that the resulting reduced superstructure of the second step is less computationally intensive in terms of its solution generation process due to the presence of fewer binary variables. The result of the method of this paper gives better payback period when compared with those in the literature.

Keywords: retrofit, mass exchange network, superstructure.

1. Introduction

The rising concerns over the emissions of pollutants into the environment by process plants has necessitated the need for mass exchange network synthesis (MENS) which was first presented by El-Halwagi and Manousiouthakis (1989). The authors drew analogies from pinch technology as applied to heat exchanger network synthesis (HENS), for the synthesis of mass exchange networks. Hallale and Fraser (2000a) improved on the synthesis method of El-Halwagi and Manousiouthakis (1989) by developing capital cost targeting methods as well as pinch design methods for mass exchanger networks. Mathematical programming based synthesis methods have also found applications in MENS. Some of these applications include the approach of Sztikai et al. (2006), which is a MENS equivalent of the stage-wise superstructure (SWS) of Yee and Grossmann (1990) where rich and lean streams are made to participate in intervals of a superstructure for the purpose of mass exchange. The method presented by Azeez et al. (2013) is also a stage-wise superstructure based approach, however the stages are defined based on the supply compositions of the participating rich and lean streams in the problem. Another mathematical based synthesis approach was presented by Papalexandri et al. (1994) where a simultaneous approach was used. Further extensions to MENS in the aspect of multi-period operations was presented by Isafiade and Fraser (2009) while the aspect of accounting for more detailed mass exchanger

designs in MENS was presented by Isafiade et al. (2016) using the supply based superstructure of Azeez et al. (2013).

It is worth stating at this point that the MENS methods reviewed so far have mostly involved grass-root scenario, whereas some existing plants whose designs are not optimal in terms of usage of mass separating agents (MSAs) need to be optimally retrofitted so as to minimise operating costs. In the aspect of retrofitting of process plants, HENS has received more attention with very few papers presented for mass exchanger network (MEN) retrofit. One of the earliest papers presented on MEN retrofit is the work of Fraser and Hallale (2000) where pinch technology was adopted. The method entails three steps which are, setting of utility savings targets and investment targets, construction of a savings investment curve for a range of minimum composition differences and the generation of designs that meets the set targets. Alfadala et al. (2001) used a two-stage approach for the synthesis of retrofit MENS. The first step entails identifying potentially optimal configurations through heuristics, while the next step involves the development of a new mass pinch analysis approach which aims at maximising the use of existing equipment and minimising newly added capital. Chen and Hung (2005) were the first to adopt a simultaneous mathematical programming approach for the retrofitting of MENS. The technique used by the authors is based on the stage-wise superstructure (SWS) for MENS. To the best of the knowledge of the current author, only the work of Chen and Hung (2005) has adopted a simultaneous mathematical programming approach to the retrofit of MENS. Hence this paper is presented so as to further develop this field of process synthesis by proposing a method that uses a simultaneous synthesis approach that has the ability to generate cost effective retrofit networks with relatively low payback periods. The solution generation of the new method is also less computationally intensive due to the adoption of the reduced superstructure synthesis approach which was first presented for multi-period HENS by Isafiade et al. (2015).

2. Problem statement

The problem addressed in this paper can be stated as follows: Given an existing MEN having the following: a set of mass exchangers of known sizes and location in the network, a set of rich and lean process streams with supply compositions, target compositions, flowrates and their pairings within each unit of the existing network. Also given are available external MSAs, as well as their supply and target compositions and unit costs, cost per equilibrium stage for newly added trays and reassignment of tray in staged columns. It is desired to minimize the total annual cost of the retrofitted MEN in terms of MSA consumption while ensuring that existing mass exchanger stages are used as much as possible so that only minimal trays/columns would be added to the network if needed.

3. Methodology

The first step entails extracting the process data from the existing MEN and solving it for a grass-root scenario using the SWS model for MENS presented by Sztikai et al. (2006). The capital cost function used in the objective function of the superstructure model at this stage are those earmarked for new mass exchangers that may need to be installed. The stream matches selected in the optimal solution of this step are identified and used as the set of initialising binary variables for the reduced superstructure of the

next step. The second step is where the reduced superstructure is generated and solved. The process adopted entails constructing the reduced superstructure using two sets of matches as initialising binary variables. The first set entails the matches selected in the solution of the grass-root model of step 1 while the second set involves the set of matches that existed in the original unretrofitted network. Matches that are common to these two sets of matches are only represented once in the reduced superstructure. This reduced superstructure at this stage is still constructed using the SWS model with the same number of stages as used in step 1. The superstructure is also solved as a mixed integer non-linear program (MINLP) model because the final optimal retrofitted network may need fewer number of units compared to that of the reduced superstructure. Another reason the reduced superstructure is solved as a MINLP model is to make provision for a scenario where the designer may want to explore the possibilities of getting a better retrofitted network by including other promising matches that may not have been among the selected matches in the grass-root network solution of step 1. The model in this step is called a reduced superstructure because the number of participating binary variables in the superstructure is fewer than what obtains for the grass-root superstructure of step 1. The capital cost component in the objective function of the resulting reduced superstructure needs to be adjusted for the purpose of accommodating new exchangers. These new exchangers are those that were not present in the original network. They also include those exchangers present in the original network that may need to be reused or have their sizes increased through addition of extra stages. It should be known that the detailed model equations for step 1 of the newly presented synthesis method of this paper are the same as those of Szitkai et al. (2006). These same set of model equations are used in step 2 but with fewer number of binary variables. However, the objective function of this new method, and its associated equations (i.e. Equations 1 and 2 shown in section 4), are newly presented in this paper.

4. Model equations

Equation 1 illustrates the number of stages $N_{i,j,k}^{Select}$ selected after solving the reduced superstructure. In this equation, Δy^n is the rich stream concentration difference, Δy^{*n} is the lean stream equilibrium concentration difference, Δy_1^n is the rich end of the exchanger driving force, Δy_2^n is the lean end of the exchanger driving force, n is defined as 1/3 by Underwood (1970).

$$N_{i,j,k}^{Select} = \left[\frac{\Delta y^n + \Delta y^{*n}}{\Delta y_1^n + \Delta y_2^n} \right]^{1/n} \quad (1)$$

In Equation 2, subscript i represents index for rich stream, subscript j represents index for lean stream, subscript k represents index for stages in the superstructure, $N_{i,j,k}^{Exist,orig}$ is the number of stages in each of the existing mass exchangers in the original network while $N_{i,j,k}^{New}$ is the difference in number of stages between $N_{i,j,k}^{Select}$ and $N_{i,j,k}^{Exist,orig}$. In order to further illustrate the model equations adopted, consider a case where mass exchanger $N_{2,4,3}^{Select}$ is selected after solving the reduced superstructure as presented in step 2. If that same exchanger, i.e. $N_{2,4,3}^{Exist,orig}$ existed in the original network, then the difference in the number of stages between $N_{2,4,3}^{Select}$ and $N_{2,4,3}^{Exist,orig}$ determines the number of stages of $N_{i,j,k}^{New}$. This $N_{i,j,k}^{New}$ is the number of stages that is then costed as part of the capital equipment that would be paid for as illustrated in the objective function shown in Equation 3. On the other hand, if $N_{i,j,k}^{Select}$ was selected in the second step but

$N_{2,4,3}^{Exist,orig}$ did not exist in the original network, then the implication of this is that a completely new mass exchanger, represented as $N_{i,j,k}^{New}$ will be included as part of the capital cost in the objective function.

$$N_{i,j,k}^{New} = N_{i,j,k}^{Select} - N_{i,j,k}^{Exist,orig} \quad (2)$$

If $N_{i,j,k}^{Select}$ is less than $N_{i,j,k}^{Exist,orig}$, then the difference between the two can be systematically reassigned for use in some other location in the network. Although considering the way the model is set up, i.e. $N_{i,j,k}^{Exist,orig}$ being included as part of the initializing binary variables of the reduced superstructure, then $N_{i,j,k}^{Exist,orig}$ is most likely going to be selected and fully utilized most of the time. This implies that fewer new exchangers would be need to be included in the retrofitted network.

$$TAC = \min \left(\sum_{j \in S} CUL_j \cdot L_j + \sum_{i \in R} \sum_{j \in S} \sum_{k \in K} CF_{i,j} \cdot z_{i,j,k} + ACT_{i,j} \cdot \sum_{i \in R} \sum_{j \in S} \sum_{k \in K} N_{i,j,k}^{New} \right) \quad \forall i \in R; j \in S; k \in K \quad (3)$$

In Equation 3, CUL_j is the cost per unit of lean stream j , L_j is the flowrate of lean stream j , R represents set of rich streams, S represents set of lean streams, K represents set of stages in the superstructure, $CF_{i,j}$ represents installation cost for mass exchangers, $z_{i,j,k}$ represents the binary variable in the reduced superstructure, $ACT_{i,j}$ is the annual cost per stage. General Algebraic Modelling System (GAMS), version 24.2.3 (Rosenthal, 2012), is used as the solver environment for the models of this paper. The machine used operates on Microsoft® Windows 7 Enterprise™ 64 bit, Intel® Core™ i5-3210M processor running at 2.50 GHz with 4 GB of installed memory. CPLEX and CONOPT, in conjunction with DICOPT, were used as the solvers for the MILP and NLP sub-problems respectively.

5. Example

The example considered in this paper, which is a coke-oven gas sweetening process was first presented by El-Halwagi and Manousiouthakis (1989). The grass-root design presented for this problem by Papalexandri et al. (1994) is used as the original network to be retrofitted. Also, the capital cost presented by the authors (\$4552 per stage per year with an annualisation period of 5 years) is adopted. This same original network shown in Figure 1 has been retrofitted by very few authors which are Fraser and Hallale (2000) and

Table 1: Stream data for the coke-oven gas sweetening process

Rich streams	G_i (kg/s)	Mass fraction		Lean streams	L_j^c (kg/s)	Mass fraction		Annual cost (\$/y)/(kg/s)
		Y^s	Y^t			X^s	X^t	
R_1 Coke-oven gas	0.9	0.07	0.0003	S_1 Aqueous NH_3	2.3	0.0006	0.031	117,360
R_2 Claus tail gas	0.1	0.051	0.0001	S_2 Chilled methanol	∞	0.0002	0.0035	176,040

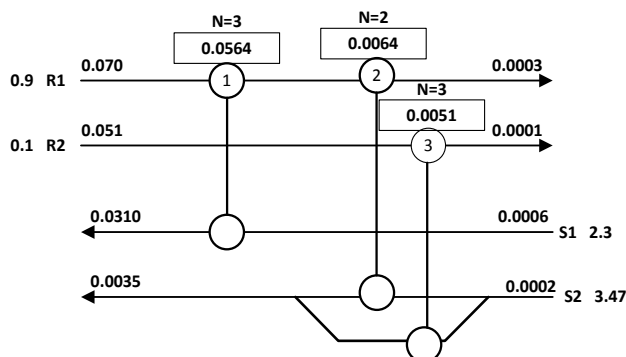

Figure 1: Original network for the coke-oven gas process

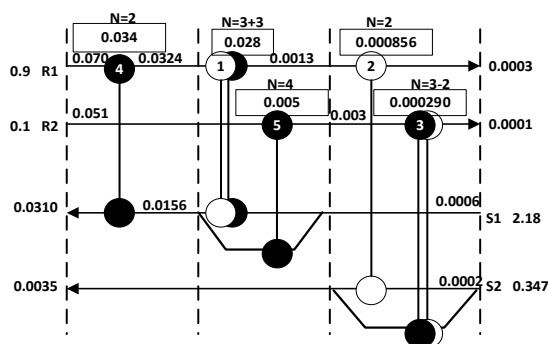

Figure 2: Retrofit network of the coke-oven gas process using proposed method

Chen and Hung (2005). The stream data for the problem is shown in Table 1. The equilibrium constants for the lean streams are: $S_1: y = 1.45x_1$; $S_2: y = 0.26x_2$. Applying step 1 of the newly developed method of this paper gives a structure with 5 matches which are (R1,S1,1); (R1,S2,3); (R2,S2,3); (R1,S1,2); (R2,S1,1). Three of these matches (i.e. R1,S1,2; R1,S2,3; R2,S2,3) exist in the original network, hence the reduced superstructure of step 2 was constructed using the five matches selected in step 1. Solving the reduced superstructure gives the solution shown in Figure 2. This solution has an objective value of \$477,833 for the first year which is about 13.3% less than the objective value presented by Chen and Hung (2005). The \$477,833 cost of this paper involves an annual operating (AOC) cost of \$318,513 and \$159,320 as the cost of network modification in the first year. The AOC saved is $\$881,463 - \$318,513 = \$562,950$. This savings corresponds to a payback period of $159,320/562,950 = 0.28$ year. This is lower than the payback time of Chen and Hung (2005) which is 0.33 year. In Figure 2, exchangers 1, 2 and 3 exist in the original network. Exchanger 2 is fully utilised as it was in the original, exchanger 1 is increased by 3 stages while exchanger 3 is decreased by 2 stages. Exchangers 4 and 5 are newly added exchangers.

6. Conclusions

A new method for retrofitting MENs has been presented in this paper. The method entails generating a reduced superstructure from a combination of the set of matches existing in the original network and those selected when the problem data is solved as a

grass-root model. An example from the literature was considered and the solution obtained compares favourably with those in the literature. The method presented in this paper has only been applied to staged mass exchangers, however it can easily be extended to continuous contact columns as well.

Abstract

The simultaneous control of crystal size and shape is particularly important in fine chemical and pharmaceutical crystallization. These two quantities not only influence significantly the dissolution rate and bioavailability of final drug products, but also contribute to the manufacturability and efficiency of downstream operations. The manipulation of crystal shape, however, is difficult since it requires the decoupled growth rate control of individual crystal faces. The supersaturation and solvent system dependency of these rates are often not strong enough to enable impactful crystal shape control through temperature and/or solvent composition variation.

The aim of this work is to analyse and evaluate the control possibilities of bivariate size distribution (which by definition involves crystal size and shape information) of high-aspect ratio crystals in an integrated crystallizer-external wet mill system. The crystallizer is modelled by primary and secondary nucleation, crystal growth and dissolution along the length and width axes, whereas in the wet mill – in addition to the aforementioned sub-processes - fragmentation and attrition are also considered. The advanced hydrodynamic description enables the direct implication of stirrer revolution speed in the model. The generated system of hyperbolic partial differential and ordinary differential equations is solved by the fully discretized high-resolution finite volume method, involving graphical processing unit acceleration, which brings significant – generally two orders of magnitude - speed-up. The dynamic optimization of wet-mill rotation speed, crystallizer temperature and recirculation flowrate revealed that the target bivariate crystal size distribution can be achieved much better with the integrated system than manipulating only the temperature profile of the batch crystallizer.

Keywords: crystallization, crystal breakage, integrated system, population balance, shape control

1. Introduction

Batch crystallization is one of the most efficient and economic separation and purification technique available in the fine chemical and pharmaceutical industry. It is also significant from the particle formation point of view, as during the batch the crystal size distribution (CSD) can be adjusted, although within a certain domain determined by supersaturation and crystallization mechanisms that occur during the batch. There are

many techniques to broaden the achievable crystal size domain, which is desired for quality reasons as well as for good operation of downstream processes, from optimal dynamic seeding (Aamir et al. 2010) through application of growth rate modifiers in tailored quality and quantity (Jones & Ogden 2010). A recently proposed system involves an external wet mill through a recirculation loop (Yang et al. 2015), which was shown to increase simultaneously the overall system flexibility and achievable crystal size domain (Vetter 2016).

In the last decades it was revealed that, in addition to the crystal size, the crystal shape also impacts the drug-substance relevant properties (Ma et al. 2002). After this discovery the interest turned into the direction of understanding and controlling simultaneously the crystal size and shape during crystallization (Nagy et al. 2013). The shape control is more challenging than the size control as the supersaturation generally has significantly lower impact on the crystal shape than on the size. The growth rate modifiers are known to be effective tools when comes to shape control, which has the strongest impact on the crystal habit (Klapwijk et al. 2016; Borsos et al. 2016). Mechanical methods, such as breakage, are also applicable and its effect on crystal shape was analysed in detail (Szilágyi & Lakatos 2017). This work shows that the optimal operation of crystallizer-wet mill integrated system is able to improve tremendously the CSD in terms of target satisfaction (Szilágyi & Nagy 2017).

A work that employs external wet-milling during crystallization for simultaneous crystal size and shape control for the best knowledge of authors has not been published yet. In this study we attempt to fill this gap by developing a two-dimensional population balance model for the crystallization of rod-like crystals, which is often encountered amongst active pharmaceutical ingredients, in integrated batch crystallizer-wet mill system. Using the process model the integrated system operation, including the crystallizer temperature profile, circulation flowrate and wet-mill impeller speed, are optimized. It was shown that the integrated system could approximate significantly better the target 2D CSD than the crystallizer-only setup. The optimal operation strongly relied on powerful milling in the wet-mill and fines dissolution at the end of the batch.

2. Process model development

The supersaturation and temperature dependencies of growth rates along the length and width axes leads to particulate systems in which the crystal shape may exhibit complex habit variations during the crystallization process. Consequently, the crystal must be characterized with two independent size variables, namely the crystal length and width (L_1, L_2) $\rightarrow \mathbf{L}$. For the characterization of particle population the bivariate size density function $n(\mathbf{L}, t)d\mathbf{L}$ is introduced, which gives the number of crystals within the $(L_1, L_1+dL_1) \times (L_2, L_2+dL_2)$ size domain in t time moment. The process model is developed for the integrated system presented (Figure 1a) by taking into account the assumptions:

- The crystallizer and wet mill are perfectly mixed
- There is no transport delay and no crystallization occurs in the circulation lines
- Primary nucleation, growth and dissolution occurs in the crystallizer
- Primary nucleation, growth, dissolution, attrition and fragmentation takes place in the wet-mill

Then, the population balance equation (PBE) for the crystallizer takes the form:

$$\frac{\partial n_c(\mathbf{L}, t)}{\partial t} + \sum_{i=1}^2 G_i \frac{\partial n_c(\mathbf{L}, t)}{\partial L_i} = B\delta(\mathbf{L} - \mathbf{L}_n) + \frac{n_{wm}(\mathbf{L}, t) - n_c(\mathbf{L}, t)}{\tau_c} \quad (1)$$

With the initial and boundary conditions:

$$\begin{aligned} n_c(\mathbf{L}, t=0) &= n_{c,0}(\mathbf{L}) \\ n_c(\mathbf{L} = \infty, t) &= 0 \end{aligned} \quad (2)$$

Where the initial condition gives the seed distribution whereas the boundary condition expresses that the crystals must have finite size. The first term in Eq.(1) gives the temporal evolution of 2D CSD, the second term is for the growth, whereas the left hand side is the nucleation and feed/discharge streams. The PBE for the wet-mill is:

$$\frac{\partial n_{wm}(\mathbf{L}, t)}{\partial t} + \sum_{i=1}^2 G_i \frac{\partial n_{wm}(\mathbf{L}, t)}{\partial L_i} = B\delta(\mathbf{L} - \mathbf{L}_n) - S(\mathbf{L})n_{wm}(\mathbf{L}, t) + \iint b(\mathbf{L}|\mathbf{Y})S(\mathbf{Y})n_{wm}(\mathbf{Y}, t)d\mathbf{Y} + \frac{n_c(\mathbf{L}, t) - n_{wm}(\mathbf{L}, t)}{\tau_{wm}} \quad (3)$$

The Eq.(2) boundary conditions are valid. The second and third term in the right hand side of Eq.(3) express the sink and birth functions of crystal breakage. The kinetic equations of the nucleation, growth and dissolution are described by the trivial power-law functions of supersaturation. The temperature dependency of solubility is approximated with Apelblat equation. These are well-known equations, thus, for brevity, are not given here. In order to complete the model, mass balances are required for the crystallizer and wet mill, which, assuming $L_n = 0$ nucleon size, have the form:

$$\begin{aligned} \frac{dc_c}{dt} &= -k_v\rho_c \left(\iint G_1 L_2^2 n_c(\mathbf{L}, t) d\mathbf{L} + 2 \iint G_2 L_1 L_2 n_c(\mathbf{L}, t) d\mathbf{L} \right) + \frac{c_{wm} - c_c}{\tau_c} \\ \frac{dc_{wm}}{dt} &= -k_v\rho_c \left(\iint G_1 L_2^2 n_{wm}(\mathbf{L}, t) d\mathbf{L} + 2 \iint G_2 L_1 L_2 n_{wm}(\mathbf{L}, t) d\mathbf{L} \right) + \frac{c_c - c_{wm}}{\tau_{wm}} \end{aligned} \quad (4)$$

With the initial conditions:

$$c_c(t=0) = c_{c,0}; \quad c_{wm}(t=0) = c_{wm,0} \quad (5)$$

The wet-mill is a complex crystallization system. Figure 1b illustrates a snapshot from the continuous mill operation, governed by Eq.(4), in which the effects of crystallization

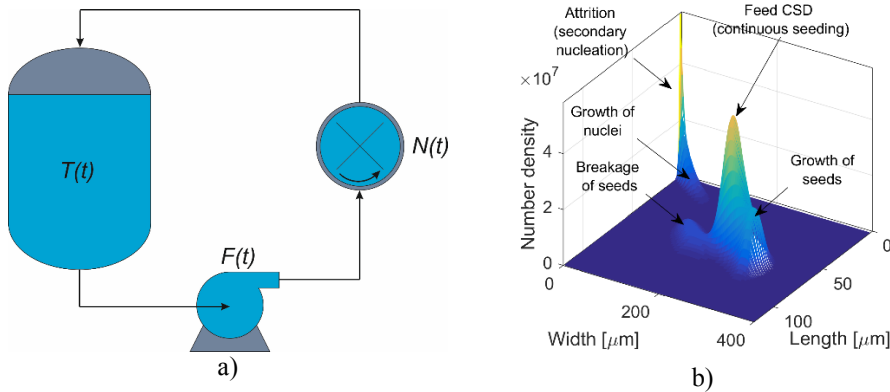

Figure 1. a) Scheme of the integrated crystallizer-wet mill system with the most important design parameters; b) the effects of simultaneously ongoing mechanisms on the crystals population in the wet-mill

mechanisms can be distinguished clearly. This figure also highlights the importance of full PBM solution when comes to distribution shaping control, over calculating and

controlling just the mean crystalline properties. The wet-mill energy balance, taking into account the effects of inlet-outlet streams, impeller energy and heat of crystallization is:

$$\frac{dT_{wm}}{dt} = \frac{P_{stirr}(N)}{V_{wm}c_{p,sol}\rho_{sol}} - \frac{k_v\rho_cH_c}{c_{p,sol}\rho_{sol}} \left(\iint G_1L_2^2n_{wm}(\mathbf{L},t)d\mathbf{L} + 2\iint G_2L_1L_2n_{wm}(\mathbf{L},t)d\mathbf{L} \right) + \frac{T_c - T_{wm}}{\tau_{wm}} \quad (6)$$

where P_{stirr} denotes the impeller stirring power, which is a function of impeller revolution speed. The initial condition for Eq.(6) is:

$$T_{wm}(t=0) = T_{wm,0} \quad (7)$$

Since the crystallizer temperature is a manipulated variable, the crystallizer energy balance is not written up. In the partial and ordinary differential model equations the nucleation and growth rates are calculated for the temperature and concentration of the modelled sub-system. In this context, the growth rates in the crystallizer and wet mill equations have the same notations but they may represent different values.

3. Process simulations and optimizations

The model Eq.(1)-(7) were solved by a full-discrete implementation of the high resolution finite volume method (HR-FVM). The algorithm contains many parallelizable operations, such as the integral calculations, breakage selection and daughter distribution function calculations as well as the HR-FVM operations, which are time consuming if solved serially. To boost the simulation time, these operations were passed to the graphical processing unit (GPU) of the computer, which has massive parallel hardware architecture thus it is natively well-suited for the execution of parallel tasks. Due to the brevity, the numerics is not presented, but the GPU acceleration brings two orders of magnitude speed-up compared to the compiled serial C code.

The existence of a high-performance system alone is not a guarantee of quality, that economic and ecologic related constraints will all be satisfied. The system operation needs to be fine-tuned. In this work, the temperature (T), circulation flowrate (F) and wet mill impeller revolution speed (N) profiles have been optimized, which in fact represents the synthesis of an integrated system operation. The objective function:

$$SSE(T, F, N) = \iiint \left(\frac{n_c(\mathbf{L}, t=t_{final}) - n_{ref}(\mathbf{L})}{n_{ref}(\mathbf{L})} \right)^2 d\mathbf{L} dt + w_1 \int N(t) dt + w_2 \int F(t) dt \quad (8)$$

The first part of Eq.(8) minimizes the difference between the target and product CSD whereas the last two terms minimize the wet-mill and pump usage. Thus, the system is supposed to produce the target CSD with minimal equipment (which translates to energy) utilization. The optimization was solved in Matlab environment using the evolution strategy with covariance matrix adaptation (CMA-ES) global optimization algorithm. Both systems involve a final cooling for fines dissolution. The optimal circulation ensures both the optimal transport of crystals and the optimal temperature and concentration conditions in the wet-mill. The crystallizer-only configuration cannot even approximate the target CSD – despite it favors width growth significantly, which highlights the importance of controlled breakage through the wet-mill. The target CSD can be approximated better by enabling longer batch time and/or giving more weight to the CSD part in the objective function. This optimization itself demonstrates clearly the high potential of the presented integrated system for simultaneous size/shape control.

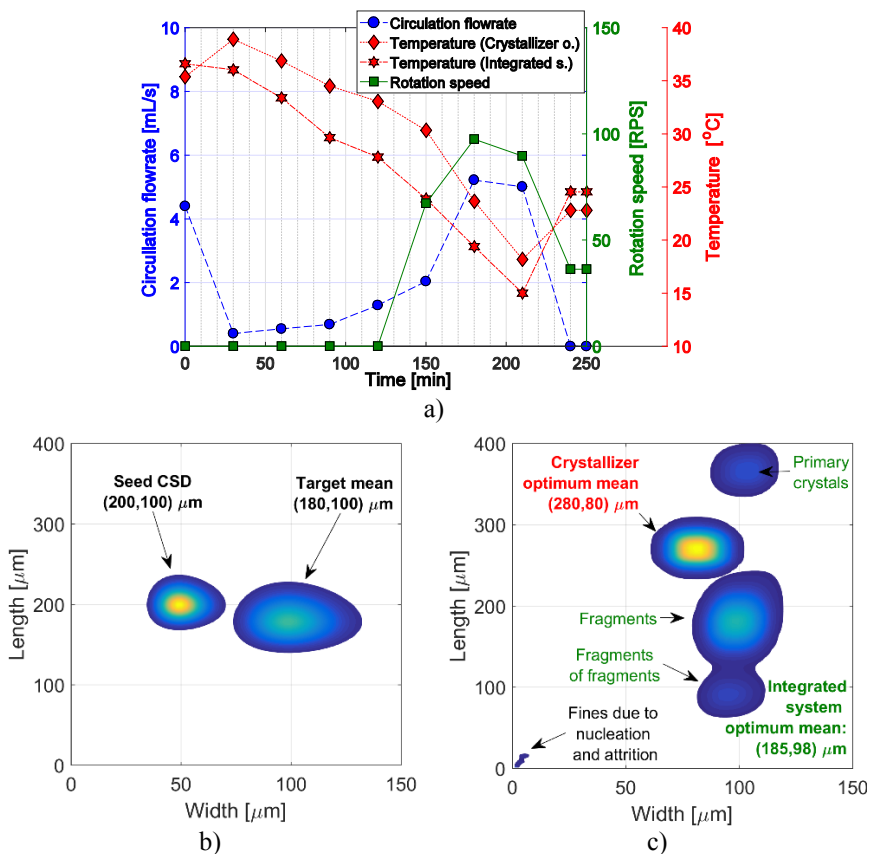

Figure 2. a) Optimal profiles for the integrated system and for the crystallizer-only configuration; b) initial and target CSD; c) CSD realized by the crystallizer-only configuration and by the integrated system

4. Conclusions

In this study the concept of simultaneous size and shape control of high aspect ratio crystals was evaluated in an integrated crystallizer-wet mill system based on mathematical modeling and simulation. The population balance model involves primary nucleation, growth and dissolution along the length and width faces in the crystallizer but for a more realistic wet-mill description, next to the attrition (collision generated secondary nucleation) and binary breakage, primary nucleation, crystal growth and dissolution mechanisms were also included, as well as the impeller heating effect.

The model-equations were solved by a full-discrete implementation of the high-resolution finite volume method (HR-FVM). For simulation time improvement the graphical processing unit (GPU) was also implied for the execution of parallel operations (such as breakage, HR-FVM and integral calculations), which leads to two orders of magnitude speedup compared to the serial C implementation.

The dynamic optimization was carried out based on evolutionary global optimization algorithm and it revealed that the wet-mill is indispensable for the production of low

aspect ratio product of material with high length-growth kinetics directly in the crystallization step. The optimal system operation involves both cooling (for crystal growth) and heating (for fines dissolution) stages in the crystallizer as well as variable circulation flowrate and wet-mill rotation speed. Further investigations are required to clarify the individual role of crystallization mechanisms in the crystallizer and wet mill under optimal conditions as well as to find economically advantageous operations. However, the current work demonstrates clearly the high potential of the integrated system for efficient and elegant crystal shape control.

Abstract

Production intensification is nowadays done using mathematical models and universal process simulators, where modeling of specific biocatalytic kinetics can be difficult because often such models are simply not available. For the study of parametric influence on the system or for intensification tasks, specific biocatalytic kinetics has to be programmed individually. An example of such kinetics is also the bioproduction of 2-phenylethanol from L-phenylalanine by yeasts *Saccharomyces cerevisiae*. For the subsequent separation of 2-phenylethanol from the fermentation medium, membrane processes (microfiltration and membrane extraction) are applied, models of which are also missing in universal process simulators. Therefore, mathematical models of biotransformation and separation steps were developed and a model library with individual unit operations (bioreactor, microfiltration, membrane extraction, distillation) was assembled in this work. Description of the mathematical models is given and the approach towards the development of a custom simulation tool is presented. The finalized tool can simulate bioproduction of 2-phenylethanol in the batch mode as well as in a hybrid production system with continuous product removal. Simulation results can be used to study the production system as well as to master intensification tasks.

Keywords: process intensification, 2-phenylethanol, hybrid system, bioreactor, modeling.

1. Introduction

The past decade has shown that consumers search for the label natural, especially in food and cosmetic products, for which they are willing to pay higher prices. Flavors and fragrances are widely used in the food and cosmetic industry and, according to legislation, a product can be labeled as natural only if the substrate used for the production process is of natural origin (Etschmann et al., 2002). Many natural aromas can be produced in a biotechnological way via enzymatic and microbial processes but a common hindrance of more effective bioproduction is the toxicity of the precursor or the product. In case of precursor toxicity, the enhancement in production can be achieved by gradual precursor addition to the bioreactor; in case of product toxicity, production can be intensified by integration of the bioreactor and continuous product removal techniques thus creating a hybrid system (Krishna, 2002). Extensively used separation techniques in the design of biotechnological hybrid systems are membrane separations, which operation currently cannot be simulated in the universal process simulators. Also, biocatalytic reactions often have very specific kinetics which is not

easily implemented into these simulation environments. In general, sophisticated models not only of biotechnological hybrid systems but also of highly integrated configurations of classical separation processes (e.g. divided wall columns) are missing in the universal process simulators (Waltermann et al., 2017). In such cases, custom made mathematical models of hybrid systems have to be individually programmed to provide a tool for the study of the variety of parameters influencing the behavior of the whole hybrid system. After the verification of the mathematical models used, these custom tools can be applied for intensification tasks. In this work, mathematical models of different hybrid systems for biotechnological production of 2-phenylethanol (PEA), which is an important aroma with characteristic rose-like fragrance, were programmed. Computational tool with graphical user interface was created facilitating the study of hybrid systems and for the use in further intensification tasks.

2. Bioproduction of 2-phenylethanol

Biocatalytic production of PEA runs according to the Ehrlich metabolic pathway, where the precursor L-phenylalanine (Phe) is transformed to PEA. When the amino acid is the sole nitrogen source available, many yeast strains utilize the Ehrlich pathway for its metabolization and *Saccharomyces cerevisiae* provide high production yields (Etschmann et al., 2003). Production of PEA is growth related and since *Saccharomyces cerevisiae* are also used as a producer of other important products, mathematical models of their growth are available in literature. Published mathematical models differ in complexity depending on the structure or segregation of the model. Currently, universal process simulators have been successfully used in the development of unstructured and unsegregated models for *Shimwellia blattae* growth on specific substrates (Rodriguez et al., 2017). However, more complex kinetic models are still programmed individually using various computational software. *Saccharomyces cerevisiae* can exhibit diauxic growth when their overall growth is dependent on three metabolic pathways where two substrates are utilized. Such growth can be described by structured and unsegregated model proposed by Di Serio et al. (2001), where the optimal metabolic path is chosen at any moment in order to maximize the growth rate. This model consists of eight ordinary differential equations (balancing the biomass, glucose, ethanol, dissolved oxygen, enzymes for glucose oxidation and fermentation, enzymes for ethanol oxidation and volume of the fermentation medium) and provides information about the influence of the operation condition on the growth, which is very useful in case of further optimization of the conditions. However, the kinetic model by Di Serio et al. (2001) does not consider the inhibition of biomass growth induced by ethanol or PEA. Both inhibitors are able to stop the biomass growth but at different concentrations in the fermentation medium. For ethanol, total growth inhibition occurs at about 70 g/L and biomass growth is influenced by ethanol concentration of above 15 g/L. But ethanol formation in the fermentation medium can be limited employing a good strategy of glucose feeding, developed by the kinetic model of biomass growth involving the inhibition aspects. For comparison, total inhibition of the biomass growth occurs at much lower PEA concentration in the fermentation medium, of about 4 g/L, and first signs of growth inhibition can be observed at 0.6 g/L. Therefore, inhibition aspects of both products in PEA biocatalytic production have to be included in the mathematical model describing the biomass growth kinetics. Mathematical model of the inhibition by ethanol and PEA was presented by Strak et al. (2003), where the inhibition extent is calculated from the actual concentration of the respective inhibitor which is then applied

to the specific growth rate of biomass. Since the model by Di Serio et al. (2001) does not consider consumed Phe and produced PEA, these equations were added to the model by Mihal' et al. (2012). Production of 2-phenylethanol runs at aerobic conditions and more intensive aeration during the bioproduction increases the capacity of oxidative metabolism, which is in favor of more intensive growth of biomass. Also, ethanol can be stripped in the gaseous phase used for the aeration and leave the bioreactor in the off-gas stream. The second effect of intensive aeration is also in favor of more intensive biomass growth since the inhibitor is stripped from the reactor. This phenomenon can be described by adding the expression for mass transfer of ethanol to the gaseous phase to the ethanol balance in the kinetic model by Di Serio et al. (2001). Also, the ethanol balance in the gaseous phase with the expression for mass transfer has to be added to the mathematical model. The mathematical model described above consist of 11 differential equations balancing the main components of the production system and eight more equations for the calculation of parameters in the actual time of simulation. This complex model was firstly assembled in the work of Mihal' et al. (2012), where it was also verified by experimental results of PEA production proving an acceptable agreement with experiments. Because of the specific kinetics of the model it is not possible to assemble it in a process simulator, therefore, graphical user interface (GUI) was built in MATLAB for the PEA biotransformation model.

3. Separation of 2-phenylethanol

Effectivity of the separation has a significant role in overall production economics with respect to the selection of suitable separation steps as well as the scale of used equipment. Many separation techniques have been examined for possible PEA separation from the fermentation medium e.g. adsorption, absorption, extraction. These techniques were mainly studied for in situ product removal to effectively reduce the strong inhibitory effect of PEA, which leads to significant intensification of its overall productivity. Mathematical models of PEA continuous separation from the fermentation medium were published only by Mihal' et al. (2012), where microfiltration and membrane extraction coupled with distillation were used. Mathematical model of microfiltration consists of steady-state flux through membrane calculation based on the biomass concentration, experimentally obtained at the transmembrane pressure of 20 kPa. The calculated flux through the membrane is then used in the balances of individual fermentation medium components and volume. In membrane extraction, hollow fibers were considered as the membrane module construction material and film theory was applied for the mass transfer description. According to the film theory, the solute of interest passes three resistances in a series when it is transferred from the aqueous to the organic phase: the aqueous phase boundary layer, membrane, and the organic phase boundary layer. The membrane module was divided into the shell side and the fiber side, which were both fractionated into 100 ideally mixed tanks in series in the mathematical description of the transported component. These models were verified by experimental data with acceptable agreement and they can be used for the study of the whole hybrid system for PEA production as well as for the intensification tasks and scale up of the system. Also, the models can be used to simulate and design batch PEA production after including changes in equations expressing mutual connections of the separation processes. To develop a complex tool for the study and design of PEA production, verified mathematical models of microfiltration, membrane extraction and distillation were programmed in MATLAB and they were connected to a biotransformation model through GUI.

3.1. Batch production

Batch production starts with the biotransformation of Phe to PEA in a bioreactor. The production ends when the PEA concentration of 4 g/L is reached in the fermentation medium since it is not continuously removed during the process. The bioreactor is emptied after the biotransformation and the fermentation medium is transported to the accumulation tank. The separation part of the technology starts with microfiltration, in which cell free fermentation medium is obtained in the permeate stream. The next separation step is membrane extraction, where heptane is used as an organic solvent. In case of the presence of unreacted Phe in the fermentation medium, heptane provides selective PEA separation due to the Phe insolubility in heptane. Membrane extraction is coupled with a distillation column for heptane regeneration from which regenerated heptane is recycled back to the membrane extraction unit. The described production procedure in the batch configuration can be simulated in GUI.

3.2. Hybrid systems

Continuous PEA removal reduces its inhibitory effect on the biomass growth; therefore, creating a hybrid system with a bioreactor interconnected with a separation system enables the intensification of the whole production process (Červeňanský et al., 2017). In the hybrid production of PEA, the bioreactor is connected to a microfiltration unit in which cell free fermentation medium is obtained and the retentate stream is recycled back to the bioreactor. Permeate from the microfiltration is then led to the hollow fiber membrane extraction module, where PEA from the medium is transported to the organic phase. Heptane is used as an extractant in which Phe is insoluble; thus, heptane provides selective PEA separation. Fermentation medium from the membrane extraction is recycled back to the bioreactor and heptane is led to the distillation unit for its regeneration. Regenerated heptane is recycled back to the membrane extraction module. Bioproduction and separation processes used in the hybrid system are mathematically described by the models presented above but their mutual interaction has to be added to the already prepared model equations. Equations describing individual components of the hybrid system and those describing their mutual interactions are solved simultaneously, thus equation-oriented approach is applied in the modeling of hybrid systems. Prepared GUI can be used for the study and design of hybrid systems with the same user dependent parameters as described in the batch production system. The presented hybrid system corresponds to only one possible configuration of hybrid system, but also other configurations can be simulated with the prepared GUI.

4. Graphical user interface and results from simulations

Mathematical models of bioproduction and all used separation processes as well as the GUI were programmed in MATLAB. Graphical user interface is divided into five main sections: Options, Fermentation, Microfiltration, Extraction and Distillation and its outline is presented in Figure 1. In Options, the user can choose whether the batch production or hybrid production should be applied for the simulation. The user can also choose what separation processes are applied in either production mode. In this section, also changes in the glucose and Phe feed can be specified. In the Fermentation section, the user can change the initial conditions of the system as well as important parameters (volumetric mass transfer or yield coefficients). There is a possibility to enable or disable the ethanol stripping phenomenon with additional information needed for the calculation. In the Microfiltration section, the main design parameter is the membrane

area. Design parameters in the Extraction section are connected to the geometry of the selected hollow fiber membrane module (e.g. number of fibers, length of the module, fibers dimension) and also to the user dependent parameters (time of membrane extraction, volume of organic phase used, volumetric flow rates on shell and fiber side). Distillation coupled with membrane extraction is defined in the Distillation section, where the main design parameter is the delivered heat. Found optimal conditions in the Batch or Hybrid production can be saved through the interface and loaded for future work.

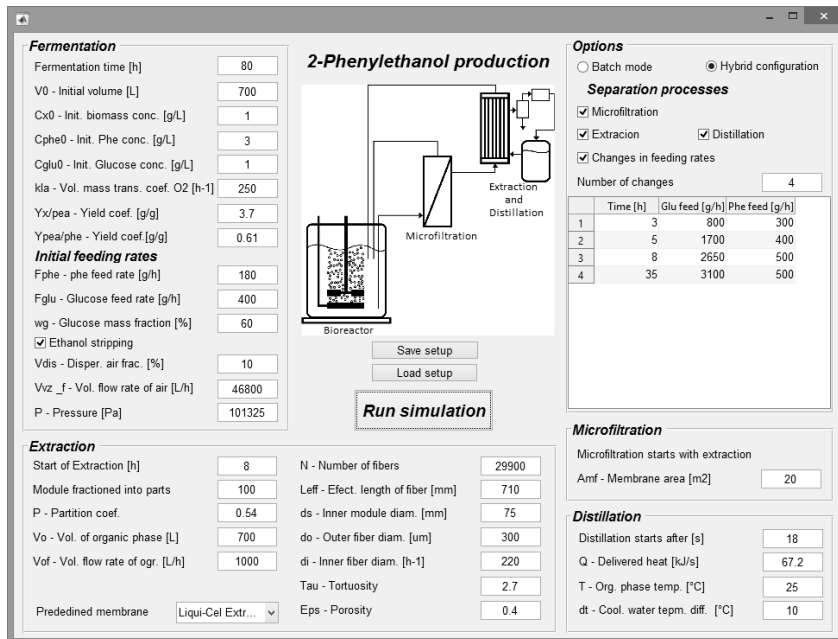

Figure 1. GUI for the simulation of PEA production in batch and in hybrid system configuration.

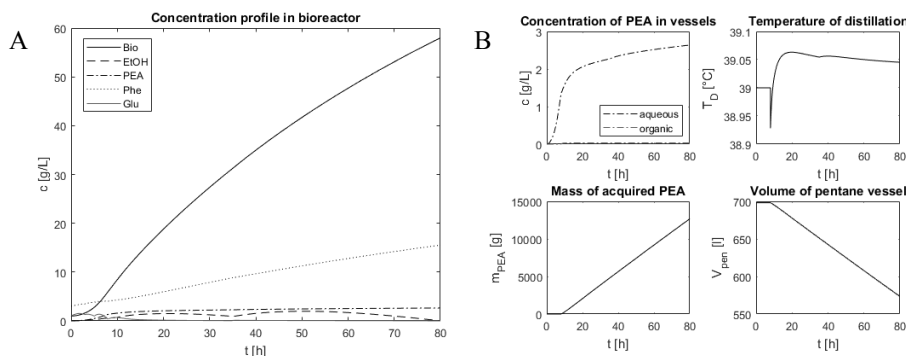

Figure 2. Results of the simulation from GUI for PEA production in hybrid system. A – concentration profiles in the bioreactor, B – result of membrane extraction coupled with distillation.

Results of the fermentation simulation are presented in form of graphs with concentration changes of biomass, ethanol, glucose, Phe and PEA in time. Results of the

separation processes simulation are time dependent concentration profiles of PEA in connected accumulation tanks. In case distillation is a part of the system, also information about separated PEA and distillation temperature are provided.

5. Conclusions

Mathematical modeling has currently an irreplaceable position in process intensification but its application in biocatalytic production of natural flavors and fragrances is difficult mainly because of very specific kinetics of the biotransformation process. Such specific kinetics cannot be easily implemented into universal process simulators which are often used for the search of optimal working conditions. Also, mathematical models of membrane separation processes are not developed in process simulators. Therefore, in these cases the only way of using mathematical modeling for the search of optimal working conditions is creating a custom program tool. In this work, such a tool has been created for the bioproduction of PEA, which is an important natural flavor. The developed program tool combines mathematical models of bioproduction, microfiltration, membrane extraction and distillation which can work in batch configuration or as one hybrid system with continuous product removal. This tool can be used to compare batch and hybrid systems or to study and intensify PEA bioproduction.

Abstract

NO_x is one of the major pollutants present in the exhaust gas of marine diesel engines. Normally, NO_x is difficult to remove using scrubbers because NO, which accounts for 90 % of NO_x, has very low water solubility. However, if NO is oxidized to other highly soluble nitrogen oxides, the removal efficiency of NO_x in a wet scrubber can be greatly improved. In this study, we estimated the efficiency of NO_x removal from the exhaust gas of a 50 MW diesel engine using H₂O₂ solution. Then, we compared the results with the removal efficiency of a conventional exhaust gas recirculation (EGR) system. The amount of H₂O₂ consumption varied from 0 to 760.30 kg/h to satisfy emission regulations, depending on the amount of NO_x input in the scrubber. In this study, we conducted an economic evaluation of the operation costs of NO_x removal using H₂O₂, considering other parameters affecting the operation cost and by comparing the results with that of the conventional EGR system. The results of the economic evaluation show that the use of EGR in ECAs was 2.307 M\$/y, which is more economical than that of H₂O₂, and the use of H₂O₂ in non-ECAs was 1.044 M\$/y, more economical than that of EGR. If the ECA ratio is less than 31.5%, the operation cost of using H₂O₂ is lower than using EGR.

Keywords: NO_x removal, EGR (Exhaust Gas Recirculation), H₂O₂, Low-speed diesel engine.

1. Introduction

With increasing awareness on the global environment, the International Maritime Organization (IMO) has further enforced stronger regulations on the emissions of SO_x and NO_x from the exhaust gases of ships since 2016 (Figure 1). While SO_x, which is

Figure 1. IMO regulation: NO_x emission and fuel sulfur contents.

water soluble, can be easily removed by using a wet scrubber, NO, which accounts for 90 % of NO_x, has very low water solubility and is difficult to remove through a wet scrubber. Many technologies for NO_x removal exist including selective catalytic reduction (SCR), EGR, oxidizing agents.

Although SCR can effectively remove NO_x, the equipment is large and heavy and the installation cost is high; as a result, installation on large ships would not be economically feasible. In contrast, the equipment size for EGR is smaller and the installation cost is lower than those for SCR. However, EGR is disadvantageous in that it can remove only 80 % of NO_x. Moreover, it also leads to fuel penalty as the fuel consumption rate increases, along with the increase in the release of other harmful substances. Among the oxidizing agents used for NO, H₂O₂ can oxidize NO and other substances, has a simple reaction mechanism, and does not generate secondary pollutants.

There are two methods for NO oxidation using H₂O₂. In the first, H₂O₂ is decomposed into OH radicals by UV to react with NO. However, this method is difficult to use on large ships that have a high emission of NO_x because the number of UV lamps required increases as the amount of NO_x increases. The second method is to initiate a reaction between NO and H₂O₂. This method does not require any additional equipment other than the H₂O₂ storage tank, which is available on large ships and takes up lesser space than that required with other technologies. This study developed a model for the NO_x removal process for low-speed two-stroke ships using H₂O₂. Furthermore, this study simulated the model by using Aspen Plus and performed an economic evaluation in comparison with the EGR process without using H₂O₂.

2. Simulation

2.1. Process flow diagram (PFD)

Exhaust gas from the engine enters the bottom of the scrubber, and H₂O₂ and water enter the top and flow downward in the scrubber. In the wet scrubber, the gas that has been cleaned through the reaction in the gas-liquid phase is discharged from the top of the scrubber into the air, and the dirty water is released from the bottom (Figure 2).

Figure 2. Process flow diagram (PFD) in Aspen plus and details.

Table 1. Engine data for simulation.

Item	Data
Engine model	11S90ME-C V9.2
100 % load	53,250 kW(81 rpm)
Experiment load (75 %)	39,938 kW(73.6 rpm)
Exhaust gas temperature	365 °C
Before turbine temperature	342 °C
After turbine temperature	193 °C
NOx	15.79 g/kWh

Table 2. Gas composition data.

Component	Typical	Calculated
N ₂	75.80 %	88.52 kg/s
O ₂	13.00 %	15.18 kg/s
H ₂ O	5.35 %	6.25 kg/s
CO ₂	5.20 %	6.07 kg/s
SO _x	0.06 %	0.07 kg/s
NO _x	0.15 %	0.18 kg/s
etc.	-	-
Total.	99.56 %	116.27 kg/s

2.2. Engine specification and exhaust gas composition

Engine data such as NO_x emissions, temperature, power, and rpm used for the simulation were based on the data from a master's thesis (Kim, 2014) of Ulsan University. Table 1 shows the exhaust gas emissions and other components of the exhaust gas calculated in reference to the exhaust gas composition (Woodyard D., 2004) of a typical low-speed two-stroke vessel (Table 2). In this study, typical compositions such as N₂, O₂, H₂O, CO₂, SO_x, and NO_x were included as the exhaust gas, and other substances such as PM and hydrocarbon (HC) were not considered. The simulation was performed by normalizing the major components based on the NO_x emission data.

2.3. Scrubber model

2.3.1. Reaction kinetics

The reaction kinetics used are shown in Table 3. HNO₂, which is the product of the reaction between H₂O₂ and NO, is an unstable intermediate product that exists only for a very short time. Thus, the simulation was performed by using the integrated reaction

equation. To identify the removal rate of ρ in the scrubber, the SO_x reaction equation in the liquid phase was used and it was assumed that other substances do not react.

2.3.2. Scrubbing water input

As the amount of water entering the scrubber increases, the removal rate of SO_x increases. Thus, in this study, the amount of water that removes 99 % of SO_x was set as a fixed variable when the amount of SO_x was the greatest. The removal rate of SO_x was the highest when EGR was 0 %. The removal rate of SO_x was 99 % when the ratio of water to gas entering the scrubber was 0.398 L/m³.

3. Simulation results

3.1. EGR ratio and H₂O₂ consumption according to NO_x removal

3.1.1. Case study

In this study, the simulation was performed by dividing cases according to the EGR ratio and the emission control areas (ECAs) to identify the consumption of H₂O₂, depending on the specific removal amount of NO_x.

- i) Case 1–5: H₂O₂ consumption according to the EGR ratio in ECAs.
- ii) Case 6–7: H₂O₂ consumption and EGR ratio in non-ECAs.

Table 4. Simulation result for NO_x removal with H₂O₂ and EGR.

ITEM	Unit	In ECAs					In non-ECAs	
		1	2	3	4	5	6	7
Case								
EGR ratio	%	0.00	20.76	31.34	34.31	34.50	0.00	4.90
Fuel Penalty	%	0.00	2.09	3.80	4.36	4.40	0.17	0.45
NO _x removal	%	0.00	-33.30	-66.67	-76.07	-76.67	0.00	-1.05
NO _x outlet	g/kWh	3.40	3.40	3.40	3.40	3.40	14.40	14.40
H ₂ O ₂ consumption	kg/h	760.30	428.42	98.77	3.78	0.00	10.37	0.00
H ₂ O ₂ cost	\$/h	532.21	299.89	69.14	5.82	0.00	7.26	0.00
Fuel cost	\$/h	2488.78	2540.77	2540.77	2597.39	2598.34	2488.78	2500.00
Total cost	\$/h	3020.98	2840.66	2840.66	2601.46	2598.34	2496.03	2500.00

3.1.2. Case study result

The amount of H₂O₂ necessary to satisfy the emission regulations without using EGR was 760.30 kg/h in ECAs and 10.37 kg/h in non-ECAs. Furthermore, as the EGR ratio increases, the H₂O₂ consumption to remove NO_x decreased. The NO_x removal rate and fuel penalty according to the EGR ratio were based on the results obtained from other studies. (S. I. Raptotasios et al., 2014). The EGR ratios required to satisfy the emission regulations were 34.5 % and 4.9 % in ECAs and non-ECAs, respectively. The cost of each case was calculated considering H₂O₂ and Fuel. Cost of H₂O₂ 50 % solution is 350 \$/t and Cost of IFO380 (Intermediate Fuel Oil 380) which is commonly used for fuel oil for large marine vessels is 360 \$/t. (table 4).

3.2. Parameters affecting cost

As shown in Table 4, the parameters affecting cost are the consumption of H₂O₂ as well as the fuel penalty according to the EGR ratio. When considering only two parameters,

it is cheaper to use EGR in ECAs and H₂O₂ in non-ECAs. But there are many parameters exists in real operation, like maintenance cost, power consumption, etc. The results of this study and other parameters affecting operating costs were used to evaluate the economics of the NOx removal method using H₂O₂.

4. Economic evaluation

4.1. Assumptions and parameters

- i) CAPEX was not considered because it depends on the ship size and ship manufacturer. Only the operation cost was compared. Although the capex of EGR and scrubber is shown table 5, it is just used for calculation of maintenance cost.
- ii) The ship considered uses IFO380 for fuel and uses the scrubber to remove SOx.
- iii) The evaluation was conducted for each NOx removal technology separately in both ECAs and non-ECAs.
- iv) NaOH is used in order to neutralize the sulfuric acid in scrubber and protect the engine components for corrosion. (Kotakis NK, 2012) We assumed that NaOH is consumed only EGR-method because the side-reactions of H₂O produce the OH- which can neutralize the solution. (Liu Y xian and Zhang J, 2011)
- v) The evaluation parameters include power consumption of the EGR and scrubber system, NaOH price in EGR, maintenance, and fuel and H₂O₂ solution prices. The operating costs, which included the fuel and H₂O₂ prices, were based on the results of this study, and other parameters were in reference to other studies. (J.P. Hansen et al., 2014), (M. Jeppesen, 2016), (E. den boer and M. Hoen, 2015) (Table 5).

Table 5. Operation cost parameters.

Item	Value
Maintenance of EGR	3.20\$/MWh
Maintenance scrubber	1.11\$/MWh
NaOH	350 \$/t
H ₂ O ₂ (50 % solution)	350 \$/t
IFO380	360 \$/t
Power	0.1098 \$/kWh

Figure 3. Annual operation cost.

4.2. Results

The most important parameters were H₂O₂ cost and power consumption according to the EGR ratio. As shown in Figure3, The operation cost was lowered by 1.044 M\$/y when H₂O₂ was used in non-ECAs, and by 2.307 M\$/y when EGR was used in ECAs (Table 6). Because the ratio of ECAs differs according to each ship type, route and loop in the actual operation, calculations were performed by adjusting the costs of the method using H₂O₂ as equal according to the ratio of ECAs. As a result, when the ratio of ECAs was approximately 31.5 % or less, the operating cost of H₂O₂ was advantageous, and when it was 31.5 % or more, and the operating cost of EGR was advantageous.

5. Conclusions

1. H_2O_2 is a powerful oxidizing agent that can effectively remove NOx. The results of this study show that 760.30 kg/h and 10.37 kg/h of H_2O_2 were consumed in ECAs and non-ECAs, respectively, to satisfy the emission regulations.
2. The factors significantly affecting the operation cost were fuel penalty according to the EGR rate and cost based on H_2O_2 consumption. The results of the economic evaluation show that the use of EGR in ECAs was 2.307 M\$/y, which is more economical than that of H_2O_2 , and the use of H_2O_2 in non-ECAs was 1.044 M\$/y, more economical than that of EGR.
3. The operation costs for the EGR and H_2O_2 were calculated according to the ratio of ECAs, and it was observed that the operation cost of the method using H_2O_2 was equal to that of the method using EGR when the ratio of ECAs was approximately 31.5 %.

Abstract

The objective of this work is to develop a framework to compare the performance of an industrial scale Catalytic Steam Reformer (CSR) with that of a Membrane Steam Reformer (MSR) and to decide on the choice of MSR as a viable alternative to CSR for production of hydrogen. For this purpose, a mathematical model is developed in this work to represent the industrial scale operation of MSR. Using the mathematical models, operations of CSR and MSR are optimized to achieve maximum methane conversion. The advantage of higher methane conversion achieved in MSR as compared to CSR has to be weighed against the additional cost of Pd membrane used in MSR. A mathematical equation is presented in this work to calculate and compare the unit costs of hydrogen as a function of optimal values of various operating parameters obtained for CSR and MSR.

Keywords: Process intensification, Process design, Process optimization, Membrane steam reforming, Techno-economic analysis

1. Introduction

With increasing demand for hydrogen as a clean fuel and with abundant availability of natural gas resources across the globe, Catalytic Steam Reforming of methane is gaining prominence as the most attractive process for production of hydrogen. In a conventional CSR, the maximum achievable conversion of methane is limited to equilibrium conversion. Whereas, in a MSR, the equilibrium is shifted in favour of higher methane conversion by letting the hydrogen produced in the reactor to permeate out through a Pd membrane. Although a number of studies have been reported (Silva et al, 2016) on laboratory scale MSR, there is no evidence of any industrial application of MSR technology. This is mainly due to enormous cost of preparation of Pd membranes (Criscuoli et al., 2001), which is expected to decrease in future with growing number of industrial applications of MSR.

The present work addresses the need to develop a mathematical model to appropriately represent the industrial scale operation of MSR and evaluate the economic feasibility of replacing the existing CSR technology by MSR technology. For this purpose, the design

of industrial scale side fired CSR reported in Rajesh et al. (2000) is taken and is suitably altered to represent the industrial scale MSR. A mathematical model for the MSR is developed by modifying the model equations for CSR reported in Rajesh et al. (2000) to account for transport of hydrogen through Pd membrane. A systematic comparative analysis of optimum performances of CSR and MSR is carried out for various surface areas of Pd membrane tubes used in MSR. An equation for calculating the unit production cost of hydrogen as an explicit function of optimal values of feed and operating parameters of CSR and MSR is presented in this work for the purpose of economic feasibility analysis.

2. Process Description of CSR and MSR

Figure 1: (a) Single reactor tube in a CSR (b) Single reactor tube in a MSR

Three chemical reactions listed below take place in the Catalytic Steam Reformer:

Kinetic rate equations reported by Xu and Froment (1989) are used in this work. Industrial scale side fired CSR (Fig.1a) reported in Rajesh et al. (2000) is taken in this study. CSR contains $n_t = 176$ numbers of catalyst filled reactor tubes (outer diameter $d_o = 102$ mm, inner diameter $d_i = 79.5$ mm, length $L = 11.95$ m) placed in a refractory lined furnace. The catalyst is Ni on Al_2O_3 pellet of diameter $D_p = 17.4$ mm. The furnace has 112 burners. The feed gas is a mixture of CH_4 , H_2O , CO_2 , H_2 and N_2 . F_{CH_4} is the molal feed rate of methane. S/C, H/C, D/C and N/C are respectively the molar ratios $\text{H}_2\text{O}/\text{CH}_4$, H_2/CH_4 , CO_2/CH_4 and N_2/CH_4 in the feed gas.

The design of CSR (Fig.1a) is altered into a MSR as shown in Fig.1b. In MSR, each reactor has two concentric tubes. Inner empty tube (radius r_o) is made of Pd membrane of thickness $\delta = 7.5 \mu m$ through which a sweep gas (steam) is passed. Annular section is the reactor packed with catalyst pellets through which feed gas is sent. H_2 permeates through Pd membrane wall into the inner tube at a molar flux of J_{H_2} (Sieverts law)

$$J_{H_2} = \frac{Q_o}{\delta} \exp\left(-\frac{E_p}{RT}\right) \left(P_{H_2}^{0.5} - P_{H_2p}^{0.5}\right) = \frac{Q_o}{\delta} \exp\left(-\frac{E_p}{RT}\right) \left((P y_{H_2})^{0.5} - (P_p y_{H_2p})^{0.5}\right) \quad (1)$$

P_p is the permeate pressure and y_{H_2p} is mole fraction of hydrogen in permeate. Values of parameters Q_o and E_p are taken from Johannessen et al. (2005)

3. Mathematical Modelling of CSR and MSR

In this work, one dimensional mathematical model for side fired industrial scale CSR reported in Rajesh et al. (2000) is adapted with some modifications. Further, a model is developed to represent the industrial scale side fired MSR by suitably modifying the model equations of CSR to account for flux of hydrogen through the Pd membrane. The model equations for CSR and MSR are combined using a switching parameter α which takes a value $\alpha = 1$ for MSR and $\alpha = 0$ for CSR.

Model Equations for Catalytic Reactor Section of CSR and MSR:

Over all mass balance equation is

$$\frac{dG}{dz} = -\alpha \left[\left(\frac{4\pi r_o L}{A_c} \right) J_{H_2} \right] \quad (2)$$

Component molal balance equation is written in terms of $x_i = \frac{y_i}{M}$ as

$$\frac{dx_i}{dz} = \frac{L \rho_b \eta_i R_i}{G} + \alpha(1 - \beta) \left[\frac{x_i}{G} \left(\frac{4\pi r_o L}{A_c} \right) J_{H_2} \right] + \alpha \beta \left[\frac{(2x_i - 1)}{G} \left(\frac{2\pi r_o L}{A_c} \right) J_{H_2} \right] \quad (3)$$

$i = CH_4, H_2O, CO, CO_2, H_2$

Over all heat balance equation is

$$\frac{dT}{dz} = \frac{L}{GC_{pg}} \left[\left(\alpha \left(\frac{\pi D_i U}{A_c} \right) + (1 - \alpha) \left(\frac{4U}{d_i} \right) \right) (T_{wi} - T) + \rho_b \sum_{j=1}^{III} \eta_j r_j (-\Delta H_j) - \alpha \left(\frac{U_m (2\pi r_o)}{A_c} \right) (T - T_p) \right] \quad (4)$$

Pressure drop in reactor channel is calculated using Kozney – Karman equation

$$\frac{dP}{dz} = -\frac{1.75 L G^2 (1 - \varepsilon_b)}{\varphi_s D_p \varepsilon_b^3 \rho_g} \quad (5)$$

A_c : cross sectional area of the reactor channel, y_i : mole fraction, \bar{M} : average molecular weight, R_i : rate of formation of chemical species, G : mass velocity of gas, β : switching parameter ($\beta=1$ for $i=H_2$ and $\beta=0$ for $i \neq H_2$), η_i : catalyst effectiveness factor (equal values of 0.03 assigned for all three reactions as reported in E. Johannessen et al. 2005), C_{pg} : specific heat capacity of gas, T : gas temperature, T_{wi} : inner tube wall temperature, U : catalyst bed side heat transfer coefficient, T_p : permeate gas temperature, U_m : overall heat transfer coefficient across the membrane.

Model Equations for Permeate Tube Section of MSR:

Hydrogen mole balance, Heat balance and Pressure drop equations are as follows,

$$\frac{dy_{H_2p}}{dz} = \left(\frac{2\pi r_o L (1 - y_{H_2p})}{G_p} \right) J_{H_2} \quad ; \quad \frac{dT_p}{dz} = \left(\frac{(2\pi r_o L) U_m}{G_p C_{pp}} \right) (T - T_p) \quad ; \quad \frac{dP_p}{dz} = - \frac{4fL}{d_p} \left(\frac{v_p^2}{2g} \right)$$

(6), (7), (8)

G_p : molal flow rate of permeate gas per unit area, G_{pp} : specific heat capacity of the permeate gas, f : friction factor, v_p : gas velocity, d_p : permeate tube diameter

4. Simulation and Optimization of CSR and MSR operations

The main objective of this work is to quantify the improvement in performance of MSR over CSR when the surface area (A_m) of Pd membrane is increased. For this purpose, identical tube lengths (L) and catalyst bed volumes are taken for both MSR and CSR and A_m is varied by changing the inner membrane tube radius r_o . To accommodate equal catalyst bed volumes in CSR and MSR, the inner diameter D_i of the outer tube of MSR is increased as $D_i = \gamma d_i$. By changing the value of parameter $\gamma > 1$, the values of r_o and A_m are changed respectively as $r_o = \frac{d_i}{2} \sqrt{\gamma^2 - 1}$ and $A_m = \pi d_i \sqrt{\gamma^2 - 1} L n_t$.

Matlab®R2015a was used to simulate CSR and MSR models. Simultaneous stiff ordinary differential equations (Eq. 2-8) were solved using function subroutine *ode15s* to obtain the profiles of mole fractions, temperature and pressure for different feed and operating conditions. Factors that influence CH_4 conversion (M_c) in CSR are feed temperature T_i , feed pressure P_i , furnace gas temperature T_g , S/C and H/C. In addition to all these factors listed for CSR, conversion of CH_4 in MSR is also influenced by permeate feed temperature T_{pi} , permeate feed pressure P_{pi} and sweep ratio S_r which is the ratio of feed rate of sweep gas (steam) to the feed rate of methane.

In this work, CSR and MSR operations were optimized to achieve maximum CH_4 conversion (M_c) for fixed values of $F_{CH_4} = 1000$ kmol/h, $D/C = 0.091$ and $N/C = 0.02$, subject to operational constraints and bounds (Rajesh et al. 2000) listed here, $T_{wo} \leq 1200$ K, $F \leq 5000$ kmol/h, $725 \leq T_i \leq 900$ K, $2400 \leq P_i \leq 3000$ kPa, $2.0 \leq S/C \leq 6.0$, $0.01 \leq H/C \leq 0.5$, $1375 \leq T_g \leq 1650$ K, $1.0 \leq S_r \leq 3.0$, $600 \leq T_{pi} \leq 800$ K, $200 \leq P_{pi} \leq 300$ kPa. MSR is optimized for different values of γ varying between 1.15 and 2. The constrained optimization problem is solved using *fmincon* optimization routine of Matlab® R2015a.

5. Results and Discussion

Optimal values of feed and operating variables and the corresponding values of methane conversion (M_c), H_2 production rate (P_{H_2}) and CO_2 production rate (P_{CO_2}) are reported in Table 1. In CSR, an optimal methane conversion of only 49% was achieved, whereas 99.9% conversion was achieved in MSR for $\gamma = 2$. Although methane conversion increases steadily with increase in γ , the increase is not very significant for $\gamma > 1.75$ suggesting that $\gamma > 1.75$ is not economical. Further, optimal operation of MSR requires the feed gas to be at a higher pressure P_i and furnace gas to be at a higher temperature T_g compared to CSR in order maintain a higher hydrogen concentration gradient across the Pd membrane.

Table 1: Comparison of Key Optimum Performance indices of CSR and MSR

Operating Parameters	CSR	MSR					
		$\gamma = 1.15$	$\gamma = 1.30$	$\gamma = 1.40$	$\gamma = 1.65$	$\gamma = 1.75$	$\gamma = 2.00$
T_g (K)	1,575.5	1,644.5	1,650.0	16,50.0	1,643.2	1,630.4	1,606.7
T_i (K)	900.0	878.8	891.8	900.0	900.0	900.0	900.0
P_i (kPa)	2,400.0	2,505.6	3,000.0	3,000.0	2,519.4	2,988.5	2,539.7
S/C	3.879	3.879	3.879	3.878	3.877	3.863	3.647
S_r	-	2.998	3.000	2.595	3.000	2.971	3.000
T_{pi} (K)	-	800.0	800.0	800.0	800.0	799.6	793.1
P_{pi} (kPa)	-	200.0	200.0	200.0	200.0	200.0	200.0
P_{H_2} (kmol/h)	1,817.9	3,039.3	3,497.1	3,668.0	3,891.8	3,945.2	3,938.0
P_{CO_2} (kmol/h)	346.7	712.6	836.2	876.7	925.7	951.4	940.3
M_c (%)	49.0	77.6	88.7	93.0	98.9	99.8	99.9

The economics of choice of MSR over CSR has to take into account influence of various parameters listed in Table 1 on the fixed and operating costs of steam reformer.

In this work, an explicit equation (Eq. 9) is derived to calculate the unit cost of production of hydrogen C_{PH} as a function of these parameters (Table 1)

$$C_{PH} = \frac{C_{RM} + C_{FR} + C_{SP} + C_{OT} + C_{OC}}{\bar{P}_{H_2}} \quad (9)$$

$$C_{RM} = C_M \left(\frac{M_C}{100} \right) \bar{F}_{CH_4} + C_{H_2O} (S/C + \alpha S_r) \bar{F}_{CH_4} \quad ; \quad C_{FR} = C_R \bar{F}_{CH_4} + \alpha C_{P_d} \left(\pi d_i \sqrt{\gamma^2 - 1} L n_t \right)$$

$$C_{SP} = C_{MS} \left(1 - \frac{M_C}{100} \right) \bar{F}_{CH_4} + (C_{CS} - C_{CO_2}) \bar{P}_{CO_2} + C_{HS} \bar{P}_{H_2} \quad ; \quad C_{OC} = c_1 (\bar{F}_{P_i})^{d_1} + \alpha \left[c_2 (S_r \bar{F}_{CH_4} P_{P_i})^{d_2} \right]$$

$$C_{OT} = a_1 (\bar{F}_{T_i})^{b_1} + a_2 (T_f)^{b_2} + \alpha \left[a_3 (S_r \bar{F}_{CH_4} T_{P_i})^{b_3} \right]$$

Here, C_M , C_{H_2O} , C_{CO_2} : unit costs of methane, steam, carbon dioxide, C_R : annualized fixed cost of catalytic reactor tubes per unit kmole of methane processed, C_{P_d} : annualized fixed cost of palladium membrane tubes per unit area, C_{MS} , C_{CS} , C_{HS} : annualized fixed and operating costs of separators for methane, carbon dioxide hydrogen per unit kmole of separation, a_i , b_i , c_i , d_i : coefficients of empirical cost correlations for C_{OT} cost for thermal heating and C_{OC} cost for feed gas compression.

By comparing the unit production costs of hydrogen C_{PH} calculated for CSR and MSR for different values of γ , one can make a decision on the choice of MSR over CSR and the value of γ at which the cost is minimum.

6. Conclusions

In this paper, a mathematical model has been developed to represent the industrial scale operation of a side fired Membrane Steam Reformer (MSR). The mathematical models of CSR and MSR are used to compare their optimal performances and to evaluate the suitability of MSR over CSR. The economics of choice of MSR in place of CSR is to be evaluated by taking in to account a number of cost factors. A frame work is developed in this paper to calculate the unit cost of production of hydrogen by representing various cost factors as functions of optimal feed and operating parameters.

Abstract

In this work, we present a systematic framework for the synthesis of safely operable process intensification systems. Herein, intensified designs are automatically generated by using phenomena-based Generalized Modular Representation Framework, while their safety and operability performances are guaranteed by incorporating: (i) flexibility analysis and multiperiod design, (ii) inherent safety analysis utilizing quantitative risk assessment, and (iii) multi-parametric model predictive control strategies developed via the PAROC framework. As an example from a broader set of intensified systems, the proposed framework is applied to heat exchanger network synthesis for thermal intensification, demonstrating its capability on enhancing safety and operability at early design stage.

Keywords: Process intensification, flexibility analysis, quantitative risk assessment, multi-parametric Model Predictive Control, heat exchanger network

1. Introduction

Modular process intensification provides opportunities for drastic process improvement to meet the increasing demands for sustainable production through the integration, or enhancement, of operations, functions, and phenomena (Lutze et al., 2010). However, these schemes are often highly integrated due to the maximization of synergy effects, thus resulting in a loss of degrees of freedom for safe operation and process control (Baldea, 2015). In recent years, despite increasing efforts towards a systematic synthesis strategy to generate novel intensified processes from phenomena level (Demirel et al., 2017), there is a lack of approach to simultaneously assess process operability, control,

and safety at the synthesis stage to ensure the expected functionality of the derived intensified structures under varying conditions.

To address the aforementioned challenges, this work introduces a systematic framework, which utilizes the phenomena-based Generalized Modular Representation Framework (GMF) to discover intensification opportunities from process fundamentals, and also embeds flexibility analysis, inherent safety analysis, and controller design to guarantee expected operability performance. The full framework (Figure 1a) and its detailed methodologies (Figure 1b) are described on a step-by-step basis in section 2. In section 3, the proposed framework is applied to a heat exchanger network (HEN) synthesis problem for thermal intensification.

2. Framework Description

As shown in Figure 1a, this framework comprises three interactive toolboxes (i.e., process intensification/synthesis toolbox, process simulation/optimization toolbox, and process operability/control/safety toolbox). Each toolbox is open to different techniques implemented in multiple software environments, thus rendering this framework a desirable flexibility and opening up the potential to deliver multiple design alternatives. By interconnecting steady-state synthesis, dynamic analysis, and operability assessment, this framework allows for the systematic identification of verifiable and operable process intensification designs. The stepwise procedure for this purpose and the techniques employed in the current work are described as follows (Figure 1b).

Step 1: Process Intensification/Synthesis Representation – The phenomenological representation of chemical processes is achieved via the Generalized Modular Representation Framework (Papalexandri and Pistikopoulos, 1996). Built on aggregated multifunctional mass/heat exchange modules and pure heat exchange modules, GMF discloses intensification possibilities by optimizing mass and heat transfer performances based on Gibbs free energy (Ismail et al., 2001).

Step 2: Process Optimization – A superstructure formulation is developed based on GMF without any pre-postulation of plausible unit operations or flowsheets. This results in a mixed integer nonlinear programming (MINLP) problem to be solved in GAMS.

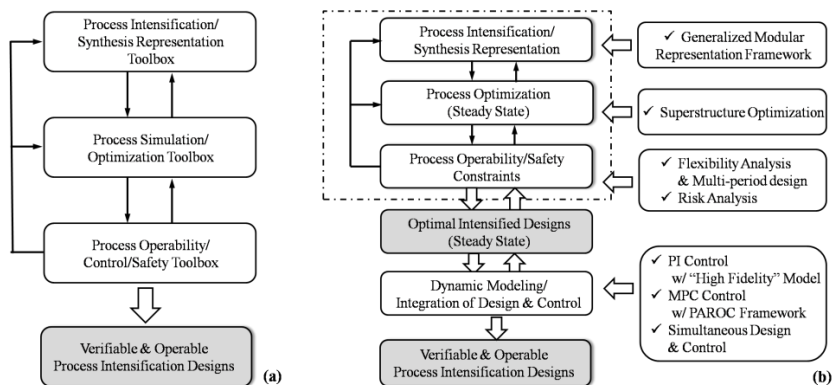

Figure 1. Proposed framework for the synthesis of operable intensification systems
(a) The systematic framework, (b) Methodology flow

Step 3: Process Operability/Safety Assessment – The initial design from previous steps is tested with feasibility analysis to evaluate system performance against uncertain parameters. If any critical operation point is detected, a multiperiod MINLP model is reformulated to accommodate uncertainty. Meanwhile, risk assessment (Nemet et al., 2017), which accounts for equipment failure frequency and consequence severity, is incorporated as a constraint into the synthesis model to derive inherently safer designs.

Step 4: Optimal Intensified Steady-state Designs – At the exit of Step 3, the derived intensified designs with enhanced flexibility and safety performance are fully analyzed with steady-state simulation tools.

Step 5: Dynamic Modelling/Integration of Design and Control – “High fidelity” dynamic models are then developed to validate the intensified designs. This task takes place in gPROMS® Process Systems Enterprise (1997-2017). Two approaches, with different computational complexity in control strategy and model fidelity, are investigated to integrate design and control via the formulation of a (mixed-integer) dynamic optimization (DO) problem, namely: (i) simultaneous design and PI control using “high fidelity” model, and (ii) multi-parametric model-based predictive controller (mp-MPC) design via the PAROC framework (Pistikopoulos et al., 2015) followed by a further simultaneous design and control step (Diangelakis et al., 2017).

Step 6: Verifiable and Operable Process Intensification Designs – Closed-loop validation is finally performed to ensure the consistency throughout the framework, after which verifiable and operable intensification designs are ready to be delivered.

3. Heat Exchanger Network Synthesis

As an example from a broader set of process intensification systems, the proposed framework is applied to a heat exchanger network synthesis problem for thermal intensification. The case study aims to demonstrate the steps of the proposed framework and its capability to incorporate operability assessment at synthesis stage.

3.1. Problem Description

This HEN problem to be addressed here considers two hot streams, two cold streams, and one hot utility. Given are: (i) stream flowrate data (Kotjabasakis and Linnhoff, 1987); (ii) uncertain heat transfer coefficients (U_{H1-C1}) within a specific range, which arouses flexibility concerns; (iii) disturbance and control objective, for which controller design is essential; and (iv) stream toxicity data (LC_{50}) and equipment data for four types of heat exchanger (HE), namely: double pipe HE (DP), plate and frame HE (PF), fixed plate shell and tube HE (SF), and U-tube shell and tube HE (UT), which necessitates inherent safety evaluation (Nemet et al., 2017). The objective is to synthesize a HEN with minimized total annual cost and desired operability.

3.2. Steady-state Synthesis with Flexibility and Safety Considerations

The superstructure-based optimization problem for steady-state HEN synthesis is formulated based on the pure heat exchange module representation in GMF. A nominal HEN design without flexibility or safety considerations is first performed to obtain a reference network (Figure 2a). Feasibility analysis identifies two periods of operation characterized by the extreme values of U_{H1-C1} . To obtain an inherently safer design, the overall HEN toxicity risk is constrained to be 25 % less than that of the nominal design.

This results in the change of H1-C2 exchanger type from SF to UT (Figure 2b), as UT has much higher area density to significantly reduce the amount of hazards contained in the equipment. However, as the individual risk of H1-C2 HE takes up more than 75 % of the overall process risk in this case, the risk tolerance is further decreased by constraining individual HE toxicity risk to be less than 50% of overall risk. As a result, a different network configuration is synthesized in order to render H1-C2 HE a lower risk level by relieving its heat exchange burden (Figure 2c). These two safely operable HENs are exported as Candidate 1 and 2 for the next dynamic analysis.

Figure 2. Topology of HEN at different operability level:
(a) Nominal design, (b) Candidate 1, (c) Candidate 2

3.3. "High Fidelity" Modelling and Dynamic Analysis

The dynamic HEN is described by a Partial Differential Algebraic Equation (PDAE) model based on gPROMS® Process Model Library for Heat Exchange (PSE, 1997-2017). To ensure the consistency between steady-state synthesis and dynamic simulation, the dynamic model is validated to match its steady-state synthesis analogue.

The controller design, as well as the simultaneous design and control, takes place for the two candidates individually under the schemes of PI control and mp-MPC control. In each case, the network configuration is fixed as per Figure 2b or 2c and heat exchanger areas are used as design variables. The bypass flowrate and the heat utility duties are the degrees of freedom, and the outlet temperature of stream H1 and C1 are the system outputs. The inlet temperature of stream H2 is treated as a disturbance to the operation. The dynamic optimization problem is formulated and solved to minimize the sum of the total annual cost and scaled deviation penalty, the latter term of which minimizes error with respect to controller design.

3.4. Design and PI Control Optimization

Decentralized PI control structure is implemented for operation. The pairing scheme is chosen based on the following HEN heuristics (Luyben, 2010): (i) manipulate utility stream flowrate to control a process temperature; and (ii) bypass the stream whose outlet temperature is to be controlled. With the selected control structure, DO is performed to optimize the design of the heat exchangers and the gains of the controllers using the "high fidelity" model. As the outcomes, the controller parameters are reported in Table 1, while the optimal design variables and costs are summarized in Table 2.

Table 1. PI controller configuration for HEN candidates

Candidate	Controller	K _p	K _i
1	Bypass	9481.6	5101.2
	Utility	9958.0	10000
2	Bypass	9647.2	5335.1
	Utility	10000	10000

3.5. Design and mp-MPC Control Optimization

The mp-MPC controller is designed following the PAROC framework (Pistikopoulos et al., 2015). Each mp-MPC problem is formulated using corresponding linear state-space model approximated by the System Identification Toolbox of MATLAB®. Via POP® toolbox in MATLAB®, the problem of Candidate 1 is solved for an output horizon of 2 and a control horizon of 2 resulting in 118 critical regions in solution map, while that of candidate 2 is solved for an output horizon of 2 and a control horizon of 1 resulting in 89 critical regions.

Given random disturbances deviating within ± 10 K per second, the designed controllers are tested against the “high fidelity” model but at fixed design configurations for closed-loop validation. With these validated mp-MPC controllers, the dynamic optimization step is implemented to determine the optimal design variables as shown in Table 2. The corresponding output profile at the optimal design configuration is shown in Figure 3, indicating the agreement between the outputs and setpoints.
