et al., 2012). Recently, ILs have become the potential entrainers used in the ED for difficult separations. However, The design and selection of the suitable ILs as entrainers is a significant topic especially when a systematic methodology is established one can reduce extensive experimental work and time consuming (Roughton et al., 2012). The objectives of this research are to further develop the systematic methodology for IL selection and design simulation of the best IL-based separation processes. The proposed methodology was tested and demonstrated on several applications: ethanol + water, ethanol + hexane, benzene + hexane, and toluene + methylcyclohexane.

2. Methodology

In order to get the best IL-based separation process, the systematic methodology in Figure 1 has been mainly designed into three stages; selection, verification, and comparison.

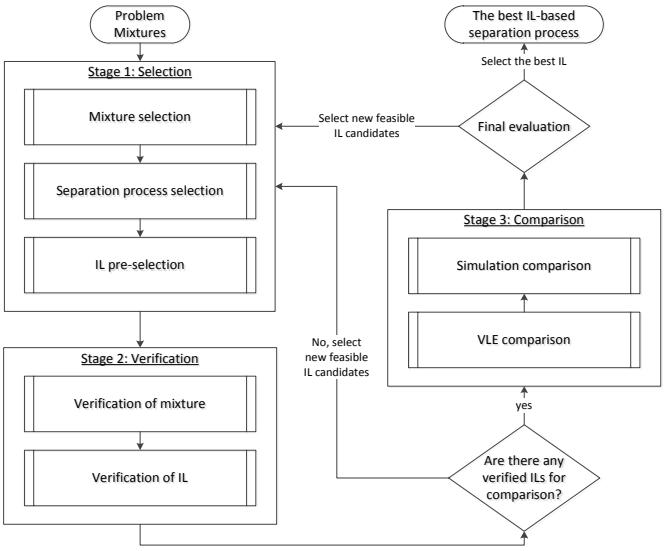

Fig. 1 the systematic methodology of IL-based separation processes

2.1. Stage 1: Selection

2.1.1. Mixture selection

Firstly, homogeneous binary problem mixtures are collected from literature databases and then classified the mixtures as two systems (e.g. aqueous or non-aqueous systems). The final lists are selected based on their wide usage in industry.

2.1.2. Separation process selection

Several alternative technologies of separation process can be performed but this work has been focused on ED because it is the most common and efficient separation process (Hernández, 2013).

2.1.3. IL pre-selection

The following parameters are used as criteria for screening of feasible ILs as entrainers in selected azeotropic systems: (1) Hildebrand solubility parameter (δ), (2) capacity (C_2^{∞}) in Equation 1, and (3) selectivity (S_{12}^{∞}) in Equation 2. The Hildebrand solubility

parameters of ILs (δ_{ILs}) are successfully calculated using the group contribution concepts (Roughton et al., 2012 and Kulajanpeng et al., 2014). The capacity (C_2^∞) and selectivity (S_{12}^∞) are calculated from the activity coefficient at infinite dilution at 298 K of every component in the mixture (e.g. γ_1^∞ and γ_2^∞). Two vertical lines shown in Figure 2 represent the Hildebrand solubility parameters of the each solute in the mixture (e.g. $\delta_{solute1}$ and $\delta_{solute2}$). Hence, One line is selected to be the target solute (e.g. $\delta_{solute1}$) and further calculated the capacity (C_2^∞) and selectivity (S_{12}^∞) of feasible ILs in the target solute. The calculated Hildebrand solubility parameters of feasible ILs are plotted in the *x-axis* against the capacity (C_2^∞) and selectivity (S_{12}^∞) in the primary and secondary *y-axis*, respectively. An example of these plots is illustrated in Figure 2.

$$C_2^\infty = 1/\gamma_2^\infty \quad \text{(Eq.1)}$$

$$S_{12}^\infty = \gamma_1^\infty / \gamma_2^\infty \quad \text{(Eq.2)}$$

The feasible IL candidates were selected based on the closest to the Hildebrand solubility parameter (δ) of the target solute (i.e. shaded area in the vicinity of $\delta_{solute1}$ shown in Figure 2). Beyond that, these feasible IL candidates should have both high capacity (i.e. ~0.5-1.5) and high selectivity (i.e. ~5-15). However, the minimum and maximum ranges of the capacity and selectivity are reasonably flexible to change depending on the availability of ILs in the database.

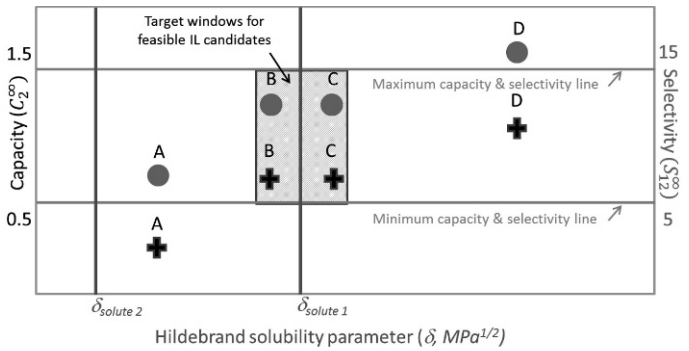

Fig. 2 IL pre-selection graph: ✚ and ● represent the capacity (primary *y-axis*) and selectivity (secondary *y-axis*) of feasible ILs in target solute.

2.2. Stage 2: Verification

2.2.1. Verification of mixture

A vapor-liquid equilibrium (VLE) graph is plotted using the ICAS program to find out the composition of azeotrope. The solute with less concentration at azeotrope is tentatively selected i.e. ethanol is the target solute in the ethanol + hexane azeotrope since the amount of ethanol is ~21 % mol at azeotrope. Two graphs of vapor pressure and heat of vaporization from ProPred program are plotted to verify whether the target solute plus ILs are the bottom product in the ED column.

2.2.2. Verification of IL

Since IL properties are not available in any commercial chemical database, the predictive equations proposed by Valderrama (2012) are employed to calculate the

critical properties. Next, VLE graph of the target azeotrope with the addition of IL as entrainer is generated using non-random two liquid model (NRTL) binary parameters from experimental data of each feasible IL candidate in IL pre-selection step to ensure the capability for breaking the azeotrope or increasing the relative volatility of the mixtures.

2.3. Stage 3: Comparison

2.3.1. VLE comparison

The VLE graphs from verification of IL step are compared each other at the same concentration of ILs to observe the most capable IL for breaking the azeotrope or increasing the relative volatility of the mixture as the best IL. However, the final evaluation of the best IL is considered in advance along with simulation comparison.

2.3.2. Simulation comparison

In order to get the best IL-based separation process in the final evaluation, ProII software is employed to simulate the separation process and design other parameters especially the energy requirement and solvent usage based on the minimum values as compared to the conventional organic solvent process.

3. Results and Discussion

The proposed methodology was demonstrated through several case studies: ethanol + water, ethanol + hexane, benzene + hexane, and toluene + methylcyclohexane mixtures to ensure the viability. The summarized results are expressed in Table 1.

Table 1 the summarized results from each stage of the systematic methodology

Stage 1: Selection				
Mixture selection	Aqeueous system Ethanol + Water (organic solvent: EG)	Non-aqueous system Ethanol + Hexane (organic solvent: sulfolane)	Non-aqueous system Benzene + Hexane (organic solvent: NMP)	Non-aqueous system Toluene + MCH (organic solvent: NMP)
Separation process selection	ED	ED	ED	ED
IL pre-selection	Target window: capacity (2-12), selectivity (1-6) and solubility (23-46 $MPa^{1/2}$)	Target window: capacity (0.5-1.5), selectivity (5-15) and solubility (23-31 $MPa^{1/2}$)	Target window: capacity (0.3-2.1), selectivity (6-42) and solubility (18-28 $MPa^{1/2}$)	Target window: capacity (0.5-1.5), selectivity (5-15) and solubility (18-28 $MPa^{1/2}$)
	Feasible IL candidates: 9 ILs	Feasible IL candidates: 8 ILs	Feasible IL candidates: 34 ILs	Feasible IL candidates: 11 ILs
Stage 2: Verification				
Verification of mixture	Azeotrpic mixture□ (target solute: water)	Azeotrpic mixture□ (target solute: ethanol)	Azeotrpic mixture□ (target solute: benzene)	Close-boiling mixture□ (target solute: toluene)
Verification of IL	Verified ILs for comparison: 3 ILs ([mmim][dmp], [emim][N(CN)2], and [emim][etso4])	Verified ILs for comparison: 2 ILs ([emim][bti] and [bmim][bti])	Verified ILs for comparison: 2 ILs ([emim][bti] and [emim][etso4])	Verified ILs for comparison: 2 ILs ([hmim][bti] and [hmim][tcb])
Stage 3: Comparison				
VLE comparison	Capability for increasing relative volatility: [mmim][dmp] > [emim][N(CN)2] ≈ [emim][etso4]	Capability for increasing relative volatility: [emim][bti] > [bmim][bti]	Capability for increasing relative volatility: [emim][etso4] > [emim][bti]	Capability for increasing relative volatility: [hmim][tcb] > [hmim][bti]
Simulation comparison	Target purity (%mol): ethanol (99.8) and water (99.6)	Target purity (%mol): hexane (99.8) and ethanol (99.9)	Target purity (%mol): hexane (99.7) and benzene (99.9)	Target purity (%mol): MCH (99.5) and toluene (99.9)
	Energy requirement (MW): [mmim][dmp] (5.39) < [emim][etso4] (5.66) < [emim][N(CN)2] (6.02) EG (6.33)	Energy requirement (MW): [emim][bti] (45.60) < [bmim][bti] (49.50) < sulfolane (60.50)	Energy requirement (MW): [emim][etso4] (23.30) < NMP (25.60) < [emim][bti] (30.00)	Energy requirement (MW): [hmim][tcb] (35.52) < NMP (37.30) < [hmim][bti] (66.79)
	Solvent usage (kmol/hr): [mmim][dmp] (40) < [emim][etso4] (60) < [emim][N(CN)2] (90) < EG (210)	Solvent usage (kmol/hr): [emim][bti] ≈ [bmim][bti] (400) < sulfolane (1500)	Solvent usage (kmol/hr): [emim][etso4] (400) < NMP (1200) < [emim][bti] (1300)	Solvent usage (kmol/hr): [hmim][tcb] (250) < NMP (1370) < [hmim][bti] (2600)
Final evalution (the best IL)	[mmim][dmp]	[emim][bti]	[emim][etso4]	[hmim][tcb]

3.1. Stage 1: Selection

3.1.1. Mixture selection

From several homogeneous binary problem mixtures, they could be divided into two main systems; aqueous and non-aqueous systems. Based on industrial applications, the

following problem mixtures were selected in this study. For aqueous system, ethanol + water were represented. Non-aqueous system composed of alcohol + aliphatic hydrocarbons (e.g. ethanol + hexane), aromatic + aliphatic hydrocarbons (e.g. benzene + hexane), and aromatic + cyclic hydrocarbons (e.g. toluene + methylcyclohexane).

3.1.2. Separation process selection

All selected mixtures were employed in IL-based ED.

3.1.3. IL pre-selection

A system of ethanol + hexane azeotrope was employed as an example in this step. Figure 3 illustrates the Hildebrand solubility parameter versus the capacity and selectivity of ILs in ethanol as the target solute. The target windows of feasible IL candidates are highlighted. Only 8 feasible IL candidates were selected for the ethanol + hexane mixture.

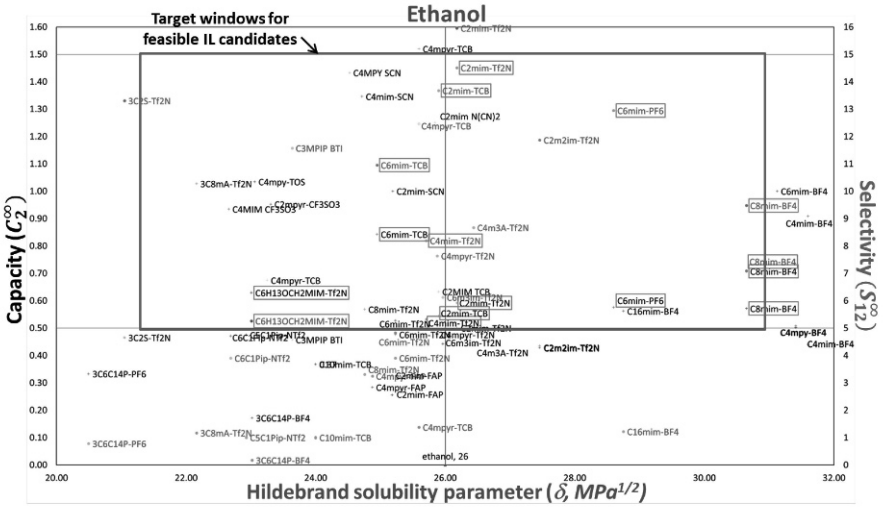

Fig. 3 Hildebrand solubility parameter of ILs vs Capacity and selectivity of ILs in ethanol for ethanol + hexane mixture.

3.2. Stage 2: Verification

3.2.1. Verification of mixture

In ethanol + hexane mixture, the mixture behavior showed ~21 % mol of ethanol at azeotrope and ethanol was guaranteed to select as the target solute due to (1) its lower vapor pressure and higher heat of vaporization than hexane, confirming that ethanol is present as the bottom product in the ED; (2) its lower concentration at azeotrope, i.e. easier to extract ethanol since smaller quantity is present at azeotrope. For other mixtures, the target solutes are water, benzene and toluene of ethanol + water, benzene + hexane, and toluene + methylcyclohexane, respectively.

3.2.2. Verification of IL

After confirming the breaking of azeotropic mixture through VLE plots, the following ILs for each system were selected. For aqueous system, 3 suitable IL candidates were [mmim][dmp], [emim][N(CN)2], and [emim][etso4]. Due to limitation in availability of the NRTL binary parameters from experimental data in several literatures of feasible IL candidates in non-aqueous systems, only 2 suitable IL candidates of each system were found: [emim][bti] and [bmim][bti] for ethanol + hexane mixture, [bmim][tcb] and

[hmim][tcb] for toluene + methylcyclohexane mixture, and [emim][etso4] and [emim][bti] for benzene + hexane mixture.

3.3. Stage 3: Comparison

3.3.1. VLE comparison

At the same concentration, for instance, 30 % mol of ILs, [mmim][dmp] was the best IL for ethanol + water mixture. For ethanol + hexane mixture, [emim][bti] was better than other ILs, whereas [emim][etso4] could perfectly break the azeotrope of benzene + hexane mixture. In addition, [hmim][tcb] was the most efficient IL to increase the relative volatility in toluene + methylcyclohexane mixture.

3.3.2. Simulation comparison

According to Table 1, the best IL candidate of each system as screened required the lowest both energy requirement and solvent usage. Moreover, they performed better than the conventional organic solvent processes.

4. Conclusions

The proposed systematic screening methodology has been successfully demonstrated for one aqueous system (e.g. ethanol + water) and three non-aqueous systems (e.g. ethanol + hexane, benzene + hexane, and toluene + methylcyclohexane). All results showed that the best IL of each azeotropic mixture gave a lower energy requirement while using less solvent usage as compared to the conventional organic solvent processes.

Abbreviations of ILs and conventional organic solvents

[mmim][dmp]	1-methyl-3-methylimidazolium dimethylphosphate
[emim][$N(CN)_2$]	1-ethyl-3-methylimidazolium dicyanamide
[emim][etso4]	1-ethyl-3-methylimidazolium ethylsulfate
[emim][bti]	1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide
[bmim][bti]	1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide
[hmim][bti]	1-hexyl-3- methylimidazolium bis(trifluoromethylsulfonyl)imide
[hmim][tcb]	1-hexyl-3-methylimidazolium tetracyanoborate
EG	Ethylene glycol
MCH	Methylcyclohexane
NMP	N-methyl-2-pyrrolidone

Abstract

The production of biofuels must be economically and ecologically viable, in particular due to the competition with existing mature fossil-based fuels. There are many alternative products and pathways to generate biofuels. Hence, focusing on the most promising products and process alternatives requires identification of corresponding pathways from biomass to biofuel candidates using scarce data of high uncertainty. This contribution presents a methodology for i) process evaluation of fermentation and downstream processing (DP) in terms of costs and primary energy demand (PED) as main sustainability criteria and ii) identification of the most promising platform chemicals gained by fermentation for a biofuel production. The methodology considers the energy requirement already at an early design stage bridging the gap between performance screenings solely based on reaction stoichiometry and time-consuming process design, enabling an early process analysis, detection of bottlenecks and ranking of various processes. The focus herein is on lignocellulosic biomass.

Keywords: screening methodology, process performance, platform chemical, biofuels

1. Motivation

With the increasing relevance of sustainability and the desired raw material change from fossil towards renewable sources, a high number of potential processes for the production of biofuels have been proposed. The most prominent ranking of products was already published in 2004 by the US Department of Energy (Werpy and Petersen, 2004) considering chemically as well as biochemically gained molecules synthesized from biomass. The evaluation criteria comprised the number of related publications, possible applications and technical barriers. Recently, Bomgardner et al. (2014) ranked the products according to their probability of soon entering the market and identified succinic, fumaric and malic acid as the most promising platform chemicals from biomass. In contrast to these market studies, Klein-Marcuschamer et al. (2013) proposed a first framework for the selection of fermentation products according to their yield and productivity and the resulting raw material and investment cost identifying ethanol and butanol as superior fermentation products.

A selection of the most promising processes and products to guide future research is clearly mandatory. The potential of the process ideas is usually evaluated using a conceptual process design. However, a full conceptual process design for a varying feedstock composition and for all different processing possibilities faces a lack of data

and is usually too expensive for screening purposes. Consequently, process designs only exist for a few processing pathways starting from very specific raw materials. These designs are mostly evaluated according to their primary energy demand (PED) or global warming potential (Caspeta et al., 2013). Both parameters are based on the process energy requirement and indicate the sustainability of a process.
Bridging the gap between first rankings and time-consuming conceptual process design, this contribution presents for the first time a comprehensive evaluation of the process performance for fermentative products as future platform chemicals for biofuels. For these early-stage design decisions Reaction Network Flux Analysis (RNFA) has been developed as a rapid screening methodology to identify optimal processing pathways based on the reaction stoichiometry (Voll and Marquardt, 2012). Up to now, the process energy requirement was not explicitly addressed, hence neglecting one of the most important metrics for process and sustainability analysis. In this contribution, the RNFA methodology is extended to include the process energy requirement. This is illustrated for the example of fermentation products and the required downstream processing (DP).

2. Methodology

In a first step, the potential of the fermentative products as future platform chemicals for a biofuel production is analyzed by comparing the raw material costs resulting from the highest yield reported in literature with the raw material costs based on the theoretical maximum. In a second step, the PED, and the minimum production costs (MPC) are calculated and benchmarked to existing fuels. The comparison is done per unit enthalpy of combustion of the product (as opposed to per unit mass or volume) due to the envisaged production of biofuels where the energy content of the fuel is the most important criterion. The results of the case study are presented in Section 3 identifying the most promising fermentative products for a subsequent biofuel production. All calculations are executed using Matlab.

2.1. Analysis of process potential based on a comparison between literature and theoretical yield

Directed evolution or genetic engineering can improve selectivity and conversion rate of microorganisms. As raw materials are typically the main cost-driver in the production of bulk chemicals and fuels, the yield is a key parameter for viable processing. Any improvement is however limited by the theoretical yield due to the overall stoichiometry of the fermentation. In order to establish a robust ranking, both the theoretical yield and the maximum yield reported in literature are used. This reveals both the actual research status and any future improvement potential. The maximum yield reported in literature is then benchmarked to the theoretical yield by calculating the resulting raw material costs to provide unit energy. The raw material costs c_R are calculated by

$$c_R \left[\frac{\$}{MJ}\right] = \frac{c_{sugar}}{Y \cdot h_{comb}} \tag{1}$$

with a sugar price c_{sugar} of 0.33 \$/kg (Viell et al., 2013), the yield Y (theoretical or reported maximum) of the fermentations and the enthalpy of combustion h_{comb}. By comparing the raw material costs to E10 as a state-of-the-art fuel with an average price in Germany of 0.625 \$/l without taxes (Sommer, 2014), the potential of the fermentation products as future platform chemical for the production of biofuels is determined.

2.2. Process energy requirement

The PED is based on the energy requirement for fermentation as well as for DP. For a low specific energy requirement, a high yield, productivity and titer are required. By changing the operating conditions during fermentation, e.g., by altering the stirrer speed or aeration rate, an improvement of the yield or the productivity (space time yield) is possible. However, typically there is a tradeoff between these two important metrics. Moreover, the conditions for minimal energy requirement per unit product are difficult to identify. Hence, herein different fermentation strategies are analyzed for each product, first the strategy with the highest reported yield in literature (dataset I) and second the highest productivity (dataset II). An additional key parameter is the titer of the product in the fermentation broth. A lower titer at shorter fermentation time gives a lower energy demand of the fermentation. Conversely, the lower titer increases the separation effort.

The electricity requirement for agitation and aeration during fermentation is based on a value of 0.5 $\mathrm{kW/m^3}$ for anaerobic and 3 $\mathrm{kW/m^3}$ for aerobic fermentations (Hermann and Patel, 2007). For DP, a binary mixture of the fermentation product and water is considered representative of the minimum energy requirement of the separation. In this first assessment, evaporation and distillation are applied for DP since they are established technologies. Evaporation is considered if the products exhibit a higher melting point than the boiling point of water. In the other cases, the energy demand for distillation is estimated by computing the minimum energy requirement using the rectification-body-method by Bausa et al. (1998) for a simple distillation or pressure-swing distillation in case of azeotropes. The PED is then calculated as

$$PED = \frac{f_P \cdot E_{Elec} + f_Q \cdot E_{Heat}}{\dot{m}_{product} \cdot h_{comb,product}}. \quad (2)$$

It considers the product mass flow $\dot{m}_{product}$, the electricity requirement E_{Elec} for fermentation with a fermenter volume set to 5000 m³, as well as the heating requirement E_{Heat} for DP and primary energy factors $f_P = 2.5$ for electricity generation and $f_Q = 1.1$ for steam production.

2.3. Cost evaluation of fermentation processes

For a final selection of platform molecules for an envisaged biofuel production, the MPC is determined and again benchmarked to the price for E10. For reasons of simplicity, only the fermentation routes with the lowest overall PED are herein considered. The MPC consists of the investment cost for the fermenter, the raw material costs as well as the utility costs for fermentation and DP. The investment costs are estimated using the values given by Kumar et al. (2012). The raw material costs are based on the yield (cf. Section 2.1), while the utility costs for heat and electricity are assessed using the demand calculated above (cf. Eq.(2)). Hence the MPC considers the overall process performance based on these early design criteria, often available already at lab-scale. The price of electricity and steam is 0.07 \$/kWh and 0.036 \$/kWh, respectively (Viell et al., 2013).

3. Case Study

A set of 10 fermentation products is analyzed including alcohols as well as various carboxylic acids. The molecules are benchmarked to ethanol and E10 as state-of-the-art fuel and finally ranked as future platform chemical for the production of biofuels.

3.1. Potential analysis of fermentative products

In Figure 1, the raw material costs resulting from the maximum reported and theoretical yield are depicted. The actual market price of E10 is indicated as dashed line. While the worst performance is shown by 3-hydroxypropionic acid (3-HPA), the lowest costs can be observed with ethanol, 2,3-butanediol, 1,3-propanediol, succinic and lactic acid, all achieving a yield equal or very close to the theoretical maximum. Interestingly, 1,3-propanediol seems to offer the largest potential for further improvement of the fermentation yield. While ethanol is already a promising fuel candidate, the other four are only platform molecules requiring a subsequent conversion into biofuels, which might be competitive if high yields are achieved. The production of biofuels could become even more interesting when being produced from cheaper raw materials. Therefore, sugar prices lower than 0.33 $/kg are mandatory for a viable production of future biofuels.

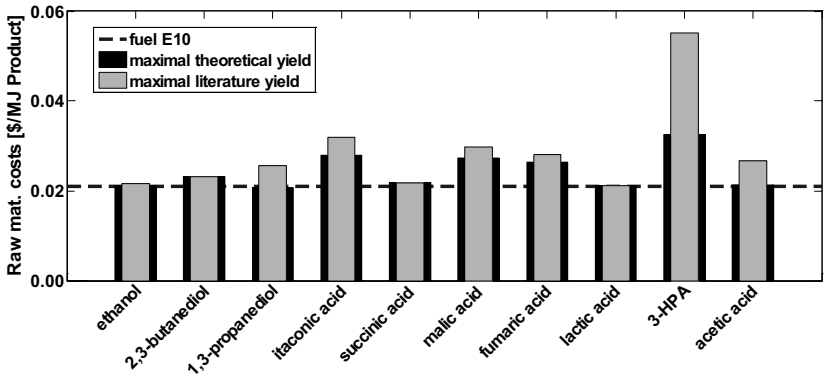

Figure 1: Analysis of process potential of fermentation products according to the reported yield in literature and the theoretical yield.

3.2. Primary energy demand of fermentative products

The PED for fermentation and DP is presented in Figure 2, comparing the performance of the fermentation strategies with the highest yield (wide bars) as well as the highest productivity (narrow bars). The figures are based on evaporation of water after fermentation, if the products are marked with a star. Distillation is applied for the unmarked ones except ethanol and acetic acid that form an azeotrope with water and were separated by pressure swing distillation.

While the worst performance is observed in the case of acetic acid, the lowest total PED is calculated for the fermentation of ethanol, 2,3-butanediol, 1,3-propanediol and lactic acid. Remarkably, all of these four fermentations have a productivity of at least 1.8 g/l/h and titers higher than 110 g/L.

In most cases, the operating conditions corresponding to highest productivity show a lower PED compared to the conditions corresponding to maximum yield. This is caused by the dominating energy factor for electricity. The only exception is succinic acid. The PED of 2,3-butanediol and 3-HPA at maximum yield differs by an order-of-magnitude in comparison to the value for maximum productivity rendering an application as a fuel precursor prohibitive.

While the resulting ranking is similar to Section 3.1, an analysis of the medium performing fermentations reveals an improvement of the productivity in case of itaconic

and malic acid and an increase of the titer for succinic, fumaric, acetic and 3-HPA as the key factors for increasing the competitiveness to ethanol. The improvement of the titer comes along with a reduction of the energy demand in DP. While evaporation and distillation are the most common unit operations in industry, further methodological work is necessary for a fast assessment of additional DP options such as heat integration measures, crystallization or extraction.

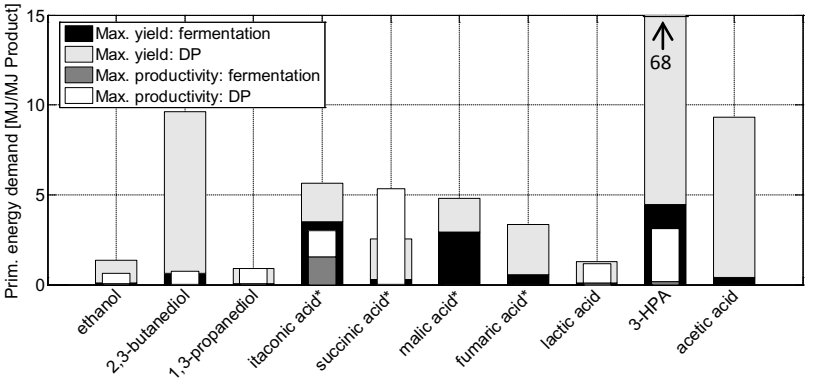

Figure 2: Primary energy demand of fermentation and downstream processing. In case of malic, fumaric and acetic acid the dataset for maximum productivity equals the one for maximum yield.

3.3. Cost performance of fermentation products

A comprehensive cost analysis is shown in Figure 3 revealing the influence of the investment, raw material and utility costs to the overall costs for each product. In addition, the benchmark of E10 is shown as dashed line. Only the best performing fermentation strategies identified in Section 3.2 are considered in this step.

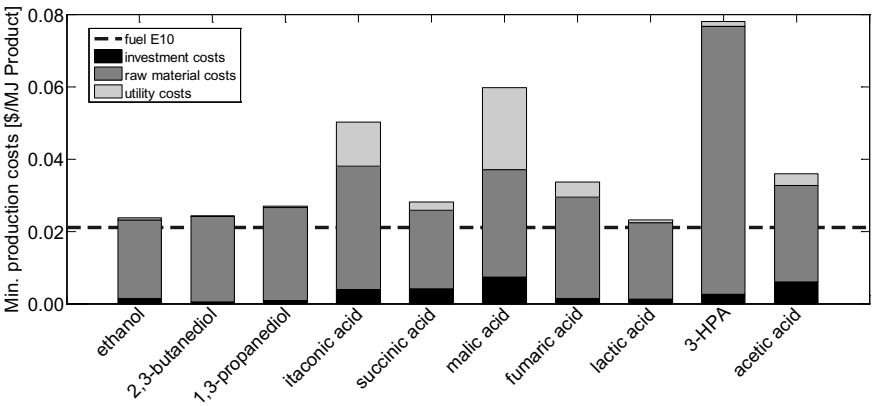

Figure 3: MPC of fermentation products considering only datasets with a lower PED.

The processes for ethanol, 2,3-butanediol, 1,3-propanediol, succinic and lactic acid show again the lowest MPC, which is in line with the ranking in Section 3.1. These similar results are due to the high contribution of the raw material costs to the total costs. The investment costs only play a minor role and the contribution is only relevant for fermentations with a low productivity or aerobic fermentations. In comparison with

E10 the overall difficulty of producing competitive biofuels is obvious, which can only be overcome by using cheap raw materials gained from high yield biomass pretreatment processes with a low PED and capital costs.

4. Summary and conclusion

In this contribution, a methodology is presented for a fast evaluation of fermentation processes at an early conceptual design phase. The methodology consists of an analysis by benchmarking the literature yield to the theoretical maximum and comparing the fermentation product to E10 as a state-of-the-art fuel. The comparison identified the need for raw material prices lower than 0.33 $ per kg of sugar in order to make biofuels competitive with existing fuels. In a second step, the PED of the production is estimated by considering the energy demand of the fermentation and product recovery by evaporation or distillation. In general, an acceptable energy demand requires a titer larger than 110 g/L and a productivity of at least 1.8 g/L/h. Finally, a comprehensive cost evaluation of the processes emphasizes the need for cheap raw materials and low PED. The most promising fermentation products in all analysis steps are ethanol, 2,3-butanediol, 1,3-propanediol, succinic and lactic acid. The methodology proves to be a fast and thorough evaluation of processes based on minimal information, but already considering the process energy requirement at this early design stage and hence identifying bottlenecks and key parameters for future improvement.

5. Acknowledgements

This work was performed as part of the Cluster of Excellence “Tailor-Made Fuels from Biomass”, which is funded by the Excellence Initiative by the German federal and state governments to promote science and research at German Universities. In addition the authors like to gratefully acknowledge Mirko Skiborowski for support with the rectification-body-method.

Abstract

In this this paper, we use mechanistic modelling to guide the development of a continuous enzymatic process that is performed as a fed-batch operation. In this work we use the enzymatic biodiesel process as a case study. A mechanistic model developed in our previous work was used to determine the reactor operating conditions for a desired conversion. However, in using a detailed mechanistic model, given the large number of parameters and few experimental data points, the parameters were found not identifiable. The model is then only applicable within the limited operating range for which the model was validated. We hypothesize that fitting this model to fed-batch and continuous stirred tank reactor (CSTR) data together will enable us to use the model for determination of residence times to reach a specified conversion in a CSTR. With this approach, the model fits the experimental data for the five measured components (triglycerides, diglycerides, monoglycerides, free fatty acid and fatty acid methyl esters (biodiesel)) much better than using fed-batch data alone given the smaller residuals. We also observe a reduction in the correlation between the parameters.
The model was then used to predict that 5 reactors are required (with a combined residence time of 30 hours) to reach a final biodiesel concentration within 2 % of the 95.6 mass % achieved in a fed-batch operation, for 24 hours.

Keywords: Process modelling, Parameter estimation, Enzymatic Biodiesel

1. Background

When using a liquid lipase as a biocatalyst for biodiesel production by transesterification, the reaction is conventionally performed in fed-batch operation with respect to methanol to minimize inhibition and deactivation of the biocatalyst (Nordblad et al. 2014). The main disadvantage of fed-batch operation is the downtime between batches. Continuous operation will afford many advantages, such as, steady state operation, smaller reactors which mean that higher mixing rates are possible and easier handling of cheaper, high melting point substrates. However, it is unclear how the continuous enzymatic biodiesel process needs to be designed and operated to ensure optimal economics. The use of conventional Levenspiel plots is an easy and effective way for sizing continuous reactors based on batch reaction data (Levenspiel 1999). Under certain conditions fed-batch data can also be used to guide reactor sizing for other reactor configurations, provided that the rate of change in the reactor volume is substantially smaller than the initial reactor volume. However, Levenspiel plots are only valid for one reaction trajectory and are not an optimization tool. This makes the mechanistic modelling approach quite attractive. The downside to a detailed mechanistic model for a biocatalytic process is that, given the large number of

parameters and the often limited experimental data points, the parameters found are not identifiable. The model is then only applicable within the operating range for which it was validated (Vasić-Rački et al. 2011). In such cases, the non-identifiable parameters may be fixed, while the others are estimated, resulting in reasonable parameter values rather than "true parameter values" (Brun et al. 2002).

To aid in the model calibration, we follow a modelling work flow based on the work by Heitzig et al. (2011). The methodology is based on the concept of decomposing the modelling work into a sequence of modelling tasks and the associated methods, tools and data needed to perform such tasks. What we add to the work flow is the use of differences in the mass balance of the system (different modes of operation between fed-batch and CSTR operation) to aid in the model fitting process. The developed mechanistic kinetic model from our previous work describing the transesterification reaction is used to evaluate the feasibility of a continuous process using a soluble lipase formulation (Price et al. 2014).

2. Modelling workflow

What we add to the modelling workflow of Heitzig et al. (2011) is illustrated in Figure 1. When acquiring the experimental data in step one of the modelling workflow, the reaction is carried out using different modes of operation (e.g. running as fed-batch then switching to CSTR operation) to aid in the model development step where the parameter estimation is performed.

We use the model developed in our previous work describing the transesterification reaction using a liquid lipase, Callera™ Trans L to evaluate the feasibility of a continuous process using a soluble lipase formulation (Price et al. 2014). As part of the statistical analysis, in this work, we will only focus on the parameter confidence intervals and cross correlation.

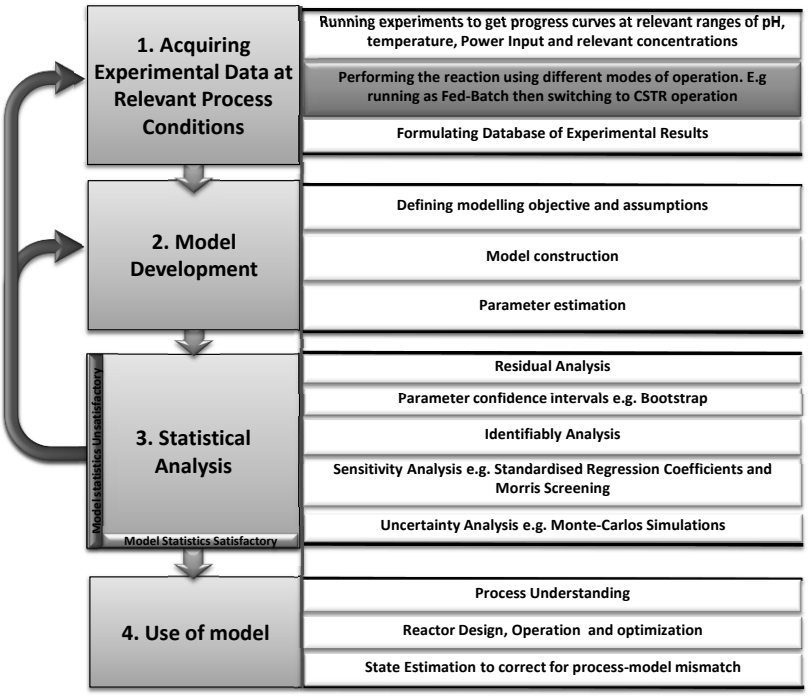

Figure 1 Work flow in the model development for the reaction system

3. Experimental Methods

Information on the chemicals, biocatalyst and analytical method used in this work can be found in Price et al. (2014). In the following sections we present the experimental setup and procedure.

3.1. Experimental Setup

The reaction was carried out in a 2.5 L glass reactor with a tank diameter of 12 cm (T) and 5 baffles, each 0.1×T wide. Two Rushton turbines (impeller diameter 0.42 T), spinning at 515 rpm provided the mixing (power input approximately 0.6 W/L). Temperature control in the reactor was maintained at 35 °C (DT Hetotherm, Apeldoorn, Netherlands). The substrates were fed to the reactor using a KNF STEPDOS .03 pump (KNF Neuberger AB, Stockholm, Sweden), calibrated prior to each experiment. Where the oil, water-enzyme solution and methanol each had their own pump.

3.2. Fed-batch into CSTR Experiment (Fitting and model evaluation dataset)

The reactor was charged with 1980 g of rapeseed oil and 0.525 equivalents (eq.) methanol based on the oil in the reactor. One equivalent corresponds to the stoichiometric amount of alcohol needed to convert all fatty acid residues in the oil to biodiesel (i.e. 1 mol oil : 3 mol alcohol). When the reaction mixture reached the reaction temperature, the reaction was then started as a fed-batch operation. The amount of water (5 wt%) and enzyme (0.5 wt %), was then added to the reactor and methanol feeding started (0.152 eq./hr). After 2 hours and 20 minutes the outlet of the reactor was opened (switched to CSTR operation) and the flow rate of oil (7.52 mL/min), water-enzyme solution (0.41 mL/min) and methanol (0.47 mL/min or 1.5 eq./hr) to be used in the experiment, was then continuously added to the reactors with a resulting residence time of 5 hours. After steady state was reached, a step change in the methanol feed rate from 1.5 eq./hr to 3 eq./hr (based on the feed rate of oil to the reactor) was made. The reaction progress was then monitored until a new steady state was achieved.

4. Numerical Methods

4.1. Model calibration

The 20 unknown kinetic constants (k_1-k_{10},k_{-1}-k_{-10}), were estimated by fitting the model equations with the experimental data for the fed-batch part of the reaction (first 2 hrs and 20 min of the reaction) and the initial CSTR part of the reaction where the methanol feed rate was 1.5 eq./hr.

4.2. Model evaluation

To judge the quality of the fitting, the second part of the CSTR reaction where the methanol feed rate was changed to 3 eq./hr was used.

4.3. Parameter estimation and confidence intervals

The differential equations were solved using a stiff variable order solver based on numerical differentiation formulas (*ode15s*). For the parameter fitting, the squared-sum of the relative errors between the simulated and experimental values for triglycerides (TAGs), diglycerides (DAGs) , monoglycerides (MAGs), free fatty acids (FFAs), and fatty acid methyl esters (FAME) were minimized using *fminsearch* (based on a simplex search algorithm). Using the bootstrap method, 5,000 samples were used to estimate the confidence interval of the parameter, where the mean of the distribution is used as the mean parameter estimate. The 95^{th} and 5^{th} percentiles of the re-estimated parameters were then used as the upper and lower bounds of the parameter estimates, respectively (Joshi et al. 2006).

5. Results and discussion

5.1. Parameter estimates and confidence intervals of the parameters

The model captures the dynamics for the five components over the entire course of the reaction for the three different stages of the reaction as seen in Figure 2. The simulation using the previously obtained kinetic constants (fitted only to fed-batch data) from our previous work is also shown (Price et al. 2014). The combined fed-batch and CSTR experiment fitting has much smaller residuals compared to the previous kinetic constants for all the measured components. The model qualitatively follows the model evaluation part of the dataset (after 19.5 hours) and gives good predictions for the endpoint value compared to using the previous kinetic constants. This is important to note given that being able to predict the concentration of the acylglycerides and FFA at the end of the reaction is just as crucial as the FAME concentration given that a product specification has to be met. It should also be noted (results not shown) that the newly determined kinetic constants also fits the fed-batch validation dataset (biodiesel conversion over 90%) from our previous work (Price et al. 2014). Also, an interesting observation is that a reasonably good fitting is obtained (residuals on the same order of magnitude of the experimental error) by the fitting of the fed-batch into CSTR experiment which required much less data (one experiment, 240 data points) compared to the previous fitting (eight fed-batch experiments, 580 data points (Price et al. 2014)).

As part of the methodology, statistical analysis of the parameter estimates is essential. The parameter estimates and confidence intervals are shown in Table 1. Most of the parameters have quite reasonable confidence intervals except for the inhibition constants (k_{10} and k_{-10}) whose range compared to the mean parameter estimate is over 100%. What is observed is that the strong correlation between most of the parameters have been reduced (between ±0.65) compared to the correlation for the parameter estimates in our previous work (a correlation coefficient of ±0.75 was used to signify strongly correlated parameters) (Price et al. 2014). Usually to arrive at better parameter estimates and reduce correlation between parameters various experiments are performed at different experimental conditions (e.g. variance in enzyme and methanol concentrations). To our knowledge this is the first time that it is shown that by using differences in the reactor mass balance (fed-batch into CSTR operation) that the

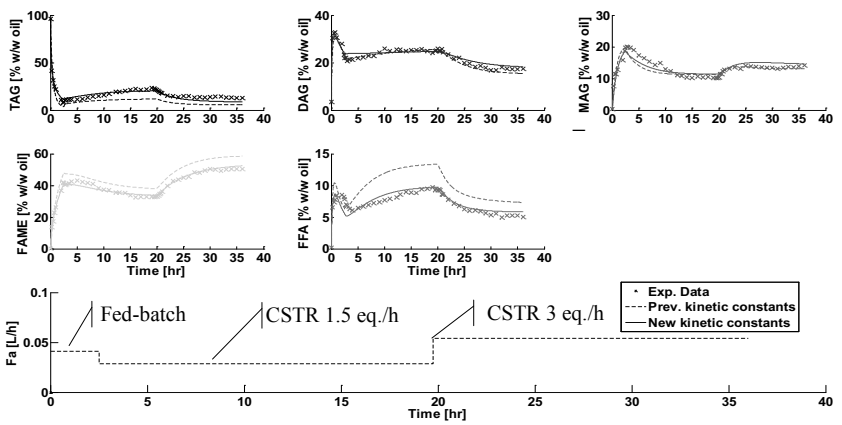

Figure 2 Comparison of the previously reported kinetic constants to the new kinetic constants for the fitting of the combined fed-batch and CSTR experimental data. Switching from fed-batch to CSTR operation can be seen on the methanol flowrate (F_a) plot

Table 1 Mean Parameter estimates and confidence intervals from the 5000 bootstrap samples

Parameter	Mean Estimate	Confidence Intervals	
		Lower	Upper
k_1 [L/mol.min]	1.32×10^5	1.14×10^5	1.43×10^5

k_{-4} [1/ min]	7.10×10^5	6.74×10^5	7.86×10^5
k_5 [1/ min]	4.21×10^4	3.95×10^4	4.75×10^4
k_{-5} [L/mol. min]	1.42×10^6	1.24×10^6	1.59×10^6
k_6 [L/mol. min]	4.39×10^4	3.93×10^4	4.64×10^4
k_{-6} [1/min]	1.02×10^7	9.09×10^6	1.11×10^7
k_7 [L/mol. min]	4.14×10^6	3.95×10^6	4.37×10^6
k_{-7} [L/mol.min]	2.91×10^0	2.74×10^0	2.96×10^0
k_8 [L/mol.min]	1.39×10^5	1.26×10^5	1.58×10^5
k_{-8} [L/mol.min]	3.62×10^5	3.28×10^5	3.83×10^5
k_9 [L/mol.min]	3.29×10^5	3.08×10^5	3.75×10^5
k_{-9} [L/mol.min]	4.61×10^4	4.33×10^4	5.14×10^4
k_{10} [L/mol.min]	2.73×10^3	1.51×10^3	7.94×10^3
k_{-10} [1/min]	3.07×10^5	2.47×10^4	4.06×10^5

correlation between the parameters can be reduced.

5.2. Reactor simulations

Number of CSTR's and conditions to achieve comparable fed-batch performance: The model was then used to investigate for continuous operation, the number of tanks and operating conditions to achieve the same biodiesel conversion as the best fed-batch experiment; in which the final biodiesel value after 24 hours (t_{batch}) was 95.6 mass % (plant productivity 28.2 g FAME L^{-1} h^{-1}) using 0.5 wt% enzyme and 5 wt% water (Price et al. 2014).

The most favourable simulation is shown in Figure 3 which was for 5 tanks with a residence time of 6 hours in each reactor. A FAME conversion of 93.9 mass % is achieved which corresponds to a plant productivity of 22.0 g FAME L^{-1} h^{-1}. However, considerably longer time (40 h) is required to reach the same FAME conversion in the CSTR system compared to the fed-batch system. The simulations show for the CSTR case, that compared to fed-batch operation, plant productivity is sacrificed in favour of continuous operation. Given the reaction slows down in the latter half of the reaction this indicates that the best way of running this process is likely a combination of CSTR operation in the first reactor followed by fed-batch operation. Having a CSTR up front means that the converted FAME in the first reactor (a CSTR) can solubilise higher melting point substrates that are cheaper than virgin oils (e.g. animal fats) which can have a significant positive effect on the economy of the process. To achieve continuous operation in this alternative setup (CSTR into fed-batch) requires proper scheduling of the tanks which adds some complexity to the system, which need to be further evaluated.

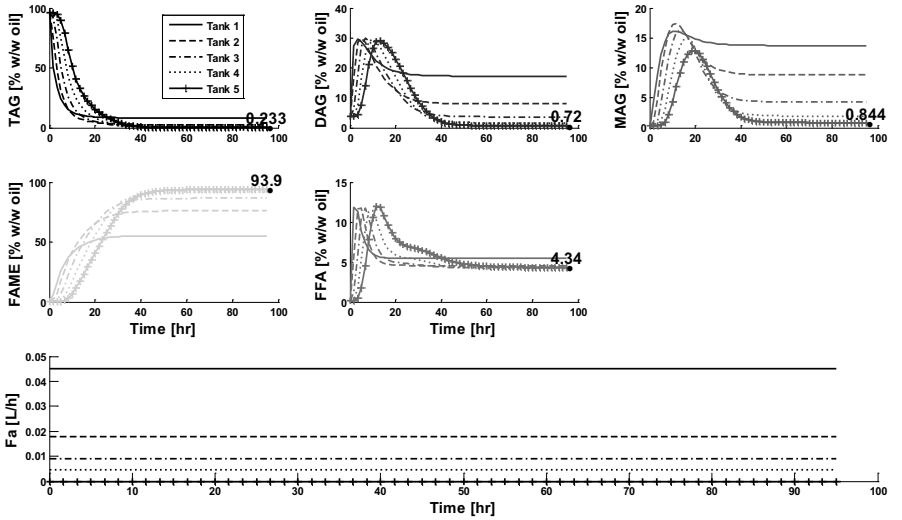

Figure 3 Simulation of the concentration profile of the main components in the oil for 5 CSTR's with a combined residence time of 30 hours. The concentrations in tank 5 are reported.

6. Conclusions

A mechanistic kinetic model is employed to carry out a study dealing with the moving from fed-batch to continuous enzymatic biodiesel production. The method of fitting fed-batch into CSTR data was superior to fitting fed-batch data alone to predict how the continuous process should be operated for the enzymatic biodiesel process. Also, fitting fed-batch into CSTR data reduced the number of data points necessary to calibrate the model compared to fitting fed-batch data alone.The simulations show that in terms of the plant productivity fed-batch operation is better than CSTR operation. However, we propose an alternative setup (CSTR into fed-batch operation) which takes advantage of having a CSTR up front to easily be able to utilise higher melting point substrates followed by a fed-batch reactor which is more efficient in the last half of the reaction.

Abstract

Natural gas with high CO_2 content is a readily available resource, whose application for synthesis gas (syngas) production through dry reforming is strictly limited to processes that require low H_2/CO ratios. In a recent work we have demonstrated that methanol production through a process scheme based on combined reforming of methane (with $CO_2 + H_2O$) becomes a viable alternative from both technical and economic viewpoints. The use of a H_2 separation membrane, as well as a partial H_2 reinjection into the loop reactor, has been considered for the syngas composition adjustment to stoichiometric conditions ($M \approx 2$). The reformer and the methanol synthesis reactor were assumed to be working at thermodynamic equilibrium conditions, i.e. at 950 °C and 20 bar for the former, and at 250 °C and 71 bar for the latter. By using a natural gas feed containing 30 % CO_2 and $H_2O/CH_4 = 2$, it is feasible to operate the synthesis reactor with a lower recycle ratio, as well as a CO_2 concentration close to the one employed in industrial practice. Under the operating conditions mentioned above, the use of combined reforming for methanol synthesis turns out to be economically advantageous over the classical steam reforming process.

In this work a study of the feed flexibility for combined reforming is carried out taking into account the existence of gas fields with CO_2 contents higher than 30 %. Feed mixtures containing 35 % and 40 % CO_2 were analyzed, while maintaining the operating conditions for the reformer (P, T, H_2O/CH_4) and the synthesis reactor (P, T, M). For comparative purposes, a methanol plant producing 400,000 mtpy was considered. A higher CO_2 content in the feed does not significantly alter the CH_4 conversion, but increases the CO_2 conversion and lowers the H_2/CO ratio. Consequently, it is necessary to increase the separation and reinjection of H_2 to keep stoichiometric conditions in the synthesis reactor. However, a moderate increase in CO_2 concentration in the synthesis reactor cannot be avoided. It is also shown that the recycle ratio should be markedly reduced in order to achieve stable operation. This situation reduces the operating cost of the recycle compressor. On the other hand, the flow of $CH_4 + CO_2$ to the reformer should be increased for a constant methanol production, which in turn affects the reformer's energy balance. The main operating costs of the methanol plant, with respect to the reference case ($CO_2/CH_4 = 0.43$), grow for $CO_2/CH_4 = 0.55$ and $CO_2/CH_4 = 0.67$ by 9.5 % and 25 %, respectively. This preliminary technical and economic analysis shows that combined reforming of natural gas with CO_2 content up to 40 % is a feasible process to produce methanol without CO_2 removal.

Keywords: CO_2/CH_4, methanol, CO_2 removal, energy, natural gas.

1. Introduction

More than 40 % of the world's conventional gas reserves are estimated to lie in reservoirs that contain significant amounts of Hydrogen Sulfide (H_2S) and CO_2 (Duissenov, 2013). Natural gas (NG) with a high CO_2 content can be found in many different places all around the world at various regions of economic interest, such as Indonesia (Suhartanto et al., 2000), the Colorado Plateau on the South of the United States (Allis et al., 2001), Norway (Nørstebo et al., 2012) and also Argentina (Crotti et al., 2007). As some of these fields are located far away from main natural gas processing areas, they are usually kept in reserve.

For the recovery of NG Liquids cryogenic processes are nowadays preferred (Kidnay and Parrish, 2006). Under low temperature conditions CO_2 might solidify, hence obstructing pipes and other equipment items. Then, prior to NG fractionation, the addition of a CO_2 removal stage becomes necessary. Moreover, in Argentina the highest allowable CO_2 content for transportation and domestic use is limited to 2 %, since CO_2 contributes not only to lower NG's heat capacity, but also to cause corrosion. Therefore, processing NG with a high CO_2 content in order to obtain conventional NG is difficult and above all uneconomical. Without requiring a previous CO_2 removal, it might be interesting to employ the NG stream with its high CO_2 content as a feedstock for the production of higher value derivatives.

Over the last few years the production of liquid fuels or methanol through the Combined Reforming (CR) process (with $CO_2 + H_2O$) of NG has gained special interest (Roh et al., 2008), due to the employment of two of the most important greenhouse gases: CO_2 and CH_4. CR allows obtaining synthesis gas (syngas) with a higher H_2/CO ratio than the one obtained in Dry Reforming (DR), while avoiding the troublesome carbon formation. In Cañete et al. (2014) we have shown that for a NG feed with 30 % CO_2, it is economically feasible to produce methanol through CR without the need of a partial CO_2 removal. In the present work, the effect of higher CO_2 concentrations in the feed gas on the main operating conditions and the economy of the process are analyzed.

2. Methodology

The simulation of the scheme shown in Figure 1 was made by means of GAMS software (Brooke et al., 2014), where both the reformer and the synthesis reactor were considered to operate at thermodynamic equilibrium conditions. For these calculations the Gibbs-free-energy minimization method was employed, also taking into account carbon formation for the reformer. Table 1 shows the main operating conditions for both the reformer and the methanol synthesis reactor.

Table 1. Simulation parameters

Unit	Inlet Temp. (°C)	Outlet Temp. (°C)	Inlet Pressure (bar)	Pressure Drop (bar)	Thermal Efficiency (%)
Reformer	600.0	950.0	20.0	0.0	50.0
Synthesis reactor	250.0	255.0	71.0	3.0	----

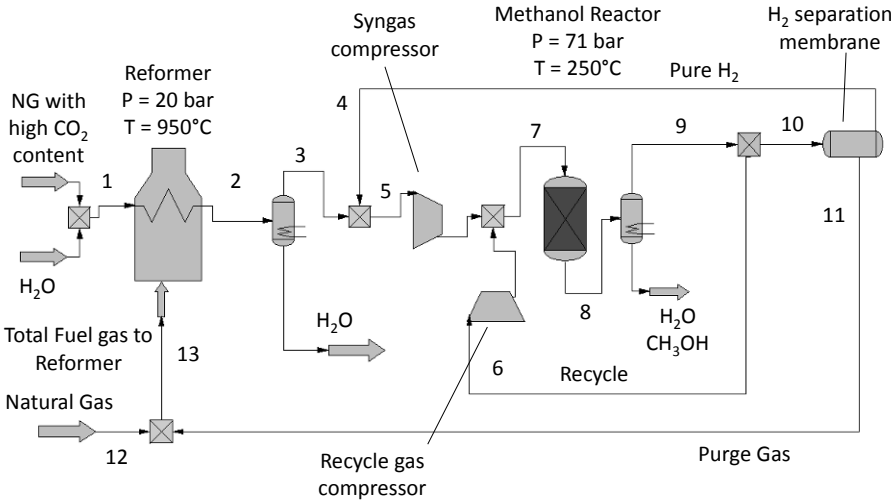

Figure 1. Simplified process scheme

For this analysis a methanol production of 400,000 metric tonnes per year (mtpy) has been set. The simulations aim at analysing the effect of the CO_2/CH_4 feed ratio on the process operating conditions and their impact on the overall energy balance. The M module (H_2-CO_2/CO+CO_2), which is commonly employed to characterize the obtained syngas, was fixed in 2.05 after H_2 reinjection (Stream 5 in Fig. 1). This number is close to the stoichiometric value (M = 2) and was determined to be a suitable composition for methanol synthesis (Cañete et al., 2014).

An important design parameter that has been set free was the CO_2 concentration at the methanol reactor inlet. Although a high value has a negative effect over methanol synthesis kinetics (Lim et al., 2009), it is inconvenient to set an upper limit for this composition, since in this analysis the requirement of a CO_2 separation stage is intended to be avoided. However, the resulting CO_2 concentrations were closer to those employed at industrial practice. For example, Lim et al. (2009) have concluded that the maximum methanol concentration obtained with a $Cu/ZnO/Al_2O_3/ZrO_2$ catalyst corresponds to a CO_2 concentration around 10 %. A common value for reformer efficiency (50 %) was established by Dybkjaer (1995). It relates the total heat transferred to reaction (the one required for heating the feed up to the outlet temperature level plus the heat of reaction) to the total heat generated by fuel combustion.

It is important to remark that both purge gas flow (Stream 11 in Fig. 1) and recycle gas flow (Stream 6 in Fig. 1) have strong influence on the overall energy balance. Therefore, they affect the economy of the process.

3. Results and discussion

For CO_2/CH_4 feed ratios of 0.55 and 0.67 and H_2O/CH_4 = 2.1, Tables 2 and 3 show the effect of CO_2 content on the CH_4 and CO_2 conversions, as well as on the compositions of the main streams for the methanol plant. Stream numbers correspond to the flowsheet given in Figure 1. It can be envisaged that a higher CO_2/CH_4 ratio implies a growth in the consumption of feed gas (Stream 1 in Fig. 1) and fuel gas (Stream 12 in Fig. 1). NG with higher CO_2/CH_4 ratio shows a major tendency for DR, resulting in higher CO_2 conversion (XCO_2 in Tables 2 and 3) at the reformer unit and a syngas with lower

H_2/CO ratio. Meanwhile, CH_4 conversion (XCH_4 in Tables 2 and 3) is only slightly altered by changes in CO_2/CH_4 feed ratio.

Table 2. Computational results (CO_2/CH_4 = 0.55: 35 % CO_2 in NG)

Figure 2 shows partial methane conversion for DR and Steam Reforming (SR) reactions. It is evident that a higher CO_2/CH_4 feed ratio produces a higher CH_4 partial conversion by DR and a slightly lower methane partial conversion by SR.

Due to the lower H_2/CO ratio the pure H_2 flow to be separated at the membrane unit (Stream 4 in Fig. 1) is also higher. In addition, the feed with a higher CO_2/CH_4 ratio leads to a lower recycle ratio (Stream 6/Stream 5 in Fig. 1) that is beneficial for the economy of the process, because the compression work at the methanol loop reactor decreases. For CO_2/CH_4 = 0.55 the recycle ratio is 1.2, while for CO_2/CH_4 = 0.67 it is 0.65. Even when syngas compression requirement slightly increase with CO_2/CH_4 ratio (Stream 5 in Fig. 1), a considerably lower value appears for the recycle stream.

The results in Tables 2 and 3 also show that the CO_2 concentration at the methanol reactor inlet increases with CO_2/CH_4 ratio, which might be detrimental for methanol production. As mentioned before, this concentration is commonly limited to a maximum of approximately 10 %, which is close to the figures shown in Tables 2 and 3 (Stream 7

in Fig.1). Nevertheless, our results indicate that the methanol concentration increases, thus revealing a higher syngas conversion. This behaviour is another consequence of the large reduction in recycle ratio.

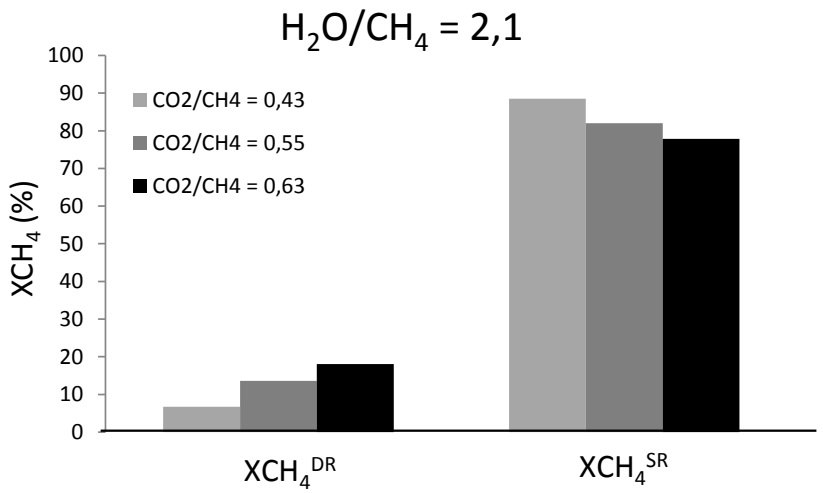

Figure 2. CH_4 partial conversion for DR and SR reactions dependence on CO_2/CH_4 ratio for a feed gas with $H_2O/CH_4 = 2.1$

In this work the considered CO_2 emissions account for the amount present in the flue gas at the reformer unit. For a conventional 400,000 mtpy methanol plant based on SR, CO_2 emission rounds 367 tpd (tonnes per day). In contrast, for CR the CO_2 emissions are approximately 1495 tpd and 1945 tpd for $CO_2/CH_4 = 0.55$ and $CO_2/CH_4 = 0.67$, respectively. There is a net CO_2 production for each alternative of 735 tpd and 1007 tpd, respectively. Total fuel gas (Stream 13 in Fig. 1) for SR is rich in H_2 (≈ 80 %, v/v), while fuel gas for CR is almost exclusively composed of CH_4 (60-75 %). Due to this fact, for CR a significant amount of CO_2 is yielded through CH_4 combustion.
The main operating costs for the process scheme shown in Fig. 1 are those related to the NG requirement (as feedstock and fuel gas), as well as costs arising from recycle and syngas compressor operation. Compared with $CO_2/CH_4 = 0.43$ (Cañete et al., 2014), for CR the operating costs rose steadily in 9.5 % and 25 % for a feed gas with $CO_2/CH_4 = 0.55$ and $CO_2/CH_4 = 0.67$, respectively. Besides, in comparison with SR, operating costs increased to about 2.1 % and 14.3 %, thus indicating that the CR alternative would still remain competitive, even for CO_2 content in NG higher than 30 %. In short, while the capital costs of a CR plant are considerably lower than those for SR, the operating costs are only slightly higher for CR.

4. Conclusions

Natural gas with a high CO_2 content is a promising resource for the production of valuable derivatives, like methanol. For a process plant where H_2 is partially separated and reinjected to the inlet of the methanol loop, augmenting CO_2/CH_4 ratio in the feed gas produces an increase in the CO_2 conversion at the reformer because of a major contribution from DR reaction. Methane conversion is only slightly altered with

changes in CO_2/CH_4 ratio. The increase in CO_2/CH_4 ratio leads to higher NG consumption (as feed gas and fuel), lower H_2/CO ratio, higher H_2 separation rate, higher CO_2 concentration in the syngas and a lower recycle ratio. The latter reduction results in less operating costs as a consequence of lower compression requirements. The operating costs for CO_2/CH_4 = 0.55 and CO_2/CH_4 = 0.67 are approximately 9.5 % and 25 % higher than the alternative design with CO_2/CH_4 = 0.43, while these costs become 2.1 % and 14.3 % higher than that for SR. Then, the Combined Reforming of NG with CO_2 content up to 40 % is a feasible process to produce methanol without CO_2 removal.

Abstract

In ethanol production from sugarcane juice, sugarcane bagasse is used as fuel for the boiler, to meet the steam and electric energy demand of the process. However, a surplus of bagasse is common, which can be used either to increase electric energy or ethanol production. While the first option uses already established processes, there are still many uncertainties about the techno-economic feasibility of the second option. In this study, some key parameters of the second generation ethanol production process were analyzed and their influence in the process feasibility assessed. The simulated process includes the enzymatic hydrolysis of sugarcane bagasse pretreated with liquid hot water, and the analyzed parameters were the solid consistency in the hydrolysis and pretreatment reactors and the hydrolysis reaction time. The solid consistency in the hydrolysis reactor had the highest influence on the economic feasibility of the process. For the economic scenario considered in this study, using bagasse to increase ethanol production yielded higher ethanol production costs compared to using bagasse for electric energy production, showing that further improvements in the process are still necessary.

Keywords: Bioethanol, sugarcane, techno-economic analysis, process simulation

1. Introduction

The production of ethanol from sugarcane juice is well established in Brazil. In this process, sugarcane juice is extracted and used to produce ethanol, while sugarcane bagasse is sent to boilers, producing steam and electric energy to meet the process demands. However, a surplus of bagasse is frequently possible and this opens opportunities to produce and sell electric energy to the grid or alternatively to increase ethanol yields through second generation (2G) ethanol production. It is expected that these processes would be integrated to the already existing first generation (1G) ethanol process, taking advantage of the economy of scale and decreasing transportation costs. This system will be a highly integrated one with the steam and electric energy demands being met by the burning of by-products of ethanol production. Therefore, it is not a trivial task to infer the effect of some process parameters on the overall process economic performance. In this sense, process systems engineering (PSE) tools can be applied to assess these effects for some key parameters in order to provide insights about the process. Additionally, it will allow

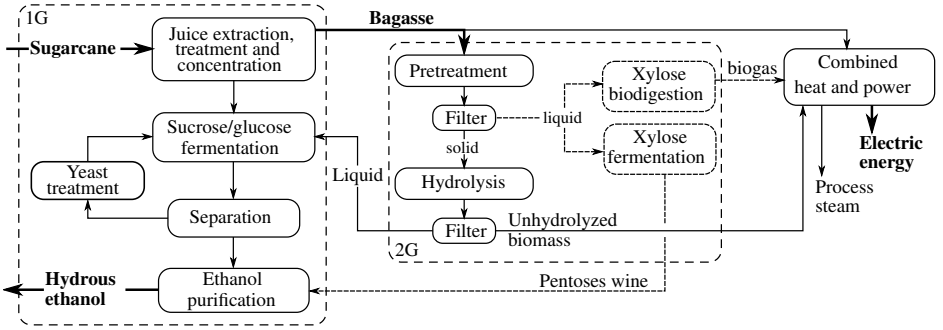

Figure 1: First and second generation ethanol production process. 1G stands for the first generation process, adapted to the integrated process, while 2G stands for the specific second generation process.

new experimental datasets to be quickly evaluated from the whole process perspective and search directions to be derived.

In this study, second generation ethanol production following the biochemical route is considered, including the enzymatic hydrolysis of sugarcane bagasse, pretreated with liquid hot water. The influence of key process parameters on the economic feasibility of the integrated process (first and second generation ethanol) was assessed. The solid consistency in the pretreatment unity and in the hydrolysis reactor were considered, along with the hydrolysis reaction time. Additionally, both fermentation and biodigestion of the pentoses produced in the pretreatment stage are studied.

2. Methodology

The process considered in this study uses liquid hot water for pretreatment of the sugarcane bagasse. The solid fraction from the pretreatment stage is hydrolyzed and the glucose solution is subsequently fermented by *Saccharomyces cerevisiae* along with the treated sugarcane juice. The liquid fraction, consisting mainly of xylose from the hemicellulose hydrolysis, can also be fermented or, alternatively, it can be anaerobically digested to produce biogas. The ethanol solution is sent to the purification stage and hydrous ethanol is produced. Unhydrolyzed cellulose and remaining lignin are separated from the liquid fraction after the hydrolysis reactor and sent to the boiler. The process steam and electric energy demands are still met by the burning of bagasse (in addition to biogas and the solid fraction from the hydrolysis reactor), which limits the amount of bagasse that can be diverted to 2G ethanol production. Therefore, the amount of bagasse diverted to this process varies for each case studied. Figure 1 shows the second generation process and how it is integrated to the (1G) ethanol process: bagasse is diverted to the 2G process, glucose liquor from cellulose hydrolysis is fermented with sugarcane juice and xylose wine is purified with 1G ethanol.

Minimum ethanol selling price (MESP) was determined as the ethanol price that yields a zero net present value. The investment costs for the first generation process were derived from Pinto (2010) and adapted to represent the integrated process. The investment in the combined heat and power stage was based on Dantas (2013) and the investment for the xylose biodigestion system was based on Procknor (2009). Finally, the investment cost of the second generation stage was based on the technical report from the National Renewable Energy Laboratory (Humbird et al., 2011). Other parameters used for the economic analysis are described in Furlan et al. (2013), while the enzyme price was updated to 10.14 USD/kg of enzyme, as reported by Klein-Marcuschamer et al. (2012)

and represents the baseline production cost for the enzyme. Additionally, since sugarcane bagasse does not have an established market price, to assess the feasibility of the process, its opportunity cost regarding electric energy production was considered. This was accomplished by comparing the surplus of electric energy produced with a base case were all bagasse is burnt.

The software EMSO (Environment for Modeling, Simulation and Optimization, Soares and Secchi (2003)) was chosen as the platform for the simulations. This is an equation-oriented simulator with its own modelling language enabling the user to add models to the ones already present in the software. EMSO has several numerical packages for solving algebraic and differential-algebraic systems and also a thermodynamic package, where the user can add compounds and properties as needed.

3. Results and Discussion

Three process parameters were considered in this study: solid consistency (solid mass fraction) in the pretreatment reactor, in the hydrolysis reactor and the hydrolysis reaction time. Table 1 shows the range considered for each parameter. The effect of the parameters were analyzed for three levels of conversion in the hydrolysis reactor: 45, 60 and 75% of the theoretical, i. e., for each set of solid consistencies in the hydrolysis reactor, in the pretreatment reactor and reaction time, three levels of conversion were evaluated.

Table 1: Ranges considered for the parameters studied. Underlined values were used as standard for each parameter when the values of the other parameters were varied.

	Solid fraction in hydrolysis reactor	Solid fraction in pretreatment reactor	Hydrolysis reaction time
Range	10, <u>20</u>,30 and 40%	10, <u>20</u> and 30%	48, <u>72</u> and 96h

As a general case, the biodigestion of xylose allowed a higher amount of bagasse to be diverted to 2G ethanol, resulting in higher ethanol production (23.0 % increase (biodigestion) vs. 21.5 % (fermentation), for the highest increase). However, it also increases investment costs, due to the biodigestors and bigger boilers. Consequently, the MESP of the biodigestion option was on average 46 USD/m^3 higher than the fermentation one. Table 2 shows the cases with the lowest MESP for the xylose fermentation and biodigestion and compares it to 1G base case, with all bagasse being burnt and electric energy surplus being produced. The use of biogas as fuel for steam production allowed 61.9 % of the bagasse to be diverted to 2G production in the biodigestion case. In this case, 50.8 % of the steam demand is met by burning the biogas and the unhydrolyzed fraction of bagasse. At the same time, the higher sugar concentration decreased the specific steam demand (kg of steam/l of ethanol) in 4.4 % compared to the 1G ethanol process. It is worth noticing that this study does not consider the use of sugarcane trash as fuel for the boiler.

As it can be seen in Table 2 the MESP for the best 1G+2G ethanol process with xylose fermentation is 6.3 % higher than the base case, although only 3.1 % higher than the ethanol selling price considered (513.7 USD/m^3, relative to the average price between Jan/2003 and Dez/2012 in Brazil). This shows that second generation ethanol still needs further development in order to compete with electric energy production, at least for the electricity prices used in this study (80.8 USD/MWh), which correspond to the average value of auctions in Brazil in the period 2005-2011.

Among the parameters considered in this study, the solid consistency in the hydrolysis reactor had the most significant effect on the economic feasibility of the process, as it can be seen in Figure 2 for the xylose fermenting case, while the other parameters had only marginal effect on the MESP. Interestingly, 2G MESP is not monotonic with respect to the solid consistency in the hydrolysis reactor, which can be related to a decrease in glucose recovery in the separation step after the

Table 2: Base case (1G burning all bagasse) and best cases (lowest 2G MESP) for the 1G+2G process, for xylose biodigestion and fermentation. Hydrolysis reaction time was 72h for the last two cases.

	1G	1G+2G (xylose biodigestion)	1G+2G (xylose fermentation)
Solid consistency (hydrolysis)	–	20 %	20 %
Solid consistency (pretreatment)	–	10 %	30 %
Hydrolysis reaction yield	–	75 %	75 %
Bagasse fraction burnt	100 %	38.1 %	48.3 %
Increase in ethanol production	–	17.6 %	20.4 %
1G+2G MESP (USD/m^3)	498.4	565.2	529.6
2G MESP (USD/m^3)	–	943.9	682.0
Steam produced (kg/TC)	522.9	404.6	380.4
Contribution to steam production (bagasse /unhydrolyzed biomass/ biogas)	100 % / 0 % / 0 %	49.2 % / 37.4 % / 13.4 %	66.4 % / 33.6 % / 0 %

hydrolysis. This suggests the importance of a washing step to increase sugar recovery when high solid consistencies are used, although in this case there will be a trade-off between sugar recovery and its final concentration in the stream.

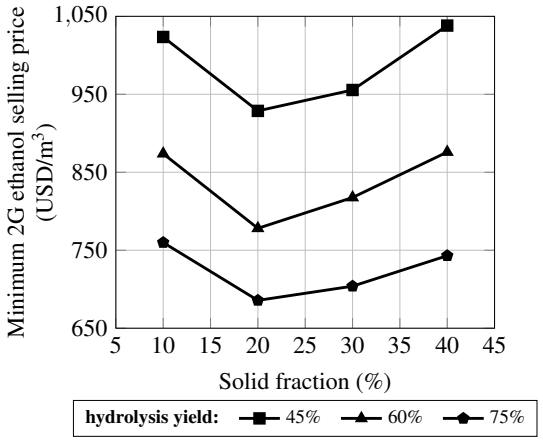

Figure 2: Influence of the solid consistency in the hydrolysis reactor on the minimum 2G ethanol selling price when xylose is fermented.

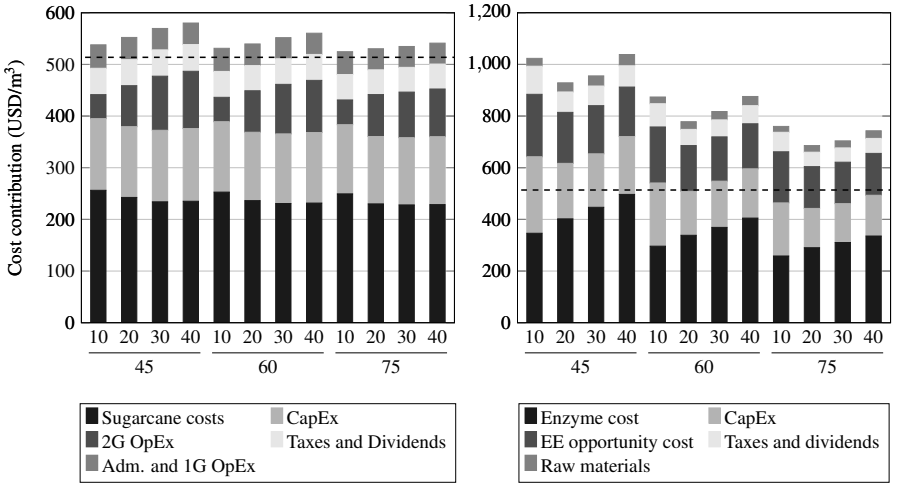
For the overall cost of ethanol (1G + 2G), sugarcane cost clearly dominated the contribution, followed by capital expenditures (CAPEX) and other operating expenses (OPEX) related to 2G production (enzyme cost, electric energy opportunity cost and other raw material costs), as shown in Figure 3a. The specific 2G cost, on the other hand, is highly dominated by the enzyme costs which is on average 42 % of the total production costs, while the CAPEX cost (second higher) accounts for 23 % of the total cost. The solid consistency in the hydrolysis reactor has a clear effect on the enzyme and CAPEX cost contributions while its effect on the other components of 2G ethanol costs are much weaker, as shown in Figure 3b. Also, it can be inferred that the effect of solid consistency on MESP decreases for higher yields. Since more ethanol is produced for higher yields, the influence of the parameter is softened.



(a) Overall production cost of ethanol.

(b) production cost of 2G ethanol.

Figure 3: Influence of the solid consistency in the hydrolysis reactor (10–40% m/m) and of the hydrolysis yield (45–75% of the theoretical) on the overall production cost of ethanol (a) and on 2G ethanol (b) when xylose is fermented. The dashed line represents the current selling price for ethanol.

To assess the current state of the technology and its feasibility, the yields reported by Souza et al. (2014) for the enzymatic hydrolysis of sugarcane bagasse pretreated with liquid hot water were used. Based on these data, Figure 4 shows the 2G MESP obtained, for the process with xylose fermentation to ethanol. It can be seen that 2G MESP generally decreased for the whole time range considered in the study, showing that the negative effect of the reaction time on 2G MESP is in general lower than the positive effect of the increase in the yield. Only for the higher solid consistency (20%), an increase in 2G MESP is seen in the final hours of reaction. If results similar to the best experimental ones (solid consistency of 15 % and 72 hour of hydrolysis reaction) could be obtained in industrial scale, an increase in ethanol production of 13.9%, with a MESP of 540.3 USD/m^3 (841.9 USD/m^3 for the 2G MESP) could be expected.

4. Conclusions

An integrated first and second generation ethanol industrial plant based on the enzymatic hydrolysis of sugarcane bagasse pretreated with liquid hot water was simulated, and its economic feasibility assessed. In general, for the economic scenario considered, the second generation ethanol cost was higher than the first generation one, even when high solid consistencies in the reactors was considered. This shows that the process still needs further developments in order to compete with electric energy production. Xylose fermentation to ethanol yielded lower MESPs than its biodigestion, although the latter option allowed a higher ethanol production. Among the process parameters considered, the solid consistency in the hydrolysis reactor showed the strongest influence on 2G MESP: the lowest prices were between 20 and 30% of solids, with a slight increase after that. Additionally, simulations based on experimental yields reported in the literature showed that, for the time range considered for the hydrolysis reaction, its negative effect on the 2G MESP was lower than the positive effect of the increase in the yield. For the experimental data considered, a MESP of 540.3 USD/m^3 could be reached if similar results were to be achieved in industrial scale. This is 5.2% higher than the prices in Brazil in the period 2002-2012, but 8.4%

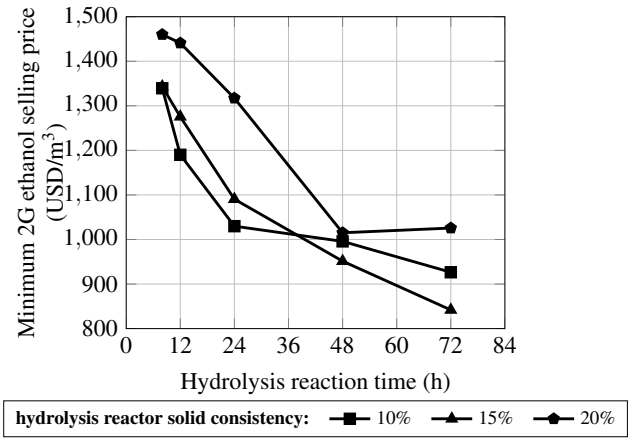


Figure 4: Minimum ethanol selling price considering experimental data reported by Souza et al. (2014) and xylose fermentation.

higher than the MESP for the stand alone 1G process.

Simulation Study of Heat Transfer Enhancement due to Wall Boiling Condition in a Microchannel Reactor Block for Fischer-Tropsch Synthesis

Krishnadash S. Kshetrimayum, Park Seongho, Jong Ikhwan, Na Jonggeol, Han Chonghun*

School of Chemical and Biological Engineering, Seoul National University, Seoul 151-744, Republic of Korea
chhan@snu.ac.kr

Abstract

A microchannel reactor block, with process and coolant channel planes arranged in alternate fashion and cross flow mode was considered for Fischer-Tropsch(FT) synthesis. Computational Fluid Dynamic (CFD) simulation of heat transfer in the microchannel block was carried out to gain insights on the complex thermal behavior. Cooling oil, subcooled water and saturated water were chosen as coolants to simulate the heat transfer phenomena.The study revealed significant enhancement in heat transfer across the channel walls due to wall boiling condition which occures in case of saturated water as coolant. Consequently, near isothermal condition was able to achieve by adjusting saturated water flow rate. Scenario for partial boiling, with saturated water as coolant, was investigated. Simulations were carried out to study effects of different conditions of heat generation and coolant flow rate on reactor performance parameters.

Keywords: Computational fluid dynamics, wall boiling, heat transfer, microchannel, Fischer-Tropsch synthesis.

1. Introduction

Fischer-Tropsch(FT) synthesis is the main step in Gas-to-Liquid(GTL), coal-to-liquid(CTL) and biomass-to-liquid(BTL) processes(Arzamendi et al., 2010). In GTL, natural gas is used as feedstock to produce syn-gas (a mixture of carbon-monoxide-CO and hydrogen-H_2) needed for FT reaction where the reaction then produce liquid hydrocarbon fuels(Fischer and Tropsch, 1930). In CTL and BTL, syn-gas is produced from coal and biomass through coal and biomass gasification. GTL is particularly of interest to oil and gas industry today, partly due to rising fuel price, and partly due to environmental restrictions of flaring offshore stranded and associated gas. FT synthesis involves complex hydrodynamic, chemical and thermal interaction of three material phases: reactant gases in the form of bubbles, liquid as FT product and solid catalyst particles loaded as filled or coating on the microchannel internal walls. The reaction can be represented as the following: $n\mathrm{CO} + (2n+1)\mathrm{H_2} \rightarrow \mathrm{C}_n\mathrm{H}_{2n+2} + n\mathrm{H_2O}$. The reaction is highly exothermic (heat of reaction = 165 kJ/mol CO) with reaction products showing selectivity based on reaction temperature and catalyst deactivation highly sensitive to temperature. Hence, adequate heat removal and temperature control in the reactor is demanded for high reactor yield(Deshmukh et al., 2010).

Microchannel reactors are said to shorten the diffusion distance, and lower heat and mass transfer resistance thereby standing out as a promising candidate for FT synthesis applications. Reduced mass and heat transfer distances provides enhanced process intensification, when compared to conventional reactors. Also, the high exothermic nature of the reaction and shorter residence time of microchannel reactor demands that a coolant having high heat removal capacity, for instance, saturated water be used (Deshmukh et al., 2010). They tested a pilot scale microchannel reactor with 276 process channels and 132 coolant channels arranged in cross-flow mode using saturated water as coolant. Arzamendi et al.(2010) studied the buoyancy effect on the thermal behavior of a microchannel reactor block through CFD simulation considering partial boiling of coolant. However they considered wall coated catalytic reaction zone. Gamze and Ahmet (2011) carried out parametric analysis of FT synthesis, also for wall coated catalytic microchannel reactor, but considering only 2D simulation to represent a unit cell of a parrallely arranged microchannels and using steam a coolant. Shin et al.(2013,2014) presented experimental and simulation study of catalytic bed modular microchannel reactor. But they considered 40 mm wide and 140 mm long channels stacked up to form plate heat exchanger configuration and using silicon oil as coolant.

In this work, we considered a microchannel network in the form of microchannel block, adapted from the microchannel reactor block of Arzamendi et al.(2010), to carry out heat transfer simulation using different coolant types and process channels as catalyst packed bed. The aim of this work is to simulate the complex phenomena associated with two-phase wall boiling heat transfer and quantitatively evaluate the heat transfer enhancement due to wall boiling condition as compared to the non-boiling single phase convective flow of coolant. Effect of practically relevant scenarios: higher or lower heat generation rate and coolant flow rate were studied. Further, we investigated scenario for partial wall boiling condition to avoid critical heat flux and ensure reactor safety.

2. Model Description

2.1 Reactor block model

Microchannel reactor block used by Arzamendi et al.(2010) and adapted in the present work is shown in figure 1. It has dimensions: 21mm x 21mm x 17mm, with four process channel planes and four coolant channel planes stacked up in alternate fashion. Each channel planes has 10 parallel channels of 1mm x 1mm x 17 with gap between adjacent channels as 1mm.

2.2 Process channels

Process channels are assumed to be filled with catalyst and modeled as pack bed reactor with certain void fraction determined by the catalyst and inet material loading. Reaction scheme and kinetics as proposed by Marvast et al.(2005) for Fe-based byfunctional catalyst was considered for the present study, the detail of which is not shown here for brevity. Heat is continuously generated in the process channels as the syn-gas ($CO + H_2$) undergoes catalytic conversion to various hydrocarbon products.

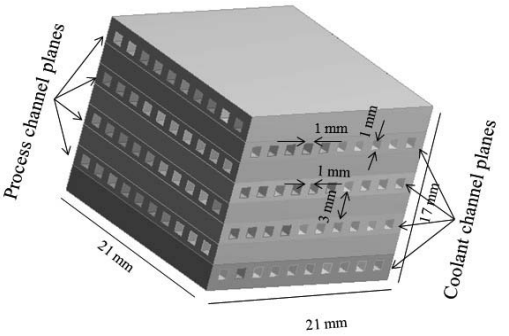

Figure 1: Microchannel reactor block

2.3 Coolant channels

For single-phase coolant flow as is the case with subcooled oil and subcooled water, convective heat transfer is assumed to be the only means of heat removal. In case of saturated water as coolant, the fluid comprises of saturated liquid water and water vapor, with pure liquid at the inlet. The flow of liquid water and vapor is modeled as Eulerain-Eulerian multiphase flow with continuity and momentum equations described by Navier-Stokes equations, separately for both the phases. Mass transfer from the liquid phase to vapor is accounted by the rate of evaporation or wall boiling. Heat transfer between the two phases is assumed to be insignificant as compared to the heat transfer from the channel wall. Details information including the mathematical description is not given here for brevity and can be found in ANSYS FLUENT 14.5 Manual.

2.4 Wall boiling

In the microchannel block, heat is transferred from the process channel, where exothermic reaction occurs, to the adjacent coolant channels through channel walls. If the coolant is saturated water, phase change occurs in the coolant channel due to wall boiling. Mechanistic wall heat flux partioning model for boiling heat transfer as proposed by Podowski (2012) is used for heat transfer from heated channel wall to saturated water. Under the heat flux partitioning model, the total heat flux through the wall is partitioned into convective, quenching and evaporative heat flux as follows:

$$\dot{q}_{Wall} = \dot{q}_F + \dot{q}_Q + \dot{q}_E \tag{1}$$

where $\dot{q}_{Wall}$ represents the total wall heat flux, $\dot{q}_F$, $\dot{q}_Q$, and $\dot{q}_E$ the convective, quenching and evaporative heat flux, respectively. The detail equation of heat flux is not given here for brevity. For the coolant as subcooled oil and subcooled water without phase change, only convective heat transfer is expected to occur.

3. Simulation Conditions

3.1 Single channel

Reaction in a single channel packed bed with void fraction 0.4, dimensions as given in figure 1, at isothermal condition using multiple reactions and kinetic data of Marvest et al.(2005) was considered. Syn-gas composition of H_2/CO ratio of 1 and 1.5, and reactor pressure at 20 bar was used. Temperatures of both syn-gas feed and reactor were assumed to be constant at 503 and 523 K. Catalyst density of 50 - 1060 kg/m^3 was used along with inert. Simulation was carried out using commercial software-ASPEN.

3.2 CFD Model

Simulation was carried out using commercial CFD software- ANSYS FLUENT. Hui et al. (2012) satisfactorily simulated micro-reactor for various configurations using the software tool to demonstrate the applicability. Since heat transfer study is the focus here, fluid flow inside a process channel is neglected and CFD model consist of two types of solid zones--one for process channels and other for reactor body; and one fluid zone for coolant flow. Process channels are zones for constant heat source with heat profile as obtained from single channel reactor simulation and implemented into CFD model using User Defined Function (UDF). Coolant channels are zones for heat sink. Zones are meshed with tetrahedral and hexagonal elements with grid count as 2.2 million to ensure fine mesh quality. Eulerain-Eulerian model of multiphase flow is

applied for multiphase coolant type, as in saturated water, and single phase model for single phase coolant type, as in cooling oil and subcooled water. Simulation model setups are as follows: Laminar for single phase coolant; SST-k Omega for turbulent model in multiphase; SIMPLE algorithm for pressure velocity coupling; second order discretization for momentum and energy equatio; RPI boiling model (Podowski, 2012) for wall boiling. Reactor body is assumed to be made of stainless steel with density 2820 kg/m^3 and heat capacity as 473.3 J/Kg-K with thermal conductivity of 23.2 J/s-m-K. Densities of subcooled oil, subcooled water and water vapor as taken as 936 kg/m^3, 998.2 kg/m^3 and 1.55 kg/m^3 ; heat capacity as 1967 J/Kg-K, 4182 J/Kg-K and piecewise polynomial; thermal conductivity as 0.0974 J/s-m-K, 0.261 J/s-m-K and 0.261 J/s-m-K, respectively. Saturation temperature for wall boiling model was set as 500 K, which is the value at operating pressure of 20 bar. Coolant flow rates in the range of 0.4 g/min to 43.2 g/min were considered.

4. Results and Discussion

4.1. Mole fraction of CO and H_2

Deshmukh et al. (2010) in their experiments on microchannel reactor achieved 71.8 % CO conversion. A conversion value between 71 to 72 % was taken as constraint in our simulation too, by adjusting the catalyst loading (50 - 1060 kg/m3) for syn-gas feed rate considered. Figure 2 shows, mole fraction of syn-gas (CO and H_2) for H_2/CO ratio of 1 and 1.5, and heat generation for different syn-gas flow rates from single channel catalyst packed bed simulation. H_2 consumption rate was observed to be faster than that of CO and mole fraction profile crosses at a point along the channel in case of H_2/CO ratio 1.5. For same final CO conversion, heat generation was higher for higher syn-gas flow rate.

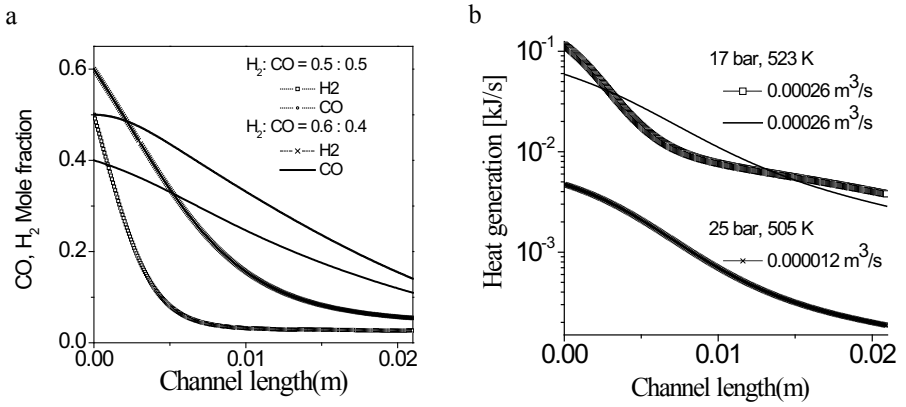

Figure 2. Single channel packed bed simulation, (a) mole fraction of CO, and H_2 for H_2/CO ratio of 1 and 1.5, (b) heat generation for different syn-gas flow rates for same final CO conversion.

4.2 *Wall boiling CFD simulation and heat transfer enhancement*

For better performance of a microchannel reactor, temperature inside the reactor internal is desired to be maintained within temperature difference lesser than about 15 K. This condition is obtained in the CFD simulation with wall boiling heat transfer in coolant channels, as can be seen from temperature profile in Figure 3(a). Figure 3(b) shows

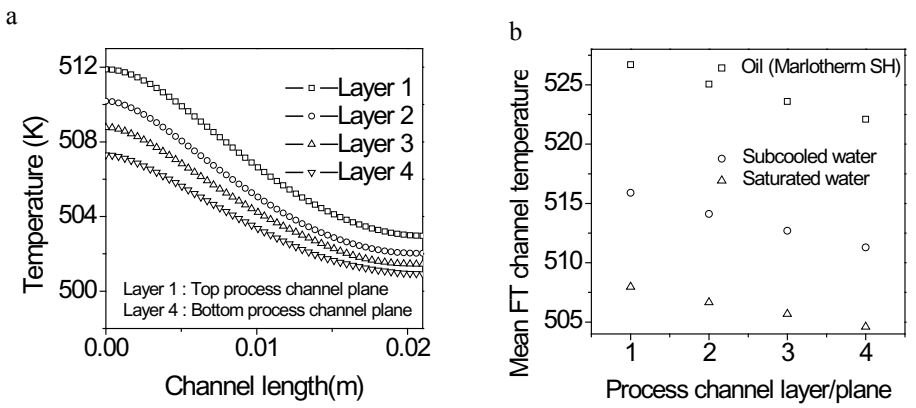

Figure 3. (a)Temperature profile in process channel from wall boiling CFD simulation, (b) Mean FT channel temperature showing heat transfer enhancement due to wall boiling.

mean FT temperature for three cases of coolant type: cooling oil, subcooled water and saturated water. With saturated water as coolant, all FT channel layers have mean temperature below 510 K, whereas in case of subcooled oil and subcooled water, temperatures are above 512 K. Lower mean FT temperature in case of saturated water implies heat transfer enhancement due to wall boiling condition in coolant channels.

4.2 Effect of heat generation and coolant flow rates

In a typical operation, there can be situations of higher or lower heat generation than the normal condition. Accordingly, coolant flow rate has to be adjusted to maintain reactor temperature to the desired value. Effect of heat generation and coolant flow rates are explored. Figure 4(a) shows higher extend of wall boiling for higher heat generation rate, which is evident from lower liquid fraction at coolant channel exit. As expected mean FT channel temperature is larger for higher generation rate, as in figure 4(a) secondary y-axis, and smaller for larger coolant flow rate, as in figure 4(b).

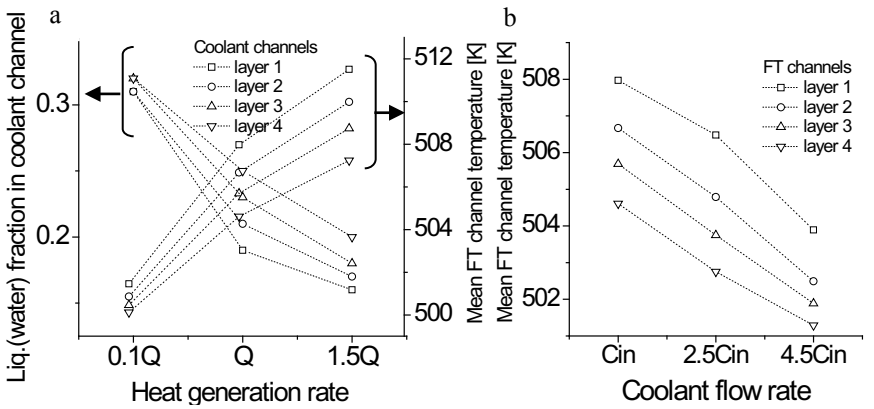

Figure 4. (a) Heat generation rate[Q = heat generation for syn-gas flow rate 0.0026 m^3/s] vs. liquid (saturated water)fraction and FT channel temperature , (b) coolant flow rate[Cin = 1.2 g/min] vs. mean FT channel temperature.

A common concern in microchannel wall boiling heat transfer is critical heat flux. Therefore, flow regime in coolant channels has to be such that situation for critical heat flux is avoided. Adjusting coolant flow rate can ensure flow regime limiting only to partial boiling. For instance, flow regime under partial boiling condition as shown in figure 5, where liquid fraction in coolant channels are high enough, can ensure safe operation of microchannel reactor.

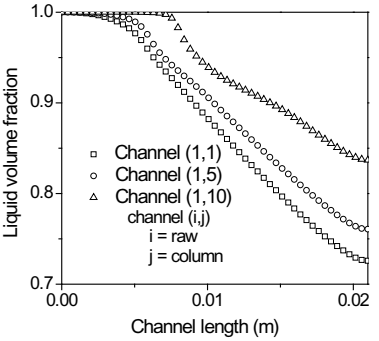

Figure 5: Partial boiling condition in coolant channels (flow rate=3g/min).

5. Conclusions

A systematic simulation study of heat transfer in a microchannel reactor block is presented. Study revealed enhancement in heat transfer due to wall boiling condition which occurs with saturated water as coolant. Concequently, adjusting saturated water flow rate can achieve near isothermal condition in microchannel reactor. Effect of heat generation and coolant flow rate on reactor parameters are investigated. A method to avoid critical heat flux is suggested. Further, Song et al. (2004), from their experimental work, proposed a correlation for chain-growth probability as a function of temperature and H_2/CO ratio. At the maintained FT channel temperature range, 500 K - 510 K, the value of chain-growth probability was calculated to be between 0.79 to 0.85 for H_2/CO molar ratio as 1. This value falls under the desired growth-probability of FT synthesis.

CO_2 vs Biomass: Identification of Environmentally Beneficial Processes for Platform Chemicals from Renewable Carbon Sources

André Sternberg,[a] Holger Teichgräber,[a] Philip Voll[a] and André Bardow[a*]

Abstract

Conventionally, platform chemicals are produced from fossil feedstock. In recent years, the production of chemicals from renewable feedstock has been considered. One possible renewable carbon source is biomass. Another option is carbon dioxide (CO_2). A rigorous comparison of processes employing renewable carbon sources is missing today. We therefore identify the environmentally most beneficial process routes for platform chemicals. All processes are integrated into a single superstructure, which is analyzed using linear optimization minimizing global warming impacts. The optimal solutions exploit synergies between the different process routes and feedstocks.

Keywords: LCA, optimization, CO_2, Biomass, platform chemicals

1. Introduction

The dependency on fossil fuels and the related global warming impacts can be reduced through the utilization of renewable carbon sources such as biomass and CO_2. The utilization of renewable carbon sources is therefore drawing increasingly attention in the chemical industry (Peters et al. 2011). In biomass-based process routes (Biomass-to-Chemicals), biomass provides the required C-building block and also energy for the chemical reaction. In contrast, in CO_2-based process routes (CO_2-to-Chemicals), CO_2 provides only the C-building block. Thus, most CO_2-based reactions require hydrogen as additional high energy feedstock (Peters et al. 2011). However, conventional hydrogen production based on steam-methane-reforming has very high environmental impacts (Cetinkaya et al. 2012) conflicting with the motivation for renewable carbon sources utilization. To minimize the environmental impacts of hydrogen production, electrolysis using surplus power is a promising option. The multitude of process routes is further complicated as hydrogen can not only be used for CO_2-to-Chemicals process routes but also for Biomass-to-Chemicals process routes to increase the product yield (Gassner and Maréchal 2008; Clausen et al. 2010).

We aim to identify the environmentally most beneficial process routes for platform chemicals from renewable carbon sources. For this purpose, CO_2-to-Chemicals and Biomass-to-Chemicals process routes are integrated into a single superstructure model, which is analyzed using linear optimization minimizing the environmental impacts. The conversion of biomass and CO_2 relies on biomass and surplus power which are limited feedstocks. From a macro perspective, the limited feedstocks should only be used for process routes with highest environmental impact reduction potential. In fact, these feedstocks could also be used outside the chemical industry, e.g., in the energy or transportation sector. Hence, our analysis also considers utilization of the limited

feedstocks outside the chemical industry (Biomass-to-Alternative, Power-to-Alternative).

2. Identification of environmentally beneficial process routes

We use superstructure-based optimization to identify environmentally most beneficial process routes. First, a mathematical superstructure model is formulated incorporating all potential process routes (section 2.1). Secondly, the generated model is analyzed using optimization algorithms to identify process routes minimizing the total environmental impacts (section 2.2).

2.1. Superstructure

The superstructure contains the following process routes (cf. Figure 1): (I) Biomass-to-Chemicals process routes, (II) CO_2-to-Chemicals process routes, (III) hydrogen production processes, (IV) conventional process routes for chemicals, and (V) alternative utilization of biomass and surplus power. The process routes are modeled by constant conversion factors representing the ratio between inputs and outputs. Note that the process routes are coupled in the superstructure model, thus enabling an integrated analysis to exploit possible synergies of the considered process routes: Hydrogen is mandatory for the CO_2-to-Chemicals process routes and optional for the Biomass-to-Chemicals process routes; CO_2 for the CO_2-to-Chemicals process routes could also be supplied from biomass-based process routes.

Process route (V) represents alternative utilization of the limited feedstocks biomass and surplus power outside the chemical industry. An alternative utilization would lead to environmental impact reductions by substituting a conventional process and its related environmental impacts (cf. section 3.4). For the alternative utilization, we do not consider specific technologies but determine threshold values for the environmental impact reduction of these alternative utilization pathways. The threshold value indicates when the alternative utilization achieves higher environmental impact reductions than the utilization for production of chemicals.

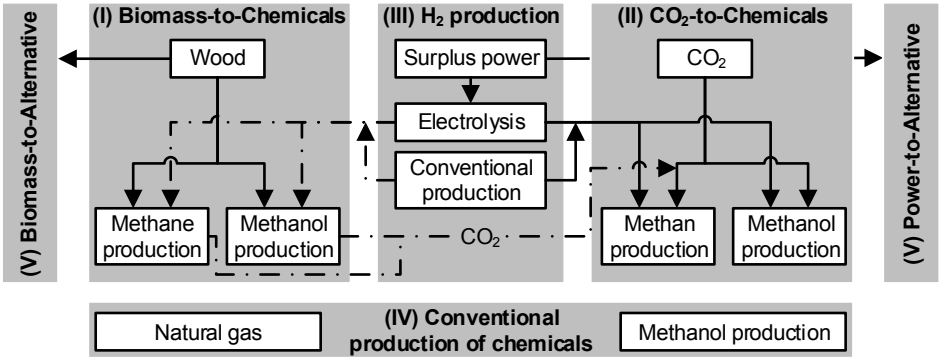

Figure 1: Superstructure embedding all considered process routes for platform chemicals. Dashed/dotted lines indicate optional connections, solid lines indicate mandatory connections.

2.2. Linear optimization model

In this work, optimization is carried out minimizing the total environmental impacts of the considered system (cf. Figure 1):

$$\min z = \underline{EI}^T \underline{x}, \tag{1}$$

$$\text{s.t.} \quad A\underline{x} = 0. \tag{2}$$

The objective function is formulated in terms of the environmental impacts $\underline{EI}$ of the single processes and the scaling factors $\underline{x}$ of the single processes (decision variables). The scaling factors $\underline{x}$ represent the choice and the utilization level (continuous value $\underline{x}$) of the single process routes. Total environmental impacts are to be minimized such that mass and energy balances are fulfilled (Equation 2), where A contains all inputs and outputs of the considered processes.

3. Methanol and methane from renewable carbon sources

In section 3.1, a case study is presented for the production of methanol and methane. The approach is exemplified using global warming impact (GW) as environmental impact category. The results of the case studies for methanol and methane are presented in section 3.2 and 3.3, respectively.

3.1. Problem setting

3.1.1. Considered feedstocks

For the Biomass-to-Chemicals process routes, waste wood with a global warming impact of -0.418 kg CO_2-eq/kWh_{LHV} (Gassner and Maréchal 2008) is considered as feedstock. The CO_2-to-Chemicals process routes use CO_2 captured from a coal-fired power plant. The global warming impact of CO_2 is -0.654 kg CO_2-eq/kg (Gerdes et al. 2013). Furthermore, both process routes can use surplus power with a global warming impact of zero.

However, wood and surplus power are limited feedstocks. Thus, the useable amount is constraint by maximum 1 kWh_{LHV} wood and 1 kWh surplus electricity.

3.1.2. Considered Wood-to-Chemicals and CO_2-to-Chemicals process routes

Most of the considered Wood-to-Chemicals and CO_2-to-Chemicals process routes require additional hydrogen (cf. Table 1). Hydrogen can either be produced from electrolysis using surplus power with an efficiency of 55 kWh/kg H_2 (Schüth 2011) or from steam-methane-reforming with water-gas-shift (GW = 10.8 kg CO_2-eq/kg). All considered chemical processes routes require additional grid electricity for compression and separation of reactants and products. The global warming impact of grid electricity is 0.4 kg CO_2-eq/kWh (German target for 2020).

3.1.3. Conventional production of considered platform chemicals

The following conventional processes are considered (PE International 2013):

- Methanol: production from natural gas-based syngas (GW = 0.88 kg CO_2-eq/kg)
- Methane is assumed as natural gas (GW = 0.034 kg CO_2-eq/kWh_{LHV}).

3.1.4. Alternative utilization of wood and surplus power

While we vary global warming impact reductions ($GW_{reduction}$) for the alternative utilization of wood and surplus power, we also define two reference cases with very high $GW_{reduction}$.

- Wood can be converted to electricity. If the wood-fired power plant replaces a coal-fired power plant, the $GW_{reduction}$ is 0.35 kg CO_2-eq/kWh (Steubing et al. 2012).
- Surplus power can be stored in a pumped hydro storage. If electricity from the pumped hydro storage replaces electricity from a natural gas turbine $GW_{reduction}$ is 0.5 kg CO_2-eq/kWh (Sternberg and Bardow 2015).

Table 1: Inputs, outputs and direct greenhouse gas emissions of considered Wood-to-Chemicals and CO_2-to-Chemicals process routes. All values for Wood-to-Chemicals and CO_2-to-Chemicals process routes are per 1 kWh_{LHV} wood input and 1 kg CO_2 input, respectively. Positive values are inputs and negative values are outputs. For CH_4, inputs are natural gas and outputs are methane.

	H_2	CH_3OH	CH_4	Electricity	Emissions
	kg	kg	kWh	kWh	kg CO_2-eq
CO_2 (+H_2)-to-CH_4[a]	0.172		-4.73	0.112	0.066
CO_2 (+H_2)-to-CH_3OH[b]	0.136	-0.696		0.926	0.032
CO_2 (+H_2, NG)-to-CH_3OH[c]	0.075	-1.537	8.71	0.953	0.583
Wood-to-CH_4[d]			-0.86	0.032	0.246
Wood-to-CH_3OH[e]		-0.103			0.212
Wood (+H_2,min)-to-CH_4[d]	0.001		-0.89	0.033	0.240
Wood (+H_2,max)-to-CH_4[d]	0.035		-1.77	0.066	0.066
Wood (+H_2)-to-CH_3OH[c]	0.014	-0.216		0.140	0.036
Wood (+H_2, NG)-to-CH_3OH[c]	0.011	-0.306	0.76	0.190	0.060

[a]Müller et al. 2013, [b]Rihko-Struckmann et al. 2010, [c]Clausen et al. 2010, [d]Gassner and Maréchal 2008, [e]C. N. Hamelinck and A.P.C. Faaij 2002

3.2. Minimal global warming impacts for methanol production

Figure 2 shows the optimal process routes for methanol production as function of global warming impact reductions ($GW_{reduction}$) for the alternative utilization of wood and surplus power. Five process combinations (zones) are identified. In each zone, the given process route has the lowest overall global warming impacts. Thus, the product (methanol or methane) was not specified. However, the production of methanol from renewable carbon sources always achieves lower global warming impacts than the production of methane.

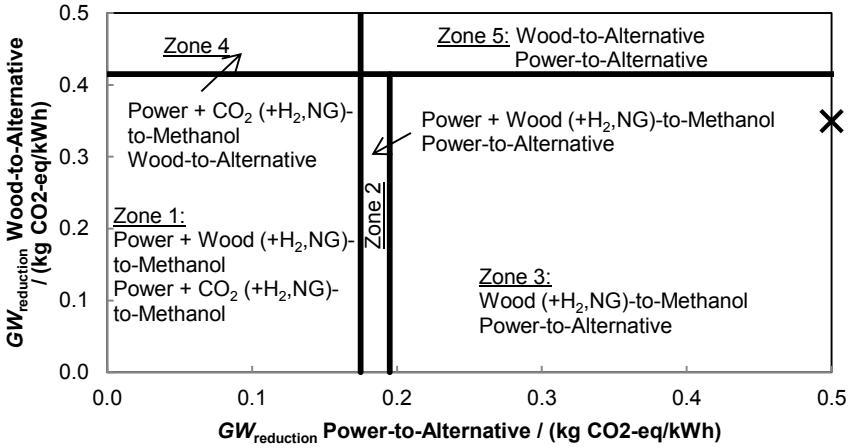

Figure 2: Process routes for methanol production with lowest global warming impacts depending on the global warming impact (*GW*) reduction for Power-to-Alternative and Wood-to-Alternative. "Power +" means that the required hydrogen is produced from surplus power. The cross indicates the considered reference case Power-to-Alternative and Wood-to-Alternative processes.

The combination of Wood-to-Methanol and CO_2-to-Methanol (Zone 1) achieves the lowest global warming impacts as long as the $GW_{reduction}$ for alternative utilization of wood and surplus power is lower than 0.41 and 0.18 kg CO_2-eq/kWh, respectively. Both processes use also natural gas and hydrogen from surplus power. If the $GW_{reduction}$ for Wood-to-Alternative is higher than 0.41 kg CO_2-eq/kWh, Wood-to-Methanol processes are no longer used (Zone 4). If the $GW_{reduction}$ for Power-to-Alternative is higher than 0.18 kg CO_2-eq/kWh, CO_2-to-Methanol processes are not used (Zone 2). In Zone 2 and 3 the production of methanol from wood achieves the lowest global warimg impacts. The difference between Zone 2 and 3 is only the production process for the required hydrogen. The threshold value (0.2 kg CO_2-eq/kWh) between Zone 2 and 3 is exactly the $GW_{reduction}$ for the hydrogen production from surplus power and the subsequent substituion of conventional produced hydrogen. Thus, for higher $GW_{reduction}$ it is environmentally more beneficial to produce the hydrogen conventionally and use the surplus power alternatively. In Zone 5, both wood and surplus power are used alternatively and the methanol is produced conventionally.
If the global warming impact of CO_2 is lower than -0.73 kg CO_2-eq/kg (not shown in Figure 2), the lowest global warming impacts are achieved for CO_2-to-Methanol together with conventional produced hydrogen and natural gas.
For the reference alternative utilization of surplus power and wood presented in section 3.1.4 (Cross in Figure 2), Methanol-to-Wood is the prefered conversion route.

3.3. Minimal global warming impacts for methane production

We repeat the analysis by specifying methane as product. Fig. 3 shows six zones with optimal processes routes for methane production.
In Zone 1, the maximal possible amount of wood and surplus power is used to produce methane. In Zone 4, the maximal possible amount of surplus power is used but only a part of wood is used to produce methane. In Zone 2, the maximal possible amount of wood is used but only part of surplus power. The difference between Zone 2 and 3 is the production of hydrogen (cf. section 3.2.). If the $GW_{reduction}$ for Wood-to-Alternative is higher than 0.25 kg CO_2-eq/kWh, all wood is used for alternative processes. As long as

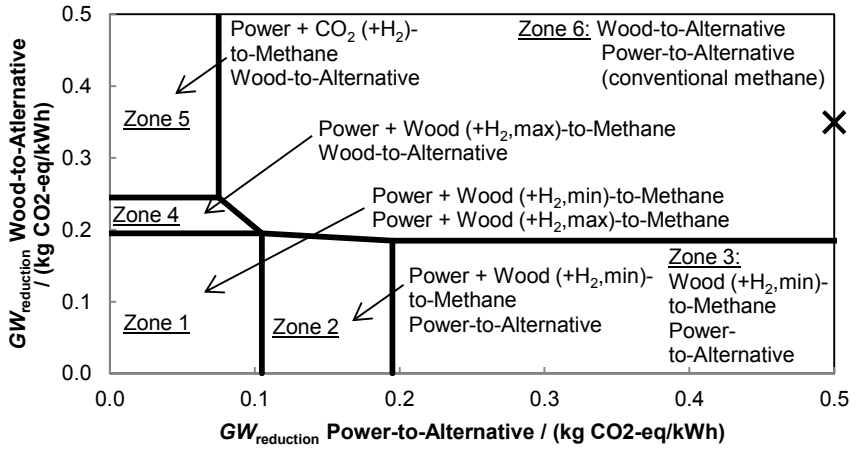

Figure 3: Process routes for methane production with lowest global warming impacts depending on the global warming impact (*GW*) reduction for Power-to-Alternative and Wood-to-Alternative. "Power +" means that the required hydrogen is produced from surplus power. The cross indicates the considered reference case Power-to-Alternative and Wood-to-Alternative processes.

the $GW_{reduction}$ for Power-to-Alternative is lower than 0.07 kg CO_2-eq/kWh, CO_2 and surplus power are used to produce methane (Zone 5). In Zone 6, surplus power and wood are both used alternatively and methane is no longer used to replace natural gas.

4. Conclusions

We present a superstructure-based optimization of chemical process routes based on renewable carbon sources. The approach identifies the environmentally most beneficial process routes for platform chemicals from a macro perspective. Thus, the approach also includes alternative utilization options for the limited feedstocks wood and surplus power. The results are presented as function of global warming impact reductions of the alternative utilization of wood and surplus power.

Our reference case allows alternative utilization of wood for electricity and surplus power in pumped hydro storage. In this case, wood is converted to methanol to achieve the lowest global warming impacts.

Abstract

From its first introduction in 1965, the Petlyuk column received a high interest in the research community. Applied for the separation of three-component mixtures, the Petlyuk column is able to perform the separation with a reduced number of equipment and with a consistent reduction of the energy consumption compared to the classical sequences with simple columns. For a three-component separation the Petlyuk arrangement is composed by a prefractionator fully coupled with a main column that performs the separation of the products. Considering the great potential of these sequences it is natural to think about a possible extension to more than three component separations. In the present work a four component case is examined. If the divided wall column configuration is considered, the presence of three walls inside the main column makes the design and the control too complex to attract the industrial interest for a real application. New intensified sequences were proposed for the separation of four-component mixtures. These configurations use a less number of columns compared to the Petlyuk configuration. The case study reported proves the potential of the alternative configurations.

Keywords: Petlyuk configuration, distillation sequencing, design, energy saving.

1. Introduction

Two milestones are recognized by the research community as meaningful improvements in separations performed by distillation. The former is the introduction of structures with a partition wall inside the shell and the latter can be considered the definition of the Petlyuk configuration. Both of them were introduced almost fifty years ago but only recently have been successfully applied into the industrial practice for a limited number of feed components. Considering three-component separations, the Petlyuk configuration is composed by a prefractionator connected by two thermal couplings to the main column where the three products are obtained. If the prefractionator is included in the main column, the corresponding divided wall column (DWC) configuration is obtained. In both cases only one condenser and one reboiler are employed. It was clearly demonstrated that for a three-component mixture the Petlyuk configuration can

save up to 30 % of the energy consumption compare to the classical separation sequences (Emtir et al, 1999). Despite this evidence at least three valid hurdles contributed in the late development of Petlyuk and DWC configurations in the industrial practice. The first is the absence of recognized design methods, the second is the complexity of the structure and the third reason is the difficult in the process control. The research efforts, focused around these three points, contributed to reach more than one hundred operative DWCs around the world.
It is possible to assert that for the case of three component separations the Petlyuk and its equivalent DWC configuration has the potential of a noteworthy energy saving, different design methods are available, structure complexity are overcame by using the thermodynamically equivalent configurations and moreover the control issues are solved. It is clear that the same results are aimed for different number of feed components. Moving from three to four components the complexity of the Petlyuk and DWC structure increases and up to now only few studies are focused on the possible applications of these configurations. The aim of the present work is to propose alternative configurations to the Petlyuk/DWC configuration for a four-component separation. The benefit of the alternatives proposed is a simple design with a less or comparable total annual cost compare to the corresponding Petlyuk/DWC configuration. A case study is presented to support the new sequences.

2. Synthesis Procedure

The synthesis procedure is a systematic methodology that allows the prediction of all the alternatives generable from a sequence chosen as a reference. For a four-component mixture, the non-sharp configuration reported in Figure 1 is considered to start the generation procedure.

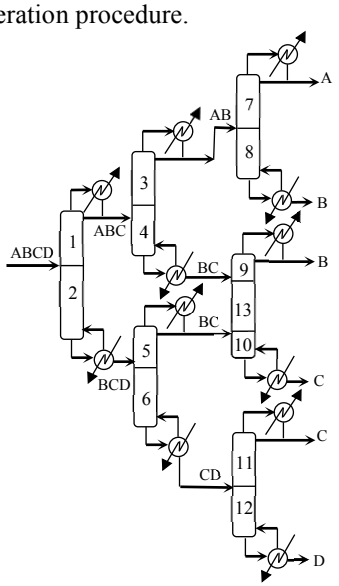

Figure 1. The six-column sequence for the fully sloppy separation of a quaternary mixture.

In this six-column sequence, usually referred as fully sloppy configuration, all the mixtures with three or more components are separated by symmetric sloppy splits. The corresponding Petlyuk configuration can be obtained in two steps: in the first one the

column sections where the same mixture or component is separated are merged. In the case considered sections 4 and 5, 8 and 9, 10 and 11 are combined reducing the number of column to three. Then, considering that in the Petlyuk configuration there is only one condenser and one reboiler independently from the number of component to be separated, all the condensers and reboilers associated to non-product streams can be substituted with a thermal coupling. The corresponding configuration is showed in Figure 2.

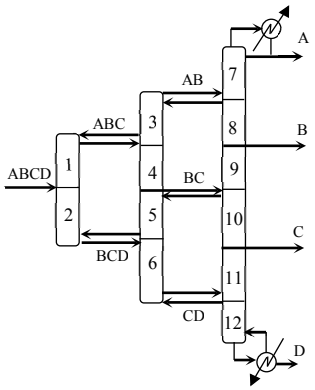

Figure 2: quaternary Petlyuk configuration

The Petlyuk configuration has three columns and five thermal couplings. Intensified sequences alternative to the Petlyuk arrangement can be obtained starting from the fully sloppy configuration of Figure 1 applying four different strategies (Rong at al, 2014):

1. Closed-Heat-Integration strategy to combine individual columns. This strategy is used to combine two columns by heat integration between a condenser and a reboiler co-producing a same product. This will reduce the number of columns.
2. Thermal coupling strategy to eliminate a condenser or a reboiler. This strategy is used to eliminate a condenser or a reboiler associated to a mixture of two or more components. This will reduce the number of heat exchangers.
3. Rearrangement of column sections strategy to generate thermodynamically equivalent structures. This strategy is used to recombine the column sections in a thermally coupled configuration through movement of the movable column sections. This will generate the thermodynamically equivalent structures which have different columns than the original thermally coupled configuration.
4. Elimination of the single-section-side columns strategy to produce the intensified distillation systems. For a thermally coupled configuration, there are thermodynamically equivalent structures in which there are single-section-side columns. This strategy is used to eliminate the single-section-side columns to generate the intensified distillation systems with fewer columns.

Applying the four point strategy presented the five configurations reported in Figure 3 are obtained. In particular the configuration reported in Figure 3(a) is obtained applying the strategy 1 to merge section 8 with section 9 and section 10 with section 11, then following the strategy 2 the condenser associated to the submixture ABC and the reboiler associated to the submixture BCD are substituted by thermal couplings. Strategy 3 is used to rearrange section 3 above section 1 and section 6 below section 2, finally single sections 4 and 5 are eliminated as indicated in the strategy 4. Similarly the configurations reported in Figure 3 (b-e) are obtained. Analyzing all the configurations generated is possible to notice that are all composed by two columns, moreover in

sequences 3(b) and 3(d) the stream C is obtained twice, in sequences 3(c) and 3(e) the component B is recovered in two separate streams. Only the sequence 3(a) is associated to the minimum number of streams.

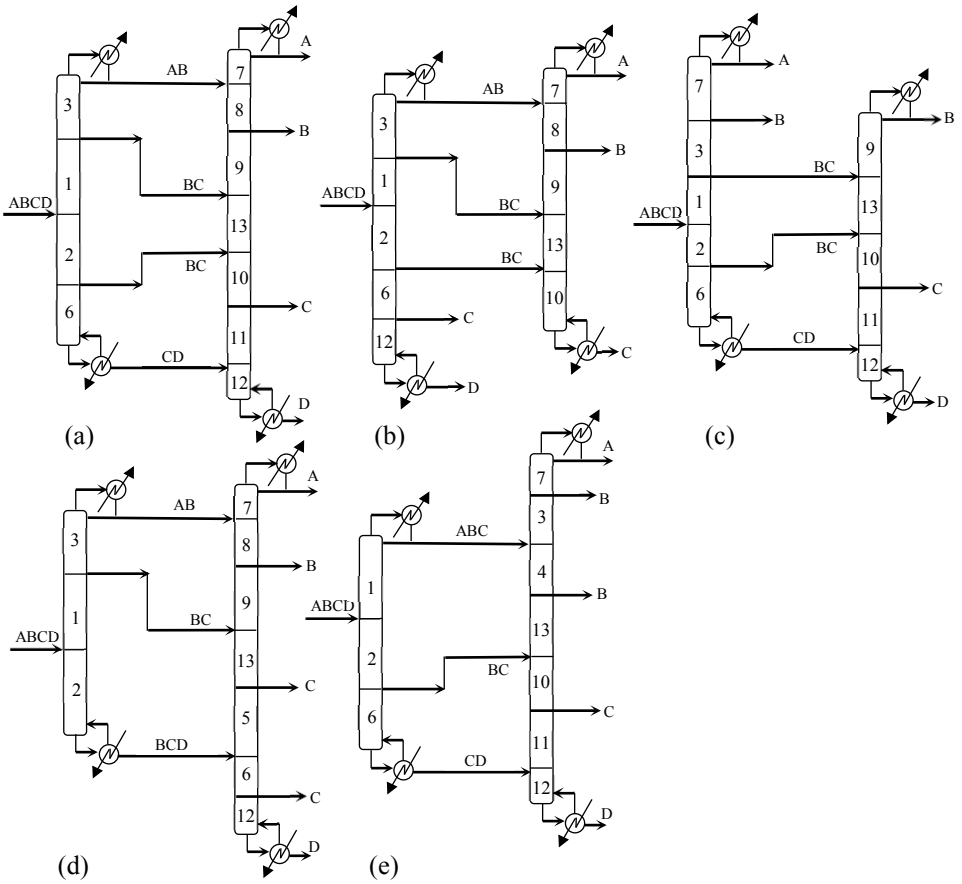

Figure 3: The intensified distillation alternatives for quaternary Petlyuk configuration

3. Case Study and Comparison Indexes

To test the applicability of the new intensified sequences, a case study has been considered. The composition and the product purity targets are shown in Table 1.

Table 1: feed composition and purity target

	Component	Feed composition [mol frac.]	Purity target [mol frac]
A	Butane	0.05	0.990
B	Hexane	0.10	0.970
C	Heptane	0.10	0.974
D	Nonane	0.75	0.997

A saturated liquid feed flowrate of 100 kmol h^{-1} is considered. All the configurations were simulated by means of Aspen Plus V8.0. The NRTL thermodynamic method was used and sieve trays columns were considered. The column pressure was optimized for

each column considering the possibility to use water in the condenser. The minimum temperature for the columns overhead vapor was defined to 323K.
Three different indexes were selected for the configurations comparison: the total annual cost, the thermodynamic efficiency and the carbon dioxide emission. The Total Annual Cost (TAC) is obtained as a sum of the operative and the annualized capital costs as reported in Eq. (1).

$$TAC = \sum \left[\left(\frac{Capital\ Cost}{Time\ of\ Investment} \right) + (Operative\ Costs) \right] \quad (1)$$

The operative costs were evaluated taking into account the cost of the water and the vapor in the condenser and reboiler respectively. The costs of the auxiliary fluids were obtained from Rev et al., 2001. The capital costs were considered as the sum of the costs of the condensers, reboilers, column shell and trays, evaluated according to the Guthrie's method reported in Turton et al., 2004. A mean investment time of 10 years was used to annualize the capital costs. The second index considered is how efficient the energy is being used. This information is expressed by the thermodynamic efficiency (η) evaluated as reported by Seader et al., 2009 and defined in Eq. (2)

$$\eta = -W_{min}/(-LW - W_{min}) \quad (2)$$

where W_{min} is the minimum work of separation and LW the lost work.
The last index used to compare the different configurations is the carbon dioxide emission (m_{co2}) since as a greenhouse gas is directly related to the global warming. The amount of carbon dioxide emitted was evaluated by the Eq. (3) following the method reported by Gadalla et al., 2005:

$$m_{CO_2} = \left(\frac{Q_{FUEL}}{NHV} \right) \left(\frac{\%C}{100} \right) \alpha \quad (3)$$

where Q_{fuel} is the heat generated by the combustion reaction, NHV the net heating value of a fuel with a carbon content of %C and α the ratio of molar masses of CO_2.

4. Simulations and results

In order to get the design parameters of all the alternative sequences, the fully sloppy configuration of Figure 1 was first simulated using the short-cut method of Underwood-Gilliland-Winn already implemented in Aspen Plus. The parameters obtained were used to initialize the stage-to-stage rigorous method RadFrac. The number of stages, feed location, reflux ratio were then optimized for the minimum energy consumption.
The design of the Petlyuk configuration was performed considering the correspondent among the column sections functionality (Errico et al., 2014). In this way once the design of the fully sloppy configuration of Figure 1 was obtained the configuration parameters were transposed to the analogous sections. The thermal coupling the flowrates were defined as the minimum possible value to assure the products purity targets. Following the same design methodology cited for the Petlyuk configuration, the alternative configurations reported in Figure 3 have been simulated using the correspondence of column functionality. Only the results for the configuration of Figure 3(a) are reported in Table 2 since, for the composition cases considered, was most convenient from the energy consumption point of view. Among all the alternatives predicted, the one in Figure 3(a), is the only sequence that performs the separation of the middle components once.

Table 2: Sequences comparison

	Petlyuk	Fig. 3(a)
TAC [$/y]	433	432
η [%]	47	52
CO2 [kg/h]	601	598

5. Conclusions

The work presented a new space of alternatives to the Petlyuk configuration for quaternary separation. The motivation of the work starts from the interest in the Petlyuk configuration due to its potential in energy reduction. Anyway for a four-component separation, the complexity of the design and control limit its application. A synthesis methodology is presented to generate a complete space of alternatives with a simpler design. For the case considered, among all the sequences it was obtained once with similar or better performance compare to the Petlyuk configuration. It is possible to conclude that the alternatives proposed are a valid alternative to the complexity of the Petlyuk configuration but still with the same benefit of less energy consumption.

dbarletta@unisa.it

Abstract

The techno-economic analysis of an IGCC plant for power and hydrogen production with CO_2 capture by means of Pd-based H_2 membranes was carried out. The case studies were referred to the modifications of the existing 330MWe Integrated Gasification Combined Cycle (IGCC) plant of ELCOGAS based on entrained flow gasification of a dry mixture of coal and pet-coke. The pre-combustion section consisting in a sour water gas shift reactor integrated with Pd-based H_2 selective membranes and CO_2 selective membranes was simulated by process simulation techniques. Heat integration of the new process section was also addressed to minimize the energy loss. Power and energy penalty were evaluated as a function of the CO_2 capture percentage and of the electricity and hydrogen output.
Economic assessment of the additional capital and production costs was also performed to evaluate the mitigation cost of the carbon capture and storage (CCS) based on membrane technology. Sensitivity analysis was carried out to derive the breakeven price and the threshold performance of hydrogen membranes. The results on the cost of electricity, calculated without accounting for the revenues of the hydrogen sales, provided preliminary data for the economic feasibility of H_2 membranes in the IGCC process.

Keywords: IGCC, CO_2 capture, membranes, hydrogen.

1. Introduction

In recent years the interest for IGCC plants has increased, since it is a highly efficient and low emissions technology to produce energy from coal. This technology is also currently used to convert the pet-coke produced from petroleum processing in several refineries (e.g. ISAB Energy plant, ELCOGAS plant) with limited emissions of pollutants. Moreover, the flexibility of IGCC plants allows using also renewable fuels like biomass materials to reduce the greenhouse gas (GHG) emissions (Emun et al., 2008). Alternative solutions to address the GHG reduction are based on the introduction of CO_2 capture units in the process before the gas turbine combustion (Cormos et al., 2011). Some studies have also assessed the possibility to combine co-gasification with biomass and CO_2 capture by different technologies (Maxim et al., 2011) In general, the results of these analyses indicate that the improved process requires significant additional capital costs for the new CO_2 capture units and, therefore, implies high marginal cost of electricity per ton of avoided CO_2 (i.e. mitigation cost). Also the co-

production of electricity and hydrogen has been assessed in several studies with a range of technologies (Cormos et al., 2010).

This work is part of the FECUNDUS EU funded project aiming at demonstrating for IGCC plants the feasibility of co-gasification with biomass and of pre-combustion CO_2 capture process schemes based the combination of water gas shift reactors and two alternative product removal technologies: solid sorbents for CO_2 capture and metallic membrane selective to H_2. The present paper reports the techno-economic assessment of the process flowsheet based on H_2 selective membranes.

2. Process flowsheet synthesis and simulation

The IGCC process flow diagram of the ELCOGAS plant in Puertollano was modeled using the steady-state process simulator Aspen Plus Version 8. The gasifier was simulated assuming chemical equilibrium for all reactions except two for which "temperature approach to equilibrium" was assumed. Optimal ΔT values for these two reactions were found by searching the best fitting between the simulation results and the experimental data of raw syngas. Main gas cleaning units (Venturi scrubber and methyl diethanolamine absorber) were modeled by rigorous multistage vapor-liquid equilibrium approach accounting for electrolytic reactions in the liquid phase. Simplified methods were used for other process units (carbonyl sulfide hydrolysis reactor, Sour Water Steam stripper, sulphur recovery Claus process). The units of the combined cycle (gas turbine, gasifier heat recovery, heat recovery steam generator and steam turbine) for power generation were modeled in detail accounting for heat integration. More details on the model and on its validation with industrial data are reported by Sofia et al. (2014).

A new process section for the pre-combustion capture of CO_2 was developed in the simulation flowsheet after the gas cleaning section (Figure 1). The core of the new section is based on the combination of the water gas shift reactor with hydrogen selective Pd-based membranes (Barreiro et al., 2014) in an integrated water gas shift membrane reactor (WGSMR). The latter is fed with the clean syngas, leaving the purification section of the plant, sand with intermediate pressure steam. The membrane permeate stream consists in a mixture of hydrogen and waste nitrogen, coming from the air separation unit (ASU), used as sweep gas in the membrane. The retentate stream mainly formed by CO_2, H_2O and N_2 is dehydrated by partial condensation of water and then sent to a carbon dioxide polymeric membrane unit to separate CO_2 from N_2. The CO_2 permeate is compressed and cooled down up to storage conditions (30°C, 110bar). The N_2 in the retentate stream is used to further dilute the hydrogen in the H_2-waste N_2 stream before sending it to the gas turbine. The co-production of electricity and hydrogen was considered by splitting part of the the H_2-waste N_2 stream and sending it to further hydrogen separation units.

Simulation of the new process section was addressed as follows. The WGSMR was simulated as an adiabatic multistage catalytic reactor (RPlug blocks) with interstage hydrogen separation (Sep2 blocks). HT-WGS kinetics reported by Adams et al. (2009) was assumed for operating conditions in the range 300 °C-400 °C and 20-22 bar.

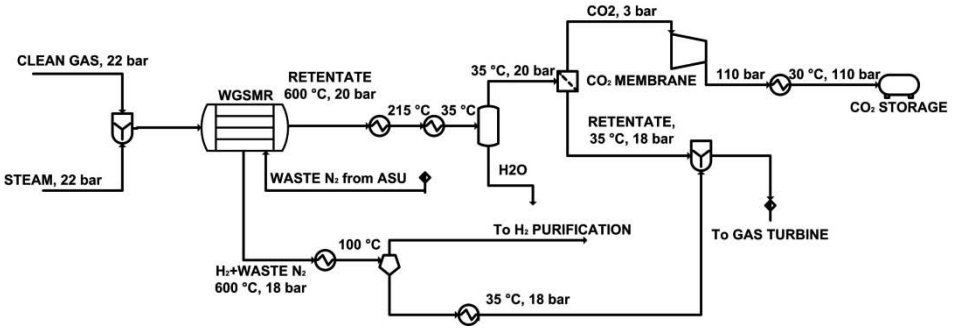

Figure 1 Flowsheet of the CO_2 capture section of the IGCC plant.

The sizing of the area of the membranes was approached by a simplified design equation assuming characteristic values of the molar flow of Pd membranes for H_2 (Barreiro et al., 2014) and polymeric membrane for CO_2 (Grainger and Hägg, 2008). The compressor train for CO_2 was simulated by a multistage compressor model (MCompr block). Process heat integration was performed in the new process section in order to obtain the required utilities and the size of the heat exchangers.

3. Results

Simulations were carried out for the design fuel feed of the IGCC plant consisting in a blend of coal and petroleum coke 50 % in weight with a LHV of 24.89 MJ/kg and 686 MW thermal power input. Further details on the design fuel are reported by Sofia et al. (2013). The technical performances of the WGSMR and of whole IGCC plant was studied as a function of the H_2O/CO feed ratio to the WGSMR. As expected, the water gas shift reaction conversion increases from 85 % to 98 % for increasing values of the H_2O/CO ratio in the range 2-3 due to the beneficial effect of the H_2O/CO ratio on the WGS equilibrium conversion. Moreover, the continuous hydrogen product removal in the membrane reactor allows the conversion exceeding the thermodynamic equilibrium conversion boundary. This reactor performance affects the overall CO_2 capture increasing from 77.8 % to 81.1 % with increasing H_2O/CO feed ratio. On the other hand, the net electrical power produced by the plant decreases from 286 MW obtained without CO_2 capture to 220 MW and 219 MW for 77.8 % and 81.1 % CO_2 capture, respectively. The corresponding net electrical efficiency drops from 41 % of the conventional IGCC to 32.1 % and 32.0 % for 77.8 % and 81.1 % CO_2 capture, respectively. The resulting energy penalty is about 9 %.

The co-production of hydrogen was assessed as well by introducing a split on the H_2-N_2 waste stream coming out of the WGSMR. Results indicate that the hydrogen flow rate is limited by an upper bound value due to the thermal sustainability of the whole IGCC plant. In fact, increasing the H_2 split, the power produced by the gas turbine and by the steam turbine decreases. The steam turbine power has lower bound given by the critical value corresponding to the minimum flow rate of intermediate pressure steam required to feed the gasifier and the WGSMR. As a result, it is possible to increase the maximum H_2 split ratio by decreasing the H_2O/CO ratio of the WGSMR. In fact, the maximum H_2 split ratio that is achievable for H_2O/ equal to 3, 2.5 and 2 is 24 %, 28 % and 30 %, respectively. These results correspond

Table 1 Plant performance and economic analysis results for the CO_2 capture schemes.

	without CO_2 capture	with CO_2 capture		
H_2O/CO to WGSMR [-]	-	2	2.5	3
Gross power [MW]	320.7	281.4	281.1	281.0
Net power [MW]	285.7	220.5	219.8	219.4
Net efficiency	41.6	32.1	32.0	32.0
Capital costs [M€]				
IGCC base installed costs	458	458	458	458
Total new installations	-	215.9	222.2	225.9
Specif. investment [€/kW]	1603	3057	3095	3117
COE [€/MWh_{net}]	55.5	84.7	85.5	86.0
CO_2 captured [%]		77.8	80.0	81.1
CO_2 emitted [kg/MWh_{net}]	828	216	192	181
Mitigation cost [€/tCO_2]	-	47.8	47.2	47.1

On the other hand, the reduction of the H_2O/CO ratio causes a lower conversion of CO to CO_2 in the WGSMR and, thus, a lower pre-combustion CO_2 capture. Obtained results are summarized in Figure 2 in terms of power distribution and CO_2 emissions per MWh as a function of the H_2 spilt ratio.

Economic analysis of the flowsheet was carried out only for the case of power production with CO_2 capture. A total investment cost of 458 M€ was assumed for the Puertollano IGCC plant at the time of the project (Campbell et al., 2000). This cost was not updated intentionally since the aim is to estimate the effect of the different fuel cost and plant performance on the COE over the entire life of a plant built years ago. The capital expenditure for the additional equipment of the new CO_2 capture section was evaluated by scaling factors and cost index methods. For Pd membranes H_2 molar flow of 0.1 kmol m^{-2} h^{-1} (Barreiro et al., 2014) and unit cost of 3500 €/m^2 were assumed for the base case. Manufacturing costs, including reactants, catalysts and utilities, were assessed from data available in the literature. The total investment cost (TIC) and the total annual costs (TAC) were derived.

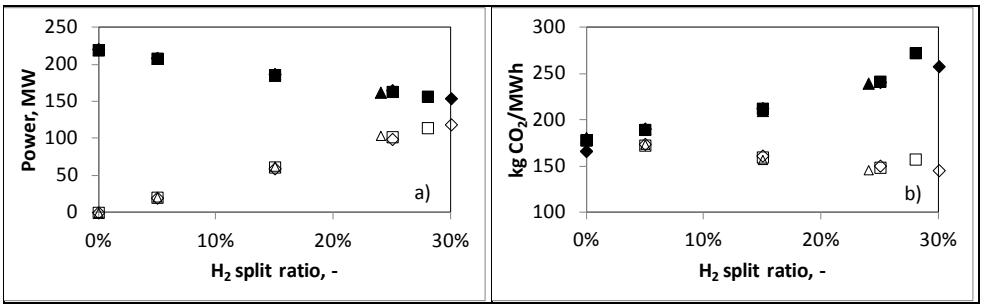

Figure 2 Plant performance for the CO_2 capture schemes with H_2 co-production: a) electric power (solid symbols), H_2 power (hollow symbols); kg CO_2/MWh of electricity (solid symbols) kg CO_2/MWh of electricity and H_2 (hollow symbols). H_2O/CO = 2 (diamonds), 2.5 (squares), 3 (triangles).

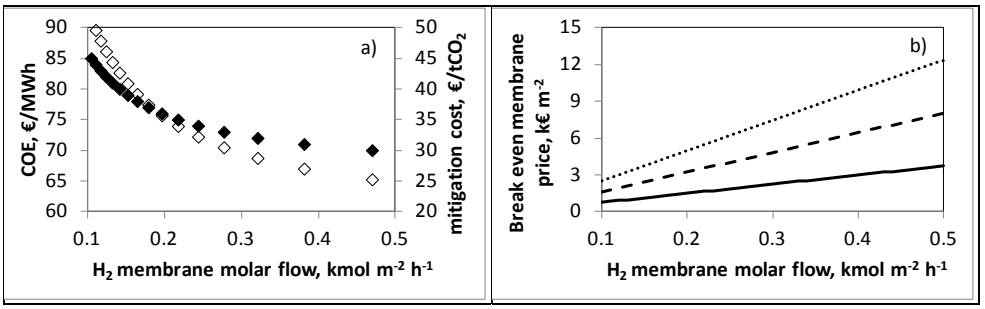

Figure 3 Effect of the H_2 membrane molar flow on a) COE (solid diamonds) and mitigation cost (hollow diamonds); b) break even membrane price for COE = 70 €/MWh (continuous line), 75 €/MWh (dashed line), 80 €/MWh (dotted line). All results are for the 80% CO_2 capture case.

Finally, a profitability analysis based on the discounted cash flow method assuming a plant lifetime of 25 years and an interest rate of 7.5 % was performed to derive the cost of electricity (COE) as the break even cost of electricity (i.e. the value of the cost of electricity which makes the net present value equal to zero). Moreover, the additional cost of electricity due to carbon capture was related to the avoided CO_2 emissions in terms of the so called mitigation cost, defined as follows:

$$\text{mitigation cost} = \frac{\text{COE}_{\text{CCS}} - \text{COE}_{\text{base}}}{\text{CO}_{2\,\text{base}} - \text{CO}_{2\,\text{CCS}}} = \left[\frac{€}{\text{tCO}_2}\right] \quad (1)$$

where COE_{base} and COE_{CCS} are the cost of electricity for the base case IGCC and for the IGCC with CCS, respectively, CO_{2base} and CO_{2CCS} are the corresponding tons of CO_2 emitted per MWh.

Membrane technology for H_2 separation is still under development and continuous improvement since membranes with satisfactory H_2 molar flow values are still really expensive. Thus, it is necessary to find a trade-off between satisfactory separation performance and sustainable cost of the membranes. As a result, a sensitivity analysis on the effect of the membrane molar flow an of the membrane price for unit area on the economic indicators of the whole process as a function of was carried out to preliminary address this point for the 80% CO_2 capture (H_2O/CO to WGSMR = 2.5). In particular, Figure 3a reports the COE and the mitigation cost as a function of the H_2 membrane molar flow. Results indicate a decrease of the COE from 86 to 70 €/MWh and a decrease of the mitigation cost from 47 to 25 €/tCO_2 for increasing membrane molar flow in the range 0.1-0.4 kmol m^{-2} h^{-1}. Furthermore, the break even price (i.e. the price value which makes the net present value equal to zero) of the membrane per unit area was calculated as a function of the H_2 membrane molar flow assuming different values of COE (70, 75 and 80 €/MWh), and, thus, different mitigation cost values (25, 34 and 43 €/tCO_2). Results reported in Figure 3b indicate a linear increase of the break even price with increasing H_2 membrane molar flow. Of course, further calculations are necessary to account for the additional investment costs for H_2 purification and the revenues of the H_2 sales. It is expected that these further evaluations will significantly affect the profitability indicators of the whole plant and the break even price of the membranes.

4. Conclusions

The technical feasibility of an innovative process section including a WGSMR and CO_2 selective membranes to address the CO_2 capture and separation was demonstrated for an IGCC plant fed with a coal-petcoke blend. A CO_2 capture between 77.8 % and 81.1 % was achieved as a function of the H_2O/CO feed ratio to the WGSMR. The maximum carbon capture value achieved corresponds to an energy penalty of about 9%. The conceptual design of a hydrogen co-production revealed that the maximum H_2 flow rate achievable was limited by the steam demand of the WGSMR.
Economic analysis confirmed that the membrane technology for H_2 separation is still very expensive for plants producing only electrical power. This results in high cost of electricity and high mitigation cost. The significant effect of the H_2 molar flow and the price of membrane per unit area on the profitability indicators was also highlighted. Economic improvement deriving from the co-production of electricity and H_2 will be addressed in the future work. Co-firing with biomass could be also considered in combination with the CCS section in order to reduce the fossil carbon in the feedstock and to aim at CO_2 emissions closer to zero.

Abstract

With exerting pressures on water systems, efforts have recently been focused on optimisation of existing, and design of new treatment facilities. Modelling, specifically, offers the advantage of early stage processes synthesis at minimum design change expenses. Current research and industry gaps lie in overall construction of water treatment flowsheets by crossing various disciplines.

In the current work a systematic approach for the synthesis of water treatment processes is proposed. The design combines technological robustness, improved economic performance and environmental reliability. The problem is formulated as a mixed integer non-linear programming (MINLP) model. A case study of seawater desalination is presented where conventional and non-conventional treatment technologies are considered. The flowsheet structure is selected based on units separation and recovery efficiencies, operating and capital costs, and carbon footprint. The model is solved for desired water purity to meet drinking water standards with the objective to minimise water production costs. The results are analysed to investigate the applicability of the presented approach.

The developed methodology can have a significant impact on reducing the design time and simultaneously, increasing the cost effectiveness of water treatment processes.

Keywords: water treatment synthesis, mixed integer non-linear programming, technological robustness, economic performance, environmental aspects

1. Introduction

Water treatment is assigned a major role in mitigating the current and future demographic, geographic and industrial global water resource challenges. Early stage optimisation with design of treatment facilities conduce to technically, economically and environmentally more advantageous systems. However, so far little work has been done on their systematic synthesis where both, individual units and their interconnections, are optimised.

Desalination of seawater for drinking water purposes, in particular, has recently been a focus of attention worldwide. The most common alternatives used in the process include coagulation-flocculation, sedimentation, dissolved air flotation, media filtration (conventional pretreatment), microfiltration, ultrafiltration (non-conventional pretreatment), nanofiltration and reverse osmosis (non-conventional desalting).

Various optimisation models have been developed to correlate the separation performance of those technologies and their characteristics and operating conditions. Vlaški (1998) investigated the separation efficiency of dissolved air flotation and sedimentation with respect to algae and particles. Tabatabai (2014) worked on the assessment of coagulation and ultrafiltration for reverse osmosis desalination. Ahsan (1995) studied the optimisation of direct horizontal filtration.

Other work has been published on reviewing the principles of design in seawater desalination. Voutchkov (2010) analysed the strategies for choosing pretreatment systems whereas Lior (2013) examined in detail the technical, economic and environmental aspects of the process. Lu et al. (2007) proposed an optimum design of reverse osmosis system for seawater desalination formulated as a mixed integer non-linear program (MINLP) problem. A methodology for overall water treatment synthesis has been suggested by the current authors in previous work (Koleva et al., 2013) where the mathematical model was tested on seawater desalination.

The present work develops the model further and incorporates the environmental aspect of carbon emissions as an inseparable part of overall systems design. The following sections of the paper are organised as follows: Section 2 gives a frame of the study, Section 3 presents the constraints necessary for the fullfilment of the various criteria, Section 4 shows a theoretical case study in seawater desalination and results and Section 5 gives observations and conclusions of the applicability of the model.

2. Problem statement

The current work presents a methodology for design of seawater desalination facilities with technical, economic and environmental aspects. Total suspended solids (TSS), total dissolved solids (TDS) and boron (B) were considered in the model as major contaminants. To the best available technologies pool belong 9 candidates, i.e. coagulation-flocculation (CF), sedimentation (SED), dissolved air flotation (DAF), multi-media filtration (MMF), microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), reverse osmosis (RO) for TDS and reverse osmosis for boron removal. The major criteria for selection are the technical performance to meet final quality product and total annual cost including carbon emissions where production of minimum water net cost is sought. The problem is formulated as an MINLP model and the overall problem definition is stated as follows:

Given:

seawater contaminants groups; best available seawater treatment technologies; seawater feed flowrate and initial contaminants concentrations; technologies operating conditions and characteristics ranges for pressures, temperatures, chemical dosage, mixing input power, flocculation times, media size and load, membrane molecular weight cut-off, hydrophobicity, hydrogen ion concentrations; efficiency parameters such as recovery, pumps and motors efficiencies; cost data such as electricity charge, carbon tax, maintenance and replacement rates

Determine:

conceptual flowsheet design, operating conditions for the selected units, contaminants and flowrates profiles, and annual operating and capital costs

So as to:

minimise the water production cost which is equal to the total annualised cost divided by the annual plant capacity.

3. Mathematical model

The methodology presented below consists of a group of constraints that assist in the selection of the best combination of technologies. For the technical performance, the mass balance constraints are explained next.

3.1. Mass balance constraints

The mass balance constraints relate the potential contaminants concentrations and flowrates from the inlet and outlet of every candidate unit. The method has been described as a MILP model in previous work (Koleva et al., 2013) where the linearity arises from the discrete values of the operating conditions. For the proposed model, the operating conditions are continuous variables taking lower and upper boundaries and an additional, integer variable, U_t, is introduced that accounts for the number of passes for every potential unit.

$$c^P_{s,t} = W_t \cdot c^F_{s,t} \cdot (1 - R_{s,t})^{U_t} + (1 - W_t) \cdot c^F_{s,t}, \qquad \forall t, s \qquad (1)$$

where $c^P_{s,t}$ and $c^F_{s,t}$ $[mg/L]$ are the permeate and feed concentrations of contaminant s for technology t, $R_{s,t}$ is a removal coefficient of contaminant s for technology t, W_t is a binary variable equal to 1 when a unit is selected and equal to 0 otherwise. The removal coefficients are calculated on the basis of regression models and therefore, they are a function of the operating conditions, specific for every technology. The flowrate profiles can be calculated on a similar principle where the main efficiency factor is the recovery, Y_t, that determines the permeate flow profiles, Q^P_t $[m^3/h]$.

$$Q^P_t = W_t \cdot Q^F_t \cdot Y^{U_t}_t + (1 - W_t) \cdot Q^F_t, \qquad \forall t \qquad (2)$$

where Q^F_t $[m^3/h]$ is the feed flowrate to technology t.

3.2. Target constraints

The final water purity should not exceed the conditions imposed by the following constraint:

$$c^P_{s,t} \leq M^{CONC}_s, \qquad \forall s, \forall t = T \qquad (3)$$

where M^{CONC}_s $[mg/L]$ is the maximum allowable concentration of contaminant s after the last candidate technology t. An additional constraint for the minimum effluent at the final stage is enforced by Eq.(4).

$$Q^P_t \geq M^{FLOW}_t, \qquad \forall t = T \qquad (4)$$

where M^{FLOW}_t $[m^3/h]$ is the minimum allowable effluent flow.

3.3. Logical constraints

The number of passes is ensured to be equal or greater than one if a technology is selected, which is expressed by Eq.(5).

$$U_t - M_{max} \cdot W_t \leq 0, \qquad \forall t \qquad (5)$$

where M_{max} is the maximum number of passes corresponding to common industrial practices. To set the passes to non-zero when a technology is selected, the following equation is used:

$$W_t - U_t \leq 0, \qquad \forall t \qquad (6)$$

3.4. Cost constraints

3.4.1. Operating constraints

The operating costs include electricity for pumps, mixers and saturators, and chemicals cost as the major components of ongoing costs.

Chemicals costs: The primary chemical used is for the coagulant which is ferric chloride as often predominating due to the more satisfactory results obtained downstream (Voutchkov, 2010). The annual cost for it is calculated from Eq.(7).

$$OC^{CHEM}_t = a \cdot CD_t \cdot C_{chem} \cdot Q^F_t \cdot U_t, \qquad \forall t = CF \qquad (7)$$

where a is a constant accounting for annualisation, CD_t $[t/L]$ is the coagulant dose selected and C_{chem} $[\$/t]$ is the cost of coagulant.

Saturator costs: The technical and economic performance of DAF depends mainly on its recirculation ratio and saturator. The former is disregarded in this study and the latter is calculated by:

$$OC_t^{SAT} = \frac{a \cdot Q_t^F \cdot U_t \cdot C_e \cdot P_t}{\eta_t}, \qquad \forall t = DAF \quad (8)$$

where P_t $[MPa]$ is the saturator pressure and C_e $[\$/kWh]$ is the electricity cost rate.

The carbon taxation is calculated from Eq.(9) with the assumption that the carbon tax does not increase throughout the lifetime of the project. The largest component for the emissions is the power used, reflected in the equation.

Carbon tax emissions:

$$CO_2C_t = \frac{a \cdot C_{CO2} \cdot CO_2e \cdot Q_t^F \cdot U_t \cdot P_t}{\eta_t}, \qquad \forall t \quad (9)$$

where C_{CO_2} $[\$/t]$ is the carbon tax and CO_2e $[t/kWh]$ is the carbon equivalent emitted.

3.4.2. Capital constraints

The capital costs incorporate economies of scale and are related by correlations for the candidate technologies.

$$CC_t = n_t \cdot U_t \cdot (Q_t^P)^{m_t}, \qquad \forall t = T \quad (10)$$

where n_t and m_t are constants and they differ for every candidate. For the annualisation of the capital costs, the capital recovery factor has been further integrated.

3.5. Objective function

The objective function is to minimise the water production cost, WC $[\$/m^3]$, where PY is the annual production yield and TC is the summation of all the annualised operational and capital costs.

$$minimise \;\; WC = \frac{TC}{a \cdot PY \cdot Q_{t=T}^P}, \quad (11)$$

subject to mass balance, target, logical and cost constraints.

4. Case study

4.1. Data

In this section a theoretical case study is presented to test the applicability of the model. Design parameters and data recommended in various literature sources are used. Influent of $Q_t^{F,IN} = 20{,}000\ m^3/h$ is chosen and for minimum allowable effluent $M_t^{FLOW} = 5000\ m^3/h$ which will ensure a medium size desalination facility. Additional water quality and cost parameters are reported in Table 1.

For conventional and non-conventional pretreatment technology full recoveries are assumed based on recommended values (U.S. Interior Reclamation Department, 2013). For high pressure membranes, NF and RO, 80 % and 40 % recoveries are assumed, respectively, to agree with published values (Lu et al., 2006; Mickley et al., 1993). The pumps and saturator efficiencies vary between 0.75 and 0.85.

It is assumed that cleaning or replacement takes place simultaneously for all trains, there are no pressure losses from pump to membrain train, every pass contains the same number of membrane modules, cleaning is performed every 6 months, replacement is recommended every 5 years, the annual maintenance and shut down time is 65 days a year, and annual production yield 95 %.

Table 1: Water quality and cost parameters

Parameter	initial c^P [TSS/ TDS/ B] $[mg/L]$	final c^P [TSS/ TDS/ B] required $[mg/L]$	C_e $[\$/kWh]$	C_{chem} $[\$/FeCl_3\,t]$	C_{CO_2} $[\$/CO_2\,t]$
Value	30/ 40,000/ 5	1/ 600/ 2.4	0.08	250	23

Source: (Lu et al., 2006; U.S. Energy Information Administration, 2013; World Health Organization, 2011)

4.2. Results

The mathematical model was tested in GAMS 23.9 on a Dell PC OptiPlex 9010 Core i5-3570 at 3.4 GHz and 3.89 GB RAM. The model was solved using BARON with a relative gap 0%. It took the solver 3.4 seconds to return an optimal solution.

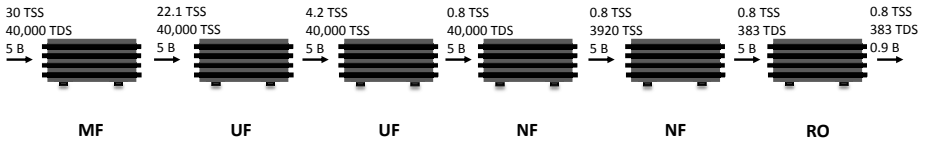

Figure 1: Optimum configuration for the given case study

The flowsheet configuration of the case study is shown in Figure 1 where 1 MF pass and 2 UF passes for the removal of suspended matter were selected, 2 NF passes for the separation of dissolved solids and 1 RO pass for the rejection of boron. The production capacity of the facility was 120,000 m^3/day.

For the selected system, the capital cost was $135 million which agrees with magnitudes for seawater desalination projects reported in reviews (UNESCO Centre for Membrane Science and Technology, 2008). The annual operating cost breakdown showed that electricity cost represented 69 % followed by the carbon emissions cost of 21 %, the labour cost of 8 % and the maintenance cost of 2 %. The water net cost was 1.07 $\$/m^3$. The costs breakdown exhibits 18 % lower maintenance cost, whereas electricity and labour costs approach published values (UNESCO Centre for Membrane Science and Technology, 2008).

The slightly higher percentage for energy consumption stems from the assumption that no energy recovery devices are used, power is taken from the grid, no offsetting for the greenhouse emissions is done by renewable energies and electricity charge is constant throughout the day. The low value of maintenance cost in comparison with the rest is due to the assumptions of cost rates and membrane modules for each unit as well as no cleaning chemicals for the maintenance cost were taken into consideration.

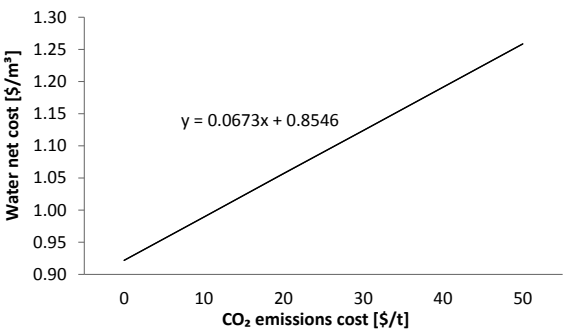

Figure 2: Sensitivity analysis of water cost with carbon price

The carbon emissions of the facility were 786 tCO_2/day assuming 24 hours of operation. For a plant of a capacity 100,000 m^3/day, UNESCO Centre for Membrane Science and Technology (2008) reported carbon footprint of 660 tCO_2/day. Next, we investigated the sensitivity of the production cost with various carbon costs that can be imposed by governments depending on time frame or plant location (Figure 2). When carbon tax at 50 $\$/t$ is included in the estimations, the water net cost increases with 27 %, 10 % more than reported

in literature sources. The elevated sensitivity of the water cost is due to the previously observed low values for the rest of the cost components.

5. Discussion and conclusions

In the current work a systematic approach for the design and optimisation of water treatment facilities was proposed. The problem was formulated as MINLP model with the objective to minimise the water net cost and was applied to a seawater desalination case study.

The optimum result fell within the values reported by AWWA (2011) for medium size seawater desalination facilities, between 0.82 $\$/m^3$ and 1.25 $\$/m^3$. With regard to the annual cost breakdown, the highest percentage allocated to electricity is due to the absence of energy recovery devices.

Nevertheless, the result demonstrates the method and model can be applied in the conceptual design of water treatment facilities. With taking into account technological, economic and environmental constraints at early stage, further design stages would rely on more robust results. Additionally, the tool could help cutting down industrial expenses and time.

Work on refining the model in order to eliminate some of the assumptions along its development would provide more accurate results on units selection and their various cost components. Additional features, such as managing the water net cost when a location specific emissions trading scheme is introduced and allowing for concentrate disposal management, will add significance to advancing in sustainable projects design.

Abstract

The recent discoveries of Pre-Salt layers in Brazil require process developments for enhanced sustainability as these reservoirs have oil with associated natural gas exhibiting an expressive amount of CO_2. Monetization of CO_2 by offshore production of methanol in a dedicated FPSO – MFPSO – is a potential alternative to sustainable E&P. Two process alternatives for an MPFSO were previously investigated by the authors, consisting of physical absorption of CO_2 with propylene carbonate and its conversion to yield methanol. Alternative 1 combines dry and steam reforming in one reactor (Bi-Reforming), while Alternative 2 segregates the two reactions - dry reforming occurs in one reactor and water gas-shift reaction in a subsequent reactor. Both alternatives considered Enhanced Oil Recovery (EOR) as a parallel path for CO_2 destination. The economic evaluation employed the software Capital Cost Estimation (CAPCOST) for calculations of CAPEX and OPEX. The software Waste Reduction Algorithm (WAR, EPA) was used to evaluate the potential environmental impacts. The analysis indicated that the performance of Alternative 1 was superior to the performance of Alternative 2: (a) methanol production (17.9 t/h) 4 times higher, (b) lower CAPEX, (c) sales revenue 181% greater, and (d) the potential environmental impact (PEI) 47.7% lower (868 PEI/h). In the present work, Alternative 1was modified by eliminating the EOR step, resulting in enhancement of methanol production as CO_2 was integrally designated to chemical conversion. The modified process (Alternative 3) inherits the environmental feasibility of Alternative 1 and, through elimination of the EOR compression train, has the potential of positive impacts on CAPEX.

Keywords: CO_2 Capture and Utilization, Physical Absorption, Bi-Reforming, Methanol Synthesis, FPSO

1. Introduction

This work approaches the production of remote natural gas exhibiting high CO_2 contents where the separated CO_2 is utilized *in situ* to produce methanol resulting in monetization of CO_2 in an FPSO – MFPSO. The concept of an MFPSO is particularly relevant in the context of Brazilian pre-salt oil reservoirs, 300km distant from the continent and exhibiting high CO_2 - reaching 70% in Jupiter reservoir (Guzzetti, 2010). The sought monetization could contribute to sustainability of natural gas production from such remote fields. The study evaluates three process alternatives where CO_2 is captured from natural gas, by physical absorption with propylene carbonate (PC), producing a natural gas stream poor in CO_2 and a stream consisting of a mixture of CO_2

and hydrocarbons. The evaluated routes for CO_2 conversion to methanol includes Bi-Reforming (Alternative 1 and 3) and Dry-Reforming (Alternative 2). In Alternatives 1 and 2, presented by Lima et al. (2014), part of the captured CO_2 is destined for EOR while Alternative 3 (proposed in the present work) integrally converts CO_2 to methanol. It is worth noting PC was selected as absorption solvent due to its easiness of regeneration, involving a simple expansion valve and a flash vessel.

Also relevant in the scope of the downstream processing of the CO_2 rich stream is that PC has also affinity for hydrocarbons, yet lower than its affinity for CO_2. This benefit is explored by the proposed alternative processes, where absorbed hydrocarbons (CH_4 and, in a lesser extent, heavier molecules) react with CO_2 in dry reforming reactions (e.g., $CH_4 + CO_2 \rightarrow 2CO + 2H_2$), steam reforming reactions (e.g., $CH_4 + H_2O \rightarrow CO + 3H_2$) and bi-reforming reactions (e.g., $3CH_4 + 2H_2O + CO_2 \rightarrow 4CO + 8H_2$). When CO_2 reforming occurs simultaneously with steam reforming, coke deposition is drastically reduced (GANGADHARAN et al., 2012). This combination, named bi-reforming, generates syngas with a H_2/CO ratio of 2, ideal for methanol synthesis (OLAH et al., 2009). Although dry reforming generates syngas with a suboptimal H_2/CO ratio, the water gas-shift reaction (WGS) adjusts the ratio to favour further methanol synthesis (GANGADHARAN et al., 2012). Alternatives 1 and 3 combine dry and steam reforming in one reactor, while Alternative 2 segregates dry reforming in one reactor and WGS reaction in a subsequent reactor. The Alternatives are evaluated with Aspen HYSYS® simulator for calculation of energy and mass balances necessary to assess economic and environment performances. The economic evaluation employed Capital Cost Estimation Software (CAPCOST) for calculations of CAPEX and OPEX, and the Waste Reduction Algorithm Software (WAR) was used to evaluate the potential environmental impacts.

2. Process Simulation

Bi-Reforming (Alternatives 1 and 3) and Dry Reforming (Alternative 2) were evaluated with Aspen HYSYS® simulator. The first process steps relates to CO_2 capture and are common to all evaluated alternatives, which is fed with raw natural gas (NG) stream exhibiting the following molar composition: 60% CH_4, 20% CO_2, 12% C_2H_6, 6% C_3H_8 and 2% N_2. The adopted process premises are: (a) the natural gas, previously dehydrated, enters at 70 bar and 40 ^oC with a volumetric flow rate of 1MMNm^3/d; (b) the treated gas meets selling Brazilian specifications (< 3% in CO_2), and (c) PC flow of 435t/h, necessary to obtain the molar ratio between CH_4 and CO_2 at treated stream suitable for reforming reactions (obtained by successive simulations). Figure 1 shows the Aspen HYSYS® process flow diagram for CO_2 PC absorption. NG enters at the bottom of absorber column (T-100), countercurrent to PC. NG correctly specified is obtained as the top product of absorber, and PC regeneration occurs at the flash vessel (V-100).

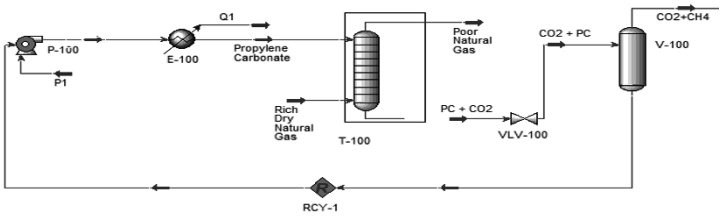

Figure 1. Process flow diagram for CO_2 absorption with PC

2.1. Bi-Reforming Process with CO_2-EOR(Alternative 1)

The stream 'CO_2 + CH_4' is divided into two parts: one goes to a compression train, for CO_2-EOR, and the other is destined to a reactor where both dry and steam reforming reactions occur, shown in Figure 2.

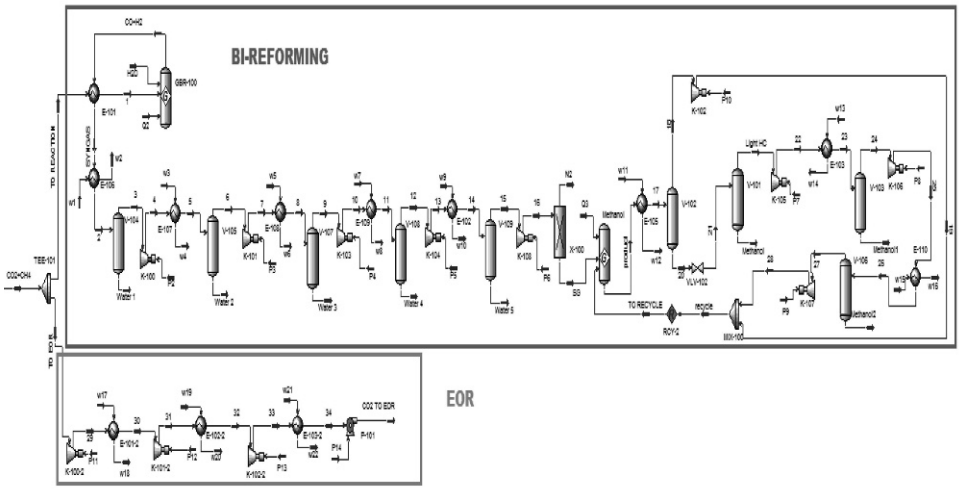

Figure 2. Process flow diagram for EOR and Bi-Reforming process – Alternative 1

With CO_2/CH_4 molar feed ratio of 1:1, GBR-100 operates at 900°C and 1 bar and water vapour is added in reactor at 10.81 t/h. After reaction, the stream 'SYNGAS' passes through a sequence of compressors, heat exchangers and vessels, in order to eliminate water and pressurize gas to 70 bar for methanol synthesis. These heat exchangers utilize seawater for refrigeration. Liquid methanol is recovered at V-101, V-103 and V-106.The remaining hydrocarbons and syngas return to Methanol reactor.

2.2. Dry Reforming Processwith CO_2-EOR (Alternative 2)

Similarly to the Bi-Reforming process, the stream 'CO_2 + CH_4' is divided into two parts. However, the stream 'To Reaction' proceeds to the GBR-100 reactor, where occurs exclusively the dry reforming. GBR-100 operates at 870°C and 1 bar. After reaction, stream 'SYNGAS' passes through a compression and intercooler train. This stream is pressurized to 70.5 bar before entering the Adjust reactor (WGS), where water vapor is added at a rate of 2 t/h. In the sequence, stream "feed" enters in the Methanol reactor. The stream that leaves the Methanol reactor has a high quantity of unreacted methane, which, after methanol recovery, is recycled to GBR-100. Methanol is recovered at V-102, and residual hydrocarbons are recycled (Figure 3).

2.3. Bi-Reforming Process without CO_2-EOR (Alternative 3)

The stream 'CO_2 + CH_4' is integrally directed to methanol conversion, accordingly to Figure 4. Reaction section proceeds as described for Alternative 1.

3. Economic and Environmental Analysis – Alternatives 1 and 2

Alternatives 1 and 2 were evaluated economically, for decision of which reaction path would be more attractive, through CAPEX and OPEX calculations. Equipment sizing

was performed according to procedures described in the literature (e.g., CAMPBELL, 2004; PERRY, 1997; TOURTON et al., 2009). For the economic analysis, the MS Excel spreadsheet CAPCOST, developed by Turton et al (2009), was employed. Table 1 presents the main results from Bi-Reforming (Alternative 1) and Dry-Reforming (Alternative 2) Processes, indicating the resulting CAPEX, OPEX and revenue for each alternative. Alternative 1 has the highest revenue as methanol production (17960 kg/h) was 4 times higher than for the Dry-Reforming Process (Alternative 2).

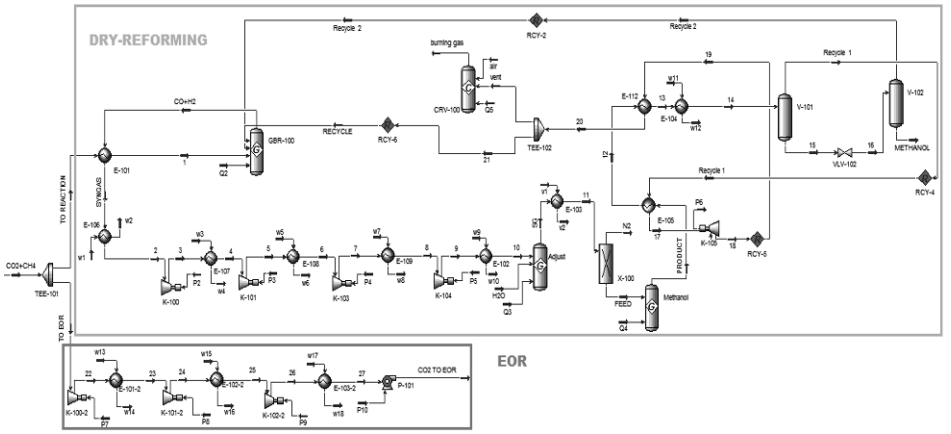

Figure 3. Process flow diagram for EOR and Dry-Reforming process – Alternative 2

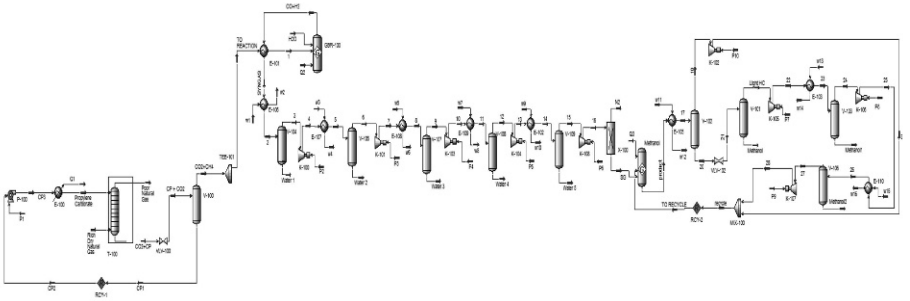

Figure 4. Process flow diagram Bi-Reforming process without EOR – Alternative 3

Table 1. Results of CAPEX, OPEX and Revenue Sales – Alternatives 1 and 2

Cost (U$$)	Bi-Reforming	Dry-Reforming
CAPEX	25,165,709	32,145,906
OPEX	122,575,216	101,189,415
Revenue Sales	144,890,686	51,463,757

The WAR Algorithm (CABEZZAS et al.,1999) was used to comparatively quantify the environmental performance of Alternatives 1 and 2, based on eight categories of environmental impacts, equally weighted. The categories are: Human Toxicity Potential

by Ingestion, Human Toxicity Potential by Exposure, Aquatic Toxicity Potential, Terrestrial Toxicity Potential, Global Warming Potential, Ozone Depletion Potential, Smog Formation Potential, Acidification Potential. WAR measures performance as output rate of PEI (Potential of Environmental Impact). PEI can be described through rates of inlet (Îin), outlet (Îout) and generation (Îgen) of impact in a given system. The mass flow and composition obtained from ASPEN HYSYS simulations were used in the WAR algorithm. Comparing the total impact for these processes two Alternatives (both employing CO_2-EOR), Bi-Reforming (Alternative 1) has a lower impact (868 PEI/hr) than Dry-Reforming (Alternative 2) (1661 PEI/hr).

4. Alternatives 1 and 3 - Bi-Reforming with and without EOR

The comparative economic and environmental analysis indicate that Alternative 1 (Bi-Reforming) is technically, economically and environmentally superior to Alternative 2. Considering the main objective of an MFPSO of enhanced methanol production, Alternative 3 was proposed with removal of the CO_2-EOR section (Figure 4). Based on the conclusion of superior performance of Alternative 1 over Alternative 2, Alternative 1 is the basis of Alternative 3. A preliminary economic analysis (exclusively based on revenue increase) shows enhancement of methanol production of around 2 times over the production achieved in Alternative 1 (35,497.56 kg/h). Consequently, Alternative 3 presents revenue of U$$ 251,502,365, (Alternative 1 showed revenue of US$144,890,686). Furthermore, Alternative 3 and Alternative 1 were compared considering the generation rate of PEI, calculated through WAR Algorithm. It was observed that Alternative 1 (Bi-Reforming) has a negative rate, higher than Alternative 3 (Bi-Reforming without EOR), what means that the first alternative is environmentally superior to Alternative 3, as shown in Figure 5. It is worth noting that methanol contributes to all impact categories evaluated while CO_2 most exclusively impacts in global warming. Consequently, WAR penalises the increase in methanol production achieved in Alternative 3.

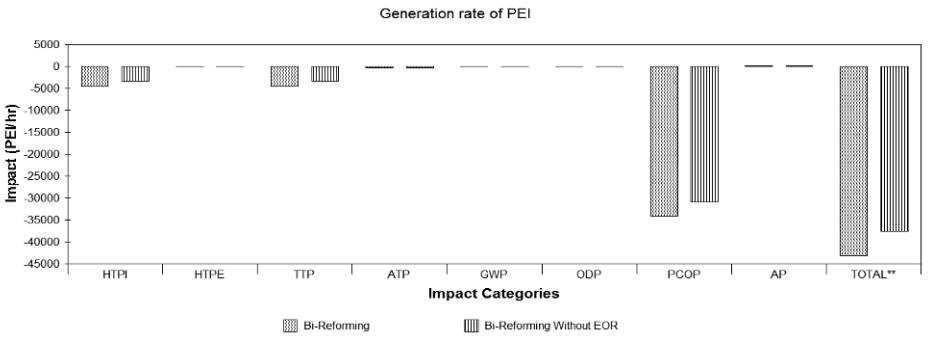

Figure 5. Generation rate of PEI for Bi-Reforming with and without EOR step

5. Discussion and Conclusions

The proposed processes are potentially amenable to methanol floating production system, MFPSO, where the regeneration of PC would present a competitive advantage over alternative CO_2 capturing technologies, since weight and space are the key considerations for floating plants. The treated natural gas stream (248.7 m^3/h) composition is (in molar basis): 90.19% CH_4, 1.67% CO_2, 3.31% C_2H_6, 0.63% C_3H_8 and

4.20% N_2. The main difference of the proposed processes is the fact that at Bi-Reforming (Alternatives 1 and 3) just one reactor is utilized, where occur both dry and steam reforming. On the other hand, for Dry-Reforming (Alternative 2) two reactors are conceived: one for dry reforming and other for WGS reaction. This difference poses a large discrepancy of methanol productivity, as methanol production by Bi-Reforming was 17905 kg/h, 4 times higher compared to Dry-Reforming. Dry reforming occurs not only for methane, but also for ethane and propane, and these last reactions are more favoured than the first one. In consequence, methane is not consumed, but rather produced in the Dry-Reforming alternative, explaining the associated low production of methanol. Since the preliminary conclusions indicate that Bi-Reforming is technically, economically and environmentally superior to Dry-Reforming, a third flowsheet was proposed, considering the elimination of CO_2-EOR section, with dedicated production of methanol. Analysis showed that methanol production in Alternative 3 (35,497.56 kg/h) present revenues around 2 times higher than Alternative 1. Regarding the environmental aspect, Bi-Reforming (Alternative 1) shows superior environmental performance over Bi-Reforming without EOR step (Alternative 3) due to the penalty attributed by WAR algorithm to producing methanol, which contributes to all considered impact categories. However, both alternatives presented negative generation of PEI, which turns Alternative 3 the most sustainable alternative. Although a more detailed economic analysis for Alternative 3 (CAPEX and OPEX) is necessary to reinforce this conclusion, it is foreseen a superior economic performance since the increase in revenues is significant and compression costs associated to CO_2-EOR are eliminated.

A Superstructure-Based Framework for Simultaneous Process Synthesis, Heat Integration, and Utility Plant Design

S. Murat Sen, James A. Dumesic, Christos T. Maravelias*

Department of Chemical & Biological Engineering, University of Wisconsin-Madison, WI 53706, USA
christos@engr.wisc.edu

Abstract

We propose a new framework for simultaneous chemical process synthesis, heat recovery network design, and utility plant design. We generate compact surrogate unit models to describe processes based on new technologies. We also consider (1) process streams with variable heat loads and temperatures, and (2) multiple steam types of variable temperature. We illustrate the applicability of our framework using a novel process for the non-enzymatic production of sugars from lignocellulosic biomass.

Keywords: Superstructure optimization, global optimization, biofuels.

1. Introduction

The goal of this paper is to develop a framework for the systematic generation and evaluation of biomass-to-fuels processes based on novel conversion technologies. One of the challenges in the design of such processes is that no *first-principles* models are available for key conversion steps which are based on novel conversion systems for which no kinetic expressions are available; the same is often true for separations that are found to be effective experimentally but for which limited thermodynamic information is available (e.g., extraction steps with new solvents). Another challenge in the area of biomass-to-fuels strategies stems from the need to design processes that are energetically effective, preferably using lignin and/or biomass residues to provide all necessary process heat and electricity (Stuart and El-Halwagi, 2012; Yuan et al., 2013).

To address these challenges, we propose a superstructure optimization framework that allows us to simultaneously perform (1) structural and parametric optimization for the main chemical plant, (2) heat integration, and (3) utility plant design. Furthermore, we develop surrogate unit models based on (1) experimental results to model unit operations for which rigorous models are not available; and (2) offline simulations to formulate tractable optimization models. Finally, we outline two solution methods for the effective solution of the resulting mixed-integer nonlinear programming (MINLP) model using global optimization solvers. The proposed framework is used to design an integrated strategy for the non-enzymatic production of sugars from biomass.

The integration of the three subsystems is shown in Fig. 1. The chemical plant converts biomass to products and byproducts, as well as biomass residues which can be used to generate process heat and electricity. The hot and cold streams from the main plant and the utilities from the utility plant are inputs to the heat integration subsystem. Finally, using biomass residues and/or fossil fuels, the utility plant produces different types of steam to satisfy heating requirements (after heat integration) and electricity to meet process power requirements, while excess electricity can be sold to the grid.

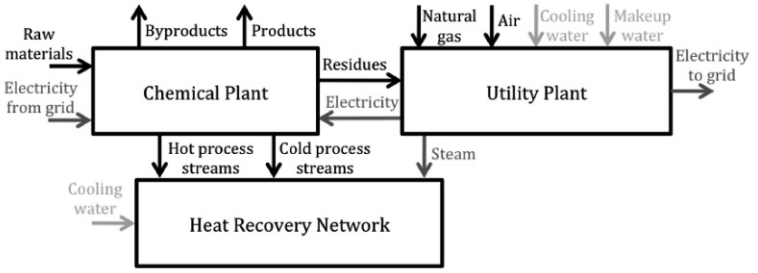

Figure 1. Three basic subsystems and their interactions in the integrated model.

2. Superstructure modelling framework

2.1. Chemical plant

The chemical plant model is based on three sets: (1) compounds, (2) units, and (3) streams. The main variables of the model include component flows, unit operating conditions (T and P), heat loads, conversions (reactors), component recoveries (separation units), and (for some units) compositions. Equality constraints arise from material and energy balances around units, design equations, and correlations of experimental data, while inequality constraints arise from product and design specifications. Unit operations are modelled using surrogate models developed from experimental results or offline process simulations (Henao and Maravelias, 2011), as well as short-cut methods with relatively simple non-linear algebraic expressions. Binary variables are used to *activate* the selected units and the associated variables (Yeomans and Grossmann, 1999). Special care is given to the formulation of the unit models so that the (de)activation of the inlet component molar flows suffices to (de)activate all associated variables, thereby avoiding the introduction of additional nonlinearities.

2.2. Heat recovery network

Steam at different pressure levels (high, medium and low) produced in the utility system is used for heating, while water is used as cooling utility. To minimize total utility requirements, the maximum heat recovery is obtained in a *heat cascade* which can be modelled as a transhipment problem (Papoulias and Grossmann, 1983). Hot streams and heating utilities (sources) supply heat to temperature intervals (intermediate nodes), and these intervals supply heat to cold streams and cooling utilities, while any heat surplus from these intervals are cascaded down to the next interval at lower T).

We propose a generalization of the transhipment model to account for (1) variable heat duties for process streams (determined by the plant subsystem), and (2) variable steam temperature (determined by the utility plant subsystem) (Fig. 2a). The temperatures of process streams are used for the construction of temperature intervals in the heat recovery network. Based on its saturation temperature, each type of steam available for heating is assigned to a temperature interval using binary variables.

2.3. Utility plant

The energy generated from natural gas or process residues is used to produce high-pressure (HP) steam in a boiler (Fig. 2b). HP steam can be used for heating, expanded through back-pressure or vacuum turbines for electricity generation, and/or expanded through a let-down valve to form medium-pressure (MP) or low-pressure (LP) steam to be used for heating and electricity generation. Electricity can be generated by any combination of steam turbines connected with a common shaft on an electric generator,

and/or purchased to meet the electricity demand. In case of electricity surplus (if process residues are used), excess electricity can be sold to the grid to generate extra revenue. Utility demands are simultaneously determined through heat integration of process streams. Selection of how much electricity to produce and/or purchase, selection of the type and amount of steam (HP, MP, LP) to produce and its conditions (temperature and pressure; superheated, saturated or wet steam) are decision variables for the utility plant. Turbines used in the utility system are modelled using isentropic expansion expression, while the total electricity generated in turbines is calculated as a function of the flow rate, enthalpy difference, and turbine efficiency. We use rigorous approaches to determine the steam enthalpy; we take non-ideal behavior of the vapor phase into account through the calculation of vapor compressibility factor as a function of temperature and pressure, which are both continuous variables (Smith et al., 2005). Then, we develop an approximation of the rigorous compressibility factor expression in terms of temperature and pressure of steam. The proposed approximation leads to a maximum error of less than 3%. The consideration of variable pressure/temperature for the three types of steam it potentially allows us to find energetically superior designs where the steam temperature satisfies exactly the minimum ΔT in the heat exchangers.

2.4. Solution methods

Despite the adoption of surrogate unit models, the resulting MINLP models are computationally expensive. They are *nonconvex MINLP* models, which means that global optimization solvers are necessary to obtain globally optimal solutions. To enhance the solution of the resulting models, we developed an algorithm for the calculation of lower and upper bounds on component molar flows. Specifically, starting from component molar flows in the feedstock streams, we *propagate* these bounds moving downstream. For example, using the upper bounds on the flow of reactants in the inlet of a reactor and the maximum yield (experimentally determined), we can calculate upper bounds on the flow of products at the outlet of the reactor. Tearing ideas are used to calculate bounds in the presence of recycle streams. We also calculate bounds for steam condition and properties.

Furthermore, to reduce the solution space, we generate inequalities using unit selection binary variables to enforce logic constraints arising from the connectivity of the units in any feasible solution. Finally, we systematically generate redundant constraints which are found to enhance the solution of the model.

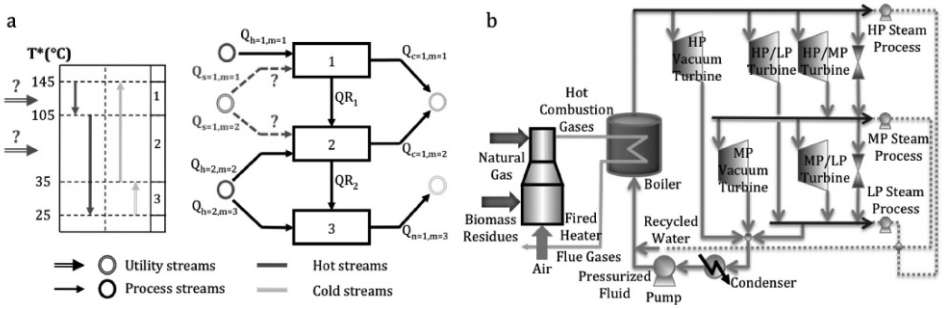

Figure 2. (a) Transhipment model for the heat recovery network. (b) Utility plant design.

3. Case study: Non-enzymatic production of sugars from biomass

To illustrate the applicability of the proposed framework, we study the production of sugars from lignocellulosic biomass via a non-enzymatic conversion technology we proposed recently (Luterbacher et al., 2014). We use the design basis (2,000 dry tons of biomass per day) and assumptions from Kazi et al. (2010).

3.1. Chemical plant superstructure

Luterbacher et al. (2014) proposed a novel non-enzymatic technology for the simultaneous catalytic conversion of hemicellulose and cellulose fractions to soluble C_5- and C_6-sugars, respectively, using biomass-derived γ-valerolactone (GVL) as a solvent. Specifically, sugars are produced in a biomass deconstruction system at 430-490 K using dilute sulfuric acid catalyst in GVL/water (4:1 wt%) solution at a biomass loading of 7 wt%. This reaction system leads to complete conversions of hemicellulose and cellulose with high yields of C_5-sugars from hemicellulose (70-86 mol% depending on the GVL-to-biomass ratio) and C_6-sugars from cellulose (70 mol%). Importantly, the sugar yields were shown to be insensitive to biomass type (Luterbacher et al., 2014). However, a major challenge towards the commercialization of this technology is the recovery of sugars at high purity (to be further converted to ethanol or other chemicals), as well as the separation of GVL (to be recycled to the reactor) from lignin and biomass residues (to be used for heat and power generation). Therefore, for a cost-effective production of fermentable sugars, a series of effective separation technologies should be developed and integrated with the upstream conversion technology.

Accordingly, we generate a superstructure that contains various alternatives for separating biomass-derived sugars from the GVL solvent, lignin and biomass residues. Sugars can be separated from GVL, lignin and residues by multi-stage CO_2 extraction, phase separation upon salt addition, or multi-stage extraction using an alkylphenol solvent as shown in Fig. 3. Following the separation of sugars, GVL solvent can be recovered from lignin and residues using precipitation of solids, or evaporation of GVL. Later, GVL can be recycled back to the sugar production step, while lignin and biomass residues can be sold to generate revenue or utilized in the utility plant for steam and power production. It is not clear that what combination of separation technologies will make the production process more cost-effective, which requires a systematic evaluation of all the alternatives.

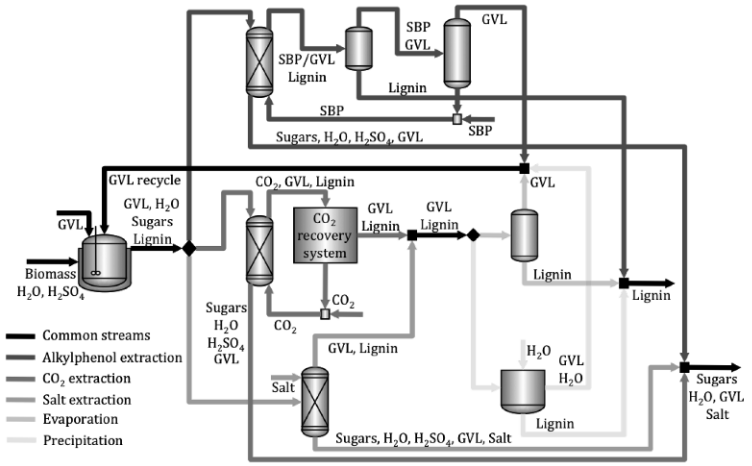

Figure 3. Superstructure for production of sugars.

3.2. The MINLP model

Based on the experimental results of Luterbacher et al. (2014), we developed an optimization model that integrates the sugar production plant with the utility system and heat recovery network. Units for which we developed surrogate models based on experimental results include (1) the reactor for the conversion of biomass to sugars (C_5 and C_6 overall yields as functions of GVL:biomass ratio), (2) the multi-stage sugar extraction using super-critical CO_2 (partition coefficients) (3) the multi-stage GVL extraction using sec-butyl phenol (partition coefficients). We also developed surrogate models based on offline simulations. For instance, Fig. 4 shows the surrogate model for a subsystem of flash tanks and compressors for the recovery and recycle of CO_2. The surrogate model calculates the major variable of this subsystem, the total power requirement, as a function of total feed flow, CO_2 composition, and recovery.

Our objective is to maximize the annual profit: revenue from sugars and by-products (lignin and excess electricity) sales minus the costs of raw materials and utilities minus other operating costs minus the annualized capital cost. The price of sugars is assumed to be 35 cents per kg. The capital costs are annualized using a capital recovery factor of 11.75% based on a 10% discount rate and an equipment lifespan of 20 years. We consider the selection of feedstock among alternatives including corn stover, sugarcane, wheat straw, hybrid poplar, switchgrass, loblolly pine and aspen wood. The model for this case study includes 78 binary variables, 2,314 continuous variables, and 2,156 constraints with 1,248 of them being non-linear.

3.3. Results

Using SCIP global optimization solver in GAMS, we obtained a feasible solution (profit, \$6.5 million/yr) with an optimality gap of 5.8% after 2 hrs of CPU time. The selected configuration includes the non-enzymatic sugar production (br_1) followed by the multi-stage CO_2 extraction (e_1) for separation of sugars, CO_2 recovery system (f_1), and the GVL evaporation (f_2) for its recovery from lignin and biomass residues (see Fig. 5). Sugarcane was selected as feedstock, which has a high total cellulose and hemicellulose content (~66 wt%). The annual feedstock cost was found to be \$28 million. A low GVL-to-biomass ratio (14:1 wt%) is selected despite leading to low C_5-sugar yield. Still, the cost of make-up GVL (\$6.6 million per year at \$120/ton GVL) is a major cost contributor (0.6% of GVL is lost in the 3-stage CO_2 extraction unit). Following the multi-stage extraction, the optimal CO_2 recovery was found to be 99% in the CO_2 recovery subsystem leading to a power demand of 20.5 MW. Then, almost 100% of GVL is separated from lignin and humins in an evaporation unit with a heat duty of 178 MW. The selected process yields 565 tons/day of C_6-sugars and 350 tons/day of C_5-sugars (89% of the sugars are recovered in the aqueous phase in the CO_2 extraction), which can potentially be converted to 47 million gallons of ethanol annually. Utilization of lignin and residues as a fuel in the utility system is a better option than selling them at a price of \$50/ton.

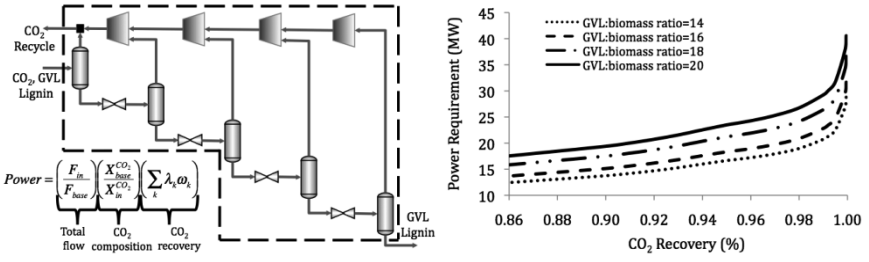

Figure 4. Power requirement for the CO_2 recovery system.

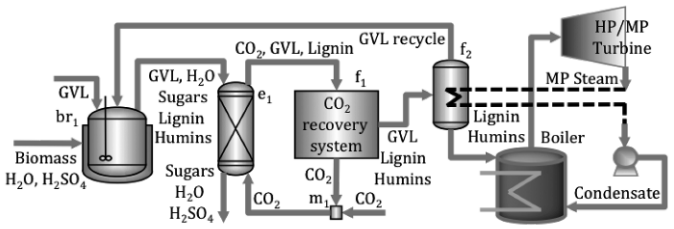

Figure 5. Selected configuration for production of fermentable sugars.

The heating requirement of the selected configuration before heat integration was found to be 178 MW. The heat recovery network, which consists of 13 temperature intervals, allows us to recover 53 MW. The entire cooling requirement is via heat integration, while the remaining heating requirements (125 MW) are satisfied using MP steam at 20.1 bar and 658 K. The boiler produces 71 kg/s of HP steam (at 44.3 bar & 750 K, 176 MW) using the heat released from the combustion of lignin and biomass residues without the need for natural gas purchase. The power requirement of the entire facility is 20.9 MW (chemical plant: 20.5 MW, utility system: 0.4 MW). The majority of the power requirement (18 MW) is satisfied with the HP/MP back-pressure turbine, while the remaining (2.9 MW) is externally supplied.

4. Conclusions

We proposed a framework for the formulation of superstructure optimization models for simultaneous process synthesis, heat integration, and utility plant design. We also proposed methods for the effective solution of the resulting MINLP models, including a bound propagation algorithm. The proposed framework addresses some limitations of previous approaches, namely, it accounts for variable stream heat loads and temperatures for heat integration, and it considers accurate molar enthalpy relationships. We also showed how surrogate models, based on experimental results or offline calculations, can be integrated resulting in computationally tractable models. The proposed framework accounts for the interactions among all three subsystems, which is critical for the generation of strategies for renewable fuels, and allows to quickly generate and evaluate energy-efficient processes that employ newly developed conversion technologies for which rigorous models are not available.

Abstract

This paper is concerned with the process design and optimization of an integrated shale gas process for greener chemicals production. From a sustainability point of view, the bioethanol is incorporated as a renewable feedstock to reduce the environmental footprint of the entire process. The proposed process integrates co-cracking of light NGLs, the oxidative coupling of methane (OCM) reaction, and bioethanol dehydration with raw shale gas processing. Overall, the process consists of four process areas, namely gas treatment, gas to chemicals, methane to ethylene and bioethanol to ethylene. A simulation-optimization method based on the NSGA-II algorithm is developed for the life cycle optimization of the process modelled in HYSYS. An energy integration model is also integrated using the mixed-integer linear programming. The results show that for a "good choice" design, the minimum ethylene selling price is \$877.2/ton and the unit GWP of ethylene (GWP_{E2E}) is 0.360 kg CO_2-eq/kg, when shale gas is considered as a high carbon fuel.

Keywords: shale gas, process design, greener chemicals, simulation-optimization

1. Introduction

The substantial development of shale gas represents a true game changer in the energy and chemical industries in the United States and other countries, including China, Argentina, and Mexico (Varma and Grossmann, 2014). This is because shale gas not only provides low-cost fuels, but also can be used as a basic feedstock in the production of value-added chemicals like plastics, synthetic rubber, adhesives, etc. (Kargbo et al., 2010). It is worthwhile to note that most of the shale formations in the U.S. are reported to be rich in natural gas liquids (NGLs), which are C_{2+} hydrocarbons (Cafaro and Grossmann, 2014). After raw shale gas is purified and fractionated, the NGLs have substantially higher market values than methane. Light NGLs, such as ethane, propane and butanes, can be used as feedstocks in the olefins production, while the remaining heavier fractions can be used as gasoline blending stocks. Currently in the U.S., 99% of NGLs-derived ethane is used as a raw material in cracking facilities because it is cheaper and cleaner than petroleum-derived feedstocks. However, the excessive supply of NGLs has become an issue in regions lacking in abundant NGLs processing and cracking facilities (He and You, 2014). In addition to NGLs, methane is the dominant ingredient in the shale gas. Direct, one-step conversion of methane to value-added chemicals is potentially more attractive. In the pioneering work (Keller and Bhasin, 1982), methane was activated with the assistance of oxygen and further converted into ethylene and ethane; this process came to be known as the OCM reaction. Unfortunately, a standalone OCM process has very little economic potential compared to well-established cracking facilities. The major limitations of the OCM process are its low C_2 yield and selectivity, which lead to a large amount of unreacted gas and byproducts. The

last concern with shale gas is the potential environmental footprint of the increased fugitive CH_4 emissions during drilling. The dispute was initiated because quantitatively assessing the leaking data of methane is complex and varies from well to well, potentially leading to serious environmental issues, in addition to challenges in water management (Gao and You, 2015). It has been concluded that the climate impact of shale gas maybe worse than that of other fossil fuels (Howarth, 2014).

In light of the aforesaid opportunities and challenges, the present work considers shale gas processing with on-site olefins production by co-cracking of NGLs-derived ethane and propane. An OCM process is also integrated to convert methane into short chain alkenes that includes ethylene and ethane. To improve the project economics of the OCM process, a complex co-processing strategy is proposed to purify and separate gas products including the OCM products, co-cracking gas and raw shale gas. The product separation cost is thereby significantly reduced, and the ethylene yield is improved by recovering the OCM-derived ethane and methane. In this process, we address the mitigation of life cycle GHG emissions for shale gas-based chemical processes using carbon capture and storage technology, and sustainable integration of bio-ethylene production. Specifically, bioethanol is incorporated as a renewable feedstock of the process and this hybrid feedstock approach was reported to enhance sustainability of the entire process (He et al., 2014). Overall, the proposed process consists of four process areas, namely gas treatment, gas-to-chemicals, methane-to-ethylene and bioethanol-to-ethylene. Based on rigorous process modeling, a simulation-optimization method based on the NSGA-II algorithm for life cycle optimization (LCO) of the proposed process is developed. In addition, an energy integration model is also fluidly nested in the simulation-optimization using mixed-integer linear programming (MILP). We subsequently conduct a techno-economic analysis, an environmental impact analysis, and energy integration simultaneously.

2. Process description

For the calculations presented in this work, it is assumed that 2,000 kmol/hr of shale gas is supplied at 60.0 bar and 35 ^{o}C, containing 74.25 mol% CH_4, 13.76 mol% C_2H_6, 5.4 mol% C_3H_8, 1.66 mol% i-C_4H_{10}, 1.11 mol% n-C_4H_{10}, 1.11 mol% i-C_5H_{12}, 0.55 mol% i-C_5H_{12}, 0.29 mol% C_6H_{14}, 0.10 mol% C_7H_{16}, 0.09 mol% C_8H_{18}, 1.52 mol% CO_2, 0.16 mol% N_2, 17.1 mg/scf H_2O and 307.2 mg/scf H_2S, based on normalized data reported from Eagle Ford formation (George and Bowles, 2011). Simulations were performed in Aspen HYSYS V7.2, using the Peng-Robinson package throughout the flowsheet, except: Amine package with Kent Eisenberg rule for acid gas (CO_2 and H_2S) removal, and Glycol package for triethylene glycol (TEG) streams.

A chemicals production process from shale gas integrated with bioethanol dehydration is shown in Figure 1. Briefly, the overall process includes four process areas below.

(1) Gas treatment area, where the raw shale gas and OCM product are purified in a gas sweetening unit. H_2S in the removed acid gas is converted into sulfur in a sulfur recovery unit. The acidic CO_2 (SG-CO_2), along with the OCM-derived CO_2 (OCM-CO_2) is collected at point M_1 and is then compressed into the liquid phase in a CO_2 compression unit. CO_2 liquid is transported through pipelines to sequestration sites. Once purified, the sweet gas is mixed with co-cracking gas at point M_2. The mixture is dried in a dehydration unit and then processed in the next process area.

(2) Gas-to-chemicals area. In this area, the heavy NGLs (butanes and natural gasoline) and low-boiling point gases (methane and H_2-rich gas) are successively taken from the dry gas using an NGLs cutting unit. The C_2 and C_3 hydrocarbons included in the

remaining stream are sent to an olefin separation unit where the olefin products are separated from the light NGLs. In the next step, the ethane and propane are mixed at point M_3 and then thermally co-cracked in an olefin production unit. Meanwhile, a pressure swing adsorption (PSA) unit is employed to recover high-quality hydrogen from the H_2-rich gas. The rejected PSA tail gas is mixed with process purges (AGR and TEG purges), a portion of methane (from point S_1), and bio-waste at point M_4. The mixture passes through the point S_2 where the upper branch goes to the bioethanol-to-ethylene area as dehydration fuel, and the lower branch is sent to power plant as gas turbine (GT) fuel. We note that all process waste heat is integrated within this power plant to generate power using the Rankine cycle.

(3) Methane-to-ethylene area, where the incoming methane (from point S_1) is partially oxidized via the OCM reaction in an O_2-rich environment. The OCM product includes ethylene, ethane, hydrogen, carbon dioxide, carbon monoxide, water, and a large quantity of un-converted methane, which is obtained from the first two process areas. As mentioned in the Introduction, bioethanol can be used as a renewable feedstock introduced to the next process area.

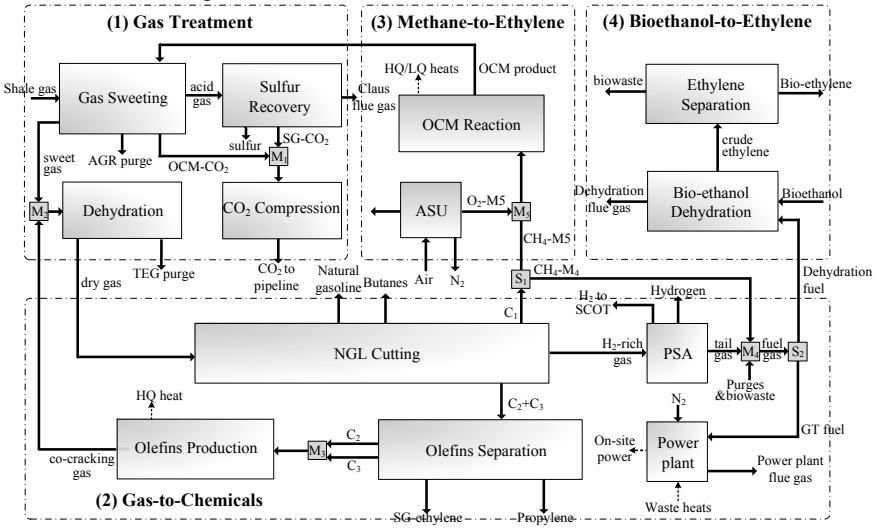

Figure 1. Shale gas/bioethanol to chemicals process

(4) Bioethanol-to-ethylene area. The input amount of bioethanol is fully dependent on that of furnace fuel, that is, by the split ratio at point S_2. The produced crude ethylene is purified via passing through a series of distillations in the ethylene separation unit. In this paper, SG-ethylene, and bio-ethylene refer to the ethylene produced from shale gas, and bioethanol, respectively.

3. Solution procedure

Figure 2 shows the framework of the simulation-optimization method, which performs LCO of the process modeled in Aspen HYSYS. We develop a simulation-optimization method based on the evolutionary NSGA-II algorithm (Deb et al., 2002). An energy integration model is integrated using an MILP approach. First, in the MATLAB control center, the initial decision variables are randomly generated. The MATLAB control center will check the convergence of HYSYS simulation. If feasible, the input/output data taken from simulation results can be mapped and prepared for the next MATLAB

optimization center where two sub-problems are performed. In the first sub-problem, an energy integration model is used to determine the minimum total cost of hot/cold/power utility. Then, the optimal utility cost, combined with the process data (feedstocks, products, emissions, etc.) is passed to a LCO model (Gebreslassie et al., 2013). This model simultaneously maximizes the NPV and minimizes the GWP of the process by using the multi-objective optimization approach (Gong et al., 2014). Sustainable and optimal process designs are then given by Pareto-optimal results (Wang et al., 2013).

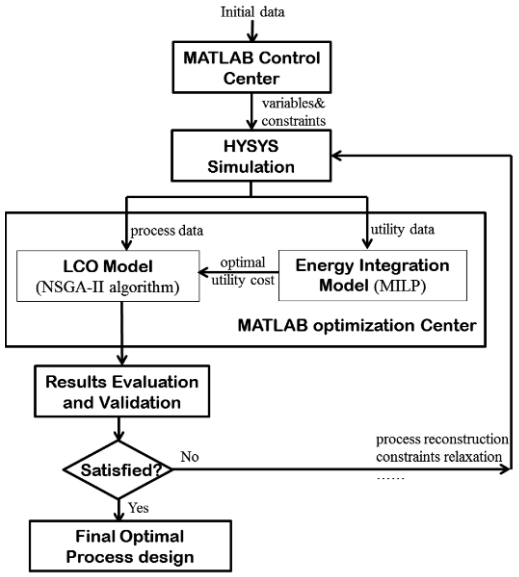

Figure 2. Simplified representation of the simulation-optimization framework

In this work, shale gas is considered as a high carbon fuel and the emission factor (methane leakage/gas produced, v/v%) is assumed to be 3.30% (Howarth, 2014). The corn-derived bioethanol is purchased from market, and the plant-level GHG emissions is equal to 0.042 kg CO_2-eq per GJ bioethanol (You et al, 2012). The decision variables for the proposed process consist of the distribution ratios at points $S_1$and S_2 (X_{S1} and X_{S2}), OCM reaction temperature, pressure and O_2 feed ratio (T_{OCM}, P_{OCM}, and R_{O2}), and co-cracking reaction temperature and pressure (T_{ccr} and P_{ccr}).

4. Result and discuss

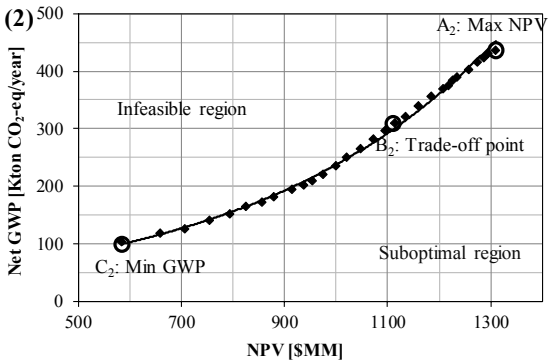

Figure 3. Pareto-optimal solutions of process design

Figure 3 shows the Pareto curve of the proposed process design. Point A on the upper right has the maximum NPV among all feasible solutions. For this design, as the NPV decreases from \$1,322 MM to \$577.7 MM, the annual GHG emissions reduces from 436.2 to 102.9 kton CO_2-eq, as listed in Table 1. In particular, the MESPs of the points A and C are \$712.2/kg and \$1,076/kg, while their corresponding annual GHG emissions are 0.804 and -0.115 kton/CO_2-eq. A comparison between points A and C validates that bioethanol as a renewable fuel can play an important role in reducing the life cycle carbon footprint. To locate a more reasonable point, we note that from point A to point B, the GWP_{E2E} is significantly reduced, while there is only a small rise of the MESP. This implies that the trade-off design of point B is a "good choice" solution.

Table 1. Results of the optimal design

Pareto point	CPU time (hr)	NPV (\$MM)	MESP (\$/ton)	GWP (kton CO_2-eq/year)	GWP_{E2E} ($kgCO_2$-eq/kg)		Bioethanol/SG (mol/mol)
A	104.2	1,322	712.2	436.2	0.804		0.319
B	100.5	1,101	877.2	313.5	0.36		0.576
C	121.2	577.7	1,076	102.9	-0.115		1.092
Pareto point	X_{S1}	X_{S2}	T_{OCM}	P_{OCM}	R_{O2}	T_{ccr}	P_{ccr}
A	0.0002	0.75	817.2	189.2	0.235	789.1	353.5
B	0.045	0.71	845.2	187.0	0.322	770.2	342.4
C	0.202	0.79	852.5	140.2	0.320	755.1	325.0

Table 2. Impacts of GWP reduction options on the CO_2 avoided cost

Reduction option [a]	MESP	GWP_{E2E}	CO_2 avoided cost
BD+CCS	877.2	0.360	197.6
BD	851.0	0.720	218.7
CCS	446.4	2.21	95.60
No reduction	385.2	2.85	baseline

[a] The operating conditions are based on the design of point B. Note that in the CCS option, X_{S2}= 0.

$$\text{Cost of } CO_2 \text{ avoided (\$/kton)} = \frac{(\text{MESP})_{\text{reduction}} - (\text{MESP})_{\text{baseline}}}{(\text{GWP})_{\text{baseline}} - (\text{GWP})_{\text{reduction}}} \quad (1)$$

As previously mentioned, GHGs reduction operations includes CCS and bioethanol dehydration (BD). It is worthwhile understanding the costs behind these two operations. In this work, we investigate the joint and single effect of these operations, as listed in Table 2. The sequence relationship of MESP is "BD+CCS" > "BD" > "CCS" > "no reduction". But as for unit GWP, the sequence reverses. In this work, we adopt the "CO_2 avoided cost" (see Eq. 1) indicator to measure the incremental MESP for a year divided by the difference in unit GWP between the baseline and reduction options. The results clearly show that, the CO_2 avoided cost is increased from \$95.60/kton for the CCS option to \$218.7/kton for the BD option. This indicates that the integration of bioethanol dehydration is an expensive choice. However, with CCS and no reduction options, the GWP_{E2E} are 2.21 and 2.85 kg $CO_{2\text{-eq}}$/kg, respectively, both of which are less competitive than the petroleum-based pathway (1.70 kg $CO_{2\text{-eq}}$/kg). In this case, the integration of bioethanol dehydration becomes a necessary choice if we want to produce greener ethylene. As listed in this table, the GWP_{E2E} can be significantly reduced to 0.720 kg $CO_{2\text{-eq}}$/kg for the BD option, and 0.360 kg $CO_{2\text{-eq}}$/kg for the BD+CCS option.

5. Conclusions

We proposed a novel process design for the conversion of C_1, C_2, and C_3 fractions in shale gas to chemicals. The renewable bioethanol dehydration process is integrated in order to reduce the life cycle GHG emissions of the entire process. Compared to previous process designs, significant production cost and life cycle GHG emissions reductions are achieved. Specifically, the high separation cost and project economics of the OCM process are mitigated by introducing a co-processing strategy of the OCM products, co-cracking gas, and raw shale gas, and recovering OCM-derived ethane and methane efficiently. We formulate a systematic simulation-optimization framework that simultaneously achieves energy integration, and performs a techno-economic analysis and an environmental impact analysis. For a "good choice" optimal design, the MESP is \$877.2/ton and the GWP_{E2E} is 0.360 kg CO_2-eq/kg. The results reveal that, even considered as a high carbon feedstock, shale gas can be converted to greener chemicals in a cost-effective way.

Value-added Chemicals from Microalgae: A Sustainable Process Design Using Life Cycle Optimization

Jian Gong, Fengqi You*

Northwestern University, 2145 Sheridan Road, Evanston, IL 60208 , USA
you@northwestern.edu

Abstract

This paper addresses the sustainable design and synthesis of producing biofuels and bioproducts from microalgae. We propose a comprehensive superstructure with multiple technology alternatives in the seven processing sections. The major products of the superstructure are biodiesel, hydrogen, propylene glycol, glycerol-tert-butyl ether, and poly-3-hydroxybutyrate. Following the life cycle optimization methodology, we propose a bi-criteria mixed-integer nonlinear programming problem to simultaneously optimize the environmental and economic performance. We apply a tailored global optimization algorithm to efficiently tackle the separable concave terms and fractional terms in the objective functions. The most environmentally sustainable processes with respect to various algal bioproducts reduce the life cycle greenhouse gas emissions by 5% to 63%, compared with petrochemical counterparts. Moreover, the minimum biodiesel production cost is $2.79 per gasoline-gallon-equivalent, if all byproducts and value-added bioproducts are considered as credits.

Keywords: Life cycle analysis, glycerol, bioproduct, algal biofuels, global optimization.

1. Introduction

Most fossil-based processes for chemical production are energy- and emissions-intensive (Hermann et al., 2007). In contrast, sustainable bioproducts converted from biomass offer the same chemicals, but tend to cause fewer environmental impacts. Therefore, it could be beneficial to investigate the production of value-added bioproducts in the emerging biofuel processes. Microalgae are very attractive feedstocks owing to high lipid-accumulation rates and minimum competition with food and crops (Silva et al., 2014). Although algal biodiesel production are well studied (Rizwan et al., 2013), little attention is paid to the byproduct converted from glycerol (Pagliaro et al., 2007). Therefore, the goal of this work is to explore the potential environmental and economic benefits of producing both biodiesel and four types of glycerol-derived bioproducts from microalgae: hydrogen, propylene glycol (PG), glycerol-tert-butyl ether (GE), and poly-3-hydroxybutyrate (PHB). We propose a comprehensive superstructure with a number of technology alternatives the conversion of microalgae to biodiesel and bioproducts. Based on the superstructure, we perform a cradle-to-gate life cycle analysis (LCA) focusing on greenhouse gas (GHG) emissions measured by carbon dioxide equivalent. Following a life cycle optimization methodology, we formulate a mixed-integer nonlinear programming (MINLP) problem to simultaneously optimize the environmental and economic performance. A tailored global optimization algorithm is

applied to circumvent the computational difficulties. The results could be used to justify the importance of manufacturing bioproducts in algal biodiesel processes.

2. Process description

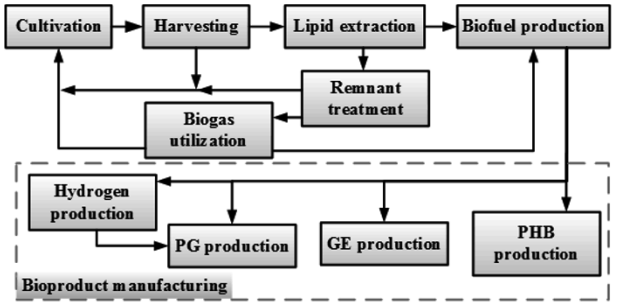

Figure 1. The superstructure for the production of algal biodiesel and bioproducts.

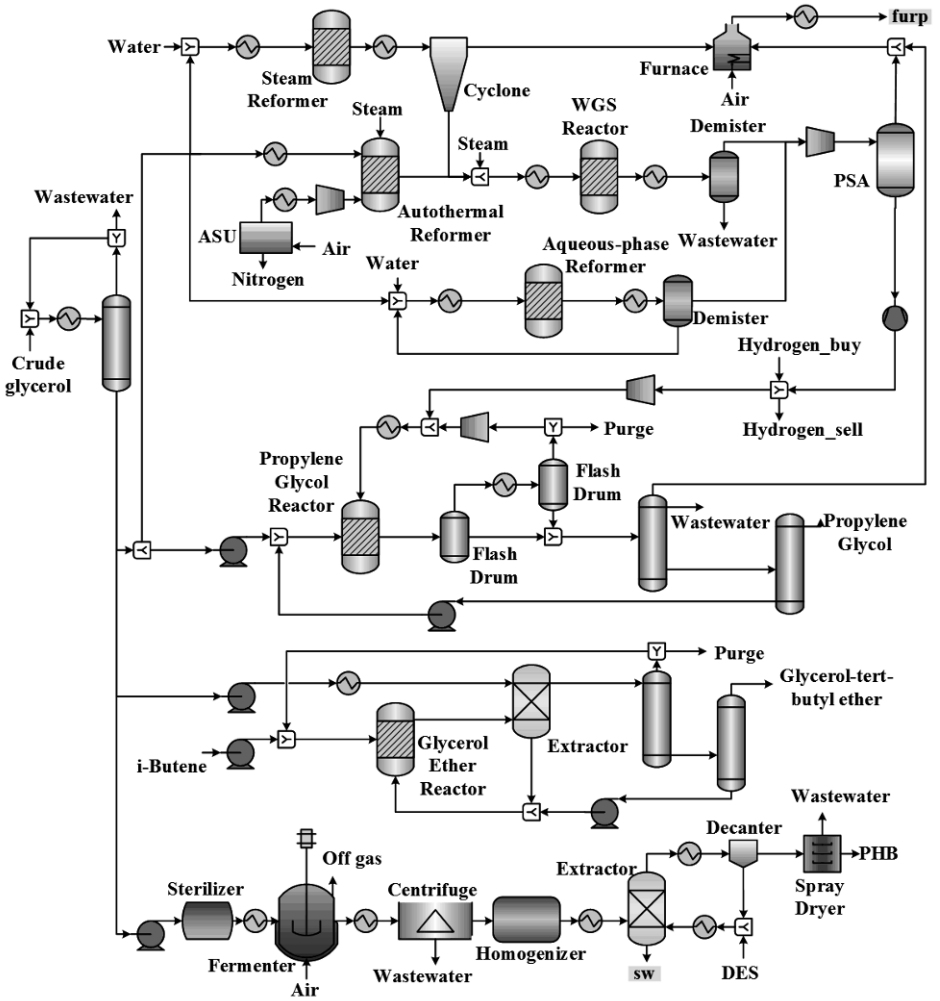

Figure 2. Process diagram of the bioproduct manufacturing section.

We develop by far the most comprehensive superstructure (Figure 1) for the production of biodiesel and bioproducts from the microalgae strain *Chlorella vulgaris*. The superstructure is divided into seven sections: cultivation, harvesting, lipid extraction, remnant treatment, biogas utilization, biofuel production, and bioproduct manufacturing (Gong and You, 2014b). Multiple technology alternatives are incorporated in the superstructure (Gebreslassie et al., 2013b). Pressure filtration and centrifugation are included in the harvesting section; bead beating, microwaving, high pressure homogenization, and sonication in the cell disruption section; hexane, n-butanol, and supercritical carbon dioxide as alternative solvents in the lipid extraction; direct combustion (Gutierrez-Arriaga et al., 2014) and methanol synthesis in biogas utilization; sodium methoxide-catalyzed, heterogeneously catalysed, enzyme-catalyzed, and supercritical methanol-catalyzed transesterifications in biofuel production. Hydrogen, PG, GE, and PHB can be produced in the bioproduct manufacturing section (Figure 2). Three alternative methods, including steam reforming, autothermal reforming, and aqueous-phase reforming, are considered for the hydrogen production . The steam reforming reaction converts glycerol to carbon monoxide, hydrogen, methane, ethylene and char. The autothermal reforming, however, achieves a net zero energy consumption by combining the endothermic reforming reaction and the exothermic oxidation of glycerol. The aqueous-phase reforming takes place under a relatively mild condition, but can only achieve a 9% single loop conversion. The direct product of the catalytic hydrogenolysis of glycerol is a mixture of water, PG, propanol, acetone, and unreacted reactants. Two flash drums and two distillation columns are employed sequentially to separate unreacted hydrogen and impurities from the PG product. In the GE production, the purified glycerol stream extracts most of the intermediate products from the etherification reaction, while the raffinate is introduced into a distillation column to purify the products. In the PHB process, the sterilized glycerol is converted to intracellular PHB. Next, centrifugation, extraction, and drying are employed to separate the products.

3. Model formulation and solving strategies

3.1. Model formulation

(P1)	min	$totalcost / v^{diesel}$
	min	$totalGHG / t$
	s.t.	Mass balance constraints
		Energy balance constraints
		Economic evaluation constraints
		Life cycle environmental impact analysis constraints

A bi-criteria MINLP model is formulated to simultaneously minimize the annualized cost per gasoline gallon equivalent (GGE) of biodiesel and GHG emissions per MJ of biodiesel. In the mass balance constraints, integer variables are introduced to model technology selection decisions (Gebreslassie et al., 2013a). The separation units are described based on the split fractions and mass conservation of every species. The reactions are described with stoichiometric coefficients and conversions, or product distributions. In the energy balance constraints, the consumption and generation of electricity, heating, and cooling utilities are calculated based on the mass flow rates of the input and output materials (Wang et al., 2013). The economic evaluation constraints calculate annualized investment cost based on equipment capital costs following a nonlinear scaling rule (Garcia and You, 2015). These constraints also determine the annual operating cost, taken as the sum of feedstock cost, utility cost, operating &

maintenance cost, and waste treatment cost. Next, the total annualized cost is calculated as the sum of the annualized investment cost and the annual operating cost. In order to quantify the environmental behaviour, a cradle-to-gate life cycle analysis is integrated into the multiobjective optimization problem following the life cycle optimization methodology (You and Wang, 2011). The functional unit is defined as 1 kg of bioproduct manufactured. The system boundaries of this LCA cover three life cycle stages: feedstock acquisition, transportation, and algal biodiesel and bioproduct manufacturing. The environmental impact considered for optimization is the amount of GHG emissions measured by carbon dioxide equivalent. The evaluation methods and co-product allocation methods are consistent with ISO guidelines (Institution, 2006).

3.2. Global optimization algorithm

$$\text{(P2)} \quad \min \; obj = totalcost - Q \cdot v^{diesel} \tag{1}$$

$$\text{s.t.} \quad \text{Original constraints}$$

$$totalGHG \le \varepsilon \cdot t \tag{2}$$

$$\text{Piecewise linear approximation constraints}$$

There are two types of nonlinear terms in nonconvex multiobjective MINLP: the fractional term in the objective function and separable concave functions to evaluate the equipment capital costs. Despite solvable with the ε-constraint method, it could still be computationally demanding for general purpose solvers. To enhance the computation efficiency, we further apply a tailored global optimization algorithm (Gong and You, 2014a) and relax (P1) to a mixed-integer linear problem (P2).This algorithm integrates two algorithms: parametric algorithm based on Newton's method and the branch-and-refine algorithm based on successive piecewise linear approximations to ensure the relaxed formulation achieves enough approximation accuracy. The pseudo-code of this method is shown in Figure 3.

Global Optimization Algorithm

Set $Q = 0$, $Iter^{out} = 1$
While $obj \ge TOL^{out}$
  Set $LB = 0$, $UB = +\infty$, $Iter^{in} = 1$, $G = +\infty$, build (P2) with two insertion points
  While $G \ge TOL^{in}$
    Solve (P2) and obtain optimal results (x^*, obj^*)
    Evaluate the original objective function with x^*, and obtain obj°
    Rebuild (P2) by adding x^* as a new partition point
    Set $LB = obj^*$,UB = min[UB, obj°],$G = 1\text{-}LB/UB$, $Iter^{in} = Iter^{in} + 1$
  end while
  Update $Q = totalcost^*/v^{diesel*}$, $Iter^{out} = Iter^{out} + 1$
end while
Return Q

Figure 3. Pseudo-code of the global optimization algorithm.

4. Results and discussion

4.1. Optimal environmental performance of producing bioproducts

If the bioproduct manufacturing section is devoted to hydrogen production, the lowest unit GHG emissions are 4.28 kg CO_2-eq/kg H_2. In contrast, producing hydrogen by steam reforming of methane results in 11.59 kg CO_2-eq/kg H_2, which is 2.7 times that of algal hydrogen. If we fix PG as the only bioproduct, the minimum unit GHG emissions of the proposed superstructure and three other methods are shown in Table 1. We note that environmental impact of the PG production in the superstructure achieves a 51.5% GHG emissions reduction compared with that of the petroleum-based PG. Regarding

GE, we obtain unit GHG emissions of 2.37 kg CO_2-eq/kg GE. In terms of PHB production, the optimal unit GHG emissions are 4.10 kg CO_2-eq/kg PHB, which is sustainably competitive compared with fossil-based plastic products. Overall, bioproducts in the proposed superstructure proves to be environmentally sustainable, especially compared to fossil-based chemical products. The excellent performance is primarily due to the biogas for electricity generation. The allocation of surplus electricity leads to a significant reduction in GHG emissions. Furthermore, the allocation method also averages the environmental benefit of the entire process and reduces the unit environmental impact of each product.

Table 1. Life cycle CO_2 equivalent emissions of the PG production.

PG production method	Unit GHG emissions (kg CO2-eq/kg PG)
Petroleum-based	3.75
ADM®	3.24
Zemea®	2.18
Algal glycerol-based	1.82

4.2. Optimal biodiesel production

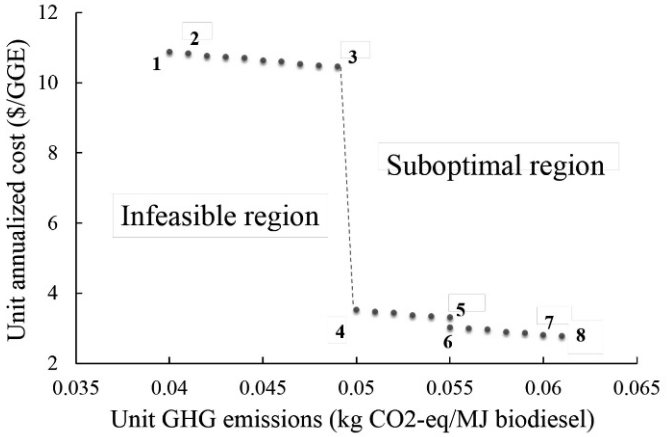

Figure 4. Pareto-optimal curve associated with the unit annualized cost and unit GHG emissions.

As shown in Figure 4, we obtain a Pareto-optimal profile if we optimize the bi-criteria problem with the global optimization strategy and the ε-constraint method. Overall, the curve demonstrates trade-offs between the two competing objective functions: that is, the minimum unit annualized cost decreases when the corresponding minimum unit GHG emissions increase. With no technology selected in the cell disruption and hydrogen production sections, the process selected by point 1 employs pressure filtration in the harvesting section, hexane as the lipid extractant, direct combustion for biogas utilization, enzyme-catalyzed transesterification for biofuel production, and GE synthesis for bioproduct manufacturing. The minimum unit GHG emissions are 0.04 kg CO_2-eq/MJ biodiesel, and the minimum unit cost corresponds to $10.89/GGE. In contrast, the optimal process selected by points 4 to 5 favours supercritical carbon dioxide in the lipid extraction section. Eventually, the optimal process selected by point 8 achieves a unit cost of $2.79/GGE and unit GHG emissions of 0.06 kg CO_2-eq/MJ biodiesel by using centrifugation and heterogeneously catalyzed transesterification. Overall, this result has a 74% decrease in unit cost with a 34% increase in unit GHG emissions, indicating that large economic savings can be achieved.

5. Conclusion

We proposed by far the most comprehensive superstructure for the production of biodiesel and four types of bioproducts from microalgae. Based on the superstructure, we conducted a cradle-to-gate LCA and incorporated it into a bi-criteria MINLP model to simultaneously optimize the environmental and economic performance following a life cycle optimization framework. Manufacturing bioproducts resulted in reduction of unit life cycle GHG emissions by 5% to 63%, compared with the petrochemical counterparts. The co-production of value-added bioproducts reduced the biodiesel production cost to \$2.79/GGE with centrifugation, supercritical CO_2 extraction, direct combustion, heterogeneously catalyzed transesterification, and GE synthesis.

The Effect of Charge Composition on the Optimal Operational Parameters of a Batch Extractive Distillation Process

Laszlo Hegely, Peter Lang*

Budapest University of Technology and Economics, Muegyetem rkp 3-9., H-1111 Budapest, Hungary

Abstract

The recovery of methanol by batch extractive distillation using water as entrainer from an azeotropic waste solvent mixture (acetone(A)-methanol(B)-THF(C)-water(D)-toluene(E)) is optimised by a genetic algorithm (GA) coupled with a professional flowsheet simulator performing the dynamic simulation. Optimization variables are the reflux ratios of the different operation steps, the location, the flow rate and duration of entrainer (water) feeding. The objective function to be maximized is the profit. The effect of changing the charge concentration of methanol and the two main organic impurities (THF and toluene) on the profit and optimal values of the operational variables was studied.

Keywords: batch distillation, extractive distillation, entrainer, optimization, genetic algorithm.

1. Introduction

For the separation of azeotropic mixtures a special (e.g. extractive) distillation method must be applied. In batch extractive distillation (BED, Yatim et al, 1993), an entrainer is fed continuously into the column, changing the relative volatilities favourably. BED is usually applied to extract pollutants of moderate concentration from the main component to be recovered. In this case the main component is extracted from beside the pollutants of low concentration forming minimum azeotropes with it. These pollutants can be removed in fore-cuts, and by using BED, it is possible to reduce the loss of the main component with the fore-cuts. However, the high amount of entrainer fed renders the separation of the main component from it more difficult.

Hegely et al. (2013) studied the recovery of methanol (in purity of 99.5 mass %) from a waste solvent mixture containing THF(C) and toluene (E) as main pollutants. The recovery of methanol (B) is disturbed by the azeotropes B–C (30 % B, 59.5 °C) and B–E (71.5 % B, 63.6 °C). The influence of water (D) as a potential entrainer on the relative volatilities was investigated. We stated that by BED using water as entrainer C and E can be removed in the fore-cuts more efficiently (with lower B loss) than by BD. The laboratory and industrial-size experiments gave also much higher recovery for the BED than for the BD. Hegely and Lang (2014) performed the optimization of both the BD and BED processes by a genetic algorithm (GA). The highest profit was reached by the optimized BED process.

The aim of this paper is to study the effect of changing the concentration of methanol (B) and the two main organic pollutants (C and E) on the profit and on the optimal

values of the operational variables of the BED. Optimization variables are reflux ratios of all operation steps, and the parameters of water feeding (feed plate, flow rate, duration). The optimization was performed by a genetic algorithm with ChemCAD performing the dynamic simulation. The objective function to be maximized is the profit.

2. The separation process

The charge (25 m^3, 22,675 kg.) contains 0.07 mass % A (acetone), 37.14 % B, 4.89 % C, 56.34 % D and 1.56 % E. The boiling points of the components and azeotropes, with the azeotropic compositions were given by Hegely and Lang (2014).
The BED separation of one batch has the following separation steps (Hegely et al., 2013):

- Step 0: heating-up of the column under R=∞. This step can be divided into two parts:
  a: heating-up of the charge without water feeding.
  b: heating-up with water feeding which decreases $x_{D,B}$ and increases $x_{D,C}$. The step is ended when the change in these concentrations becomes slow.
- Step 1: 1st fore-cut containing a high amount of C and E besides B. It is incinerated.
- Step 2: 2nd fore-cut, which contains more B and less pollutant than the first fore-cut. The 2nd fore-cut is recycled to the next batch in order to decrease the loss of B.
- Step 3: Main-cut (production of B in high purity).
- Step 4: After-cut (aqueous B). The aim is to remove B from the still residue, so that the residue can be sent to biological purification. It is recycled to the next batch.

Water feeding can be stopped at the end of Step 0b or it can be still continued in Steps 1 and 2, as well. In the latter case, the loss of B in the fore-cuts can be further reduced, but B must be recovered from a more dilute mixture B-D and the amount of the fore-cuts can also increase raising the cost of incineration and energy.

The column has 25 theoretical plates (excluding the condenser and reboiler). The top pressure of the column is atmospheric, the pressure drop: 0.25 bar. The hold-up of the condenser: 0.45 m^3, that of the column: 0.05 m^3/plate. The duration of Step 0a was 160 min, after which water feeding (of 15 °C) was started. Step 0b was 200 min long. The termination criteria for Steps 1 and 2 are optimization variables (Cr_1 and Cr_2), while the criterion for Step 4 is based on industrial experiences:

- Step 1: $x_{D,C}<Cr_1$ (mass fraction of C in the distillate)
- Step 2: $x_{D,C}<Cr_2$
- Step 3: $x_{MC,A}<99.52$ mass%
- Step 4: $x_{SR,B}<0.25$ mass% (mass fraction of B in the still residue)

The optimization was performed for 4 different charge compositions, which were chosen based on a list of compositions reported by the plant. As the variation of the A content was slight and without significant effect, it was considered to be constant. Charge 1 has the highest B and the highest organic impurity contents. The further charges were the obtained from Charge 1 by reducing the B (to 27.43%, Charge 2) or the C (to 3.27%, Charge 3) content to minimal reported value, or by reducing the E content to the average reported value (0.84%, Charge 4). This decrease of the charge concentration of the organic components was compensated by increasing that of water.

3. Optimisation method

The objective function (OF) to be maximized is the profit of the processing of one batch. It is defined as:

$$OF = p_B m_{MC} - c_{inc} m_{FC1} - c_{st} \frac{\dot{Q}_{st}}{r_{st}} t - c_{cw} \frac{Q_{cond}}{cp_{cw} \Delta T_{cw}} - c_{bio} m_{SR} \quad (1)$$

where m_{MC} is the mass of the main-cut, m_{FC1} is that of the first-fore-cut, m_{SR} is that of the still residue. p_B is the price of methanol (0.46 \$/kg), c_{inc} is the cost of incineration (0.21 \$/kg), c_{st} is cost of heating steam of 3 bar (57.6 \$/t), r_{st} is its heat of condensation (2263.5 MJ/t), $\dot{Q}_{st}$ is the heat duty (1800 MJ/h) and t is the duration of the whole process. Q_{cond} is total heat withdrawn by the cooling water, cp_{cw} is the specific heat of the cooling water and ΔT_{cw} is the increase in its temperature. c_{cw} is the cost of cooling water and c_{bio} is the cost of biological purification, which are neglected. (These are not debited to the solvent recovery plant). Therefore, operation cost is the term related to the heating steam.

The nine optimization variables were the reflux ratios of the steps: R_1 (1st fore-cut), R_2 (2nd fore-cut), R_3 (main-cut), R_4 (after-cut), the termination criteria of Steps 1 and 2 (Cr_1 and Cr_2) and the variables connected to water feeding: feed plate (f, integer variable, counted from the top of the column with plate 1 being the condenser), flow rate (F_{water}) and duration (t_F, even integer). The lower and upper bounds for all reflux ratios were 0.6 and 15. The lower bound of both termination criteria was 0.05 mass%, the upper bounds were 40 % (Step 1) and 10 % (Step 2), respectively. However, the value of Cr_1 also acted as an upper bound for Cr_2. The ranges of the variables connected to water feeding were: $1 \leq f \leq 13$; flow rate: $0 \leq F_{water} \leq 3000$ kg/h; duration: $0 \leq t_F \leq 1000$ min. (Water feeding was always stopped at the end of Step 2, even if t_F had been longer.) Another constraint is added in order to ensure the recyclability of the second fore-cut to the next batch: the B/C and B/E ratios in the second fore-cut cannot exceed those of the traditional batch distillation process applied in the plant (9.36 and 8.31, respectively).

The optimization is performed by a real-coded elitist GA written in VBA under Excel. GA was chosen as OF can only be evaluated by simulation, that is, with a black box approach. The parameters of the GA: mutation probability: 5 %, population size: 30, crossover probability: 70 %. The number of generations was 100 in all cases. OF is evaluated by dynamic simulation using different modules of the flowsheet simulator ChemCAD. The failure to reach the specified purity of B (99.5 mass%), is penalized by changing the value of OF to -10,000 \$.

4. Optimization results

The optimal value of the parameters, different costs and profits calculated for the different charges are shown in Table 1. The detailed data of the cuts are given in Tables 2-5. The optimal operational policies (water flow rate and reflux ratio as a function of time) are shown in Figure 1.

Some results were common for all charges: optimal location of entrainer feeding was always the top tray, and water feeding was stopped during Step 1.

In the basic case, the first fore-cut was taken by high reflux ratio, while the reflux ratio of Steps 2 and 3 were moderate and almost identical. The water flow rate was low, but the water feeding was continued for a long time. The recovery of B was 77.1%.

Table 1. Optimization results for the different charge compositions.

	R_1	R_2	R_3	R_4	Cr_1 %	Cr_2 %	f	F_{water} kg/h	t_F min	Income $	Incin. cost	Oper. cost	Profit
Charge 1	7.74	3.41	3.48	4.72	18.7	3.83	2	283	574	3003	390	1820	793
Charge 2	5.22	4.47	5.07	9.45	19.5	2.80	2	773	444	2054	348	1776	-70
Charge 3	7.56	3.20	3.16	7.56	19.9	3.16	2	433	408	2946	266	1718	962
Charge 4	7.59	3.97	3.49	7.70	19.1	3.79	2	424	384	3001	361	1803	837

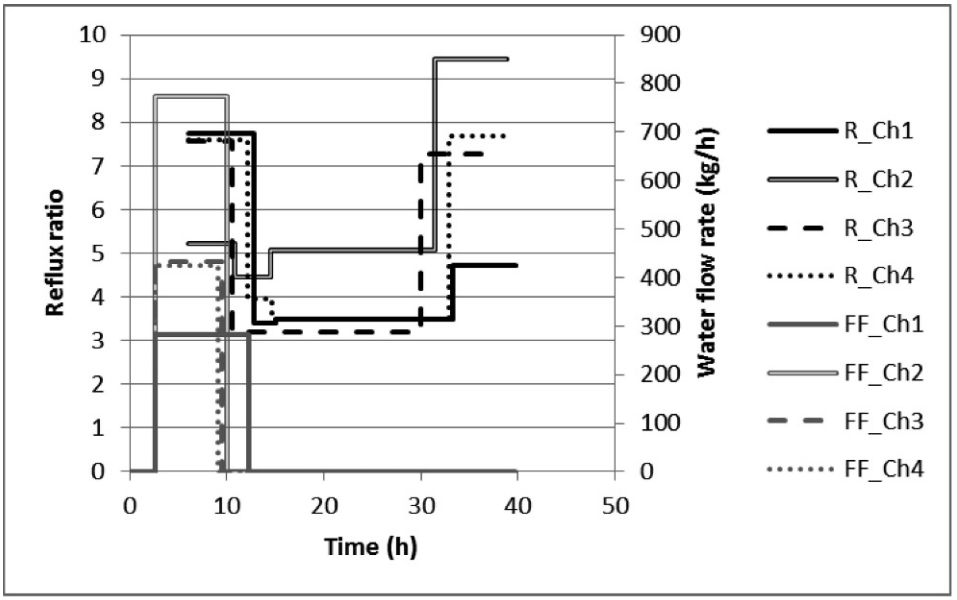

Figure 1. The optimal parameters for the different charge compositions.

The strong decrease of B content (Charge 2) resulted in an uneconomical operation, as the income dropped considerably. The decrease of income was not proportional to that of the B content, as the recovery was also lower (71.4%). The lower B concentration required higher reflux ratio in both Steps 2 and 3. The increase in R_3 was especially sharp. At the same time, the water flow rate was also considerably higher. Step 3 started later, as well. On the other hand, R_1 decreased, and Cr_1 increased, resulting in a shorter Step 1 with lower amount of first fore-cut. Nevertheless, the decrease of incineration cost could not compensate that of the income.

If the C content was reduced (Charge 3), the profit increased considerably. The reason of this was not an increased recovery of B (75.6%), but rather the significantly decreased incineration cost, which was the consequence of higher Cr_1 and lower R_1. All reflux ratios (except R_4) were lower, which resulted in faster operation and contributed to the increased profit. The flow rate of the water was higher, but the feeding duration was lower. The lower R_3 was balanced by lower Cr_2, that is, a later start of Step 3.
In the case of lower E content (Charge 4), the parameters changed less in comparison with those of Charge 1, than for Charge 3, which is explained by the fact that the change of charge composition is also smaller. The profit increased slightly, once again due to

the reduced incineration cost, achieved by a slight increase in Cr_1. R_1 was lower, R_2 was higher, while R_3 was the same as for Charge 1. The parameters of water feeding were similar to those for Charge 3. The recovery of B was the same as for Charge 1.

E	9.5	2.6	0.0	0.0

5. Conclusions

The recovery of methanol from a multicomponent azeotropic waste solvent mixture was studied by dynamic simulation and optimization. The components (acetone-methanol-THF-water-toluene) form several minimum azeotropes limiting the recovery of methanol by traditional batch distillation. By batch extractive distillation (BED) using water as entrainer the process can be made more profitable. The optimization of the BED process was performed by a genetic algorithm coupled with the ChemCAD flow-sheet simulator performing the dynamic simulation. The objective was to maximize the profit for one batch. The optimization variables were the reflux ratios of all operation steps, termination criteria of the two fore-cuts, location, flow rate and duration of water feeding. The effects of changing the feed concentration of methanol and of the two main organic pollutants (THF and toluene) on the optimal values of the variables and on the profit of the process were determined. The decrease of organic pollutant content increased the profit, mainly because the incineration cost was lower due to the lower reflux ratio and duration of first fore-cut. The reflux ratios of the second fore-cut and the main-cut, and the water feeding duration decreased; the flow rate of water increased. If the methanol content of the charge was lower, the reflux ratios of the second fore-cut and the main-cut increased, as well as the flow rate of water. However, the operation was uneconomical. The optimal feeding location was the top tray in every case.

Abstract

In this paper, the development of a systematic model-based framework for product design, implemented in the new product design software called VPPD-Lab is presented. This framework employs its in-house knowledge-based system to design and evaluate chemical products. The built-in libraries of product performance models and product-chemical property models are used to evaluate different classes of product. The product classes are single molecular structure chemicals (lipids, solvents, aroma, etc.), blended products (gasoline, jet-fuels, lubricants, etc.), and emulsified product (hand wash, detergent, etc.). It has interface to identify workflow/data-flow for the inter-related activities between knowledge-based system and model-based calculation procedures to systematically, efficiently and robustly solve various types of product design-analysis problems. The application of the software is highlighted for the case study of tailor made design of jet-fuels. VPPD-Lab works in the same way as a typical process simulator. It enhances the future development of chemical product design.

Keywords: Chemical product design, Blended product, Jet-fuels.

1. Introduction

In chemical product design, it is not only important to find the chemical product that exhibits certain desirable properties but improving the product performance and making products more versatile have become growing concerns in recent times. Chemical products can be classified in terms of molecule and mixtures. Several frameworks have been developed to design basic chemical/functional chemical products (Smith et al., 2009, and Hill, 2004). However, for more complex chemical products such as cosmetic creams, films, and detergents, no generic methodologies exist. While product design is still based on trial and error experimental approaches, it is now generally accepted that application of model-based methodologies can help to design/improve products so as to reach the market faster by reducing costly and time-consuming experiments (Gani, 2004). That is, experiments are only performed during the last stage as a verification tool. Since thousands of products involving mixtures/blends of chemicals need to be designed and/or evaluated, a huge amount of data on physico-chemical properties of chemicals and their mixtures and/or models that can reliably predict them are needed so that model-data based methods for tailor-made design of products can be developed and routinely applied. This is a challenging task requiring data acquisition, data testing, model development and model-based design method development, etc., that needs to be integrated in a computer-aided framework so that chemicals based products can be designed, analyzed and verified in a fast, efficient and systematic manner (Conte et al., 2012, Mattei et al., 2014). These motivate the development of a systematic framework for product design and evaluation.

In this study, the systematic framework employs its in-house knowledge-based system to (1) identify target properties of a desired product; (2) provide suitable property models to calculate the necessary properties classified as primary, secondary, functional, and mixture properties; (3) formulate and solve the design-analysis problems in a fast, robust and systematic manner; and (4) guide the user to the final experimental verification tasks. The framework has built-in libraries of product performance models and product-chemical property models. The built-in knowledge base has a suit of databases containing properties of different classes of chemicals (lipids, solvents, aroma, etc.) and design templates for molecular (solvents, refrigerant, etc) and blended products (gasoline, jet-fuels, lubricants, hair spray, etc.). The property models and the database together provide a very wide range of application for the various chemicals-based products. The large amount of data, models and calculation-algorithms are managed through specially developed ontology, which is implemented as the framework within VPPD-Lab. It has interface to identify workflow/data-flow for the inter-related activities between knowledge-based system and model-based calculation procedures to systematically, efficiently and robustly solve various types of product design-analysis problems. Furthermore, the flexibility of its architecture allows it to be integrated with toolboxes from ICAS (Integrated Computer Aided System) (ICAS Documentation, 2003) such as ProPred (property prediction tool), ModDev and MOT (modeling tools), ProCAMD (hybrid methodology for computer aided molecular design), and process design tools (Kalakul et al, 2014). VPPD-Lab uses template approach for specific type of chemicals-based products. The current version has design templates for microcapsule, active ingredients uptake in plant, homogeneous formulated products, emulsified products, blended products, single chemical-based products (solvents, refrigerants, polymers), and, an option to create templates for new products. The developed computer aided framework is generic and applicable to a wide range of problems. The VPPD-Lab works in the same way as a typical process simulator.

2. Framework

The framework is divided into 2 problems (as shown in Fig. 1); (1) product design, and (2) product evaluation. Each problem follows instruction steps which is integrated with VPPD-Lab knowledge base containing the links for the tools (as shown in Fig. 2).

2.1. Product design

Step A1: Define problem

Tool 1 starts with selection of sub problem (molecular or mixture design), number and type of phases, and available template/ new template corresponding to the user's product design problem. Templates are stored in VPPD-Lab KB. Each template guides the user to identify product needs and translate needs to target properties and property values using Tool 1 Problem definition

Step A2: Go to template

Tool 2: Template guides the user to follow the work-flow for the product design problem such as solvent design, blend design, and emulsion design. Each task in the work-flow is connected with the necessary toolboxes (Figure 2). Tool 3: Chemical database store the experimental property values and needed property values calculated using Property model library. Therefore, it can calculate 55 pure component properties and 10 functional properties for a very wide range of organic chemicals. In addition, it

has data for more than 24,000 compounds and contain more than 50,000 entries of various types of mixture data and several thermodynamic models to calculate mixture properties. Tool 4: Routine/Algorithm contains mixture calculation models (linear and non- linear mixing models), thermodynamic models (UNIFAC, NRTL, UNIQUAC, and PC-SAFT).

Step A3: Go to product evaluation

See 2.2. Product evaluation

Step A4: Further develop selected product-process

After evaluation of the performances of product in step A3, the performances of the process need to be evaluated. The framework has options to link with the process synthesis and evaluation tools such as PROCAFD (computer aided flowsheet design), SustainPro (process sustainability analysis tool), ECON (economic analysis tool), and LCSoft (Life cycle assessment tool).

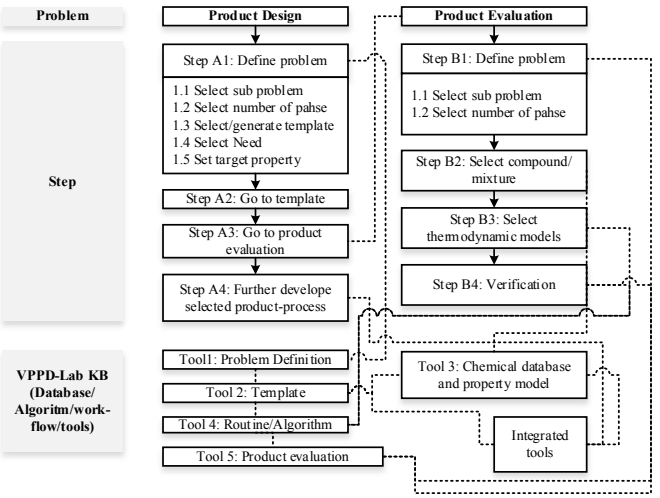

Figure 1.VPPD-Lab Framework

2.2. Product evaluation

Step B1: Problem definition

The selected product's performances need to be evaluated. Experimental verification toolbox helps user to design the experimental tests that may be needed in addition to the molecular and blended products. Product evaluation model toolbox contains product specific performance models (uptake of active ingredient for pesticide, and active ingredient delivery on surface) to evaluate their performances. Depending on the type of the product, these can be model-based, experimental based or a combination of both.

Step B2: Select compound/mixture

This step connects with the chemical database. The user selects the product that can be a single compound or mixture.

Step B3: Select thermodynamic model

This step the thermodynamic model that suitable for the product is selected. Note that, the primary, secondary, and functional properties needed for product performance

calculations are retrieved from chemical database using the suggested property models by VPPD-KB.

Step B4: Verification

This step calculates product performances or behaviors of the product.

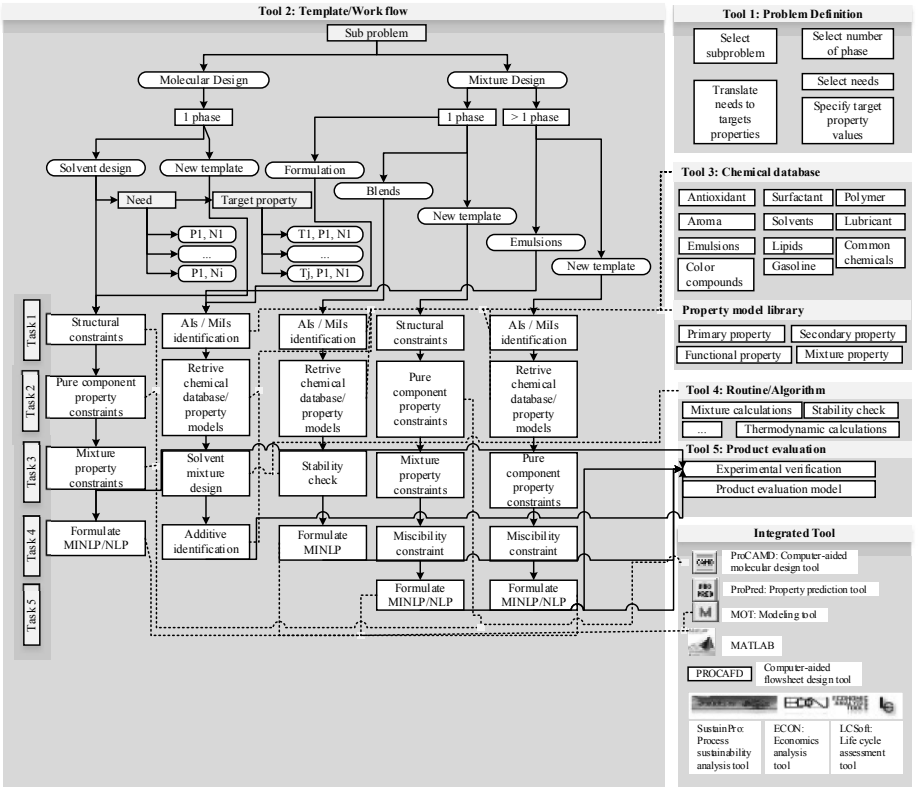

Figure 2.The structure of VPPD-Lab knowledge base (VPPD-Lab KB)

3. Case study

The application of the software is highlighted through the tailor-made fuel blends of jet-fuels.

3.1. Step A1: Define problem

The problem is product design, the sub-problem is blends. The user needs for jet-fuels in terms of target properties, and target property values are identified as shown in Table 1.

3.2. Step A2: Go to template

VPPD-Lab KB guides the user to follow the work-flow of blend design template starting from Task 1 to Task 5.

Table 1.Product needs and translated target properties

Need	**Target Property**	**Target Value**
Ability to be burned	Reid vapor pressure (RVP)	RVP > 1 kPa at 310.95 K
Engine efficiency	Higher heating value (HHV)	HHV > 6125 kJ/mol
Consistency of fuel flow	Dynamic visocosity (η) Melting point (T_m)	η< 6.8 cP at 253.15 K 775 <ρ< 840 kg/m3 at 288.15
Flammability	Flash point (T_f)	T_f>310.95 K
Stability	Gibbs energy of mixing (ΔG^{mix})	ΔG^{mix}< 0
Enviromental impacts	Toxicity (LC_{50}) Carbon footprint (CF)	$-logLC_{50}(mol/L) < 3.6$ CF < 1.8 CO_2 eq.

Task 1: AIs/MiIs identification

The case study of binary mixtures is highlighted where active ingredient (AIs) is the mixture of conventional jetA-1 which is considered as 1 component and The Additives (Minor ingredient or MiIs) are selected from 221 chemicals from different molecular types such as alkanes, cycloalkanes, aromatics, olefins, alcohols with low carbon numbers, ethers, ketones, acid and furan derivatives.

Task 2: Retrieve chemical databases/property models

Primary properties related to target property calculations; molecular weight (Mw), critical temperature (Tc), critical pressure (Pc) ,acentric factor (ω),constant of the Modified Rackett equation (Z_{RA}),LC_{50}, heat of combustion (ΔH_c), RON, and $Wt_{O2}$are retrieved from the chemical databases. The functional properties of pure chemicals; ρ, Dynamic viscosity (μ), and vapor pressure (P_{vap}) are calculated.

Task 3: Stability check

The UNIFAC-LLE group representations of MIs and MiIs are retrieved to calculate the liquid miscibility at 298.15 K (ambient temperature). The stability test is performed using the STABILITY tool (Conte et al., 2011) to check the miscibility of the blends. The blends that are totally immiscible are rejected.50 binary mixtures were found to be partially miscible with jet-fuels.

Task 4: formulate MINLP

The tailor-made blend design problems of jet fuels are formulated as MINLP problem. The objective is to minimize fuel consumption subject to product stability and target properties. The results are the formulation of blended jet-fuels and calculated target properties as shown in Figure 3.

3.3. Step A3: Go to product evaluation

The blended jet-fuels from Task 4 need to satisfy the desired target properties and aviation standards. Experimental verification toolbox in Tool 5: Product evaluation suggests to perform experimental tests to verify η, Tm, Tf, ρ, LHV, RVP. Furthermore, distillation profiles and JFTOT ΔP at 260 ∘C will be tested in order to ensure that the final blends meet the aviation fuel standards based on these properties.

3.4. Step A4: Further develop selected product-process

The process to produce the jet-fuel does not consider in this work since mixing of chemicals in order to obtain blends is a routine mixing operation.

Chemicals	Composition, vol (%)
n-dodecane	20.4
n-tetradecane	13.6
isooctane	6.8
Methylcyclohexane	13.6

Figure 3.Results for jet-fuels blend problem from VPPD Lab

4. Conclusion

A computer-aided framework for design of chemical products has been developed and implemented into VPPD-Lab. Knowledge base system has been employed to manage data-flow, making it more flexible and capable of solving a wide range of product design problems. The use of the framework has been highlighted through the case study involving a tailor-made design of jet-fuels blend. The results show that adding additive improves jet-fuel properties and reduce the consumption of conventional gasoline. VPPD Lab as the new product simulator that works in the same way as a typical process simulator, it can guide a user to design product, study product behaviors, systematically formulate and robustly solve various type product design problems. Future work is to integrate the software with the process design software in order to systematically solve product-process design problems.

Abstract

In this work, a new systematic methodology, which extends the synthesis of a flexible heat exchanger network (HEN),proposed by Braccia et al. (2013), with a designing technique of a fully-decentralized reconfigurable control structure(CS) given by Luppi et al. (2014), is presented. The strategy to design the HEN allows the optimal flexible operation inside an expected range of the plant conditions. The CS is done in the context of reconfigurable control structure which are characterized by: (i) the integration of the variables selection task (CVs and MVs) with the corresponding pairings definition (CVs-MVs), (iii) the consideration of scalar indexes to set a rank of the potential solutions. The advantage of the method is that provides alternative control structures able to act at different operating points. In addition, it only utilizes steady-state process information. One example is given in this work to illustrate the potentiality of the proposed methodology and to support the final conclusions.

Keywords: Flexible Heat Exchanger Network Synthesis, Reconfigurable controller design, Systematic methodology;

1. Introduction

The aim of the HEN synthesis consists of finding a network that minimizes the total annualized cost and the operating cost in terms of utilities consumption. Performing a successful synthesis is important because the HEN configuration has a great impact on the process energy efficiency. In addition, since the HEN introduces interactions, the process dynamic behavior is affected turning more difficult its operation and control. The need of considering control issues at early stages of process design is widely accepted and has motivated the integration presented here. Escobar et al. (2013) proposed a computational framework (Synflex) for the synthesis of flexible and controllable HEN. Synflex can be enhanced by performing the HEN design through a global optimization strategy (GOS). Braccia et al. (2013) proposed the incorporation of a new global optimization approach to Synflex for the synthesis of HEN presented by Björk and Westerlund (2002). The main objective is to generate an efficient decentralized control system able to work well over a specified range of expected variations in the inlet temperatures of the process streams. The main concepts given at Luppi et al. (2014) for designing reconfigurable controller for fault-tolerance purposes are adopted here to give an efficiently operable HEN. In the next sections the overall steps of the proposed methodology are given together with a demonstrative application example.

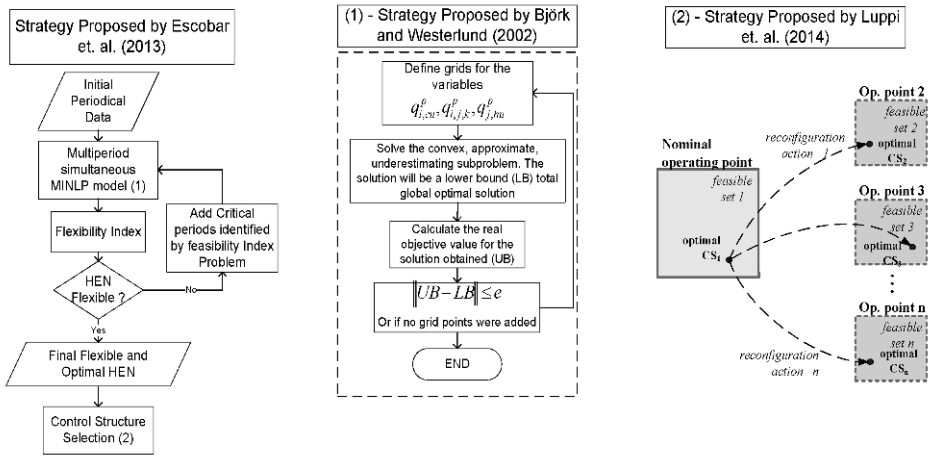

Figure 1: New methodology scheme

2. New Proposed Strategy

2.1. Multiperiod Flexible Heat Exchanger Networks Synthesis with Strategy of Global Optimization.

The synthesis of the network is accomplished based on uncertainty on the inlet temperatures. The first step consists on choosing the number and dimension of the equipments. The second one is an operation stage, for which is checked whether the selected design in the previous step is able to operate over the space of uncertain parameters. If the design is feasible it is assumed to be flexible; otherwise, the critical point obtained from the flexibility evaluation is included in the current set of periods, and a new multiperiod formulation is solved in order to obtain a new design. The GOS used here relies on a convex transformation of the non-convex terms instead of a using a branching procedure.This transformation technique will give rise to a sequence of convex problems that needs to be solved to ensure a global optimal solution. Without a global optimization procedure, one cannot easily know if it is possible to obtain better solutions or not, since there is no information to define whether the solution is a local optimum or the global one. By this procedure is possible to be sure that Synflex model does not exclude optimal configuration.

2.2. Reconfigurable control design methodology.

At Fig. 1 (2) can be seen the complete procedure for obtaining the reconfigurable control structure. By switching between alternative controllers through reconfiguration actions, the system can compensate the effects of the different operation conditions. For each particular scenario, the design of the corresponding optimal decentralized controller involves the selection of q controlled variables (CV) from m available outputs, and q manipulated variables (MV) from n available inputs, including the $q \times q$ pairing. In this work, the considered process has more inputs than outputs, i.e. $n > m$. In addition, all outputs must be controlled due to the control requisites, i.e. $q = m$. Then, in the framework of the well-known Internal Model Control (IMC) theory, at steady-state (SS) the selected MVs can be expressed as (Zumoffen (2013)):

$$\mathbf{u}_s = \mathbf{G}_s^{-1}\mathbf{y}_s^{set} - \mathbf{G}_s^{-1}\mathbf{D}_s\mathbf{d} - \mathbf{G}_s^{-1}\mathbf{G}_s'\mathbf{u}_r \tag{1}$$

where $\mathbf{G}_s$, $\mathbf{D}_s$, $\mathbf{G}_s'$, and $\mathbf{G}_r$ represent transfer function matrices of appropriate dimension, and the vectors $\mathbf{y}_s^{set}$ and $\mathbf{d}$ are setpoint and disturbance vectors, respectively. Therefore, the individual

squared deviations of the selected MVs from its operating point are available in the following vector (Luppi et al. (2014)):

$$\mathbf{e}_{us} = \sum_{i=1}^{n} \mathbf{e}^2_{us_{set}}(i) + \sum_{j=1}^{p} \mathbf{e}^2_{us_d}(j) \tag{2}$$

where:

$$\mathbf{e}_{us_{set}}(i) = (\mathbf{G}_s^{-1})\mathbf{y}^n_{set}(i) \tag{3}$$

$$\mathbf{e}_{us_d}(j) = (\mathbf{G}_s^{-1}\mathbf{D}_s)\mathbf{d}^p(j) \tag{4}$$

The SS deviations stated in eq. 2 result useful to compare alternative MVs-CVs selections. Considering a process with $n > m$ and $q = m$, the design methodology proposes to find solutions to:

$$\min_{\mathbf{C}_i} \|\mathbf{e}_{us}(\mathbf{C}_i)\|_1 \tag{5}$$

subject to:

$$\det(\mathbf{G}_s(\mathbf{C}_i)) \neq 0 \tag{6}$$

$$\mu[E(\mathbf{C}_i)] < 1 \tag{7}$$

where $\mathbf{C}_i$ is the vector of binary variables associated to the selection of the MVs, ($\mathbf{C}_i(j) = 1$ indicates that the input j is selected as MV, and $\mathbf{C}_i(j) = 0$ the opposite case). In addition, $\|.\|_1$ represents the sum of the elements of the vector $\mathbf{e}_{us}$. The constraint of eq. 6 guarantees the feasibility of the selection of the MVs. Finally, the inequality of eq. 7 corresponds to a sufficient condition for decentralized integral controllability (Skogestad and Morari (1988), Braatz (1993)). Here, the matrix E represents a normalization of the interactions introduced by the off-diagonal elements of $\mathbf{G}_s$ (Skogestad and Postlethwaite (2005)), assuming that $\mathbf{G}_s$ is arranged with the CVs-MVs pairings along its diagonal. And $\mu(E)$ corresponds to the structured singular value of E (Grosdidier and Morari (1986)). The inequality of eq. 7 ensures the stability of the control structure despite the interactions of the process and when specific change of operating condition occurs (Luppi and Basualdo (2014)).

3. Results

3.1. Alternative HEN synthesis: calculation of G and D matrices

The data for the illustrative example is given at Table 3. In Braccia et al. (2013) different HEN which consider alternative operation conditions were presented (see Table 2). Total annual cost

Table 1: Input and output variables

Input	Description	Output	Description
$uh_{i,j,k}$	bypass of hot side for exchanger between hot stream i and cold stream j in stage k	$Thout_i$	Outlet Temperature of hot stream i
$uc_{i,j,k}$	bypass of cold side for exchanger between hot stream i and cold stream j in stage k	$Tcout_j$	Outlet Temperature of cold stream j
Disturbance	Description		
$Thin_i$	Inlet Temperature of hot stream i (i=1)		
$Tcin_j$	Inlet Temperature of cold stream j (j=1,2)		
Fh_i	flow capacity of hot stream i		
Fc_j	flow capacity of cold stream j		

Table 2: Operating Conditions

$Thin_1$	$Tcin_2$	$Tcin_2$	
nominal operating point	150	60	0
second operating point	147.3	57.3	17.3

Table 3: Stream and cost data for the example .

Stream	T_{in} (C)	T_{out} (C)	Heat transfer coefficient (kWC^{-1})	Flow Capacity $(kWC^{-1}m^{-2})$
Hot 1	150	45	2	20
Cold 1	60	120	2	13
Cold 2	20	120	2	12
Hu	210	210	1	
Cu	5	15	1	

Cost of heat exchanger $(y^{-1}) = 4000 + 560 \times \mathbf{area}^{0.8}$, *Cost of utility* $(y^{-1}) = 4000 + 700 \times \mathbf{area}^{0.8}$, *Cost of Cooling utility* $(kW^{-1}y^{-1}) = 20$, *Cost of Heating utility* $(kW^{-1}y^{-1}) = 80$.

(TAC) for the first period (nominal condition) was $52,427.28(\$y^{-1})$, the Flexibility Index was 2.7° and the number of heat exchangers and utility in the obtained HEN was 4. In this example the achievable flexibility index was increased up to 20° with a global optimal solution of 5 heat exchangers producing a reasonable higher investment and operating cost corresponding to higher TAC when the second period was calculated. In this period the nominal condition and critical point identified for the first HEN was considered.As stated in section 2.2, the matrix $G(s)$ relates the set of potential manipulated variables (bypass and heats of cold and hot utilities) to the outputs (Outlet temperatures of the hot and cold streams). And matrix $D(s)$ relates the perturbation variables (Inlet temperatures and heat flow of the hot and cold streams) with outputs. For the first heat exchanger network (HEN_1), obtained in the synthesis for nominal operating point, $G(s)$ and $D(s)$ are:

$$G(s) = \begin{bmatrix} 11.355 & 10.591 & 3.173 & 7.513 & 7.482 & 4.411 & -0.133 \\ -8.139 & 0 & 0 & -5.385 & 0 & 0 & 0 \\ 1.720 & -6.620 & -1.983 & 1.138 & -4.676 & -2.757 & 0 \end{bmatrix}$$

$$D(s) = \begin{bmatrix} 0.117 & 0.310 & 0.462 & 1.249 & -0.170 & -0.542 \\ 0.222 & 0.111 & 0 & 0.259 & -0.369 & 0 \\ 0.242 & 0.047 & 0.044 & 0.375 & -0.026 & -0.481 \end{bmatrix}$$

Where the inputs, outputs and disturbances are: (i) u: uh_{111}, uh_{121}, uh_{122}, uc_{111}, uc_{121}, uc_{122}, qc_1, (ii) y: Th_1^{out}, Tc_1^{out}, Tc_2^{out}, (iii) d: Th_1^{in}, Tc_1^{in}, Tc_2^{in}, fh_1^{in}, fc_1^{in}, fc_2^{in}. Second heat exchanger network (HEN_2) obtained in the synthesis for nominal operating point and critical point (second operation point):

-HEN_2 working at nominal operating point

$$G(s) = \begin{bmatrix} 11.457 & 10.630 & 3.025 & 7.534 & 6.509 & 4.190 & -0.133 & 0 \\ -8.146 & 0 & 0 & -5.357 & 0 & 0 & 0 & 0 \\ 1.664 & -6.644 & -1.890 & 1.095 & -4.068 & -2.619 & 0 & 0 \end{bmatrix}$$

$$D(s) = \begin{bmatrix} 0.113 & 0.313 & 0.464 & 1.249 & -0.171 & -0.552 \\ 0.222 & 0.111 & 0 & 0.260 & -0.370 & 0 \\ 0.245 & 0.045 & 0.044 & 0.380 & -0.025 & -0.482 \end{bmatrix}$$

Where the inputs are: uh_{111}, uh_{121}, uh_{122}, uc_{111}, uc_{121}, uc_{122}, qc_1, qh_1.

-HEN_2 working at second operation point

$$G(s) = \begin{bmatrix} 11.611 & 11.155 & 2.814 & 7.022 & 8.182 & 3.898 & -0.054 & 0 \\ -8.144 & 0 & 0 & -4.925 & 0 & 0 & 0 & 0.034 \\ 1.566 & -6.972 & -1.759 & 0.947 & -5.114 & -2.436 & 0 & 0 \end{bmatrix}$$

$$D(s) = \begin{bmatrix} 0.111 & 0.310 & 0.468 & 1.171 & -0.156 & -0.571 \\ 0.217 & 0.116 & 0 & 0.269 & -0.405 & 0 \\ 0.251 & 0.041 & 0.041 & 0.375 & -0.021 & -0.486 \end{bmatrix}$$

Note that $G(s)$ and $D(s)$ are different for each HEN because HEN_2 includes an additional heat exchanger. Firstly can be observed a small change in the gain matrix for HEN_1 and HEN_2 (working at nominal conditions). This is caused by the increase in the area of the heat exchangers in the HEN_2 relative to the HEN_1. Furthermore, it can be seen that for HEN_2 working at nominal condition the heats of hot utilities for the first cold current (q_1)do not affect the outlet temperature (the matrix $G(s)$ has a zero column for this manipulated variable). It is produced because this utility does not work at this condition. While the HEN_2 , working at the condition generated for changes in the inlet temperature requires that this utility begins to operate. This can be seen in the column of zeros considered in the above test. Now it changes taking different values of zero for Tc_1^{out}.

3.2. Alternative decentralized control structures

Table 4: Alternative decentralized control structures

	CS_1	CS_2	CS_3	CS_4
Pairings	$Thout_1 - qc_1$ $Tcout_1 - uh_{111}$ $Tcout_2 - uh_{121}$	$Thout_1 - qc_1$ $Tcout_1 - uh_{111}$ $Tcout_2 - uh_{121}$	$Thout_1 - qc_1$ $Tcout_1 - qh_1$ $Tcout_2 - uc_{122}$	$Thout_1 - qc_1$ $Tcout_1 - qh_1$ $Tcout_2 - uh_{121}$
$\|\mathbf{e}_{us}(\mathbf{C}_i)\|_1$	887.43	887.43	4322.7	4322.5
$\mu[E(\mathbf{C}_i)]$	<1	<1	<1	<1

In this section, the procedure for reconfigurable control design is applied to the HEN process, subject to two operation modes: the nominal operating point (OP) and the second OP (critical point). In Table 1 a list of all the process variables is presented. Here, the normalized SS gain matrices G and D presented above are employed to solve the optimization problem. The objective is to

define one decentralized structure for each considered operating condition. Then, any switching mechanism can be implemented to perform a smooth reconfiguration between controllers. Taking into account that $q = 3$ (all outputs must be controlled, $q = m$), the problem is to select 3 MVs from n available inputs ($n = 7$ for the nominal OP and $n = 8$ for the second OP), together with the 3×3 CVs-MVs pairing. In this context, the length of $\mathbf{C}_i$ results 7 (or 8), according to the number of decision variables for the MVs selection. Due to the dimension of the combinatory problem, an exhaustive search was performed. Furthermore, two algorithms were utilized to pair the CVs with the MVs: (i) the Branch and Bound (BAB) solution proposed in Kariwala and Cao (2010), (ii) the iterative RGA (IRGA, Skogestad and Postlethwaite (2005)).

Finally, four alternative control structures were obtained: (i) CS_1 for HEN_1 at nominal OP,(ii) CS_2 for HEN_2 at nominal OP,(iii) CS_3 for HEN_2 at second OP, using BAB for the pairing task,(iv) CS_4 for HEN_2 at second OP, using IRGA for the pairing task. Table 4 presents these optimal solutions, including the values of $\|\mathbf{e}_{us}(\mathbf{C}_i)\|_1$ and $\mu[E(\mathbf{C}_i)]$ associated with CS_1, CS_2, CS_3 and CS_4.

4. Conclusions

In this work a novel strategy to integrate synthesis and design of control applied to a flexible HEN was presented. It is obtained from the integration of different strategies available in the literature. It was found through the example analyzed here that flexible heat exchanger synthesis generate optimal structure which must work at two operating point. For this reason, it is necessary to design a reconfigurable control capable of controlling the network at these points. The obtained CS_1 and CS_2 for controlling HEN_1 and HEN_2 result equivalent. This is because the corresponding matrices G and D are practically the same, as can be seen in section 3.1. On the other hand, two alternative control structures were designed for HEN_2 at the critical operating point (OP): CS_3 and CS_4. Both structures present similar values of $\|\mathbf{e}_{us}(\mathbf{C}_i)\|_1$ (and $\mu[E(\mathbf{C}_i)] < 1$), but the advantage of CS_4 over CS_3 is that the latter requires minimal reconfiguration. That is, CS_4 only requires the reconfiguration of the loop $Tcout_1 - uh_{111}$ by $Tcout_1 - qh_1$. While CS_3 also demands reconfiguring $Tcout_2 - uh_{121}$ by $Tcout_2 - uc_{122}$.

Abstract
There are many methods to obtain herbs phytochemicals such as the use of solvents as a phytochemical transfer medium in the extraction process. Currently, solvent is preliminarily selected based on the target phytochemicals and solvent polarities. This is followed by performing experiments to determine the potential solvents blends which give the highest desired phytochemicals content. The method uses a trial-and-error approach and is time consuming as well as resource intensive. The combination of property predictive models with computer-assisted search is one way to reduce the needs for huge amount of experiments needed to be conducted. Thus, the main objective of this work is to design solvent blends for the extraction of herbal phytochemicals using computer-aided approach. The methodology is divided into four levels which are pure component constraints (level 1), linear constraints (level 2), non-linear constraints (level 3) and stability checks (level 4). The proposed method has been applied to design a solvent mixture for the extraction of kaempferol from Kacip Fatimah herb as a case study. From the analysis, 12 feasible binary solvents mixture have been identified to be suitable for the extraction as it was within range of the design target. Thus, the optimal search has been performed to find the mixture solvents that can produce the highest kaempferol extraction yield with the lowest cost. Here, five binary solvents showed the highest kaempferol yield with the lowest solvent cost.

Keywords: Herbal extraction, Kacip Fatimah, Phytochemicals, Product design, Solvent blend.

1. Introduction

Natural products are now being extensively marketed in the form of dietary supplements, nutraceuticals, health products, traditional medicines, or as prescriptions written from national pharmacopeias such as Chinese and Indian (Khan and Smillie, 2012). One of the premier Malaysian traditional medicinal plants, *Labisia pumila* (*L. pumila*) is being investigated scientifically for their medicinal properties. *L.pumila*, or locally known in Malaysia as Kacip Fatimah has their own unique characteristic such as anti-oxidant (Shahidi et al., 1992), anti-carcinogenic (Yamamoto and Gaynor, 2001), anti-stress (Choi et al., 2010), high in vitamin C (Tsao and Deng, 2004) and induced cancer cell death (Wei et al., 1990). These characteristics are due to the presence of phytochemicals in *L.pumila* such as flavonoids, phenolic and gallic acid compound.

There are many methods that have been applied to obtain these phytochemicals, where solvent are used. Every solvent will attract different active ingredients as the "like dissolve like" theory is implemented (Barton, 1990). This is the reason why different solvent will give different result (or yield) in the extraction process. In the case of herbal extraction, the main issue need to be considered is the current solvent selection used in extraction is only based on trial-and-error method. Besides, traditional methods have focused on experiments using classes of solvent (polarity) with different classes giving rise to different solute (Karunanithi et al., 2009). This method is limited by the effort, cost and time required (Samudra and Sahinidis, 2013). In addition, in order to extract one type of phytochemical, at least six solvent are needed. If the quantity of these solvents can be reduced, the amount of waste can be minimized, the productivity can be increased or maintained and the time can be saved (Kerton and Marriott, 2013). Thus, the combination of property predictive models with computer-assisted search (Samudra and Sahinidis, 2013) is one way to overcome these drawbacks. From the literature, there is no publication reported on the computer-aided design of solvent blends to optimize the extraction of phytochemicals from herbs. Previously, Karunanithi et al. (2005) designed an optimal extractant/solvent for the separation of acetic acid from water by Liquid-Liquid Extraction (LLE) while (Conte et al., 2011, 2012) designed a solvent blend for the formulation of paint and insect repellent. Besides, Yunus et al. (2014) designed a framework to obtain the optimal blends of gasoline and lubricant base oils. In this study, phytochemicals and, solvent properties and their relationship will be considered to design a blended solvent that can extract the maximum amount of phytochemicals from herbs. The solvent to be designed will consider all the safety, economic and environmental issues. The main objective of this work is to develop a new solvent blend model for the maximum extraction of herbal phytochemicals by using computer-aided approach. The method is demonstrated by designing a solvent blend for Kacip Fatimah herb as a base case study.

2. Methodology of Solvent Design for Herbal Extraction

The systematic methodology employs the reverse design approach (Gani, 2004), where the targets of the design problem are defined and the solvent blends that match the targets are identified. This reverse design approach has been chosen because it is ideally suited to handle with the "define target - match target" problems. In this methodology, the reverse approach is applied when the target properties of solvents mixture are set then solvents mixtures that could be mixed and matched the design target are identified. Normally, a set of solvents are systematically generated and screened. It is possible to generate and screen all potential feasible blend candidates (Yunus et al., 2014). In this solvent design method, it only considers binary mixtures, but it can be easily extended to multicomponent mixtures.

The first and very important task in designing the solvent mixtures is problem definition as shown in Figure 1. In this task, an understanding of the consumers need would be the performance criteria. For herbal extraction, the solvent must have all of these criteria performance which are: can effectively extract the selected phytochemicals from herb, can be removed from the crude extract mixture (so that the pure phytochemical can be obtained), have low toxicity, must be miscible to each other and to herbs phytochemicals and stable, low price and good solvent appearance. According to the knowledge base, the solvent needs are translated to the target properties. Therefore, the target properties affecting the above performance criteria are listed in Table 1.

This method applies four levels to find the optimum solvent mixtures that match the target properties. For the Level 1 until 4, solvent mixtures that do not satisfy the properties constraints would be rejected meanwhile those that satisfy the properties constraints would be considered for the next level. Every target properties listed in Table 1 have their own constraints and solvent mixture selected must have all the properties values within that constraints.

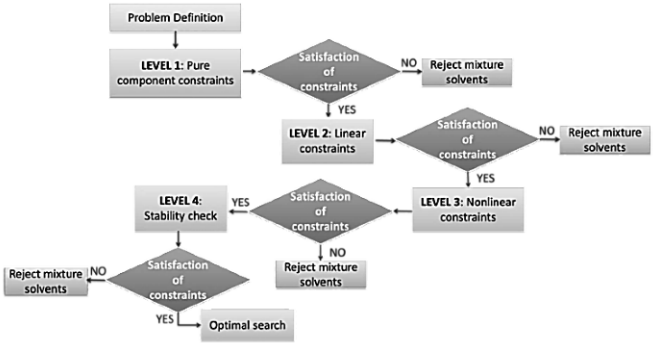

Figure 1. Work-flow diagram for the solvent design in herbal extraction.

Table 1. Translation of the performance criteria into target properties

Solvents Mixture Performance Criteria	Target Properties
Effectively extract the selected phytochemicals	$\log_p$, δ, T_m
Can be removed from crude extract (after extraction process)	μ, T_b,
Low toxicity	LC_{50}
Miscible to each other and stable	δ, $\Delta Gmix$
Low price	ρ, C
Good solvent appearance	μ

For Level 1, pure component properties of solvent in the database and target phytochemicals are compared with respect to the target values. The aim for this level is to get a list of pure solvent that match the phytochemical target properties value. For this step, three properties which are solubility parameter (δ), partition coefficient ($\log_p$), and melting point (T_m) are considered. These properties have the interrelation between solvent and phytochemicals which affect the extraction process efficiency while the other properties are used for the solvent selection only to make sure their safety and compatibility to the extraction process.

At Level 2, binary mixtures of solvents are screened according to the linear constraints. Linear models follow the linear mixing rule to compute the mixture target properties. This level considers toxicity (LC_{50}), density (ρ) and viscosity(μ) properties.

For Level 3, the non-linear mixture properties for the remaining binary mixtures which satisfy the non-linear constraints at the overall composition range are determined. Then, new composition ranges are obtained. This level considers boiling point ($T_{b)}$ properties which using model by Klein et al. (1992).

For Level 4, the stability analysis is performed. The input data consist of the UNIFAC-LLE group representation (Magnussen et al., 1981) of the solvent mixture and the temperature used in herbal extraction process. The stability routine which is Gibbs energy of mixing ($\Delta Gmix$) is solved for each mixture; result from the non-linear design constraints. The result obtained is the information of binary mixtures indicated as either stable or unstable. Then finally, the satisfying solvent mixtures are identified to search the optimal solvents that fulfill the objective of the study.

3. Case Study

The aim of this case study is to design a solvent blend that can maximise the extraction yield of kaempferol, which is one of the main phytochemical in Kacip Fatimah herb. The blend solvent formulation is considered for non-consumable phytochemicals product, to be used for the conventional extraction and the temperature considered is 90 ^{o}C. The results is then compared with the experimental data obtained from Karimi et al. (2011). 30 solvents data were used consisting of alcohol, hydrocarbon, ether and ester solvent categories. From this number of solvents, 870 possible binary solvent combination have been identified (total combinations of binary solvents (n-1) x n, where n is number of solvent in database). Meanwhile, only the main phytochemicals in Kacip Fatimah are taken into consideration, which is kaempferol. In this paper, the case study is solved using the systematic methodology as illustrated in Figure 1.

At Level 1, all 870 possible binary solvent combination were screened by comparing the solubility parameter, partition coefficient, and melting point of kaempferol with the solvents properties. Solvents that have properties value within the pure kaempferol properties will be considered in the next level. After the evaluation of Level 1, only 119 binary solvent combinations satisfy all the specified constraints. These binary solvent combinations will be further screened in Level 2. Only linear model for binary solvent properties is considered in this level. Firstly, the composition of solvent mixtures is set at 0.01 until 0.99 with an interval of 0.01. Then toxicity, density and viscosity for the binary solvents are calculated using the linear mixing rule. The solvent mixtures are then screened according to the property limit as shown in Table 2.

Table 2. Target property constraints for herb solvent blends design.

	Target property value	
Property	**Solvent constraints**	**Phytochemical constraints**
Partition coefficient	Log K_{ow}(depends on phytochemicals)	-0.3 ≤Log K_{ow}≤ 4.44
Boiling point	333.15 K ≤T_b ≤ 348.15 K	-
Toxicity parameter	-2.5 ≤-log LC_{50}≤ 2.5	-
Viscosity	1.20 cP ≤ μ ≤1.24cP	-
Density	1.0g/cm^3≤ρ≤ 1.5g/cm^3	-
Solubility parameter	δ (depends on phytochemicals)	16≤ δ≤48 Mpa$^{1/2}$

From the screening, 36 binary solvents are left and will be considered in Level 3. Level 3 is only for the properties that apply non-linear model for binary properties calculation. The overall binary solvent composition will be obtained in this level. Only one property which is boiling point was applied for this non-linear model case. After Level 3, only 12 binary solvents still remain as shown in Figure 2. These 12 binary solvents would be analyzed in level 4 which is the stability test. This test is very important to make sure that the solvent mixtures are miscible to each other. After stability test, the remaining binary solvents would be further analyzed for optimal search. This optimal search only focuses on two main objectives which are: reducing solvent mixture cost and maximizing phytochemicals yield in extraction process.

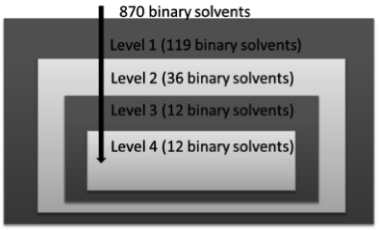

Figure 2. Number of solvent blend reduced after screening using reverse design approach.

From the solvent mixture selected, the price and kaempferol composition were calculated. Price of every pure solvent was obtained from ICIS (2008) meanwhile the kaempferol composition was calculated using Eq.(1). Figure 3 shows the solvent price and yield of kaempferol for each of the selected binary solvent

$$x_i\gamma_i = exp\frac{\Delta H_i}{RT_m}(\frac{T-T_{mi}}{T}) \quad (1)$$

where x_i is solubility of phytochemicals expressed as mole fraction, γ_i is phytochemicals activity coefficients in the solution, T_{mi} is phytochemicals melting temperature, ΔH_i is phytochemicals heat of fusion and T is extraction operating temperature. The activity coefficient, γ_i can be determined using models such as Original UNIFAC, Modified UNIFAC (Dortmund), NRTL and COSMO-SAC. In this work, Original UNIFAC and Modified UNIFAC (Dortmund) models were used to estimate the activity coefficients. The estimated activity coefficients were verified with experimental data from Karimi et al. (2011). Original UNIFAC gave 85.12% error while Modified UNIFAC (Dortmund) gave 21.46% error when compared with the experimental data. Thus, this work considered the Modified UNIFAC (Dortmund) to calculate kaempferol composition in Kacip Fatimah herb based on the lower error obtained.

The top five of solvent mixtures that give the highest kaempferol yield with their cost are plot to observe the trend. From Figure 3, it shows that methanol: isobutylraldehyde (M: IB) solvent mixture has the highest kaempferol composition yield followed by methanol: n-propionedehyde (M: PP), methanol: water (M:W), methanol: ethyl acetate (M: EA) and methanol: acetic acid (M:AA). M: W gives the lowest solvent mixture price in combination with the third place of kaempferol extraction yield as shown in Figure 3. Therefore, M: W is the best solvent mixture that could be used to extract kaempferol from Kacip Fatimah herb.

4. Conclusion

A systematic methodology for the design of blended solvent for extracting phytochemicals from herb has been developed and was tested on the extraction of kaempferol phytochemical from Kacip Fatimah herb. A decomposition method has been applied to solve the blending problem, where the objectives are to quickly screen out a large number of alternatives and to reduce the search space at each hierarchical step. The methodology applied can be used to design blended solvent for extracting phytochemicals from any herb where the scope and size depend on the solvent database available and models availability. For future work, this systematic methodology needs to be verified with different herbs as case studies.

Evolutionary Algorithm for De Novo Molecular Design Considering Multi-Dimensional Constraints

Robert H. Herring III and Mario R. Eden*

Department of Chemical Engineering, Auburn University, Auburn, AL 36849, USA
edenmar@auburn.edu

Abstract

The area of computer-aided molecular design has benefited from significant advances in technology and methodologies through consideration of problems with increasing complexity and size. The development of increasingly accurate and predictive property models, through application of powerful variable selection and improved mapping techniques, requires new approaches for designing structures meeting property requirements as informed by these models. Additionally, the long-standing desire to model and search an increasingly larger region of chemical space maintains. As such, the necessity of developing algorithms for solving these complex property models, most often containing molecular descriptors of varying type (e.g. information theoretic, charge based, constitutional) and dimensionality (e.g. 1D, 2D, 3D), within a large search space is realized. One such approach involves the implementation of guided stochastic algorithms, such as an evolutionary algorithm. This contribution outlines an evolutionary algorithm for solving computer-aided molecular design problems, with multi-dimensional criteria, in terms of spatial signature descriptors. The effect that various user defined variables have on this algorithm, and the resultant solutions, will be considered in further detail.

Keywords: Molecular Design, Evolutionary Algorithm, Descriptors

1. Introduction

Computer-aided molecular design relies on the generation of accurate and predictive structure-property (activity) relationships. When used in a forward manner, these models can predict a given property as a function of various molecular descriptors. Molecular descriptors provide a quantitative reference to structural features in a molecule and can be superficially characterized by the dimensionality of information they capture. This ranges from 0D descriptors, an example of which could be a simple atom count, to the more complex 4D descriptors, which can capture the spatial characteristics of interacting molecules (e.g. ligand/receptor binding). Additionally, there are thousands of molecular descriptors available today, each capturing a unique molecular feature. Recent advances in variable selection techniques (Nicholls et al., 2004) have enabled the identification of an optimal subset of descriptors which best captures the property or activity of interest. It is also becoming increasingly evident (Nettles et al., 2006; Kar & Roy, 2010) that a combination of descriptors with varying dimensionality is best at describing the variance seen with many properties for a wide range of data sets.

While the forward application of these multi-dimensional property models can be straightforward, significant challenges arise when using the same models in an inverse manner, which involves the identification of structures meeting a desired property value

or range of values. Previous approaches (Harper et al., 1999) have considered the lower dimensional criteria first, while consecutively narrowing the chemical search space as more complex criteria are considered. However, this technique would not be suitable for CAMD problems with property models containing both topological (2D) and topographic (3D) descriptors. While the lower dimensional descriptors are invariant with sufficient structural representation, spatial descriptors depend on the conformational space of each molecule. This space has the dimensionality of $3N$-6, with N being the number of atoms in the molecule, and can be quite complex. There are almost always multiple conformers, representing a spatial arrangement of atoms within the molecule, present in bulk chemicals, with larger, more flexible, structures having the largest set of accessible conformations.

The solution of most CAMD problems follows as the combinatorial optimization of molecular fragments, collections of which are meant to represent potential solutions. This approach works well but can fall prey to combinatorial explosion, especially with the extension to include varying spatial information within each fragment. Evolutionary algorithms have been successfully applied within the field of CAMD (Venkatasubramanian et al., 1995) and provide a potential tool for tackling the nonlinearities arising from the mapping of spatial descriptors into chemical space as well as the accompanied combinatorial explosion. As such, this contribution outlines a methodology for solving CAMD problems utilizing property models with multi-dimensional criteria. The approach utilizes spatial molecular fragments as building blocks to generate potential solutions, while estimating the accessible conformational space associated with these structures. The user defined variables associated with the genetic algorithm applied within this methodology, along with their effect on the outcome of an illustrative case study, will be considered in detail as the foundation for this work has been established (Herring and Eden, 2014).

2. Methodology

The steps developed for setting up and solving these molecular design problems with multi-dimensional criteria in a guided stochastic, specifically a genetic algorithm, manner are as follows: (1) Identify necessary property models along with desired property targets; (2) Perform conformational analysis on the common data set among all models; (3) Develop spatial atomic signatures; (4) Apply genetic algorithm, with graph based representation of population members, to identify potential solutions.

2.1. Spatial Signature Descriptors

The signature descriptor, developed by Visco et al. (2002), was created with the intent of being able to represent various types of descriptors on a common platform as well as solve molecular design problems within what is termed ‘signature space.’ This descriptor is rooted in graph theoretical concepts and essentially represents a molecular fragment in which the environment around a central atom, up to a pre-defined height, has been encoded. The representation of this information, known as an atomic signature, is canonical and follows a line notation, which is concise and suitable for programming applications. Each atom within a molecule has its own atomic signature, and the collection of these represents a potential molecular signature.

Since these atomic signatures capture the environment around each atom within a molecule, such a representation is suitable for deriving whole-molecule topological descriptors from the information contained within each fragment before their connectivity has been established. This allows one to displace the computational

expense of arranging these fragments to establish structural isomers, until certain topological constraints are satisfied. The benefits of representing physicochemical properties in terms of molecular fragments are well known from the implementation of group contribution property models in various molecular design applications (Gani et al., 1991). The use of signature descriptors affords the same benefits of reconstructing solution molecules, while extending CAMD efforts to simultaneously consider topological constraints as well.

The extension of atomic signature to include spatial information was facilitated through the fact that these descriptors overlap, by definition. This can be taken advantage of in developing a molecular geometry from fragment geometry information. A full conformational analysis is performed on the set of molecules common to all data sets used to develop the property models applied within the chosen case study. The conformers generated are broken into unique atomic signatures, and the spatial information developed within the conformational study is stored within each of these. Redundant spatial information is eliminated by compressing the data such that the effects of combinatorial explosion are minimized. These fragments are utilized to build potential solution molecules within the evolutionary algorithm discussed below.

2.2. Genetic Algorithm

The genetic algorithm developed begins with the creation of a starting population, which is meant to capture diversity within the chemical search space in terms of molecular features as well as size. To accomplish this task, a desired size range is first established, along with an initial population size. An atomic signature is chosen at random to begin a graph, which is grown until it reaches an acceptable size, which was chosen at random from the desired range. The 'growing' process involves the identification of atomic signatures which overlap with the existing structure, and satisfy the structural overlap and saturation constraints (Herring and Eden, 2014). This is facilitated through information stored within a 'bonding network', which pre-calculates and stores all possible overlaps between atomic signatures such that it only needs to be calculated once.

Once an initial population has been established, the recursive process of selecting certain graphs to undergo various changes, in an attempt to improve the overall fitness of the subsequent population and ultimately identify solutions, begins. These graphs are selected based upon their 'fitness' value, which represents closeness to the chosen property constraints and is meant to mimic the pressure of natural selection. The fitness function chosen for this methodology is shown in Eq. (1).

$$f_i = exp\left(-\alpha\left[\sum_i^n \frac{(P_i - P_{i,bar})^2}{(P_{i,max} - P_{i,min})^2}\right]\right) \quad (1)$$

This format is well suited for application within molecular design problems, which often require candidate solutions to fall within an acceptable property range or a set of property ranges. These ranges are established with $P_{i,max}$ and $P_{i,min}$, which represent the desired upper and lower bounds for a given property, respectively. With $P_{i,bar}$ being the average between this upper and lower limit, this formulation allows the fitness to be expressed as a smooth Gaussian function with values ranging from zero to one. In this case, α represents a tunable parameter known as the Gaussian decay rate, which controls how quickly the fitness value falls off as the property values leave the desired region. Graphs exhibiting a higher fitness value have an increased likelihood of being chosen to

undergo the operations of mutation and crossover. The mutation operator has been designed to drive graphs towards an optimal size identified throughout the algorithm, and as such has three forms: insertion, deletion, and random mutation. While the mutation operators require only one graph, the crossover operator requires two, which are then spliced and recombined at acceptable points, as determined through information in the bonding network, and is meant to break free from any local minima 'traps' which might be found within the chemical search space.

3. Case Study

3.1. Property Model

The property model utilized within this case study was generated through principal component regression (PCR) with principal components identified by the Dragon 6 molecular descriptor program (Talete, 2014), which utilizes the single value decomposition (SVD) algorithm. 245 structures, representing a diverse group of potential solvents with experimentally measured boiling points between 90 and 140 °C, were obtained through the ChemSpider database. These structures were downloaded as mol files and sent through Avogadro (Hanwell et al., 2012) to develop an initial geometry, which was subsequently explored in more detail through a Monte Carlo conformational search within the BOSS (Biochemical and Organic Simulations System) (Jorgensen and Tirado-Rives, 2005) program. Traditional topological descriptors, as well as geometric descriptors, were utilized in the development of principal components and six factors were able to capture around 90% of the variance seen within the chosen data set. Upon regression into property space, this model had an explained variance (R^2) of 81.3% and a standard error (s) of 15.6 °C.

3.2. Population Size

One of the first variables chosen for running a genetic algorithm is the initial population size. Within this study, varying the initial population size would have the assumed effect of considering a larger region of the designated chemical search space, which could potentially provide improved starting points, or seeds, for the continued search for feasible solutions. The effect of varying the starting population size for a case study utilizing the above property model, in an attempt to identify solutions exhibiting a predicted boiling point of between 110 and 120 °C is considered. The number of solutions identified as a function of run time is plotted in Figure 1 for varying starting population sizes.

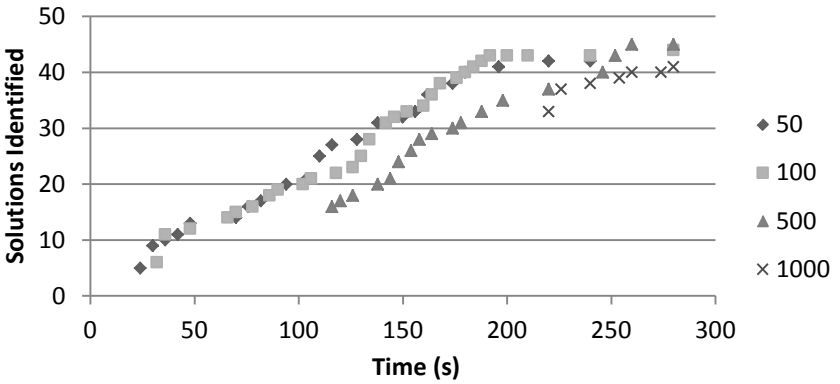

Figure 1 – Effect of initial population size on solutions generated.

Within this study, the initial population is maintained at 100, running population is 50, Gaussian decay rate variable is 10 and the crossover probability was set to 0.05. Predictably, the simulations with a larger starting population were able to begin with more solutions. However, this time sacrifice did not have a large effect on the continuation of the simulation in terms of identifying solutions. The implementation of the designed genetic operators was sufficient to explore varying regions of the search space to make up for the limitation of a smaller set of starting points. However, this phenomenon is likely to vary with respect to the complexity of a chosen chemical search space. In this case, the mutation operators were designed to control the size of solutions generated, which has a strong correlation to the respective boiling point for many groups of solvents.

Another decision to be made within this algorithm is the running population size, which is the number of new candidates generated with each iteration, or generation. It would seem that there should be an optimal running size, which could be determined by the total number of solutions generated after a given amount of time. This effect was considered in the search for solutions falling within the same property range as before, while the initial population size has been fixed at 100 and the running population size is varied. Varying the running population size from 50 to 200, in increments of 50, reveal an optimal size of 50. While all simulations were able to ultimately identify an equivalent number of total solutions, an increase in running population only had the effect of taking longer to attain these solutions.

3.3. Crossover and Mutation

The effect of varying crossover and mutation rates is considered within this section. The target property range is set between 110 and 120 °C, Gaussian decay rate variable is 10, initial population is 100, and the running population is 50. The results are exemplified below in Figure 2, where the crossover rate is varied from 0 to 0.2.

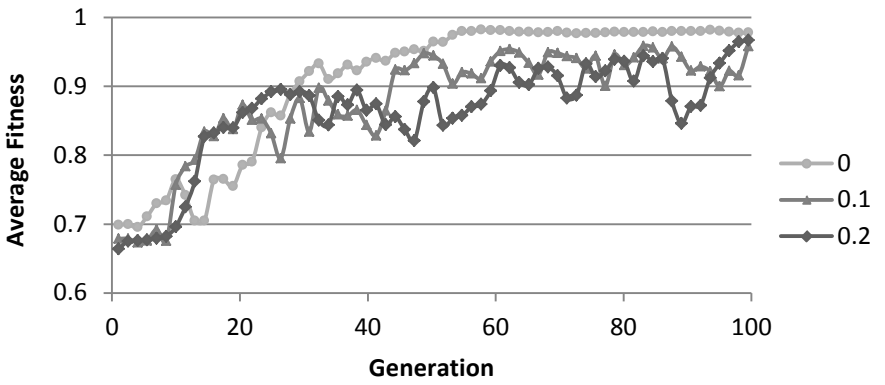

Figure 2 – Average fitness values for simulations with varying crossover rate.

The intended effect of crossover mutation is to help perpetuate diversity, in size and structural features, within the population that is unattainable through pure mutation alone. The effects of an increasing crossover rate can be seen as stochastic in relation to the average fitness of each consecutive generation. While the simulation with only mutations was able to steadily increase the population fitness towards an optimal value,

increasing the chance of encountering a crossover operation resulted in a less stable fitness improvement. However, the simulation with a crossover rate of 0.1 was able to ultimately identify the most solutions satisfying the given constraints. These results could be explained by the fact that similar solutions are likely to be revisited through implementation of the mutation operator, whereas the crossover operation increases the likelihood of arriving at unique solutions but could also create structures with a highly deviant structure and poor fitness value.

4. Conclusions

The effects of varying the starting population size, along with the rates of various genetic operators, have been considered for a genetic algorithm developed to solve CAMD problems with multi-dimensional characterization. The starting population was found not to have a huge effect on the ultimate number of solutions identified as the genetic operators, with a smaller starting population, were able to effectively search the initially uncovered regions of chemical space. Increasing the size the generations had a more pronounced effect of inflating the runtime taken to identify an equivalent number of solutions. The solution density of the chemical search space likely plays a large role in tuning this value and perhaps searching the chemical space established by a more congeneric set of structures would have an opposite effect. The crossover rate was found to induce a stochastic progression of fitness values; however, an optimal setting could potentially be established for exploring chemical search spaces of varying complexity. Future studies will consider the effects that these parameters have on data sets of varying complexity such that a more general consensus can be developed.

Data Mining and Regression Algorithms for the Development of a QSPR Model Relating Solvent Structure and Ibuprofen Crystal Morphology

Shounak Datta, Robert H. Herring III, Mario R. Eden*

Department of Chemical Engineering, Auburn University, Auburn, AL36849, USA
edenmar@auburn.edu

Abstract

Computer Aided Molecular Design (CAMD) has been used to supplement and guide experimental efforts in various fields. Currently, highly predictive models can be developed as a result of improved computing hardware along with novel methodologies for model development. Decreasing dependency on experimental efforts can also reduce the environmental footprint of companies involved in product design and development. Though being a well-practiced process, crystallization is comparatively a much less studied separation unit operation. Not much is known about the variables that affect quality and usefulness of the end product gained from crystallization. Studies suggest that the interactions between solute and solvent are quite difficult to quantify and large variance can be noticed with every solute-solvent combination. Pharmaceutical companies are widely known for using crystallization operations to develop their end product. Additionally, crystal morphology has a significant impact on how the drug is metabolized in the human body. This contribution describes the development of a quantitative structure-property relationship (QSPR) model which relates the crystal aspect ratio of ibuprofen to the structure of the solvent utilized. The work focuses on applying various data mining and regression algorithms such as PCA/PCR (Principal Component Analysis/Regression), GA-MLR (Genetic Algorithm - Multiple Linear Regression), ANN (Artificial Neural Network) to generate a QSPR model. The validation results of the models generated from these algorithms are thoroughly analyzed and explained. Three-dimensional (3D) descriptors are often found to cause degeneracy issues when applied within QSPR studies. For these reasons, singular value decomposition (SVD) was used as an alternative to PCA for its increased stability in primary component prediction. Both internal and external validation methods were used to test the predictive capabilities of the developed models.

Keywords: QSPR, modeling, crystallization

1. Introduction

CAMD has become quite an attractive field of research for its ability to identify compounds with desired properties and activities through computational efforts. The drawback, however, is the computational complexity of the calculations required for evaluation of the compounds considered (Harper et al., 1999). A requirement of any CAMD study is a property model that can predict certain properties of the compounds with reasonable confidence.

The major aim of QSPR studies is to find a mathematical model relating a specific activity or property with one or more numbers of descriptors that are related to the molecular structure. The result of such studies is a model, which, if acceptable, can be used to provide an idea of how the property and molecular structure are related. These kinds of models are widely used by synthetic chemists for making choices between alternative molecular structures (Katritzky et al., 1995). Because of their known applicability, QSPR models are widely studied within academia, industry and government settings. In this stage of expansion of QSPR modeling, it is obvious that collaboration between computational and experimental experts is needed to ensure the highest level of success for such modeling practice (Cherkasov et al., 2013).

Study of crystal morphology is required to understand the difference in crystalline products due to changes in the solvent structure. In many pharmaceutical products, slight change of crystal shape is reported to bring a significant level of variance in the metabolic characteristics of the drugs (Datta and Grant, 2004). Solvent properties that contribute to the attributes of the crystal products are not yet fully understood. The pharmaceutical industry, being a field which heavily utilizes crystallization operations, has to apply extensive experimental efforts to identify the optimal crystallization conditions for newly discovered drugs. Understanding solvent influence on crystal shape can provide a basis upon which to design experiments efficiently, potentially decreasing both the environmental impact of experiments and time consumption of crystal engineering.

Ibuprofen [2-(4-isobutyl-phenyl) propionic acid], shown in Figure 1, is a well-known anti-inflammatory drug. While insoluble in water, it is however soluble in various organic liquids. Currently, the drug is crystallized from ethanol and aqueous ethanol in industrial practice (Rashid et al., 2013). To capture the variance in Ibuprofen crystal morphology with respect to the chosen crystallization solvent, the crystal shape is considered along with the structural features of the respective solvent. Additionally, varying force fields, such as GAFF (Generalized AMBER Force Filed), Ghemical and MMFF94s (Merk Molecular Force Field for Static molecules) provided in the Avogadro software, were used to determine their effects on the resulting models. GAFF was developed by Wang et al. (2004) to better represent drug like molecules and molecules they interact with. Ghemical is highly applicable in the case of simple organic molecules. MMFF94s was developed by Halgren (1999). This force field was selected as the compound classes used in its core parameterization are expansive and each of the solvents used in this work fall within that expansive space. QSPR model development algorithms were coded using MATLAB, which was chosen for its built-in tools and functions.

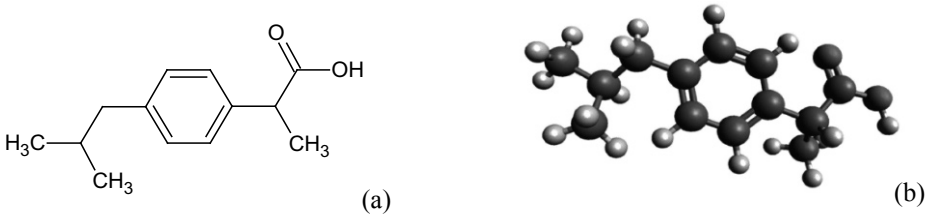

Figure 1: (a) 2D Ibuprofen structure; (b) Optimized 3D Ibuprofen structure

2. QSPR Model Development

Figure 2 highlights the steps taken for the model development methodology, which begins with geometry optimization.

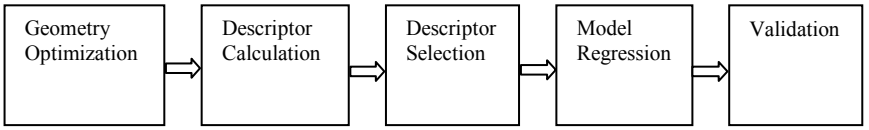

Figure 2: Steps taken in QSPR model development methodology.

Geometry optimization of molecular structures within the chosen data set is necessary to generate spatial molecular data, which is utilized in calculating 3D descriptor values. The chosen geometry optimization algorithm, along with the applied force field, is important because it determines the quality of structures produced. As mentioned before, the geometry optimization for the chosen solvents was performed using three different force-fields available within the Avagadro software package. For each optimization process, the steepest descent algorithm was used. The convergence value was kept to 10^{-7} and 500 iterations were performed. The results generated were saved as MDL mol files for further use.

The MDL mol files generated from the geometry optimization using Avogadro were used to generate molecular descriptors. This project focuses on 3D descriptors calculated using Dragon 6.0 software. To further elaborate, descriptors of the following classes were generated:

- Randic molecular profiles
- Geometrical descriptors
- RDF descriptors
- 3D-MoRSE descriptors
- WHIM descriptors
- GATEWAY descriptors

The calculated descriptors were stored in text files for ease of loading in MATLAB. The next step was to remove descriptors from each matrix that had values of zero for multiple solvents within the data set. If a descriptor had values of zero for more than ten solvents, that descriptor was removed from the data matrix. Finally, experimental results concerning crystal aspect ratio of Ibuprofen for different solvents were considered for regression purposes.

Principal component analysis (PCA) was used to develop a QSPR model relating solvent structure to crystal aspect ratio. PCA is very different from other methods because it does not eliminate descriptors from the analysis, but instead transforms the large, highly correlated data matrix into a smaller matrix of uncorrelated factors that are linear combinations of the original data set. Each factor covers a certain percentage of the variance within the original data matrix, which denotes importance of the factors to be considered. PCA gives a proper understanding of model feasibility and a basic idea on factors governing the model. In addition, principal component regression (PCR) is

used to map these components into property space, generating a model which can be further validated.

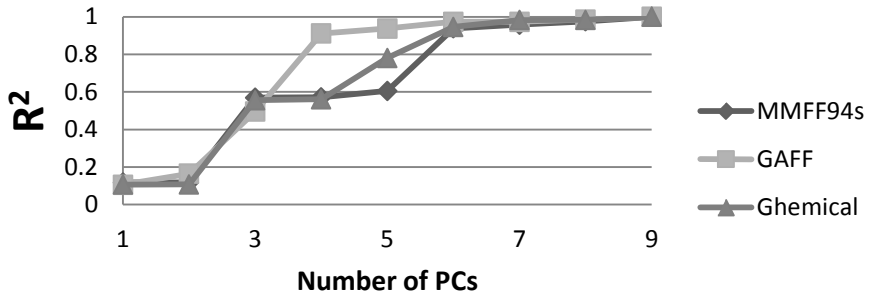
A genetic algorithm (GA), in combination with multiple linear regression (MLR) was also used to develop a QSPR model to further understand how solvent properties are related to the respectively produced crystal shape. GA, being an algorithm of optimization through random selection and objective function calculation, can in some cases be tricky if not controlled properly. Its prime operating variables, probabilities of crossover and mutation gives it a unique ability to control the approach to an optimal result after several simulated generations. Gharagheizi (2007) reported in his studies, of QSPR relating solubility parameters, that GA-MLR can be used to develop a QSPR model of high predictability.

Artificial Neural Network (ANN) is used in a wide range of applications. The algorithm designs artificial neurons, connected with coefficients (also known as weights), creating organized layers to develop neural structures (Zupan and Gasteiger, 1999). Here, Feed Forward Neural Network was used for data fitting over the results of a GA to produce a GA-FFNN system with potentially improved accuracy. This regression was performed using the nntool, available within MATLAB. GA-FFNN was performed using default settings with an increased number of neurons. Using the same tool, a radial basis approach was used to perform Radial Basis Function-NN (RBFNN) for a tighter fit.

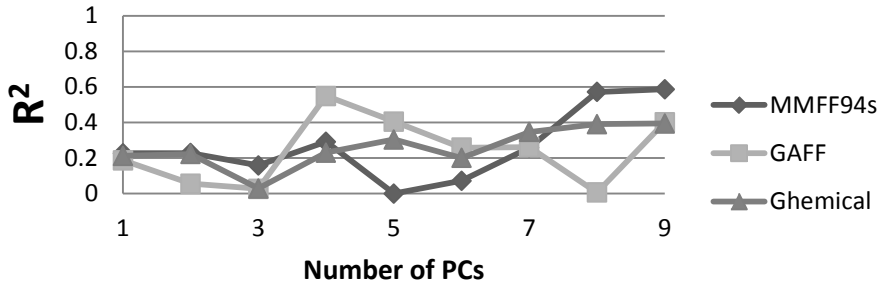
Ultimately, the developed models are required to be validated. For this purpose, both internal and external validations were performed. This ensures model feasibility for representing a training set of the available data as well as the predictability of the model for external data (e.g. test set separate from the training set). The importance of external validation in light of internal validation is that it ensures reasonable property predictions of a material not included in model development, which is desirable of QSPR models. R^2 values of the models for both the training set and test set were used as a measure of the model correctness and predictability, respectively. R^2 values indicate how well the data fit the models that are to be used for prediction. A 5:1 ratio was maintained for training and test data partitioning.

3. Results and Discussion

The results from PCA/PCR were very useful in determining the best geometry optimization algorithm for these studies. As shown for the internal validation in Figure 3(a), descriptor sets of each geometry optimization process reaches an R^2 value of 1 for models with 9 principal components. The path of external validation shown in Figure 3(b) was not as smooth as the internal validation. With various points of ups and downs, it can be seen that when 9 principal components are added in the model, the best external prediction is achieved by MMFF94s optimized descriptors. This sets a basis for further calculations using the described algorithms provided with information about the optimal types of descriptors and number of principal components.



(a)



(b)

Figure 3: (a) Internal validation and (b) External validation of PCA-PCR model for descriptor sets of three geometry optimization algorithms.

For further QSPR study, descriptors generated with the MMFF94s force field were used. Influenced by the results of the PCA-PCR model, 9 descriptors were allowed to be chosen in random manner by GA for further optimization. The best results achieved from the trials are presented in Figure 4. It should be noted that, in the case of GA-MLR, the model worked better for the test set than the training set. The results indicate that a combination of GA and RBFNN has produced an acceptable model with external validation R^2 value of 0.8624 and internal validation R^2 value of 0.9834.

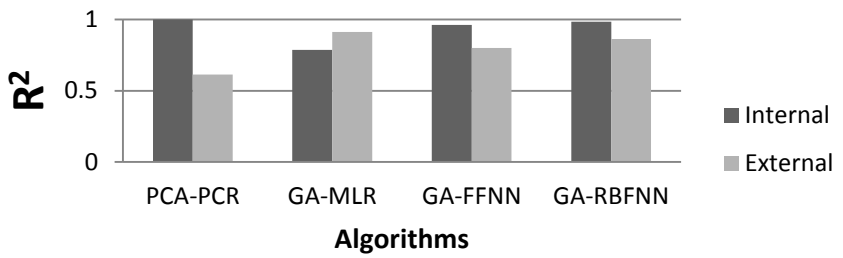


Figure 4: Performance of models developed using MMFF94s descriptors.

4. Conclusions

The necessity of developing predictive models for use within the field of computer-aided molecular design has been established. Specifically, the inclusion of spatial (3D) descriptors within these models requires certain considerations regarding the origin of the spatial data used to estimate these descriptor values. The impact of choosing a proper force field for geometry optimization is discussed in this work and investigations show that, for this case, MMFF94s serves as the optimal choice. With an exception for GA-MLR, all the models show comparatively better response for the training set data than test set data. This is likely the result of a small, and significantly diverse, data set. This study was effective in exemplifying the applicability of modern model development techniques, as applied in the area of crystallization. However, its influence on crystallization process is a matter of further studies.

5. Acknowledgements

The authors greatly appreciate the support of Dr. Charles Acquah, University of Connecticut, and Dr. Arunprakash Karunanithi at the University of Colorado for providing the experimental data which form the basis of this work. Also, thanks to Samir Hasan of Auburn University for providing advice on efficient coding strategies.

Abstract

Computer aided molecular design (CAMD) in the past has successfully been performed to design chemicals for a variety of processes including those involving reactions. However, the problem of design of reactants and products with optimal properties has not received much attention. Recently attempts have been made to address this problem. The majority of these contributions, however, are restricted to design of reactants and products when only a single reactant and product can be structurally varied. An attempt to include variation of structures of multiple reactants and products was also restricted in scope. Only the dominant properties of the product molecules could be optimized such that each product molecule was subjected to its respective set of property constraints. In this work, an algorithm has been developed that designs reactants and products such that properties that are functions of structures of reactants and products are optimized. Also, the reactants and products are subjected to their respective set of property constraints. Certain thermodynamic properties of reactions like standard Gibbs free energy change of a reaction can be optimized using the developed algorithm. Linear and nonlinear property-structure relationships based on group contributions and/or topological indices (TIs) have been utilized. They have been treated on a single platform using signature descriptors. Signatures have also been utilized to relate structures of reactants and products.

Keywords: Reactive Systems, Molecular Design, Signature Descriptors, CAMD

1. Background

1.1. Molecular Design in Reactive Systems

CAMD is progressively being carried out in reactive systems to design solvents that enhance reaction kinetics, catalysts, reactants and products. For the design of reactants and products, the reaction(s) occurring in the system is known prior to the design. The reactants and products however are structurally variable. Chemmangattuvalappil *et al.* (2012) developed an algorithm to generate structures of a single unknown reactant and product, albeit restricted to linear property models. De Vleeschouwer *et al.* (2012) employed density functional theory and optimized the photoacidity of a single variable candidate, but, without provision for property constraints. Also, quantum mechanical methods suffer from escalating computational expense with increasing number of electrons (Adjiman *et al.*, 2014). However, problems tackled by De Vleeschouwer *et al.* (2012) cannot be completely addressed using standard thermodynamic models. Dev *et al.* (2014) developed an algorithm to generate structures of reactants and products irrespective of their numbers such that the respective dominant properties of the products were optimized. The products were also subject to their respective set of

property constraints. The algorithm could also deal with nonlinear models. In this work an algorithm has been developed that designs reactants and products such that properties dependent on structures of reactants and products are optimized. Reactants and products are also subjected to property constraints.

1.2. Atomic Signature Descriptors in Molecular Design

If G is a molecular graph and x is an atom of G, the atomic signature of height h of x is a canonical representation of the subgraph of G containing all atoms that are at a distance h from x (Faulon *et al.*, 2003). Thus, a signature consists of a root atom, x, and atoms in each n^{th} out-neighborhood of x, where n varies from 1 to h. The size of each atom's first out-neighborhood is the out-degree. It can be used as a coloring function to distinguish various atom types in a molecule. Atomic signatures can be used as building blocks to form molecules. Use of signature descriptors in molecular design offers the advantage of enabling utilization of quantitative structure property/activity relationships (QSARs/QSPRs) and group contribution models (GCMs) on a single platform. Thus a wide variety of property targets can be tracked. Faulon *et al.* (2003) identified the relationship between topological indices (TIs), which constitute QSARs/QSPRs, and signatures. If k is a constant, ${}^{h}\alpha_G$ is the vector of occurrences of atomic signature of height h and *TI(root (*${}^{h}\Sigma$*))* is the vector of TI values calculated for each root of atomic signature:

$$TI(G) = k\left[{}^{h}\alpha_G \cdot TI\left(root\left({}^{h}\Sigma\right)\right)\right] \tag{1}$$

2. Molecular Design of Reactants and Products

Molecular design of reactants and products involves their structural variation until the dominant properties of interest are optimized without violation of property and structural constraints. All allowable variation in the structures is captured in the set of possible signatures. This set is generated for each atom in each reactant and product taking into account the general structural formula. In this set, different signatures for the same root atom may exist. This is due to the appearance of different possible atoms from variable groups, in the root atom's neighbourhood. Each instance of variation in molecular structure results in a subset being chosen from the set of possible signatures. The elements of this subset when combined suitably in correct numbers generate a feasible structure. The heights of utilized signatures, h, are those that are able to capture the structural information encoded in the TIs and/or groups used in the property models.

2.1. Root Atom Balance of Signatures

Chemical reactions, barring those that are nuclear reactions, involve only the rearrangement of atoms of reactants to yield products. Thus, the number of atoms is conserved in a reaction and the reactants and products are structurally related. The new position of a reactant atom in the molecular graph of the corresponding product is revealed by the reaction mechanism. Consequently, given a signature from a reactant's set of possible signatures, not only the root atom but atoms in each level of the signature tree can be tracked to the products they get repositioned to. Thus, the change, if any, in the signatures can be inferred.

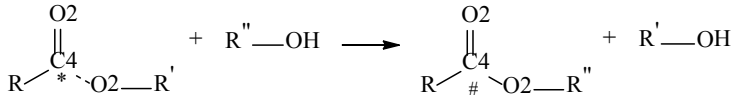
As mandated by the reaction mechanism, some or all of the atoms in the n^{th} out-neighborhood ($1 \le n \le h$) of a reactant atom may appear in the n^{th} out-neighborhood of the repositioned reactant atom. The common atoms may appear in a different n^{th} out-neighborhood after the reaction. The uncommon atoms can also be tracked from

different positions in the reactants. Thus, identification of a product signature obtained from transformation of a reactant signature, with the same root atom, can be carried out. But, due to variability of molecular structures, some atoms in reactants will exist whose *n* out-neighborhoods can be filled by different sets of possible atoms. If these different possible sets do not appear in the *n* out-neighborhoods of the repositioned reactant atom then different possible reactant signatures will exist for a corresponding product signature. Conversely, it may happen that different sets of possible atoms can be filled in the *n* out-neighbourhoods of the repositioned reactant atom. If they do not originate from the *n* out-neighbourhoods of the original reactant atom then different possible product signatures will exist. Thus, to identify the corresponding product signatures obtained after transformation of certain reactant signatures, the atoms common to the *n* out-neighborhoods of the root atom should appear in both reactant and product signatures as mandated by the reaction mechanism. The uncommon atoms if variable will generate different possible reactant and/or product signatures for the same set of common atoms. Since in a reaction, the number of atoms is conserved, the total number of tracked root atoms of signatures need to be conserved. Since, each root atom has an associated signature, a generalized root atom balance can be written as:

$$\sum_{a=1}^{p}\left(n_a \sum_{b=1}^{q} \alpha_{a,b,root\ v} \right) = \sum_{c=1}^{r}\left(n_c \sum_{d=1}^{s} \beta_{c,d,root\ v} \right) \tag{2}$$

Where p is the number of reactants, n_a is the stoichiometric coefficient of each reactant, and q is the number of possible signatures belonging to a reactant that due to the reaction transforms into specific signatures in the products. Also, r is the number of products, n_c is the stoichiometric coefficient of each product and s is the number of possible signatures in a product that are obtained by transformation of signatures in the reactants under consideration. $\alpha_{a,b,root\ v}$ is the occurrence number of possible atomic signatures of *root v* belonging to one of the reactants. These signatures can transform into possible atomic signatures of *root v* belonging to one of the products having an occurrence number $\beta_{c,d,root\ v}$. *root v* is an atom of the same element and can have different colors associated with the vertex degree in the reactants and products. Also, the occurrence numbers appearing in the sum may not be the total occurrence number.

Consider the transesterification reaction, shown below, as an example to demonstrate the application of Eq. (2). The numbers adjoining the atomic symbols are the vertex degrees, used as colors. The dashed bond between C4 and O2 is a bond that will break. R, R′ and R″ are assumed to be acyclic saturated groups.



(3)

From the mechanism it is known that the C4 atom (marked *) double bonded to the O2 atom in the reactant ester appears only in the product ester also as C4 (marked #) double bonded to same O2. Let all the possible signatures of height 3 of the reactants and products be generated. Then the root atom balance that can be written for the C4 atom when R is possibly CH_3 i.e. C1 is the following:

α[C4(=O2C1O2(C1))] + α[C4(=O2C1O2(C2(C)))] + α[C4(=O2C1O2(C3(CC)))] + α[C4(=O2C1O2(C4(CCC)))] = β[C4(=O2C1O2(C1))] + β[C4(=O2C1O2(C2(C)))] + β[C4(=O2C1O2(C3(CC)))] + β[C4(=O2C1O2(C4(CCC)))]

Where, α and β are occurrence numbers of the signatures, in square brackets, of reactant and product C4, respectively. The above holds because according to the mechanism, along with C4, the R group is also transferred to the product ester. Thus, the atoms of R group are common and will appear as is in the n neighborhoods of C4 in both reactant and product signatures. In this sub-example we have taken R to possibly be C1. So, C1 makes an appearance in each of the signatures. Also, the OR′ group is transferred to the product alcohol and the OR″ group from the reactant alcohol becomes a part of the product ester. These are the variable groups that do not share any common atom. Thus, the branch of the C4 signature tree containing atoms of OR′ can be varied. The same is done for C4 bonded to OR″. Hence, the summation on both sides includes this variation where single bonded O2 is bonded to differently colored atoms. For this example, different variations in R will have different relationships involving signatures rooted at C4. Since in the above reaction only one C4 double bonded to O2 will appear in each ester, an additional condition where the sum of occurrences of all signatures with C4 root atom equals 1 will be imposed on each ester.

2.2. Optimizing Properties dependent on Structures of Reactants and Products

In this work, properties that are functions of structures of each reactant and product are to be optimized to design reactants and products. Examples of such properties include standard entropy of reaction, standard free energy of reaction, standard enthalpy of reaction, etc. Such properties, which are to be optimized, will be impacted by property constraints and structural constraints on each of the reactants and products. Additionally, for a reaction, structures of reactants and products are related. Thus, constraints capturing this relationship will also impact the property being optimized. The previous section details a general procedure to derive such relationships.

2.3. Problem Formulation

A mixed integer nonlinear programming (MINLP) problem is formulated to optimize the property of interest. The problem is subjected to property constraints of each reactant and product. Each of the properties involved are ultimately expressed in terms of the occurrence number of atomic signatures. Structural constraints for each reactant and product need to be added to ensure that feasible structures are obtained. For this, the structural constraints developed by Chemmangattuvalappil and Eden (2013) are utilized. Additionally, to capture the structural relationships between the reactants and products, root atom balances for each of the root atoms of signatures are added to the set of constraints. The solution obtained by solving the MINLP problem consists of values of occurrence numbers of signatures of reactants and products. Using these values, the signatures are then combined to provide structures of reactants and products using the structure enumeration algorithm of Chemmangattuvalappil and Eden (2013).

3. Case Study

The aim of this case study is to design reactant and product esters RCOOR′ and RCOOR″, and reactant and product alcohols R″OH and R′OH such that the standard Gibbs free energy change of the transesterification reaction, ΔG^o_{rxn}, is minimized. RCOOR′ and R″OH are constrained by log(P) and log(LC_{50}) respectively. P is the octanol-water partition coefficient and LC_{50} is the acute toxicity. RCOOR″ and R′OH are subjected to their respective set of boiling and flash point constraints. The property ranges are listed in Table 1. ΔG^o_{rxn} has been evaluated using the following definition:

$$\Delta G^o_{rxn} = \sum a_{product} G_{f,\,product} - \sum b_{reactant} G_{f,\,reactant} \tag{4}$$

Where, $G_{f,\ product}$ and $G_{f,\ reactant}$ are standard Gibbs energy of formation values and $a_{product}$ and $b_{reactant}$ are stoichiometric coefficients of each product and reactant, respectively. The free energy of formation (G_f) of each reactant and product was expressed in terms of their structures using a GCM developed by Hukkerikar *et al.* (2012). In the GCM, C_i, D_j and E_k are contributions of first, second and third order groups of type i, j and k respectively. N_i, M_j and O_k are their respective occurrence numbers. The other property models utilized have been listed in Table 2. In the log(P) model (Soskic and Plavsic, 2005), ${}^1\chi^{opt}$ is the optimized first-order molecular connectivity index. I_{MET}, I_{PHYD}, I_{ALRIN} and I_{CONJUG} are indicator variables (IVs) for compounds containing methyl group attached to heteroatoms, H atom bonded to strongly electronegative group, an aliphatic ring and conjugation, respectively. I_{HG2} and I_{HG3} are IVs representing 2 and 3 geminal halogens on a C atom, I_{HVIC} represents halogens bonded to vicinal carbons and I_{PG2} and I_{PVIC} represent polar groups separated by 1 and 2 carbons respectively. In the log(LC_{50}) QSAR (Juric *et al.*,1992), ${}^0\chi^v$ is the zero-valence connectivity index. The boiling and flash point GCMs (Hukkerikar *et al.*, 2012) have the same form as GCM of G_f.

Table 1. Property Constraints on Reactants and Products

Reactant/Product	Property	Upper Bound	Lower Bound
All	ΔG^o_{rxn} (kJ/mol)	Minimum	
RCOOR′	log(P)	5	-
R″OH	log(LC_{50})	-	-1
RCOOR″	Boiling Point (K)	485	395
	Flash Point (K)	375	295
R′OH	Boiling Point (K)	470	385
	Flash Point (K)	380	300

Table 2. Property Models

Property	Property Model
Std. Gibbs energy of form., G_f (kJ/mol)	$G_f - G_{f0} = \sum_i N_i C_i + \sum_j M_j D_j + \sum_k E_k O_k$
log(P)	$\log(P) = 0.829 + 1.055 \times {}^1\chi^{opt} + 0.580 \times I_{MET} + 0.367 \times I_{PHYD} - 0.627 \times I_{ALRIN} + 0.454 \times I_{CONJUG} + 0.658 \times I_{HG2} + 1.726 \times I_{HG3} + 0.381 \times I_{HVIC} + 1.271 \times I_{PG2} + 0.605 \times I_{PVIC}$
log(LC_{50})	$\log(LC_{50}) = 2.975 + 1.169 \times \log {}^0\chi^v - 7.309 \times (\log {}^0\chi^v)^2$
Flash Point, F_p (K)	$F_p - F_{p0} = \sum_i N_i C_i + \sum_j M_j D_j + \sum_k E_k O_k$
Boiling Point, T_b (K)	$exp(T_b / T_{b0}) = \sum_i N_i C_i + \sum_j M_j D_j + \sum_k E_k O_k$

An optimization problem consisting of the objective function, minimize the standard Gibbs energy change of transesterification reaction, was set up in GAMS. Additionally,

the structural and property constraints of the reactant and product esters and alcohols along with the root atom balances of signatures were included. The optimization problem was solved using the DICOPT solver. Since, some of the second order groups in the group contribution models can only be represented by signatures of height 3, the maximum height of signatures utilized was 3. Also, R, R′ and R″ are assumed to be acyclic saturated groups. The optimum value of ΔG^{o}_{rxn} is obtained as -13.6 kJ/mol. A set of structures of reactants and products obtained for the minimum value is:

- Reactant ester: 2-methylpentan-3-yl pentanoate $[CH_3(CH_2)_3C(=O)OCH(CH_2CH_3)CH(CH_3)CH_3]$
- Reactant alcohol: ethanol $[CH_3CH_2OH]$
- Product ester: ethyl pentanoate $[CH_3(CH_2)_3C(=O)OCH_2CH_3]$
- Product alcohol: 2-methylpentan-3-ol $[CH_3CH_2CH(OH)CH(CH_3)CH_3]$

4. Conclusions

An algorithm has been developed to design reactants and products such that properties dependent on their structures are optimized. Additionally the reactants and products are subjected to their respective set of property constraints. Thus, certain thermodynamic properties of reactions like the standard Gibbs free energy change of a reaction can be optimized with the developed algorithm. The algorithm takes into account the information provided by reaction mechanisms to relate the structures of reactants to those of products using signatures. Future efforts include developing an algorithm where each reactant and product's respective properties are to be optimized. In such an algorithm the reactants and products are to be subjected to their respective set of property constraints. Additionally properties that are functions of structures of reactants and products are to be optimized and/or are to be added as constraints.

Abstract

This work introduces an efficient approach to the conceptual design of an internally heat-integrated reactive distillation column (HIRDiC) synthesizing ethylene glycol (EG) through the hydration of ethylene oxide (EO). A systematic method is proposed to obtain a feasible physical configuration with maximum possible extent of heat integration, in which the column diameter, the number of panels and the panel size on each plate are iteratively examined and determined according to thermodynamic and hydraulic analysis. Evaluated by the total annualized capital cost (TAC), the comparison results showed that neither of the two commonly used heat distribution schemes, i.e. uniform heat transfer area and uniform heat duty distribution, was as good as the design acquired from the proposed methodology.

Keywords: HIRDiC; Heat integration; Reactive distillation; Ethylene glycol

1. Introduction

Reactive distillation (RD) is a process in which chemical reaction and distillation occur simultaneously in one single apparatus. RD has attracted much attention in the last two decades because of its potential for lower capital investment, improved selectivity, and increased yield (Thery et al., 2005). However, because of the nature of distillation, the RD process is energy intensive in the process industries. Significant effort has been devoted to the development of novel schemes with high energy efficiency, such as the dividing-wall reactive distillation column (Sun et al., 2011), and heat pump-assisted RD processes (Jana and Mane, 2011). The latest scheme gaining researchers' attractions is the internally heat-integrated reactive distillation column (HIRDiC) (Vanaki and Eslamloueyan, 2012), with the concepts originated from internally heat-integrated distillation column (HIDiC). Unlike the conventional distillation column which has only one shell with two sections, the HIDiC configuration consists of two separate columns linked by a compressor and a throttling valve. Operated at different pressures and temperatures, the internal heat transfer from the high pressure column to the low pressure column becomes possible which has shown great potentials in energy saving (Olujic et al., 2006). Since the first illustration of the concept of HIDiC, research has focused on the modelling (Nakawaii et al., 2001), control (Ho et al., 2009), and experiments (Nakito et al., 2000). Gadalla et al. (2007) and Suphanit (2011)studied the geometric feasibility from the aspect of hydraulic analysis. In this work, we apply the concept of HIDiC into RD processes, and develop a design framework based on iterative calculations to exploit maximum possible and feasible internal heat integraion.

2. A Design Case of HIRDiC

2.1. Description of a Conceptual Design

The concept of internal heat integration is applied to the ethylene glycol (EG) RD column, which is used as an illustration example. As shown in Eq.(1-3), EG is formed from the hydration of ethylene oxide (EO) and can continue to react with EO to form (diethylene glycol) DEG and (triethylene glycol) TEG. EG is the desired product; hence, the RD process has been designed to satisfy the target selectivity to EG (≥90%). The reaction kinetics was taken from literature (Altiokka and Akyalcin, 2009).

$$C_2H_4O\ (EO) + H_2O \rightarrow C_2H_6O_2\ (EG) \quad (1)$$

$$C_2H_4O\ (EO) + C_2H_6O_2\ (EG) \rightarrow C_4H_{10}O_3\ (DEG) \quad (2)$$

$$C_2H_4O\ (EO) + C_4H_{10}O_3\ (DEG) \rightarrow C_6H_{14}O_4\ (TEG) \quad (3)$$

The boiling points at atmospheric pressure of the components are as follows: EO, 283.6 K; H_2O, 373.2 K; EG, 470.5 K; DEG, 518.0 K; TEG, 561.5 K. To maintain the temperature of the reaction, the reactive zone of the RD column favours a higher pressure, while the operating pressure for separation can be lower because of the obvious differences in the boiling points among pure components. Thus, the RD column for the production of EG is well suitable to be divided into two separate columns with the two sections operated at different pressures and temperatures. Besides, as all reactions are highly exothermic (approximately −100 kJ/mol of EO reacted), the internal heat transfer from reactive section to stripping section is allowable and applicable in theory. Figure 1 shows a schematic diagram of the HIRDiC. The reactive section contains a total condenser with total reflux. The vapour flow from the stripping section enters the compressor and delivered to the reactive section, while the liquid from the bottom of the reactive section pass through the throttling valve entering the low pressure stripping section.

2.2. Simulation Tool

The Aspen Plus software package was employed as the simulation tool for the calculation of the thermodynamic properties and phase behaviour of the studied systems. The UNIQUAC activity coefficient model for the liquid phase and the Redlich−Kwong equation of state for the vapour phase were used for phase equilibrium calculations which were verified with our previous experimental data. The heat transfer area requirement and the equipment cost of the HIRDiC were estimated by an interactive sequential calculation using Aspen and Excel.

2.3. Thermodynamic Analysis

To identify the thermodynamic feasibility of internal heat integration, the two columns were first simulated without any internal heat transfer. From Figure 2 which shows the temperature profiles of the two columns, one can see that the temperature changes little in both reactive and stripping section, leading to a nearly constant temperature difference around 32 K. This temperature difference is sound enough for a thermodynamically feasible HIRDiC design. But if it is less than allowable minimum temperature difference, the pressure of reaction column should be considered to be revised (if allowed). In later section, the two commonly used heat distribution schemes will be investigated and compared, i.e. uniform heat transfer area and uniform heat duty distribution. However, we want to point out here that the results of both schemes should

not have much difference given the nearly constant temperature differences and the same heat transfer coefficient (1000 W/m^{2}K).

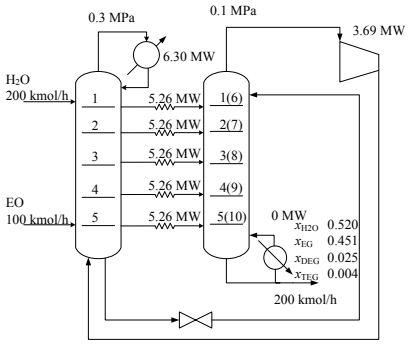

Figure 1 A schematic diagram of HIRDiC.

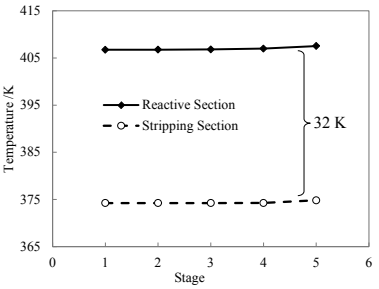

Figure 2 The temperature profile.

The uniform heat duty distribution scheme was employed for a sensitivity analysis to investigate the maximum possible internal heat integration. The results are shown in Figure 3 and 4. When the internal heat duty on each stage increases from 1 to 5 MW, the heat duty of the reboiler and condenser will decrease. The electricity consumption will increase though quite slightly, which can be attributed to the increased reversibility and undermined separation effect. However, the total energy consumption (reboiler heat duty + 3 × compressor break power) decreases. On the other hand, the vapour and liquid flow vary dramatically as the internal heat duty changes.

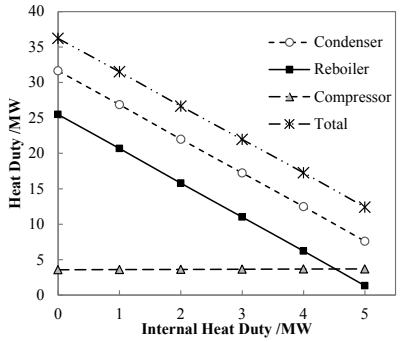

Figure 3 Effects of internal heat duty on the duty of condenser, reboiler and compressor.

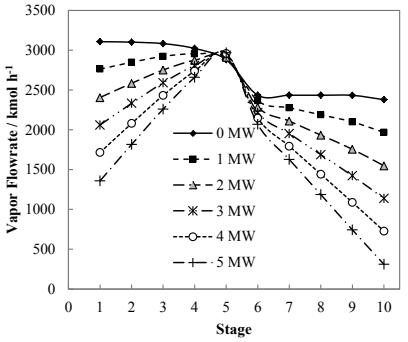

Figure 4 Effects of internal heat duty on the vapour flowrate profile.

According to the sensitivity analysis, it is thermodynamically feasible to reduce the heat duty of the reboiler to 0. Thus, an ideal HIRDiC with no external heat utilities can be obtained as shown in Figure 1. However, a trim reboiler should be considered for system start up and operation flexibility.

2.4. Hydraulic Analysis

Once a reasonable HIRDiC design based on thermodynamic analysis is obtained, its feasibility should be examined again according to hydraulic analysis. In this research we consider a typical concentric configuration with panels placed in the stripping column, as shown in Figure 5. The hot vapour enters the panel, while the cold liquid flows across the outer surface. Under the effect of temperature difference, the vapour condenses inside the panel and the liquid vaporises on the surface. The heat panel has a

fixed thickness and height. The panel length determines the panel area and it is determined by the space available between the two column sections, with the consideration some space allowances (d/L = 0.25 in this work) to ensure the fluid liquidity. However, a tray with the active area fully occupied by a multiplicity of parallel heat transfer panels implies a significant reduction in the free area available for the vapour flow and consequently a faster approach to the entrainment flooding limit. This can be counteracted by a corresponding increase in the tray cross sectional area, i.e. the diameter of the stripping section will be justified by adding up the occupied area of the heat panels.

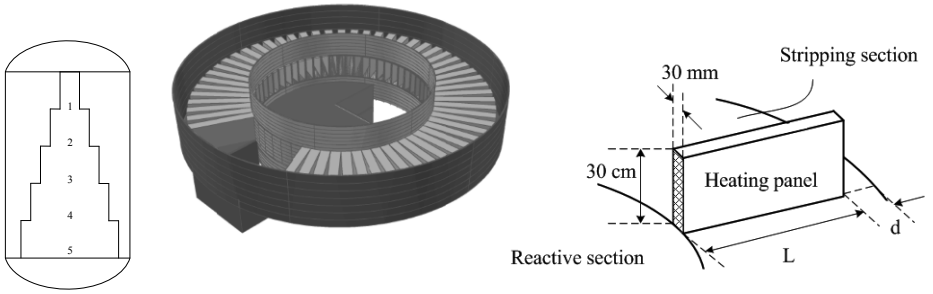

Figure 5 Geometrical analysis of concentric HIRDiC configuration.

Take the ideal HIRDiC design in Figure 1 for example. After determining the internal heat duty on each stage, it is easy to calculate the required heat transfer area on each stage upon updated temperature profile. With the information of liquid and vapour flowrates along the column, the diameter is able to be identified based on the panel layout as well as the flooding limit (0.8 in this work), in terms of which the available heat transfer area can then be calculated. Figure 6 displays the required heat transfer area vs. the available heat transfer area along the column, which shows clearly that not a single stage can provide sufficient transfer area, reflected by the feasibility indicator (required area divided by available area) greater than 1. One can claim that the diameter of stripping section could be increased to provide more heat transfer area. However, this will affect the tray performance. Thus, an appropriate choice is to decrease the internal heat duty of each stage to satisfy the available area, generating a partial HIRDiC design. Moreover, we should point out that, if the internal heat duty is decreased, the vapour and liquid flowrates will increase (according to Figure 4), which requires a larger column diameter. Then, more heat transfer areas are available which in turn allows a higher internal heat duty. Thus, to determine the hydraulically feasible design is not a one-step work. The iteration of calculations cannot be avoided.

3. Design Framework for a Feasible HIRDiC

A two-stage design framework is proposed to obtain a feasible physical configuration with maximum possible extent of heat integration, as shown in Fig 7. The first stage is based on thermodynamic analysis to ensure that the temperature difference between the columns is feasible. In the second stage, the column diameter, the number of panels and the panel size on each tray are iteratively examined and determined according to hydraulic feasibility analysis. To fully utilize the available heat transfer area, a threshold of the feasibility indicator is specified as 0.99 – 1. We emphasize that after the iteration,

the obtained internal heat distribution normally is neither uniform heat duty nor uniform heat transfer area, but a scheme with maximum possible heat integration on each stage restricted by the available heat transfer area.

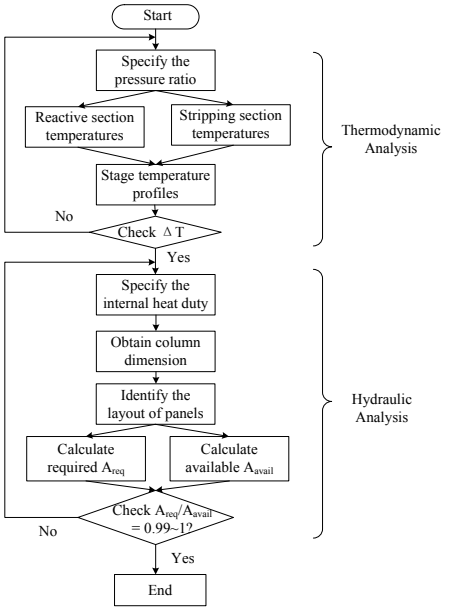

Figure 7 Design framework of feasible HIRDiC based on thermodynamic and hydraulic analysis.

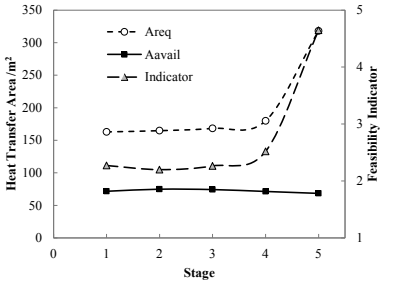

Figure 6 Required and available heat transfer area on each stage.

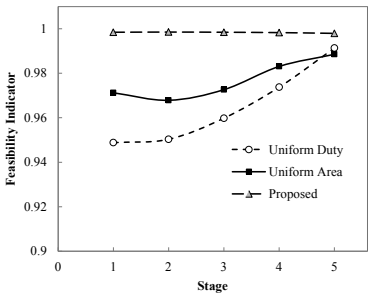

Figure 8 Hydraulic feasibility indicator of different design schemes.

Table 1 Cost information of different HIRDiC design schemes.

Cost Information	Uniform Duty	Uniform Area	Proposed
Column /M$	0.13	0.13	0.13
Panels /M$	0.72	0.72	0.74
Heat Exchangers /M$	1.47	1.45	1.42
Compressor /M$	11.1	11.1	11.1
Annualized Capital Cost /M$·y^{-1}	4.48	4.48	4.47
Electricity /M$•y^{-1}	7.31	7.31	7.31
Cooling Water /M$·y^{-1}	1.86	1.85	1.81
Steam /M$·y^{-1}	9.94	9.75	9.39
Operating Cost /M$·y^{-1}	19.1	18.9	18.5
Total Annual Cost /M$·y^{-1}	23.6	23.4	23.0
Reduction /%	base	0.92	2.58

4. Results and Discussion

Three heat distribution schemes, i.e. uniform heat duty, uniform heat transfer area, and the one obtained from the proposed design framework, were examined and compared. Figure 8 shows the hydraulic feasibility indicator of different schemes, from which one can discover that no matter uniform heat duty or uniform heat transfer area scheme, the

available heat transfer areas were not fully utilized. The scheme obtained from the proposed design framework had the maximum usage of the available heat transfer area and consequently maximum total internal heat duty as well. Table 1 lists the economic analysis results of the three schemes, showing that the uniform heat transfer area scheme is slightly better than the uniform heat duty scheme, although the difference is less than 1%. However, the best design comes from our proposed framework, reducing the total annual cost by some 2.6% compared with the uniform heat duty scheme.

5. Conclusions

A new approach has been proposed for the conceptual design of internally heat-integrated reactive distillation columns. This approach is based on the stage temperature profiles and the physical area availability by the column hydraulic capacity. Through iterative examinations and calculations, a feasible design is obtained with maximum utilization of available heat transfer area and maximum possible internal heat integration. The HIRDiC column synthesizing EG is used as an illustration. The ideal IHRDiC design without external heat utilities is proved to be infeasible according to hydraulic analysis. The feasible design scheme acquired by the proposed framework has the lowest TAC compared with uniform heat duty scheme and uniform heat transfer area scheme.

Abstract

Applying life cycle thinking at an early design stage can help engineers to deliver sustainable systems by design. To demonstrate how this can be carried out at a practical level, this paper proposes a simplified methodology for integrating life cycle considerations into process design. Combining flowsheeting and life cycle assessment, it shows how environmental 'hotspots' can be identified and translated into key design targets to improve the sustainability of a system from 'cradle to grave'.The method is applied to a carbon capture and utilisation system using waste CO_2 to produce synthetic diesel in a Fischer-Tropsch process. Although the system is energy intensive, applying life cycle thinking helps to make synthetic diesel competitive not only with fossil but also with biodiesel in terms of the climate change impact.

Keywords: carbon capture and utilisation, life cycle assessment, process design, fuels.

1. Introduction

Global emissions of CO_2 from fossil fuels are increasing steadily and are currently 60% above the 1990 levels, despite the need to reduce them by at least 50% to limit the rise of the global average temperature to 2°C by 2050 (IPCC, 2013). A range of options that could help towards this target are being considered, including carbon capture and utilisation (CCU) which converts waste CO_2 to valuable products such as fuels (Styring et al., 2011). However, conversion of CO_2 to fuels is very energy intensive because of its thermodynamic stability, as well as requiring the use of different chemicals, so that it is not clear if this option is environmentally more sustainable than conventional fossil or biofuels. As CCU technologies are currently being developed, this presents an ideal opportunity to evaluate and optimise their potential for mitigating climate change, the main driver for their development. This is best carried out at an early design stage, taking a life cycle approach to avoid shifting of environmental burdens from one life cycle stage to another (Azapagic et al., 2006). Therefore, this paper sets out to demonstrate how this can be achieved by considering a CCU system for the production of synthetic diesel from waste CO_2.

2. Methodology

The methodology for applying life cycle thinking to process design applied in this work follows the method for process design for sustainability (PDfS) previously proposed by

Azapagic et al. (2006). It takes into account the whole life cycle of a process plant and its product(s) (Figure 1a). However, in this work we consider only environmental impacts with a focus on climate change, excluding economic and social aspects integral to PDfS. Therefore, the PDfS method has been adapted for the purposes of this work and, as outlined in Figure 1b, it involves the following five steps: 1. preliminary process design; 2. life cycle assessment (LCA) of the design; 3. identification of environmental 'hotspots'; 4. identification of design targets for improvements; and 5. identification of correlations between key design variables to help optimise the design at a glance in the next design iteration. These steps are described in more detail in the next section.

3. Applying life cycle thinking to process design: Producing fuels from CO_2

3.1. Preliminary design

The carbon capture and utilisation system considered here produces synthetic diesel in a Fischer-Tropsch process using waste CO_2 from anaerobic digestion of sludge produced during wastewater treatment.The system has been modelled in Aspen Plus (Aspentech, 2014). As shown in Figure 2, it consists of an anaerobic digester that produces biogas and digestate from sewage sludge at mesophilic conditions (308 K and 0.1 MPa). The CO_2 is separated from the biogas using a 15-35 % (wt) monoethanolamine (MEA) solution. It is then recovered from the MEA in a regeneration column, with more than 99 % of the MEA recycled (Zhu et al., 2013). CO_2 and upgraded biogas are converted into syngas through a reverse water-gas shift and steam-methane reforming processes, respectively. This is followed by Fischer-Tropsch synthesis to produce diesel and a mixture of gaseous fuels (methane, ethane, propane and butane).

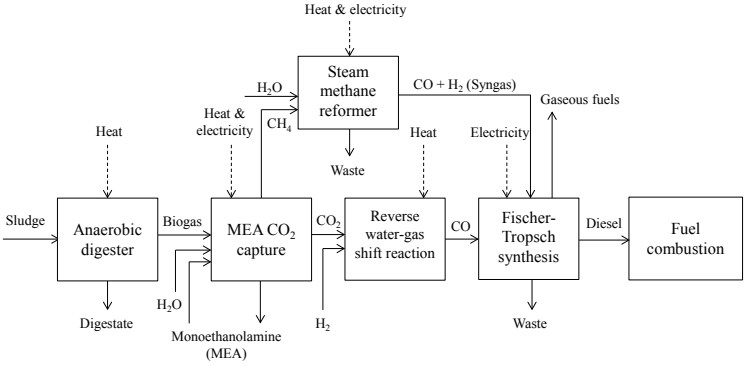

Figure 2. Outline of the process for the production of synthetic fuels from waste CO_2.

3.2. LCA of preliminary design

Following the completion of the preliminary design, LCA is carried out to estimate environmental impacts and identify hotspots which can then be targeted for improvements in the next design iteration. The scope of the study is from 'cradle to grave' and the unit of analysis (functional unit) is defined as 'the production and consumption of 1 MJ of synthetic diesel'. It is assumed that the system is based in the UK. The life cycle inventory data are obtained from Aspen design flowsheets as summarised in Table 1. Hydrogen is assumed to be produced via steam reforming of natural gas as this is the primary production route in Europe (IEA, 2007). Heat is generated from natural gas and electricity is sourced from the UK grid. All liquid waste is treated as industrial wastewater. The transport distances are assumed at 100 km for the sludge and 50 km for hydrogen and MEA. It is also assumed that the nutrients in the digestate displace an equivalent amount of artificial fertilisers (Table 2), for which the system has been credited (Mills et al., 2014). Since the system co-produces gaseous fuels together with diesel, the impacts between the co-products have been allocated in proportion to their mass flows (64 % to diesel and 36 % to gaseous fuels). The biogenic CO_2, originating from the sludge and emitted during the combustion of the fuel, is not considered.

The LCA methodology follows the ISO 14044 guidelines (ISO, 2010). The LCA modelling has been carried out in CCaLC V3.3 (CCaLC, 2014) and the CML 2001 method (Guinée et al., 2002) has been used to estimate the environmental impacts. The background LCA data have been sourced from the Ecoinvent (2010) V2.2 database.

Table 1. Life cycle inventory for the production of 1 MJ of synthetic diesel from waste CO_2.

Life cycle stage	Raw material	Amount (g/MJ fuel)	Heat (MJ/MJ fuel)	Electricity (MJ/MJ fuel)	Waste (g/MJ fuel)
CO_2 capture & separation	Sludge	4500	1.40	9.25×10^{-4}	290
	MEA[a]	9.43×10^{-3}	–	–	–
	Water	2.89×10^{-4}	–	–	–
Syngas production	Water	53	0.71	0.11	1
	Hydrogen	5	–	–	–
Fuel production	–	–	–	0.25	140
Total		4558	2.11	0.36	431

[a] Monoethanolamine

Table 2. Co-products and assumptions for system credits.[a]

Co-products	Displacing	Amount (g/MJ fuel)
Digestate		
Nitrogen	Artificial nitrogen fertiliser (as N)	7
Phosphate	Artificial phosphate fertiliser (as P_2O_5)	13
Sulphur	Artificial sulphur fertiliser (as SO_4)	7
Gaseous fuels[b]	Natural gas	13
Liquid fuels[c]	–	23

[a] The system is credited for displacing artificial fertilisers and gaseous fossil fuels (natural gas). There are no credits for synthetic diesel as that is the main product from the system.
[b] A mixture of methane (67 % wt), ethane (9 % wt), propane (11 % wt) and butane (13 % wt).
[c] A mixture of liquid fuels (C5-C30), in this study assumed to be diesel with a lower heating value of 43.25 MJ/kg.

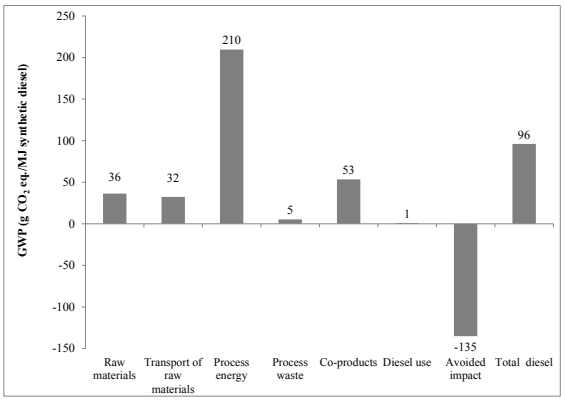

Figure 3.Global warming potential (GWP) of production and consumption of 1 MJ of synthetic diesel (The GWP of co-products refers to gaseous fuels, allocated on a mass basis (36%). The avoided impact refers to the GWP avoided by displacing artificial fertilisers – see Table 2).

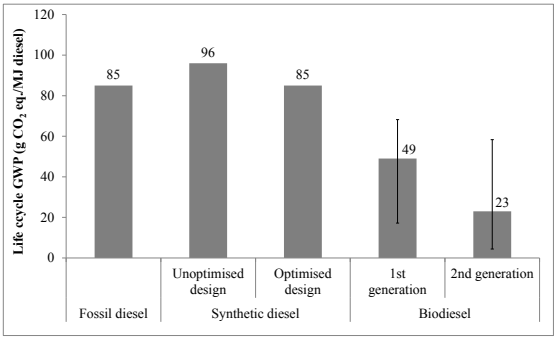

Figure 4. Global warming potential (GWP) of different types of diesel (Data for fossil and biodiesel are from Jeswani and Azapagic (2012). All results are from 'cradle to grave', including fuel use in vehicles. Biogenic carbon for synthetic and biodiesel is excluded).

3.3. Identifying hotspots

With the LCA completed, the next step involves identification of hotspots which will be targeted for optimising the system. As an example, we consider climate change impact as a key driver for CCU, in LCA expressed as the global warming potential (GWP). The GWP can also be used as a proxy for some other impacts, including depletion of fossil fuels, acidification and photochemical smog.

Using the preliminary (unoptimised) design data, the GWP of synthetic diesel from 'cradle to grave' is estimated at 96 g CO_2 eq./MJ (Figure 3). This is 12% higher than the GWP of fossil diesel (see Figure 4). It can also be noted that the GWP of synthetic diesel is 2 times higher than for 1st generation biofuels and 4 times greater than for 2nd generation. Therefore, the design is unsustainable and needs to be improved by targeting the hotspots. Figure 3 shows that the main hotspot in the system is energy consumption, accounting for 74 % of the total GWP. This is due to the high energy requirements in the anaerobic digester, the MEA capturing unit, the steam-methane reforming reactor and compressors. The raw materials and their transport contribute 13 % and 11 % of the total GWP, respectively. Among the raw materials, hydrogen is the highest contributor to the impact, followed by the rate of MEA recycling. The use of diesel in vehicles contributes little to the GWP as most of the CO_2 is biogenic, originating from sewage.

Therefore, energy, hydrogen and MEA recycling rates should be targeted for design optimisation. This is discussed in the next section.

3.4. From hotspots to key design targets

Now that the hotspots have been identified, key design targets can be defined. In this study, the GWP of fossil diesel (85 g CO_2 eq./MJ) is taken as a reference point, aiming to optimise the system so that the GWP of synthetic diesel is equal to or below that of the fossil fuel. As indicated in Figure 5a, for the current industrial practice of MEA recycling of 99.997 %, the process energy consumption must be reduced by 8 %. If the recycling rate is lower, for example 98 %, then the energy reduction of 19 % is necessary. Alternatively, switching from carbon-intensive sources of H_2 such as natural gas (7.5 kg CO_2 eq./kg H_2) to water electrolysis (0.95 kg CO_2 eq./kg H_2) or naphtha cracking (1.7 kg CO_2 eq./kg H_2) would reduce the GWP without the need to decrease energy consumption (Figure 5b). For instance, the GWP of synthetic diesel using H_2 from water electrolysis or naphtha cracking is equal to 76 and 78 g CO_2 eq./MJ, respectively; this is 8-10 % below the GWP of fossil diesel. It is also possible to match the GWP of synthetic diesel with that of 1st generation biodiesel (49 g CO_2 eq./MJ fuel, see Figure 4) with these two sources of H_2 but the energy consumption must be reduced by around 20 % (Figure 5b). Doubling the energy reduction to around 43 % would also make synthetic diesel competitive with 2nd generation biodiesel (23 g CO_2 eq./MJ fuel).

3.5. Correlations between key design targets

To help process designers see at a glance how the key design targets influence the environmental performance of the system, it is useful to plot their correlations for a range of feasible values. For example, if the target is for the synthetic diesel to be competitive with the fossil fuel in terms of the GWP, the correlation in Figure 6 indicates how this can be achieved taking into account three variables: energy consumption, H_2 sources and MEA recycling rates. The correlations suggest that using H_2 from natural gas requires energy reductions ranging from 8 % for the 99.997 % MEA recycling rate to 19 % for 98 % of MEA recycled. For the other two sources of H_2 (naphtha cracking and water electrolysis), no or little energy reduction is needed until the recycling rate of MEA falls below 99 %. At 98% of MEA recycled, the energy consumption must be reduced by 4–5 %. These correlations can be used in the next design iteration to help guide engineers in delivering a more sustainable system.

4. Conclusions

A simplified methodology for applying life cycle thinking to process design has been proposed in this work to help identify hotspots and translate them into key design targets, with the aim of improving the environmental sustainability of processes. One of the advantages of the methodology is that it is relatively simple and enables designers to identify improvement opportunities at a glance. The methodology has been applied to a process producing diesel from waste CO_2. The results show that the main hotspots are energy consumption, sources of H_2 and MEA recycling rates. Optimising these parameters can make diesel from CO_2 competitive with both fossil and biofuels in terms of the climate change impact. Therefore, the study demonstrates that applying life cycle thinking at an early stage can help engineers to deliver sustainable systems by design.

Abstract

The aim of this study is to present an innovative strategy for selecting a reactor for a specific process. Instead of adapting the process to a well-known reactor shape, a topology optimization method is used to obtain the best reactor configuration, and is applied to a biocatalyic reaction system as a case study. The Evolutionary Structure Optimization (ESO) method is applied using an interface between Matlab® and the computational fluid dynamic simulation software ANSYS CFX®. In the case study, the ESO method is applied to optimize the spatial distribution of immobilized enzyme inside a microreactor. The results allow evaluating which regions in the microreactor have more importance for the product formation. In fact, it was possible to simulate the improvement of the outlet product concentration per same amount of enzyme by modifying the spatial distribution of the immobilized enzyme.

Keywords: topology optimization, biocatalysis, immobilized enzymes, CFD

1. Introduction

Topology optimization has been used by mechanical and civil engineers for many years, for example in order to minimize the amount of used material and the strain energy of structures while maintaining their mechanical strength (Bendsoe et al., 2003).Topology optimization is a mathematical method which spatially optimizes the distribution of material within a defined domain, by fulfilling given constraints previously established and minimizing a predefined cost function. For such an optimization procedure, the three main elements are design variables, the cost function and the constraints.

The traditional solutions for structural optimization problems in buildings were determined by the use of direct search methods on an Isotropic Solid and Empty (ISE) topology. In an ISE topology, the elements are either filled by a given isotropic material or do not contain any material. However, due to the large number of elements, the application of direct search methods on an ISE topology was found to be computationally extremely expensive. Therefore, since the 1980s, the main focus in this area has been to develop more efficient methods to obtain faster solutions. In the scientific literature, there are numerous techniques to perform a topology optimization; the two most popular methods are the Solid Isotropic Material with Penalization (SIMP) technique and the Evolutionary Structural Optimization (ESO) technique.

The SIMP technique is based on determining the optimum structure by varying the material density within the predefined domain. The predefined domain is discretized in elements and a finite element (FE) analysis is applied to determine the structure performance. Conceptually, the SIMP method comprises a FE analysis of the domain followed by an optimization of the density of each element of the domain. Afterwards,

the configuration with the new element densities is analyzed and the optimization is performed again. The optimization procedure continues until convergence (Bendsoe et al., 2003).
The ESO method was developed by Xie and Steven (1993) and it has been applied in various optimization research areas. The ESO method is based on the simple concept of progressively removing inefficient material from a structure. The unneeded material is removed by using a rejection criterion (RC) which identifies the ineffective material. This method has the advantage that it is easy to understand and to learn. Moreover, this method is also simple to program and to link with existing computer-aided engineering software e.g. ANSYS CFX®, ANSYS Fluent® or Nastran®.
This contribution presents a novel adaptation of the ESO method to optimize the catalyst spatial distribution inside microreactors considering a reaction carried out by a biological catalyst, an enzyme. The goal is to improve the product formation per same amount of enzyme by optimizing the immobilized enzyme spatial distribution. This contribution applies commercially available tools such as the computational fluid dynamics(CFD) software, ANSYS CFX®, and Matlab®, and will link them with a self-programmed topology optimization method.
Previously, selected studies dealing with topology optimization of catalyst inside microreactors have been reported by Okkels et al. (2007) and by Schäpper et al. (2010) where they used the porosity of the catalyst carrier as the design variable.This study changes the surface concentration of the enzyme instead of changing the porosity of the catalyst carrier, which consequently would modify the fluid dynamic properties inside the microreactor. The optimization procedures considering porosity as design variable have resulted in configurations with large void spaces within the carrier material. These configurations are mechanically unstable and, since in the real reactor such carrier material cannot be packed at fixed locations, the material might change the locations due to the fluid flow. Therefore it is not possible to validate these results experimentally.
The consideration of the enzyme concentration as a design variable, will allow new configurations by depositing the enzyme on favourable areas of the microreactor, either on a surface or on an immobilization carrier. Therefore, the presented topology optimization procedure will allow for the first time that future experimental validations of the simulated design can be performed.

2. Materials and Methods

The shape of the investigated microreactor is an extension of the two dimensional shape presented by Okkels et al. (2007) into a three dimensional design. The view from the top of the microreactor shows that the microreactor consists of a parallelepiped measuring 30 mm of width and depth, combined with two channels for the inlet and outlet located on opposite sides of the square. The width of the inlet and outlet channels is 10 mm. The height of the microreactor corresponds to 0.5 mm. The shape of the reactor is presented in Figure 1.In this investigation, the enzyme is immobilized at the top and bottom surfaces of the reactor. Since the flow profile is symmetric on the central vertical and central horizontal planes, symmetry boundaries were created at half of the height and through the middle of the inlet and outlet as presented in Figure 1b.In this way only a quarter of the whole reactor geometry is simulated which provides an acceleration of the computational solution. The flow velocity at the inlet is set to 0.01 m/s for all simulations. The choice of the residence time was made in order to ensure that the velocity close to the bottom wall is different from zero and varies between

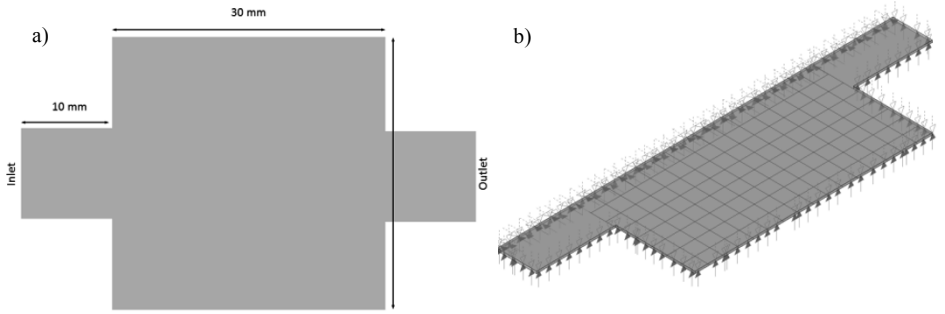

Figure 1- Microreactor configuration: a) full microreactor configuration; b) configuration with symmetry planes, horizontal and vertical planes

different locations on the bottom and top surfaces due to effects of the lateral walls and narrow inlet and outlet.The studied reaction rate (r) in this case study follows the mechanism of an enzyme, which is characterized by a Michaelis-Menten mechanism. The Michaelis-Menten reaction equation is described by Eq 1:

$$r = kcat \cdot [E] \frac{[S]}{[S] + K_M} \tag{1}$$

where *kcat* is the turnover number, [E] the enzyme concentration, [S] the substrate concentration and K_M is the Michaelis-Menten constant. In this case, the values considered for the reaction are equivalent to the values determined experimentally for a catalase reaction, *kcat* = 10^7 mol·m^{-3}·s^{-1} and K_M= 25 mol·m^{-3}(Díaz et al., 2001). The reaction catalysed by catalase corresponds to the conversion of two molecules of hydrogen peroxide forming one molecule of oxygen and two molecules of water:

$$2H_2O_2 \xrightarrow{\text{catalase}} 2H_2O + O_2 \tag{2}$$

In this study, the maximum enzyme concentration was determined considering that the molecular weight of catalase is 315 kDa and assuming that the amount of enzyme that is possible to immobilize on the surface is 4 mg·m^{-2}. From here it is possible to calculate that the maximum enzyme concentration on the surface is $1.2 \cdot 10^{-11}$ mol·m^{-2}.At the inlet, the substrate concentration, hydrogen peroxide, is 1 mM.

The method applied to this study is an adaptation of the ESO method for the topology optimization of enzyme inside the microreactor. The procedure for the topology optimization is presented in Figure 2.In this case, the design variable is the enzyme concentration immobilized on the surface and the cost function to be maximized is the concentration of one of the products at the outlet. There is only one constraint to this problem which is to maintain the same amount of enzyme (number of moles) inside of the microreactor between iterations. This constraint makes the procedure different from the original ESO method. In the ESO method, the ineffective elements are simply eliminated, but in this case study it is not meaningful to simply remove an element. If an element is removed, the amount of enzyme inside of the microreactor will be less and consequently the product concentration at the outlet will decrease. Therefore the ESO method has been modified. When an element is removed the amount of enzyme corresponding to that element is distributed evenly between all the elements which still contain immobilized enzyme.

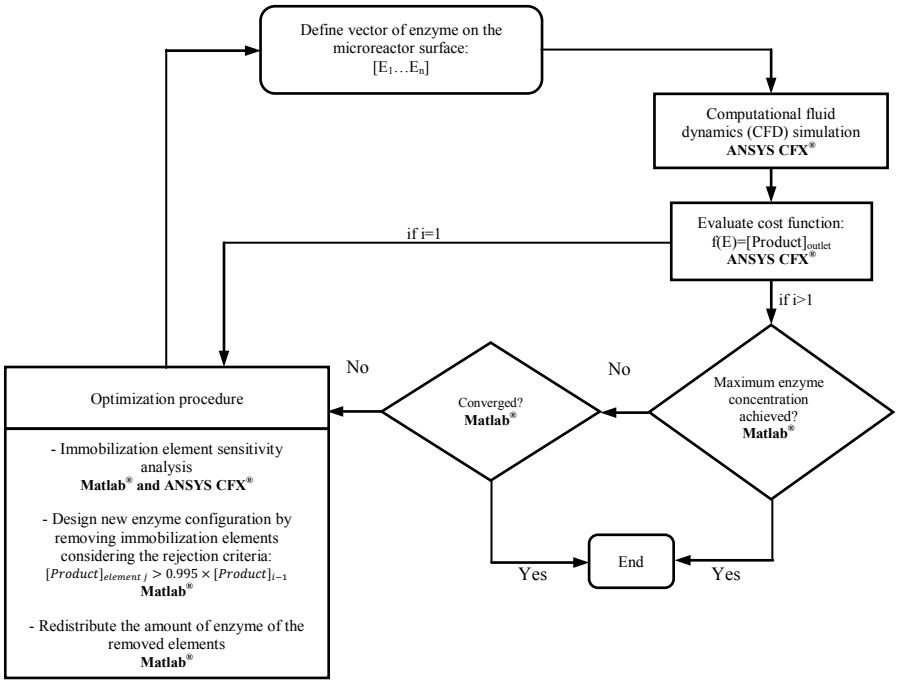

Figure 2 – Flowchart for topology optimization of enzyme in a microreactor using the ESO method through a routine coupling Matlab® and ANSYS CFX®.

The design of the microreactor is implemented into ANSYS CFX® and for this purpose the bottom surface of the microreactor was divided in small areas, in this case 128 immobilization elements as shown in Figure 1b. Then, the whole microreactor volume is discretized using a fine mesh of cells. The dynamics and the reaction parameters of the system are configured according to the conditions and the reaction system for the case study mentioned above.

The optimization procedure consists of a routine which couples the commercial computational fluid dynamics (CFD) software ANSYS CFX® to Matlab®. The optimization loop starts by setting a vector in Matlab® in which the enzyme concentration of the different locations on the surface ($[E_1 \ldots E_n]$) is defined. The enzyme was initially uniformly distributed at half of the maximum concentration on the surface of the microreactor $5.6 \cdot 10^{-12}$ mol·m^{-2}. Afterwards, the ANSYS CFX® script is changed according to the defined vector, a computational fluid dynamics simulation is carried out by ANSYS CFX® and the cost function is evaluated.

The optimization procedure starts with a sensitivity analysis of each immobilized element in order to evaluate its influence on the product concentration at the outlet. One by one the enzyme concentration of each of the immobilization elements is set to zero. This is controlled by a self-programed routine in Matlab® which makes the necessary modifications in the ANSYS CFX® script while ANSYS CFX® carries out the

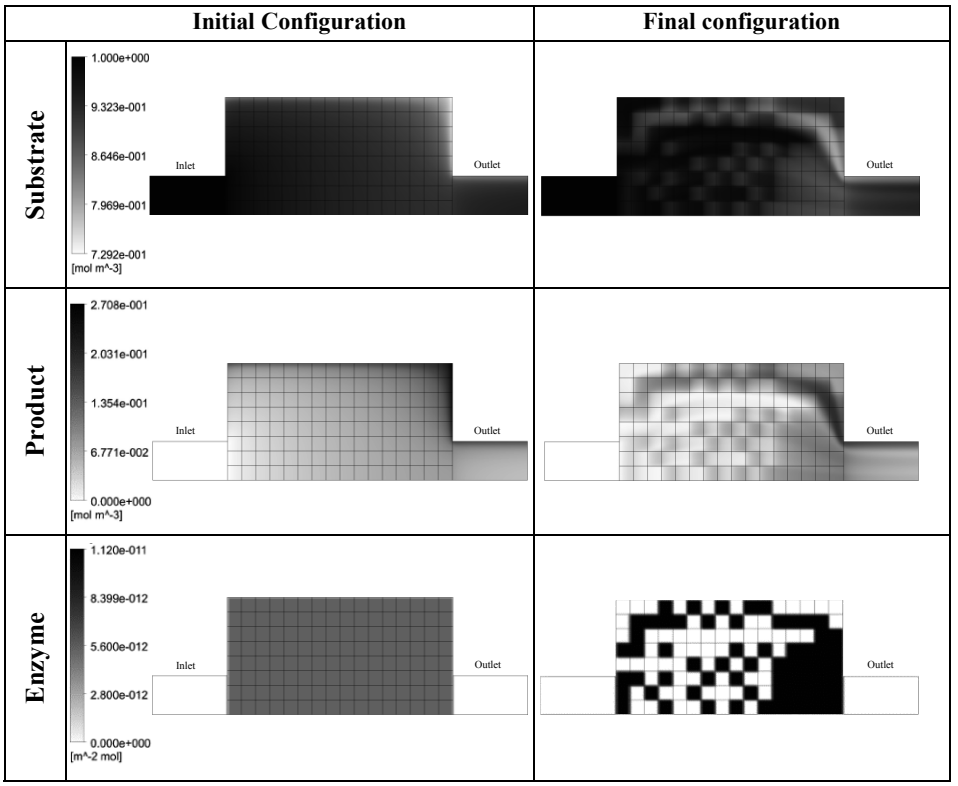

Figure 3 – Results from the topology optimization: Concentration of substrate (hydrogen peroxide) and product (water)inside the microreactor for initial and final configurations and immobilized enzyme (catalase) on the bottom surface of the microreactor.

computational fluid dynamics analysis using the new script. The Matlab® code removes the immobilized elements with the lowest sensitivity according to a predefined rejection criterion (RC). In this study the RC is defined for the immobilized element j which is removed if the product concentration at the outlet is:

$$[Product]_{element\ j} > 0.995 \times [Product]_{i-1} \quad (3)$$

being *i* the iteration number and *j* is number of the element. That means if an element is not contributing substantially to the formation of the product it is removed. The amount of enzyme present in the removed elements is distributed within all other elements that have not been removed in order to keep the same amount of enzyme (mol) inside the microreactor. Subsequently the alterations of the enzyme configuration on the surface of the microreactor and its new concentration are inserted in the ANSYS CFX® script through Matlab® and a CFD simulation is repeated to evaluate the performance of the new enzyme configuration. The procedure is repeated until the maximum product concentration is achieved, the concentration of the enzyme has reached the maximum possible value or the optimization converges.

3. Results and Discussion

The optimization loop ends when the maximum enzyme concentration ($1.2 \cdot 10^{-12}$ $mol \cdot m^2$) was achieved. On the one hand, $6.75 \cdot 10^{-2}$mM of substrate were converted with the initial configuration, on the other hand, $6.89 \cdot 10^{-2}$ mM of substrate were converted with the final shape. In the end, the topology optimization resulted in an improvement of 2%of conversion of the substrate per same amount of enzyme compared with the initial enzyme configuration. It is expected that the application of a topology optimization to a more complex reaction mechanism (with product or/and substrate inhibition) will result in larger improvements. The results of the topology optimization as well as the optimal enzyme configuration can be found in Figure 3.The final configuration of the enzyme is characterized by a higher concentration of enzyme close to the walls and in immobilization elements close to the outlet. This demonstrates that immobilized molecules at locations with higher residence time, due to low fluid velocity, contribute more to the product formation. In addition, within the immobilization elements with maximum velocity, the elements which are close to the outlet are the ones which seem to have more influence on the product formation.

4. Conclusion

The presented work demonstrates that it is possible to use existing methods and tools in an efficient way in order to use topology optimization for finding better reactor configurations for a particular reaction system. The application of the ESO method by combining a CFD software, ANSYS CFX®, with Matlab® revealed to be a feasible implementation to optimize the spatial distribution of immobilized enzyme in a microreactor. In this study, the product formation per same amount of enzyme was improved by optimizing the immobilized enzyme spatial distribution. This study contributes to the development of future innovative solutions for establishing a reactor with immobilized catalyst within a process. Currently, the studies are made in microreactors, because it will be easier to validate the results experimentally. Nevertheless, the topology optimization of catalysts can contribute to an improvement of production also at industrial scale, since the product formation is not uniform in full-scale reactors. The application of topology optimization will potentially change the development of reactors and contribute to the improvement of reaction yields.

Design of Hybrid Heat-integrated Configuration for Indirect Reactive Distillation Processes

Kuo-Chun Weng, Hao-Yeh Lee*

Department of Chemical Engineering, National Taiwan University of Science and Technology, Taipei 10607 Taiwan
haoyehlee@mail.ntust.edu.tw

Abstract

In this work, hybrid configuration which combines the concepts of thermally coupled and multi-effect heat-integrated methods has been studied. Moreover, the potential energy saving of other individual heat-integrated methods has been compared with the hybrid configuration. Ideal IIp reactive distillation process and diphenyl carbonate process are chosen as examples to demonstrate the performance of the hybrid configuration. The result shows hybrid configuration displays the highest ability in energy saving for both processes.

Keywords: Reactive distillation; Heat integration; Thermally coupled; Multi-effect; Hybrid configuration

1. Introduction

The ascension of crude oil price and global warming problem has attracted more and more attention in recent years. The development of energy savings becomes an important purpose for the research of chemical processes. Reactive distillation (RD) that integrating multifunctional unit(reaction and separation) to substitute a single function unit has been published and demonstrates its advantages in selectivity, productivity improvement and energy requirement reduction (Malone and Doherty, 2000).

In order to improve more economic benefit, the combination of two famous process intensification techniques for reducing energy usage named multi-effect and thermally coupled with RD configurations are studied in some literatures (Lee et al., 2010; Wang et al., 2010; Cheng et al., 2013). Thermally coupled configuration can eliminate the remixing effect to reduce the total energy requirement. The energy efficiency can be increased in multi-effect configuration by energy reusing. However, in indirect thermally coupled configuration such as IIp case in Wang et al (2010), it is found that more vapor is condensed in the top of second column due to energy transferred from top vapor of the first column to the middle location of the second column. It means more energy is wasted in the top of second column. To overcome the drawback of energy waste in RD process, the hybrid heat integrated configuration which combines the concepts of multi-effect and thermally coupled arrangement is investigated to improve energy efficiency and reduce overall energy requirement simultaneously in this paper. Notice the commercial simulator Asepn Plus is used for all cases.

2. Case 1: IIp ideal RD process

The ideal RD process with quaternary components can be classified into six types according to relative volatilities of reactants and products (Tung and Yu, 2007). IIp type indirect ideal RD process is used in this study to demonstrate superiorities of hybrid

heat-integrated configuration. Four components (C, D, A, B) with relative volatility 8/4/2/1 are assumed in this process. The flowsheet and information of columns refer to Lin's work (Lin, 2007). The thermodynamic and kinetic models are taken from Tung and Yu (2007). Ideal thermodynamic model and Arrhenius form kinetic equations with pseudo homogeneous expression are applied in this study.

2.1. Conventional RD configuration

An ideal reaction is assumed for IIp process. Reactants are A and B and products are C and D. IIp ideal RD process is constituted by a RD column (C1) and a separation column (C2). The reactants A and B are fed into the bottom of RD column. The C1 column only contains reactive section and rectifying section. Due to the higher boiling point of reactants, there is no bottom product at C1 column to avoid the loss of reactants. The rectifying section and the reactive section including column sump in C1 column are set between 6 and 10 stages, respectively. Both reactants are fed into the bottom of the C1 column because of their smaller relative volatility. The flow rates of both reactants are the same and set as 45.36 kmol/h. The holdup of column sump is assumed 10 times than each stage. Top product of C1 column with component C and D is fed into 19th stage of C2 column. 35 stages are in the C2 column. Component C is produced at the top of C2 column and its specification is designed in 99 mol %. Product D with 95 mol % purity can be obtained at the bottom of C2 column. The operating pressures of C1 and C2 columns are 6 and 2 bars, respectively. The overall flowsheet of conventional RD configuration is displayed in Fig. 1(a).

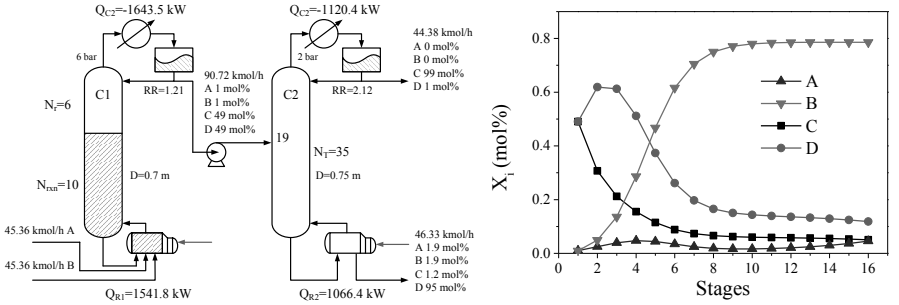

Figure 1: (a) Flowsheet of IIp RD process; (b) Composition profile of C1 column

The liquid composition profile of C1 column is shown in Figure 1(b). In Figure 1(b), the D composition represents in sphere symbol. In the upper section of RD column, the D composition shows to reach the maximum value and then decrease. This phenomenon is well-known as "remixing effect" and it means that there is potential to design a thermally coupled configuration for energy reduction.

2.2. Thermally coupled configuration

Thermally coupled configuration has widely been studied in open literatures to eliminate remixing effect and save energy. To eliminate the remixing effect of C1 column, the thermally coupled configuration of IIp process had been designed by Wang et al. (2010). In this configuration, a liquid sidedraw flow from 19th stage of C2 column is sent back to C1 column as the liquid reflux. The simulation result of thermally coupled configuration is shown in Figure 2(a). The remixing effect can be eliminated and 27.6 % energy requirement can be saved by this arrangement. However, the observation of condenser duty of C2 column presents a higher value than conventional

configuration. This larger condenser duty means a larger column diameter is required and higher energy waste is found at the top of column.

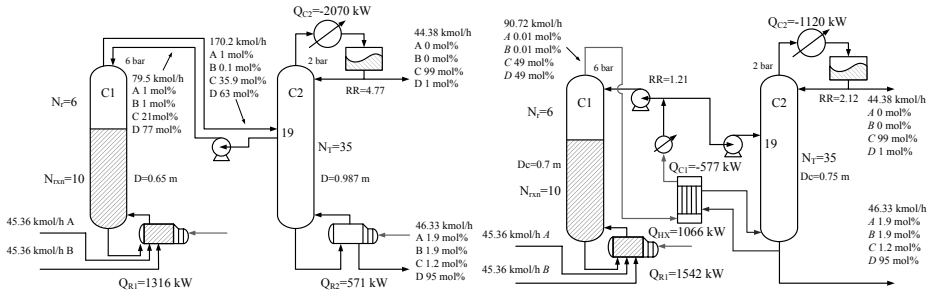

Figure 2: (a) Thermally coupled and (b) Double-effect configurations of IIp RD process

2.3. Double-effect configuration

According to different operating pressure of two columns, the higher operating pressure of C1 column shows an opportunity of double-effect heat integration. The temperature difference between top vapor of C1 column and bottom of C2 column is 22.7 ^{o}C. The top vapor temperature of C1 column will decrease after energy exchange to C2 column. An important assumption of log mean temperature difference between C1 top and C2 bottom must be higher than 10 ^{o}C for energy transfer. The heat exchanger area can be calculated by following equation:

$$A = Q/(U \cdot \Delta T_{ln}) \tag{1}$$

In Eq. (1), Q is the energy of heat transfer and relates to the overall heat transfer coefficient (U), heat exchanger area (A) and log mean temperature (ΔT_{ln}). The overall heat transfer coefficient refers to Douglas (1988) and is set as 0.17 kW/m$^2 \cdot$ h.

The double-effect configuration is shown in Figure 2(b). The energy requirement of C2 column is supplied from heat of C1 column top vapor. An auxiliary condenser is needed to remove the remaining energy. The overall energy exchange in HX unit is 1,066 kW and the calculated heat exchanger area is 300.3 m^2. The double-effect configuration has 40 % energy saving however the remixing effect cannot be eliminated.

2.4. Hybrid configuration

By observing the simulation result of thermally coupled configuration, the energy can be saved in this arrangement because of the elimination of remixing effect. However, larger condenser duty of C2 causes a larger column diameter. Energy efficiency is much higher in double-effect configuration but it cannot overcome the drawback of remixing effect. To overcome the drawback of energy waste in RD process, the hybrid heat integrated configuration which combines the concepts of multi-effect and thermally coupled arrangement is investigated to improve energy efficiency and reduce overall energy requirement simultaneously

The hybrid configuration is based on thermally coupled configuration. However, the top vapor product of C1 column is not fed to C2 directly. Energy is transferred from top vapor of C1 column to C2 bottom first and then fed to 19th stage of C2. A sidedraw flow is also needed to be as liquid reflux of C1 column. The flowsheet of hybrid configuration and liquid composition profile of C1 column is shown in Figure 3(a) and (b). The simulation result in Figure 3(a) shows the energy usage of C2 is 728 kW and all can be supplied from top vapor of C1 column. Total energy requirement can be saved around 50 % by hybrid configuration and the heat exchanger area of heat

exchanger HX is only 63 % of double-effect configuration. Condenser duty of C2 also shows a smaller value than the result of thermally coupled configuration.

The liquid composition profile of C1 column in Figure 3(b) demonstrates the composition of component D monotonic increases to the column top. It means that the remixing effect in hybrid configuration also can be eliminated as the configuration with thermally coupled arrangement.

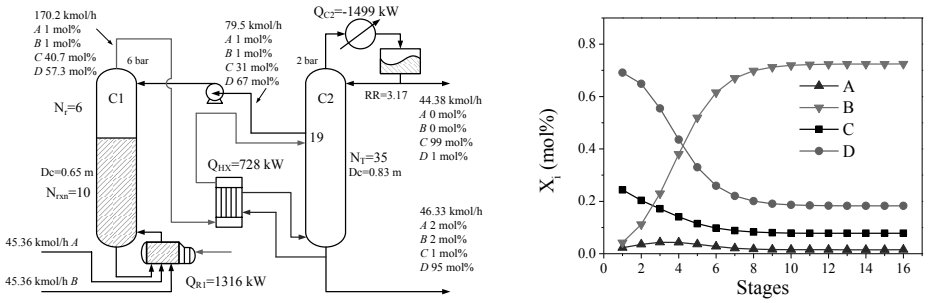

Figure 3: (a) Flowsheet (b) Composition profile of RD column of hybrid configuration

3. Case2: DPC reactive distillation process

With the issue of environmental production, phosgene-free process has gradually replaced the conventional process. Phosgene-free diphenyl carbonate (DPC) RD process has been proposed in Cheng et al. (2013). The ideal thermodynamics and power law kinetic model are taken from their work.

3.1. DPC RD configuration

The overall reaction of diphenyl carbonate production is shown in below:

$$DMC + PA \Leftrightarrow MPC + MA \quad (2)$$

$$MPC + PA \Leftrightarrow DPC + MA \quad (3)$$

The reaction is an endothermic reaction. Two reactants are dimethyl carbonate (DMC) and phenyl acetate (PA). The intermediate component is methyl-phenyl carbonate (MPC) The product and by-product are DPC and methyl acetate (MA). Due to lower reaction rate, the excess reactant, DMC, is fed into reactive section of C1 column. The overall flowsheet of DPC RD process is displayed in Figure 4(a).

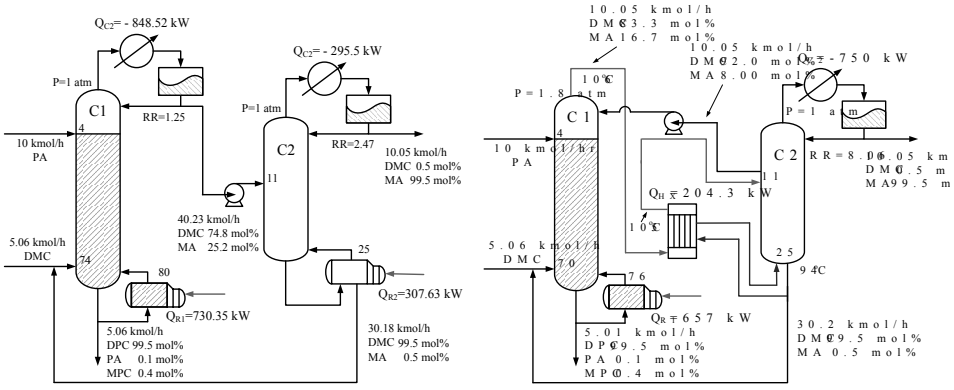

Figure 4: (a) Conventional DPC RD configuration; (b) DPC hybrid configuration

The RD process of DPC production contains a RD column (C1) and a reactant recovery column (C2). The C1 column only contains reactive section and rectifying section. The

upper 3 stages are rectifying section and another 77 stages are reactive section in C1 column. The production rate of DPC is designed to the value of 5 kmol/h. It can be estimated that the fresh feed flow rates of DMC and PA are 5 and 10 kmol/h, respectively. The DMC is chosen as excess reactant and the excess ratio is 6 in the result of Cheng et al. (2013). Therefore, 30 kmol/h of DMC should be recovered and recycle back to C1 column. Fresh feed of DMC mixes with recycle DMC first and then fed to 74th stage of C1 column. The higher boiling point reactant, PA, is fed at 4th stage of C1 column. 99.5 mol% DPC is produced from the bottom of C1column. Byproduct MA and excess DMC are removed from top of C1 column and fed to C2 column for separation. C2 column contains 25 stages and the feed location is 19th stage. The top product of C2 is 99.5 mol % MA and bottom stream contains 99.5 mol % DMC for recycling back to C1 column.

3.2. DPC hybrid configuration

Hybrid configuration in ideal RD process shows a higher energy saving potential. To compare the result of ideal RD process, the hybrid configuration of DPC RD process is discussed in this section. Operating pressure of RD column also should be examined due to minimum temperature difference requirement. 1.8 atm is required for RD column to achieve a minimum temperature difference for energy transfer. The flowsheet of hybrid configuration of DPC RD process is displayed in Figure 4(b). It is found that there is only 204.3 kW is transferred to the bottom of C2 column. Only 70 % energy of double-effect configuration is required for the hybrid configuration. Besides, the smaller energy transfer rate means a smaller heat transfer area. The overall energy requirement of DPC hybrid configuration is 657 kW, only 67 % less than the configuration without heat integration. And also, the remixing effect can be eliminated by this configuration.

4. Discussion

4.1. Remixing effect elimination for heat transfer

The RD column in both cases all shows the top compositions are quite different when the remixing effect is eliminated by the hybrid configuration. Different top compositions also mean the different vapor temperature at the top of RD column. In Case 1, the hybrid configuration shows a higher log mean temperature of heat transfer than the double-effect configuration. Figure 5 represent the temperature of RD top vapor composition location in T-xy diagram for Case 1.

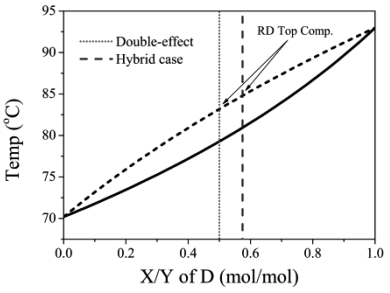

Figure 5: Top composition of RD column for IIp RD process

In Figure 5, dash-dot line shows the top liquid composition location of double-effect configuration. Top composition of D in double-effect configuration locates in 0.5 because of the remixing effect. The dash line represents the top composition location of hybrid configuration. The higher top composition in hybrid configuration can be observed because of the elimination of remixing effect. This phenomenon indicates

hybrid configuration can have higher top vapor temperature. In other words, hybrid configuration can have higher log mean temperature for heat transfer. It also implies that the heat transfer area of would be smaller under the same energy requirement.

4.2. The comparison of energy reduction

Following the simulation result in above sections, energy usage of each configuration for both cases is presented in Figure 6(a) and (b).

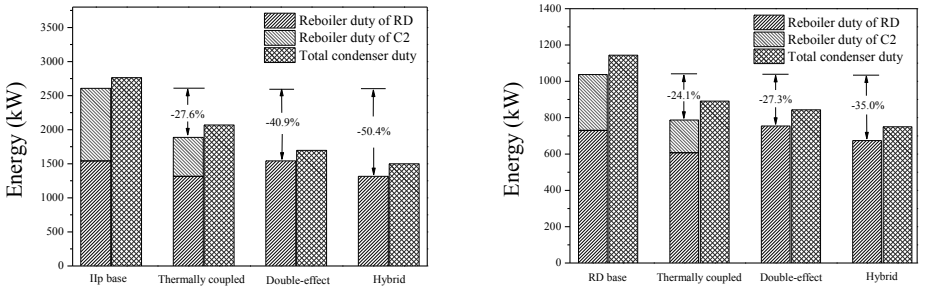

Figure 6: Energy usage for (a) IIp ideal RD process; (b) DPC RD process

The hybrid configuration that combines the concepts of thermally-coupled and double-effect configuration demonstrates the largest energy saving ability. In both cases, around 50 % and 36 % energies can be saved by the hybrid configuration.

5. Conclusions

In this study, the potential energy-saving of various heat-integrated configurations are investigated for ideal IIp and DPC RD process. A new heat-integrated method named hybrid configuration that combines the concepts of thermally coupled and double-effect configuration has been proposed. Smaller heat exchanger can be applied in hybrid configuration in contrast to the case of double-effect configuration. Energy waste in condenser of C2 in hybrid configuration is smaller than thermally coupled configuration. Simulation result shows that remixing effect phenomenon can be eliminated and 50 % and 36 % energy reductions can be achieved by the hybrid configuration.

Abstract

The economic viability of Ionic Liquid-based Three Phase Partitioning (ILTPP) processes, which have been proposed to recover proteins from waste streams, highly depends on the recyclability of the salt and, especially, the ionic liquid used in this technique. For this reason, the economic optimization of the recovery of ILTPP reagents is carried out, considering the main operational costs (reagents and energy). Results show that the process configuration with which costs are minimized is based on the use of vacuum evaporation to remove water from the salt-rich phase of the process. Therefore, the increase of salt concentration is not an economically efficient alternative to recycle the ionic liquid, even though this alternative is usually proposed in the literature. The optimum costs vary between 51.5 – 307 € kg protein^{-1} for almost all protein concentrations in the feed stream, which are significantly lower than the lowest price reported for the target protein (lactoferrin), so ILTPP processes seem to be economically viable. In addition, the price of reagents and energy has very little influence on the optimum solutions, because very large changes of prices are required to modify the obtained results.

Keywords: protein recovery, ionic liquid consumption, recycle, operating cost.

1. Introduction

The major bottleneck of the economic and technical viability of protein production processes is downstream processing, since the conventional methods to purify these biomolecules are time and cost consuming (Pei et al., 2009). In this way, Ionic Liquid-based Three Phase Partitioning (ILTPP) has been proposed as a novel technique to recover proteins at the liquid-liquid interface formed by ternary systems ionic liquid/salt/water, which combines the use of Ionic Liquid-based Aqueous Two Phase Systems (ILATPS) with results that are characteristic of Three Phase Partitioning (TPP) (Alvarez-Guerra and Irabien, 2014). However, the development of ILTPP processes highly depends on the consumption of the reagents involved, and especially of ionic liquid, because of its relative high price.

For this reason, the net consumption of ionic liquid in this process has been assessed in previous works, concluding that between 0.8 and 5% of the ionic liquid cannot be reused, depending on experimental conditions. Therefore, two additional steps to enhance the ionic liquid recyclability have been considered: the increase of the salt concentration to reduce the ionic liquid fraction in the waste stream, and the water removal by means of evaporation to increase the fraction of liquid phases that can be recirculated in the process (Alvarez-Guerra et al., 2014a). Nevertheless, the previous studies have assessed these additional recovery steps individually.

The aim of this work is the economic optimization of the ionic liquid recovery in ILTPP processes so that the costs associated with this recycling, which constitute the objective function, are minimized. This approach makes it possible to analyze simultaneously all the different alternatives to recycle the ionic liquid in the most efficient way: the individual additional recovery steps previously mentioned, a combination of them or the performance of the process without any of these steps. The target protein considered in this work for its recovery by means of ILTPP is lactoferrin, a high-added value whey protein which stands out due its nutraceutical properties (Wakabayashi et al., 2006).

2. Mathematical formulation

Figure 1 shows the general block diagram of the ILTPP process, which considers the alternatives proposed in previous works simultaneously (Alvarez-Guerra et al., 2014a). Therefore, once the protein recovery has been carried out in the first separation tank, the overall salt mass fraction may be increased to reduce the fraction of ionic liquid present in the salt-rich phase. Furthermore, a fraction of the water present in the salt-rich phase can be removed to increase the fraction of ionic liquid and salt contained in this phase that is recirculated, keeping the overall mass of the system constant. Nevertheless, the consideration of these additional recovery steps in the general diagram of the process does not imply that these alternatives to enhance the ionic liquid recyclability are actually included in the process, since they will be discarded if the amount of extra salt added or the fraction of water evaporated is equal to zero.

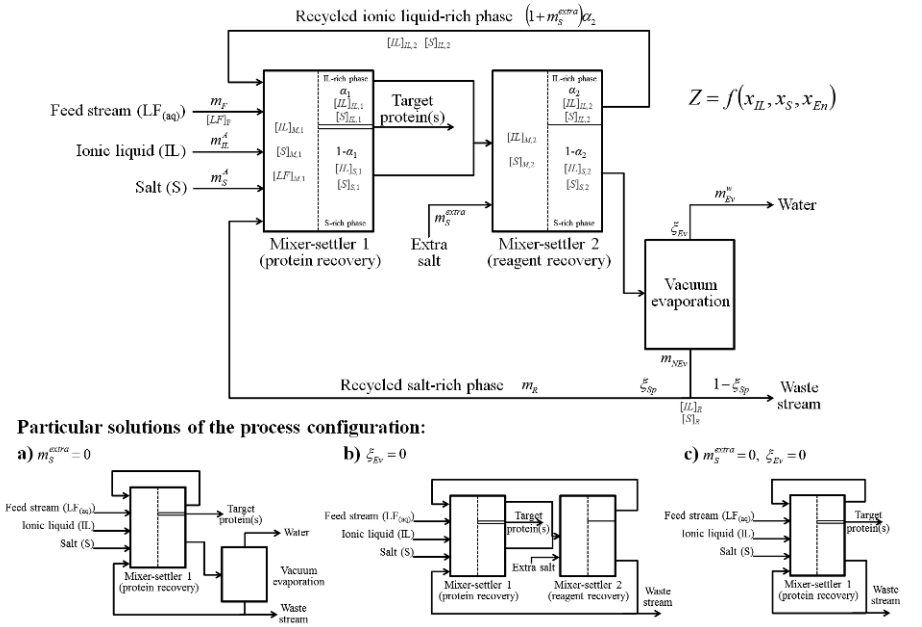

Figure 1-General block diagram and particular solutions of the ILTPP process.

The optimization of the ionic liquid recovery is based on the minimization of operating cost of the process associated with this objective. For this purpose, the three main operating costs related to the ionic liquid recyclability are: the net consumption of both ionic liquid and salt and the energy required to carry out the vacuum evaporation. However, due to the relative simplicity of the equipment involved in the process,

investment costs are considered to be neglected. In fact, for a production of 1 t LF y^{-1} and an amortization period of 10 y, the maximum fixed costs related to the equipment that is added to the process in the different particular solutions of the process configuration are estimated to be around 6 € kg LF^{-1}, according to the Guthrie's modular method (Biegler et al., 1997). These maximum fixed costs only represent around 10 % of the minimum operating costs obtained at high protein concentrations in the feed stream, as shown in the next section. Consequently, results demonstrate the applicability of the previous assumption. Therefore, the mathematical model for the optimization of the ionic liquid recovery is formulated as Figure 2 shows.

$$Min \quad Z = f_{LF}\left(\sum_i c_i x_i + c_{En} x_{En}\right) \tag{1}$$

s.t.

$$x_i = 0.01\left(1-\xi_{Sp}\right)[i]_R m_{NEv} \tag{2}$$

$$x_{En} = \frac{m_{Ev}^w RT \ln\left(P_{out}/P_{in}\right)}{M^w \eta_m \eta_c} + \lambda_{Ev}^w m_{Ev}^w \tag{3}$$

$$m_{IL}^A + m_S^A + m_F + \left(1+m_S^{extra}\right)\alpha_2 + m_R = 1 \tag{4}$$

$$[i]_{M,1} = 100 m_i^A + [i]_{IL,2}\left(1+m_S^{extra}\right)\alpha_2 + [i]_R + m_R \tag{5}$$

$$[IL]_{M,2} = \frac{[IL]_{M,1}}{1+m_S^{extra}} \tag{6}$$

$$[S]_{M,2} = \frac{[S]_{M,1} + 100 m_S^{extra}}{1+m_S^{extra}} \tag{7}$$

$$m_{NEv} = \left(1-\xi_{Ev}\right)\left(1+m_S^{extra}\right)\left(1-\alpha_2\right) \tag{8}$$

$$m_{Ev}^w = \xi_{Ev}\left(1+m_S^{extra}\right)\left(1-\alpha_2\right) \tag{9}$$

$$m_R = \xi_{Sp} m_{NEv} \tag{10}$$

$$[i]_R = [i]_{S,2}/\left(1-\xi_{Ev}\right) \tag{11}$$

$$[IL]_{S,j} = a_S \exp\left(b_S [S]_{S,j}\right) \tag{12}$$

$$[IL]_{IL,j} = a_{IL}[S]_{S,j} + b_{IL} \tag{13}$$

$$[S]_{IL,j} = d_{IL} \tag{14}$$

$$\frac{[IL]_{M,j} - [IL]_{IL,j}}{[S]_{M,j} - [S]_{IL,j}} = \frac{[IL]_{S,j} - [IL]_{M,j}}{[S]_{S,j} - [S]_{M,j}} \tag{15}$$

$$\alpha_j = \frac{[S]_{S,j} - [S]_{IL,j}}{[S]_{S,j} - [S]_{M,j}} \tag{16}$$

$$\xi_{Ev} \le 0.01\left(100 - [IL]_{S,2} - [S]_{S,2}\right) \tag{17}$$

$$x, \xi, m, \alpha, [i] \in \Re^n$$

Figure 2-Mathematical model for the optimization of the ionic liquid recovery. Notation: x_i is the net consumption of i; x_{En} is the energy consumption required for water removal by means of vacuum evaporation; $[i]$ is the mass fraction of i expressed as percentage; m is the mass fraction of the stream with respect to the total input streams in the first piece of equipment; α is the mass fraction of the ionic liquid-rich phase; ξ is the fraction of the stream evaporated (ξ_{Ev}) or split (ξ_{Sp}); f_{LF} is a conversion factor to express the cost per kg of target protein (lactoferrin, LF) recovered; η_m and η_c are the motor and compressor efficiencies; i denotes the component (IL: ionic liquid; S: salt) and j denotes the number of the mixer-settler (1 and 2: pieces of equipment where the protein recovery and the reagent recovery take place, respectively). Further details about the notation of the variables can be found in Figure 1.

The energy consumption is equal to the latent heat added to the system to keep temperature constant during evaporation and the energy required to create vacuum so that evaporation can be carried out at room temperature. For the last purpose, a vacuum pump is used that is modeled as a compressor that works isothermally due to the relatively low mass flow (McCabe et al., 2005). The compressor is modeled according to Biegler et al. (1997) for the case in which P_{out} = 1 atm and $P_{in} = P^o_{w,\ 25\ ^oC}$. Regarding the constraints of the optimization problem, Eq. 4 and 5 show the overall mass balance and the mass balance to IL and S, respectively, which assures the constancy of the total mass and composition of the system. Eq. 6-11 are also mass balances to connect the streams and compositions among the different pieces of equipment. The thermodynamic equilibrium characterization of the ILTPP systems which allows the determination of

the composition and phase ratio in the mixer-settlers is introduced by means of Eq. 12-16 (Alvarez-Guerra et al., 2014b). It should be noted that in this work $[S]_{IL,j}$ is considered to be constant, since at very high mass fraction of ionic liquid this variable shows a relatively low variability with system composition. Eq. 17 introduces the idea that the maximum fraction that can be evaporated from the salt-rich phase is equal to its water content, since the other components are not volatile (salt and ionic liquid). Eventually, a complete recovery of lactoferrin at the liquid-liquid interface in the first mixer settler, where the concentration of this protein is equal to 0.016 wt% (Alvarez-Guerra et al., 2014b), is assumed in the model.

The optimization problem, which is non-linear (NLP), is solved by means of the CONOPT solver of GAMS (v. 23.3.3). MINOS solver is also used to check the sensitivity of the solution to the resolution algorithm, obtaining almost identical results.

3. Results and discussion

The minimum operation costs of ILTPP process are assessed for different protein concentrations in the feed stream ($[LF]_F$ = 0.32 – 2.00 g kg^{-1}; Alvarez-Guerra et al., 2014a) using BmimTfO and NaH_2PO_4 as ionic liquid/salt system. Table 1 shows the values of the main variables and parameters fixed in the optimization model. The values of other parameters that characterized the thermodynamic equilibrium of the BmimTfO/NaH_2PO_4 system have been previously reported by Alvarez Guerra et al. (2014b).

Table 1-Values of the main variables and parameters fixed in the optimization model.

f_{LF}	6250 kg kg^{-1} [a]	d_{IL}	0.5 % [a]
c_{IL}	895 € kg^{-1} [b]	$[IL]_{M,1}$	26.3 % [a]
c_S	47.5 € kg^{-1} [b]	$[S]_{M,1}$	23.3 % [a]
c_{En}	0.12 € kWh^{-1} [c]	P_{in}	0.0313 atm [e]
η_m	0.9 [d]	λ_{Ev}^{w}	2430 kJ kg^{-1} [e]
η_c	0.8 [d]	T	298.15 K

[a] Alvarez-Guerra et al. (2014b); [b] Commercial suppliers; [c] Foro Nuclear (2014); [d] Biegler et al. (1997); [e] Yaws (2014)

Figure 3 shows the values of the objective function (the main operating cost of the ILTPP process) for different values of $[LF]_F$. In the range 335.3-2000 mg kg^{-1}, moderate costs are obtained (within the range 51.5 – 307 € kg LF^{-1}), which correspond to the vacuum evaporation of water from the salt-rich phase. Therefore, the lower the protein concentration, the higher the cost, because a higher fraction of water must be evaporated to achieve the complete recovery of both the ionic liquid and the salt. In this case, $m_S^{extra} = 0$, which corresponds to the process configuration of Figure 1.a. However, for $[LF]_F \leq$ 335.2 mg LF kg^{-1}, ionic liquid and salt losses are obtained and $m_S^{extra} > 0$, so operating costs increase dramatically. This region is strongly related to that previously reported by Alvarez Guerra et al. (2014a) for which water evaporation could not recycle all the reagents, even though in the present work this behaviour is exhibited for a slightly broad range of concentrations due to the combination of vacuum evaporation and increase of salt concentration ($m_S^{extra} > 0$).

Even though the price of LF is very variable depending on the commercial supplier and the quantity purchased, 600 € kg^{-1} is approximately the cheapest price that can be found for this protein. For this reason, ILTPP seems to be an economically viable process, because the price of lactoferrin is clearly higher than its main operating costs for the reagent recovery when only vacuum evaporation is performed. In fact, for $[LF]_F$ > 850 mg LF kg^{-1}, the analyzed operating costs represent a lower percentage than 20 % of the lowest price reported for LF. Nevertheless, for the production of commercial LF, additional up- or downstream processes not included in the ILTPP may be required, which might imply additional costs.

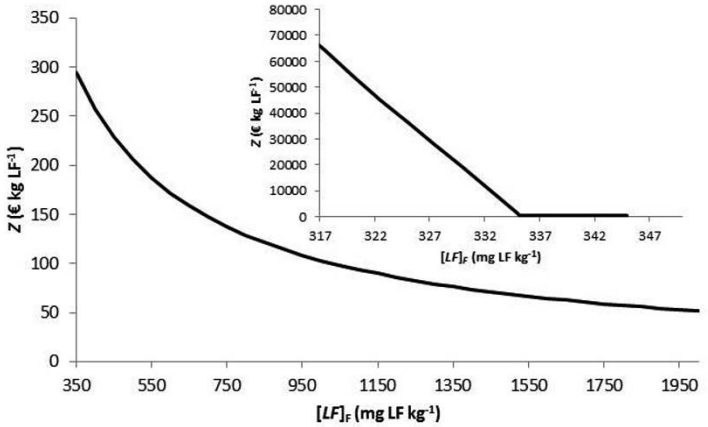

Figure 3-Minimum operating costs of the ILTPP process at different protein concentrations in the feed stream.

Due to the uncertainties associated with the cost of the reagents (ionic liquid and salt) and energy, which are the coefficients of the objective function, a sensitivity analysis is carried out. According to previous trends, it is expected a decrease of the price of reagents (especially the ionic liquid) and an increase of the cost of energy, so their coefficients are multiplied or divided by different factors as follows:

$$Z = f_{LF}\left[\frac{1}{f_{\mathrm{Re}}}\left(c_{IL}x_{IL} + c_S x_S\right) + f_{En}c_{En}x_{En}\right] \tag{21}$$

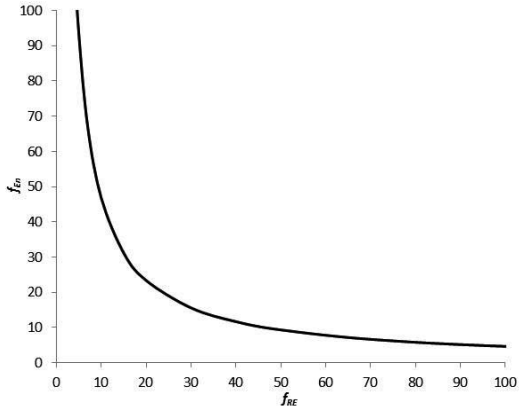

Figure 4-Combinations of the maximum values of f_{Re} and f_{En} for which m^S_{extra}=0.

It is observed that the maximum value of the product $f_{Re}{\cdot}f_{En}$ for which $m_S^{extra} = 0$ (i.e., evaporation remains as the unique reagent recovery step) is kept constant at 468 for all the protein concentrations in the feed stream. Therefore, at least an increase of f_{Re} or f_{En} higher than 468 will be required to change the optimum solution exclusively based on the use of vacuum evaporation to enhance the recovery of reagents. In this sense, Figure 4 graphs the combinations of the maximum values of f_{Re} and f_{En} for which $m_S^{extra} = 0$.

As a consequence, water removal by means of evaporation is a clear more advantageous alternative to recycle the ionic liquid and salt, even when significant changes in the price of reagents and energy occur. In this way, not only is the increase of salt concentration less effective in terms of ionic liquid recovery, but it also leads to higher operating costs, even though this approach is usually suggested in the literature to recycle the ionic liquid (Deng et al., 2009; Li et al., 2010) according exclusively to thermodynamic data.

4. Conclusions

The minimization of operating costs related to the recyclability of ILTPP reagents involves exclusively the water removal from the salt-rich phase by means of vacuum evaporation for almost all protein concentrations in the feed stream. Moreover, this optimum solution is very little sensitive to the price of reagents or energy, leading to operating costs that are significantly lower that the price of the protein to be recovered (lactoferrin), which may assure the economic viability of ILTPP processes.

Abstract

Entrained flow gasifiers are known to operate under very severe conditions in order to achieve very high conversions of up to 99%. The extreme conditions impact negatively on the capital and operating investments of the gasifier and the downstream units. There is, however, no evidence on the published models that the extreme conditions are the optimal conditions in achieving the maximum fuel gas heating value. The first part of this work presents a 1-D simulation model for a dry-fed entrained flow gasifier with oxygen and steam used as oxidizing agent. The model is then validated against published models for the similar reactor configuration and then extended to an existing entrained flow gasifier for an IGCC power plant in Puertollano, Spain. The second part then presents the optimization model in which the objective function is to maximize the heating value of the fuel gas. The results obtained during optimization of the gasifier indicate a 12% increase in heating value with a decrease of about 500K in operating temperature. A 3MPa increase in operating pressure only results in less than 2% increase in fuel gas heating value. Milder operating conditions signify the possibility of a decreasing operating and capital investments, thereby improving the operating cycle of the power plant.

Keywords: IGCC, power generation, heating value, fuel gas, simulation and optimization

1. Introduction

Integrated Gasification Combined Cycle (IGCC) is a technology to increase efficiency and reduce environmental emission associated with fossil fuels. The performance of an IGCC plant and its economic feasibility mainly depend on the cost of the gasifier island (Campbell *et al.,* 2000 and USDoE, 2001). The majority of problems experienced during gasifier operation are associated with an increase in temperature (Ruiz *et al.,* 2013). The refractory life has been identified as a limiting factor in worldwide use of this technology (Schnake, 2012). Several simulation models to study the performance of an IGCC power plant, particularly focusing on the gasification unit, have been proposed and published in open literature. These range from a less intricate 1-Dimensional model (Mitta *et al.,* 2006, Rodrigues *et al.,* 2009 and Rasid *et al.,* 2011) to complex 2-D and 3-D Computational Fluid Dynamics (CFD) models (Chui *et al.,* 2009, Ma and Zitney, 2012 and Jeong *et al.,* 2014). The gasifier which is commonly used in IGCC, the entrained flow gasifier, is known to operate under severe operating conditions of up to 2000^{o}C (Zheng and Furisky, 2005, Sun *et al.,* 2012) and pressures in

excess of 8MPa (Minchener, 2005). The entrained flow gasifier achieves very high conversions of up to 99% due to its severe operating conditions. However, the extreme conditions impact negatively on the capital and operational investments of the gasifier and the downstream units. Developed simulation models on the entrained flow gasifiers have mainly focused on maximizing the carbon conversion, and therefore resulting in the gasifier being operated at the extreme conditions. These models include but not limited to the work of Wen and Chaung (1979), who developed a mathematical model to simulate a Texaco downdraft coal gasifier. Vamvuka *et al*. (1995) proposed a steady state model to study the performance of the entrained flow coal gasifier based on the mass and energy balances of the solid-gas and homogeneous gas-phase equilibria. A simple process model for dry-feeding entrained bed coal gasifier was also proposed by Lee *et al*. (2011) to study the effect of operating conditions on key performance indicators such as conversion and cold gas efficiency. Kasule *et al.* (2012) developed a very comprehensive 1-D steady state model of a slurry-fed entrained flow gasifier to simulate an IGCC process. These are, however, simulation models aimed at predicting the performance of the gasifier under prespecified operating conditions.

Limited work has been conducted on the optimization of the IGCC, mostly focusing on the gas circuit. Madzivhandila *et al.* (2009) were amongst the first researchers to focus on the optimization of an IGCC steam-path, by applying pinch analysis. Emun *et al.* (2010) proposed a simulation tool aimed at improving the efficiency and minimizing adverse effect of the IGCC power plant on the environment. Lang *et al.* (2011) proposed the optimization of the IGCC processes using reduced order CFD models. In their comprehensive work, Lang and co-workers considered the integration of the CFD (reduced order) within steady-state process simulators and the subsequent optimization of the integrated system. Similar to the published simulation models, the optimization of the IGCC, particularly the entrained flow gasifier, has been studied under almost fixed temperatures or the operating conditions such as oxygen-to-fuel ratio and steam-to-fuel ratio have been varied discretely. There is currently no evidence indicating that the extreme conditions are the optimal conditions in achieving the maximum fuel gas heating value.

This work focuses on the gas-side of the IGCC particularly the gasifier and gas turbine. The first part of this work presents a 1-D simulation model for a dry-fed entrained flow gasifier with oxygen and steam used as oxidizing agents. The model is then validated against published models for the similar reactor configuration and then extended to an existing entrained flow gasifier for an IGCC power plant in Puertollano, Spain. The second part then presents the optimization model in which the objective function is to maximize the heating value of the fuel gas. These models were formulated using differential and algebraic equations of mass and energy balance. gPROMS platform was used as a simulation and optimization tool. Multiflash for Windows was chosen as a thermodynamic property model to obtain the physical property data for the gaseous mixture.

2. Model formulation

The mathematical model presented in this work is based on mass and energy balances of the gasifier and the gas turbine. The differential and algebraic equations defining the performance of the system were solved in *g*PROMS while the required thermodynamic data such as enthalpies, heat capacities, thermal conductivities, etc., were obtained from Multiflash for Windows. The model is divided into simulation and optimization

modules. The simulation module considers both the gasifer and the gas turbine while the optimization module only focuses on the gasifier where there objective is to maximize the fuel gas heating value. The summary of the mass and energy balance equations is provided in Table 1.

Entrained Flow Gasifier Simulation Model

There are two models generally used for modelling heterogeneous solid-gas reactions and these are Langmuir-Hinshelwood (Klose and Wolki, 2005, Roberts and Harris, 2006, Boreto *et al.,* 2013) and the *n*-order models (Tremel and Spliethoff, 2013, Lee *et al.,* 2014). *n*-order modelling has been selected for this work because of its simplicity and the available reaction kinetics data. Although this is a simplified model, the accuracy is not lost and *n*-order models have been widely used in solid-gas reaction modelling (Vamvuka *et al.,* 1995, Watanabe and Otaka, 2006, Xu and Qiao, 2012). The mass balances of the homogeneous gas-phase and heterogeneous solid-gas phase reactions are shown in Eq. (1) and (2) respectively.

$$\frac{d\dot{m}_{gi}}{dL} = A_c(Mw_i)\sum_{j=1}^{n} \nu_{ji} r_j(T_g, L) + aA_c(Mw_i)\sum_{k=1}^{m} \nu_{ki} \frac{r_{k(T_p,L)}}{Mw_c} \tag{1}$$

$$\frac{d\dot{m}_c}{dL} = aA_c \sum_{k=1}^{m} r_k(T_p, L) \tag{2}$$

The chemical reaction rates for the homogeneous gas phase and heterogeneous solid-gas reactions are calculated using Eq. (3) and (4) respectively. The pre-exponential factor k_j and k_k are determined from Arrhenius equations.

$$r_j = k_j C_a^x C_b^y \tag{3}$$

$$r_k = k_k P_a^n (1 - X_C)\sqrt{1 - \Psi_k \ln(1 - X_C)} \tag{4}$$

The model only considers two modes of heat transfer in the energy balance. Radiation heat transfer between particle-gas, gas-wall and particle-wall and convection heat transfer between particle-gas and gas-wall have been considered. The respective energy balances for gas phase and particles are shown in Eq. (5) and (6), respectively.

$$\frac{dH_p}{A_c dL} = ah_{gp}(T_g - T_p) + a\varepsilon_p\sigma(T_g^4 - T_p^4) - \frac{4}{D_R}\varepsilon_p\sigma(T_p^4 - T_w^4) \tag{5}$$

$$\frac{dH_g}{A_c dL} = -ah_{gp}(T_g - T_p) - a\varepsilon_p\sigma(T_g^4 - T_p^4) - \frac{4}{D_R}h_{gw}(T_g - T_w) - \frac{4}{D_R}\varepsilon_w\sigma(T_g^4 - T_w^4) \tag{6}$$

Where subscripts *j* refers to homogeneous gas phase reactions, *k* refers to solid-gas reactions and *i* is gaseous component in the gas mixture. a is the contact area between particle and gas per unit volume of the reactor. Subscripts *g* and *p* refer to the gas and particle, respectively. X_c is the carbon conversion, A_c is the cross sectional area of the gasifier, *T* is the temperature and P_a is the oxidizing agent partial pressure, while h_{gp} and h_{gw} are the convection heat transfer coefficients of gas-particle and gas-wall respectively.

The formulation of the optimization model to maximize the heating value of the fuel gas is described in Eq. (7) with the constraints shown in Eq. (8) to (13).

$$Maximize\ HV_{FG} = \sum_i x_i HV_i \tag{7}$$

Subject to:

$$T_R \leq T_{MAWT} \tag{8}$$

$$P_R \leq P_{MAWP} \tag{9}$$

$$T_{g,min} \geq T_{AFT} \tag{10}$$

$$\sum_i^n x_i = 1 \tag{11}$$

$$X_c < 0.9999 \tag{12}$$

$$R_{min} \leq R_{CO/H_2} \leq R_{max} \tag{13}$$

T_{MAWT} and P_{MAWP} are the maximum allowable working temperature and pressure, respectively, and they are the design constraints of the gasifier. HV_i is the heating value of the contributing gas in the fuel gas while x_i is the corresponding mass fraction of the contributing gas. The solution procedure of the model is shown in Figure 1

.

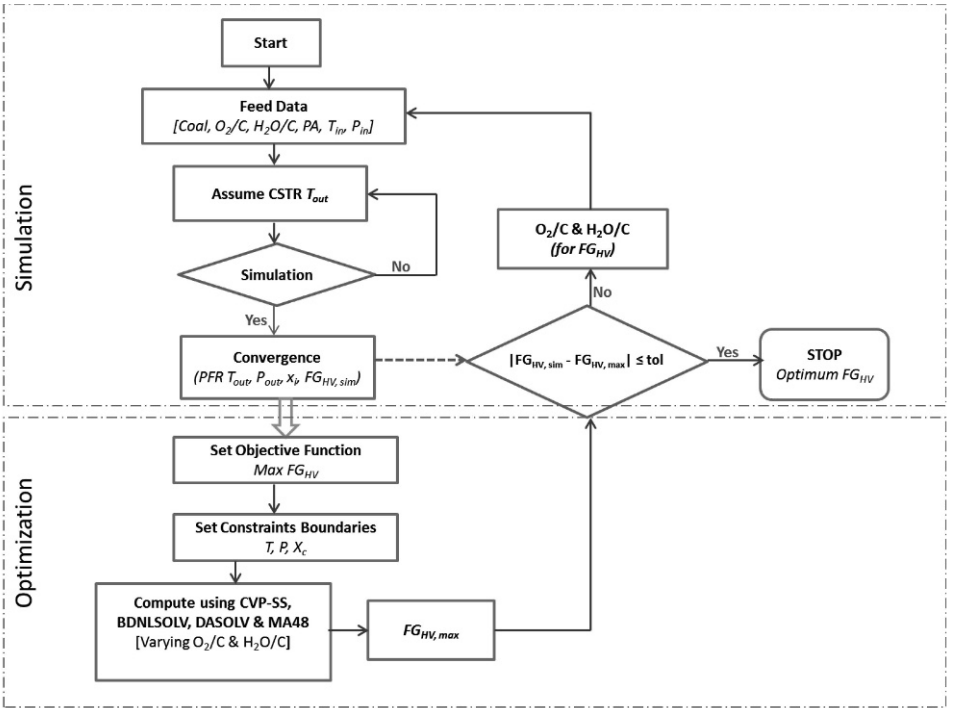

Figure 1: Mathematical model solution procedure

3. Results and discussion

A simulation model developed in this work is compared to published 1-D entrained flow gasifier models at the same input conditions. The mathematical models of Vamvuka *et al.* (1995), Lee *et al.* (2011) and an Aspen Plus model of Sofia *et al.* (2013) are used to validate the simulation model. The validation is also extended to the IGCC power plant of Elcogas in Puertollano, Spain. The performance indicators that were considered crucial were fuel gas composition, gasifier peak temperature, exit fuel gas temperature, conversion and fuel gas heating value. The simulation was based on a 45-55% coal/petcoke feed mixture. The simulation results of the key performance indicators such gasifier peak temperature ($T_{g,P}$), carbon conversion (X_C) cold gas efficiency (η_{CG}) and the fuel gas heating value (FG_{HV}) are presented in Table 1.

Table 1: Comparison of the current model prediction with Elcogas power plant

Variable	Units	Elcogas Gasifier	Current Model
X_c	%	> 98	97.8
$T_{g,P}$	K	> 2273	2882.42
$T_{g,out}$		1623	1539.57
y_{CO+H2}	vol.%	> 85	95.8
y_{CH4}		< 0.1	3.53
η_{CG}	%	-	66.1
η_{CO+H2}		81.02	95.8
FG_{HV}	MJ/kg	-	13.89

A simulated Elcogas gasifier was then optimized to determine the maximum possible heating value of the fuel gas. The resulting NLP model assumes a constant feed into the gasifier with four degrees of freedom; feed pressure, particle size, oxygen-to-coal and steam-to-coal ratios. The feed temperature is assumed to be constant. The optimized performance of the gasifier presented in Table 2 indicates an increase in fuel gas heating value, from 13.9MJ/kg to 16.2MJ/kg.

Table 2: Optimized gasifier performance

Variable	Units	Simulation	Optimized
X_c	%	97.8	64
$T_{g,P}$	K	2882.42	2543.7
$T_{g,out}$		1539.57	1020
y_{CO+H2}	vol.%	95.8	91.93
y_{CH4}		3.53	6.30
η_{CG}	%	66.1	77
η_{CO+H2}		95.8	91.93
FG_{HV}	MJ/kg	13.89	16.21

There is also about 500K decrease in exit gas temperature. The cold gas efficiency also improved as a result of the increase in H_2 and CH_4 content in the fuel gas. There is, however, as significant decrease in carbon conversion. The improved heating value of the fuel gas is preferred in the gas turbine. The increase in H_2 in the fuel gas to the gas turbine increases the expander inlet temperature and the exhaust temperature. This results in an about 2% increase in gas turbine efficiency.

4. Conclusions

The objective of this work was to establish if the severe conditions of high temperature and pressure at which the gasifier is generally operated are indeed the optimum conditions for producing the highest fuel gas heating value. The primary focus was therefore centred on the entrained flow gasifier which is the centrepiece of an IGCC power plant. The gas turbine only receives and combusts the fuel gas to produce power. The developed model was validated against three published models and produces even better results which are comparable to the Elcogas power plant gasifier published data.

The optimized model proves that there exist moderate conditions at which the entrained flow gasifier can be operated to yield the maximum possible fuel gas heating value. An increase of about 14.3% in fuel gas heating value is realized when operating the gasifier at temperatures 500K lower than the extreme temperature reported in literature. The pressure does not have a significant impact on the fuel gas heating value, with only less than 2% increase in heating value being achieved by changing the pressure from 2MPa to 5MPa. Owing to a decrease in operating temperature, the conversion was, however, reduced from 97% to about 64% and this led to a decrease of almost 60% in O_2 and 50% in steam used in the gasifier. The results also indicate an almost 2% increase in the efficiency of the gas turbine when burning the gas of the higher heating value. This is mainly due to the increase in the expander inlet temperature. The gas turbine exhaust temperature and exhaust gas heat capacity also increases, which increases the amount of heat for the HRSG. The overall gas path efficiency also increased by almost 7%. A reduction in operating temperature and pressure of the gasifier will, therefore, guarantee a longer operating cycle of the gasification unit and relatively lower operating and capital costs.

Abstract

The paper improves the existing methods of developing nonlinear soft sensors via a nonparametric approach based on the example of industrial distillation unit. The proposed procedure for soft-sensor design is aimed to overcome obstacles in practice, such as process nonlinearity, unknown model structure and narrow variability ranges of key inputs for soft sensors.

Keywords: soft sensor, distillation column, structural uncertainty, nonparametric methods.

1. Introduction

Soft sensors (virtual on-line analyzers) play a crucial role in any advanced process control (APC) system to optimize the cost of industrial plant operation through their high accuracy in estimating and predicting product quality (Fortuna et. al., 2007).

Nowadays, three methods are used to improve the quality control of the product in technological petrochemical and refining processes: laboratory analysis, the stream analyzer data and the soft sensor data. However, the analysis results, which come from industrial laboratories, are not always full and operative enough; also, they can seldom be used for real-time quality control. The stream analyzers need calibration, are extremely expensive and are sometimes not available. In contrast, the soft sensors, which only have slightly less accuracy, are much cheaper and more reliable. The principle upon which soft sensors work is based on the real-time estimation of quality through a mathematical model that utilizes all available measured process variables, such as flowrates, temperatures and pressures. A review of the existing approaches regarding soft sensor evaluation is given by Kadlec et al., 2009.

However, for industrial plants, such as energy-consuming mass-transfer apparatuses (distillation columns) used in petrochemical and refining production, it is still important to improve methods for soft sensor designs, in order to reach better accuracy, prediction and estimation of products' quality. In uncertain conditions, it is connected with the overcoming of difficulties such as accounting for the variable time of output measurement and a lack of information about the model's structure. Moreover, some of the key (informative) inputs have very low variability ranges because they seldom vary by operator (for instance, the set-point of the distillation column's top pressure). This leads to the statistical insignificance (by t-test) of the corresponding coefficients in the

regression model and contradicts the thermodynamic essence. Therefore, the current paper seeks to handle and overcome such difficulties that arise.

The accuracy of soft sensor predictions is normally investigated by calculating the coefficient of determination (R^2) and root-mean-squared error (RMSE) for both training and test samples. These performance indicators are used in this paper during the further analysis of industrial data.

2. Statement of problem

Let Y be an independent variable (soft sensor output) and $X_1,\ldots, X_n$ be independent variables (inputs). The plant model is described by the following functional relationship:

$$Y = F(\mathbf{X}, \mathbf{B}) + \varepsilon, \tag{1}$$

where $\mathbf{X} = (X_1, \ldots, X_n)^T$ and is the vector of the inputs; $\mathbf{B} = (\beta_1, \ldots, \beta_m)^T$ and is the vector of the model coefficients; and ε is the output error. Suppose that the structure of F in (1) is unknown. From the rigorous (physical-chemical) distillation model, it follows that the structure F should be nonlinear.

This paper deals with the problem of improving the available techniques for soft sensor design in plants like (1), under the following conditions that are widely encountered in practice:

- The process's inherent nonlinearity;
- The unknown model structure;
- The narrow variability ranges of some of the input variables.

The solution to the problem is demonstrated using an industrial case study of a distillation column (Fig. 1) from an FCC unit. The following variables are key inputs of a soft sensor model: x_1 is the flow of distillate (top product) kg/hr; x_2 is the flowrate of reflux, in kg/hr; x_3 is the top pressure of the column, in kgf/cm^2; x_4 is the top temperature of the column, in °C; and x_5 is the bottom temperature of the column, in °C.

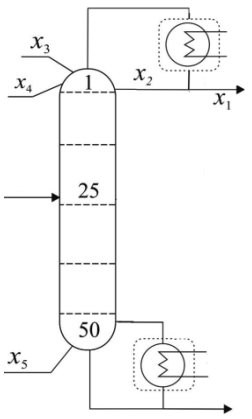

Figure 1: Distillation column: Key inputs of the soft sensor

The soft sensor is intended to predict isopentane (*i*C5) content in the overhead product. The nonparametric approach is proposed in order to solve the stated problem.

3. The use of nonparametric transformations

As pointed out above, industrial plants have a widespread lack of knowledge regarding suitable model structures. The use of a nonparametric approach allows the evaluation of a soft sensor model under structural uncertainty. Thus, the soft sensor model may be found in the following form:

$$\Phi_0(Y) = \sum_{i=1}^{n} \Phi_i(X_i), \tag{2}$$

where Φ_i is the nonparametric transformation. The estimation of transformations for multiple regression using the ACE algorithm was originally proposed by Breiman L. and Friedman J. (1985).

The optimal transformations can be obtained by minimizing the variance between the transformed output and the sum of the transformed inputs. The objective of the ACE algorithm is to minimize the error, e^2, of the transformed output on the sum of transformed input variables, under the constraint $E[\Phi_0^2(Y)] = 1$ ($E[\cdot]$ is mathematical expectation). The error is defined as:

$$e^2(\Phi_0, \Phi_1, \ldots, \Phi_n) = E\left[\left(\Phi_0(Y) - \sum_{i=1}^{n} \Phi_i(X_i)\right)^2\right]. \tag{3}$$

The minimization of the error (3) with respect to $\Phi_1(X_1),\ldots, \Phi_n(X_n)$ and $\Phi_0(X_0)$ proceeds via the following minimization of single functions:

$$\Phi_i(X_i) = E[\Phi_0(Y)|X_i], \tag{4}$$

$$\Phi_0(Y) = E\left[\sum_{i=1}^{n} \Phi_i(X_i)\middle| Y\right] \Big/ \left\| E\left[\sum_{i=1}^{n} \Phi_i(X_i)\middle| Y\right]\right\|. \tag{5}$$

In practice, the conditional expectations in (4) and (5) can be evaluated using smoothing techniques.

The ACE algorithm does not provide a direct calculation of the soft sensor output using (2). However, the nonparametric optimal transformations can be fitted, for example, by a polynomial model as:

$$\Phi_i(X_i) = b_{0,i} + b_{1,i}X_i + b_{2,i}X_i^2 + \cdots + b_{M_i,i}X_i^{M_i}, \tag{6}$$

where M_i is the order of the i-th polynomial for $\Phi_i(X_i)$-transformation ($i = 1,\ldots, n$). The same approximation procedure can be applied for backward calculation of the output (Φ_0 is assumed to be monotonic and invertible):

$$Y = \Phi_0^{-1} = a_0 + a_1\Phi_0 + a_2\Phi_0^2 + \cdots + a_{M_0}\Phi_0^{M_0}, \tag{7}$$

where Φ_0^{-1} is the inverse output transformation and M_0 is the order of polynomial (7).

The 2-step algorithm for calculating the soft sensor output is depicted in Fig. 2. The example for the parameterization of the transformation derived using the ACE algorithm is shown in Fig. 3 with the following equations: $\Phi_0(Y) = 0{,}67 \cdot Y - 12.61$; $\Phi_1(X_1) = -1.25 \cdot X_1 + 28.3$; $\Phi_2(X_2) = -0.3 \cdot 10^{-3} \cdot X_2^2 + 0.17X_2 - 8.4$;$\Phi_3(X_3) = -30.5 \cdot X_3^3 + 156.6 \cdot X_3^2 - 265.7 \cdot X_3 + 149.2$; and $\Phi_4(X_4) = 0.26 \cdot X_4 - 21.7$; $\Phi_5(X_5) = -2 \cdot 10^{-3} \cdot X_5^3 + 0.76 \cdot X_5^2 - 94.3X_5 + 3899$.

4. Handling the narrow variability ranges of the input variables

4.1. Fitting rigorous model to industrial data

The motivation for using a rigorous distillation model implies that it is necessary to extend the training sample with input variables that have low variability ranges. The fitting procedure involves the selection of the tray efficiency that minimizes the mismatch between industrial data and the rigorous model. The average steady-state operating point is involved when estimating the Murphree efficiency of industrial data.

The following residual function is utilized: $f_{iC5}(\mathrm{E1},\mathrm{E2}) = (x_{iC5}^{rm}(\mathrm{E1},\mathrm{E2}) - x_{iC5})^2$, where $x_{iC5}^{rm}(\mathrm{E1},\mathrm{E2})$ is the isopentane content calculated using a rigorous model; x_{iC5} is the industrial isopentane data; E1 is the absorption section efficiency; and E2 is the stripping section efficiency. Moreover, the data reconciliation problem of the reflux ratio (RR) is solved in conjunction with the residual function's minimization.

The calculation results of the fitting procedure and the Murphree efficiencies' feasible domain are shown in Fig. 4. The point *, with coordinates of E1 = 0.608 and E2 = 0.5, indicates the best-fitted values of the sectional efficiencies, with the optimal reconciled RR value. It should be noted that the fitting of efficiency values for each individual separation stage did not provide significant improvements in the calibration results.

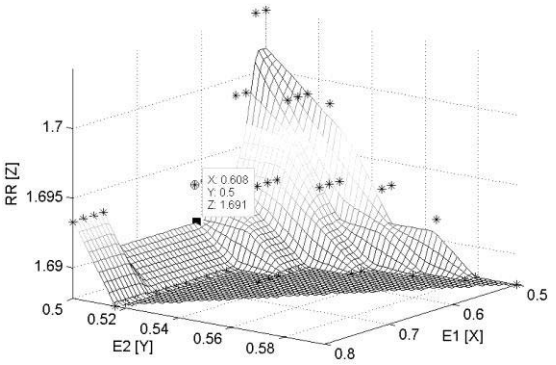

Figure 4: The results of fitting the sectional efficiencies onto industrial data

4.2. Obtaining the model structure

In practice, we have to deal with a situation where a priori information will allow for an understanding that the plant's output is significantly affected by one or more inputs, but that such inputs in the model are not statistically significant. This is due to the fact that, during the plant's operation, the variation ranges are limited by technological reasons, such as safety constraints. Below is a technique that ensures the handling of a priori data about specific input variables within the available data that were obtained from a nonlinear plant with a small range of variation in key (from a physical-chemical sense) input X_m. The model is decomposed in two parts: $\hat{Y} = \hat{Y}_d + Y_m$, where $Y_m = c_m^0 + \sum_{j=1}^{q} c_m^{(j)} X_m^{(j)}$ is obtained based on the data set from the fitted rigorous model; $\hat{Y}_d = c_0 + \sum_{i=1}^{m-1} \sum_{j=1}^{p} c_i^{(j)} X_i^{(j)}$, which is the part for inputs with sufficient variability ranges; and (j) is the j-th order of the polynomial. The resulting model evaluation scheme is as follows: $\hat{Y} = \underbrace{c_0 + \sum_{i=1}^{m-1} \sum_{j=1}^{p} c_i^{(j)} X_i^{(j)}}_{\text{fitting}} + \underbrace{\sum_{j=1}^{q} c_m^{(j)} X_m^{(j)}}_{\text{fix}}$. Note that bias c_0 consumes c_m^0.

As an input variable, pressure was found to be insignificant because of the small range of variability in the available industrial data set. When building the final model to predict the quality of the output product—a concentration of isopentane—without a priori information about the effect of pressure at the top of the column, we get a linear equation of $\hat{Y}_{d,iC5} = 181.3 + 0.39X_1 + 0.05X_2 - 1.25X_4 + 0.2X_5$ using robust regression M-estimator (Maronna et al., 2006). The coefficient of the determination R^2_{iC5} is equal to that for the testing data set and the training sample: 0.1402 and 0.8113 (Fig. 5), respectively.

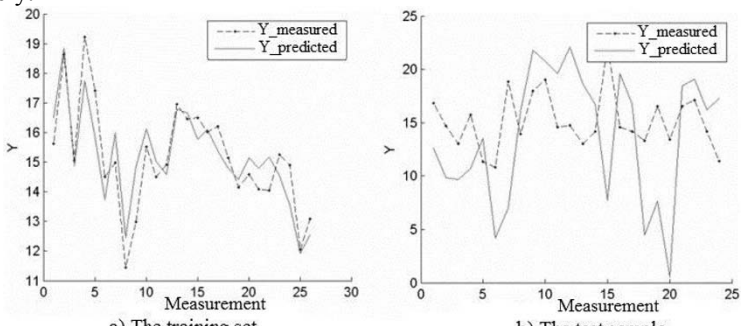

Figure 5: Soft sensor performance without the pressure correction term

Using a priori information about the effect of pressure on the concentration of isopentane in the distillate and rigorous static model, a soft sensor is made as close to the modes of operation for the industrial distillation column as possible. The dependence on the concentration of isopentane in the distillate, along with the pressure change from 1 kg/cm^2 to 2 kg/cm^2, on the fitted rigorous distillation model in form is found using $Y_m = 2.863X_3^2 - 4.432X_3 + 7.708$. Taking into account the influence of pressure, the model of the output product quality using the mass fraction of isopentane was found: $\hat{Y}_{iC5} = 66.46 + 0.48X_1 + 0.12X_2 - 1.04X_4 + 0.08X_5 + 2.863X_3^2 - 4.432X_3$. The coefficient of determination for the test sample R^2_{iC5} is 0.8727; for the training data set, it is 0.7878 (Fig. 6).

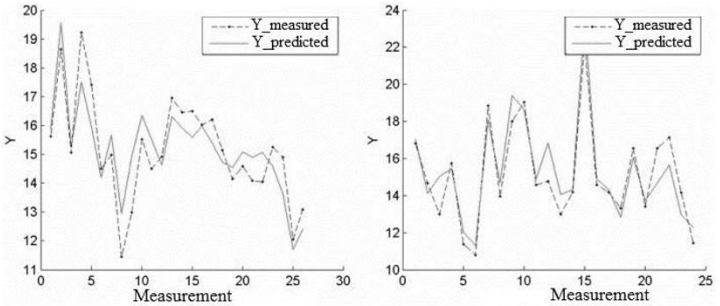

Figure 6: The performance of soft sensor with the pressure correction term

The practical result of using the proposed algorithm (taking into account the a priori information regarding the statistically insignificant inputs) includes improvements in prediction quality by 63.25% in R^2 for the test sample.

5. Conclusions

This article reviews an improved method of evaluating soft sensors for nonlinear industrial plant. The method allows a model structure to be found that counters output uncertainty and avoids the lengthy search and substantiation process for soft sensor's structures. A way to take important (with the physics-chemical meaning) inputs into account, in case of a low variability range, has been proposed. It offers the possibility of increasing the R^2 of the test sample (for example, in comparison with the robust regression *M*-estimator), if it contains new data that are not included in the training set.

Abstract

The operation of a DWDC, fractionating an ideal ternary mixture of hypothetical components A, B, and C, is studied to compare various temperature difference control schemes proposed so far, including temperature difference control (TDC) scheme, simplified temperature difference control (STDC) scheme, double temperature difference control (DTDC) scheme and simplified double temperature difference control (SDTDC) scheme. The nearly similar system performance of the STDC and SDTDC schemes to the TDC and DTDC schemes, respectively, indicates the great importance to control strictly the two sections along the dividing wall. With the two intermediate sections tightly controlled, the operation of the rectifying and stripping sections should then be tightened to improve further system performance. This gives rise to a novel SDTDC scheme involving two DTDC and two TDC loops, which enriches the potential alternatives to control the DWDC.

Keywords: DWDC, temperature control, temperature difference control, double temperature difference control, simplified double temperature difference control.

1. Introduction

Although dividing-wall distillation columns (DWDCs) can economize 30 % equipment investment and operation cost as compared with the conventional two-column separation sequences in the separations of ternary mixtures, their industrial applications are rather limited due to the complicated process dynamics and control difficulties involved. Many studies have conducted so far, but they focused merely on specific control problems (Kiss and Bildea, 2011; Wang and Wong, 2007). Ling and Luyben (2009) proposed a control structure with four manipulated variables (i.e., reflux flow rate, side-stream flow rate, reboiler heat duty, and liquid split ratio) to control the purities of the top, intermediate, and bottom products. Its major advantages lay in the capability of minimalizing reboiler heat duty. Later, they employed a temperature control (TC) and temperature difference control (TDC) schemes to achieve the same purpose. It was found that while the latter could tolerate 20 % feed composition disturbances the former could not (Ling and Luyben, 2010). Luan et al. (2013) indicated the importance of tight control of the two sections along the dividing wall and developed accordingly a simplified temperature difference control (STDC) scheme. Due to the addition of two temperature measurements, the STDC scheme was demonstrated to be superior to the TC scheme. Wu et al. (2013) devised a double temperature difference control (DTDC) scheme with 12 temperature measurements. It was characterized by great capability of suppressing steady-state deviations and rejecting feed composition disturbances. To reduce its temperature measurements, we recently proposed a simplified double temperature difference control (SDTDC) scheme with 8

temperature measurements. Similar to the DTDC scheme, it still featured relatively great capability of suppressing steady-state deviations and rejecting feed composition disturbances (Yuan and Huang, 2014).

In what follows, the operation of a DWDC separating an ideal ternary mixture of hypothetical components A, B, and C is studied. The purpose is to make a systematic comparison between the TDC, STDC, DTDC, and SDTDC schemes proposed so far and draw potentially useful guidelines for the synthesis and design of control systems for the DWDC.

2. A DWDC Fractionating a Ternary Mixture of Hypothetical Components A, B, and C

The vapor-liquid equilibrium relationship is expressed by

$$P_j = x_{A,j}P_A^s + x_{B,j}P_B^s + x_{C,j}P_C^s \qquad 1 \le j \le N \tag{1}$$

$$y_{i,j} = x_{i,j}P_{i,j}^s / P_j \qquad i = A, B, C, \text{ and } 1 \le j \le N \tag{2}$$

The vapor saturation pressure can be estimated with the following equation

$$lnP_{i,j}^s = A_{vp,i} - B_{vp,i} / T_j \qquad i = A, B, C, \text{ and } 1 \le j \le N \tag{3}$$

Table 1 summarizes the operating conditions and design specifications for the DWDC to be developed. The commercial software Aspen Plus is used to perform steady-state simulation. A stripping distillation column with only a reboiler, two paralleled absorber distillation columns with neither reboiler nor condenser, and a rectifying distillation column with only a condenser are employed to construct the DWDC. The design of the DWDC is conducted via a simple search procedure proposed in our earlier work and the minimization of total annual cost is chosen as the objective function for process screening (Wang et al., 2011). The resultant DWDC is sketched in Figure 1a.

Table 1. Operating Conditions and Design Specifications for the DWDC

Parameter		Value	Parameter		Value
Condenser pressure (bar)		3	Vapor	$A(A_{vp}/B_{vp})$	13.04/3862
Stage pressure drop (bar)		6.8901×10^{-3}	pressure	$B(A_{vp}/B_{vp})$	12.34/3862
Feed	A	33.33	constants	$C(A_{vp}/B_{vp})$	11.65/3862
compositions	B	33.33	Product	A	99
(mol %)	C	33.34	specifications	B	99
Feed flow rate (kmol/s)		1	(mol %)	C	99
Feed thermal condition (liquid fraction)		1	Relative volatility A:B:C		4:2:1

3. Various Temperature Difference Control Schemes Proposed for the DWDC

Figures 1b to 1e sketches, respectively, the TDC, STDC, DTDC, and SDTDC schemes to be studied in the current work. The TDC scheme contains four TDC loops. For the STDC scheme, while two TDC loops are used in the two sections along the dividing wall, two TC loops in the rectifying and striping sections, respectively. The DTDC scheme involves four DTDC loops. In the SDTDC scheme, while two DTDC loops are used in the two sections along the dividing wall, two TC loops in the rectifying and

striping sections, respectively. In all these control schemes, the controlled variables are paired with the nearest manipulated variables in locations (i.e., $T_R/\Delta T_R/\Delta^2 T_R$–D, $T_S/\Delta T_S/\Delta^2 T_S$–$Q_R$, $\Delta T_I/\Delta^2 T_I$–I, and $\Delta T_P/\Delta^2 T_P$–R_L). They are justified, however, by static and dynamic analysis and/or closed-loop operability studies and detailed outcomes can be found, elsewhere (Luan et al., 2013; Wu et al., 2013; Yuan and Huang, 2014).

Table 2. Controller Parameters for the TDC, STDC, DTDC, SDTDC, and NSDTDC Schemes

Scheme	Controller	K_C	T_I (min)	Scheme	Controller	K_C	T_I (min)
TDC	TDC1	0.279	14.520	STDC	TC1	3.632	13.200
	TDC2	0.745	17.160		TC2	4.020	7.920
	TDC3	0.365	10.560		TDC1	0.731	18.480
	TDC4	0.524	19.800		TDC2	0.508	21.120
DTDC	DTDC1	0.123	14.520	SDTDC	TC1	0.123	14.520
	DTDC2	0.202	17.160		TC2	0.040	10.160
	DTDC3	0.040	10.560		DTDC1	0.202	17.160
	DTDC4	0.700	19.800		DTDC2	0.700	19.800
NSDTDC	TDC1	0.208	13.200	NSDTDC	DTDC1	0.195	17.160
	TDC2	0.359	9.240		DTDC2	0.752	19.800

4. Comparison of Various Temperature Difference Control Schemes Proposed

Closed-loop operations of the DWDC, controlled, respectively, with the TDC, STDC, DTDC, and SDTDC schemes are simulated with the commercial software Aspen Dynamics. All temperature sensors contain a 1-min dead-time element and all the temperature/temperature difference/double temperature difference loops are tuned with the built-in Tyreus-Luyben rule. The detailed parameters are summarized in Table 2.

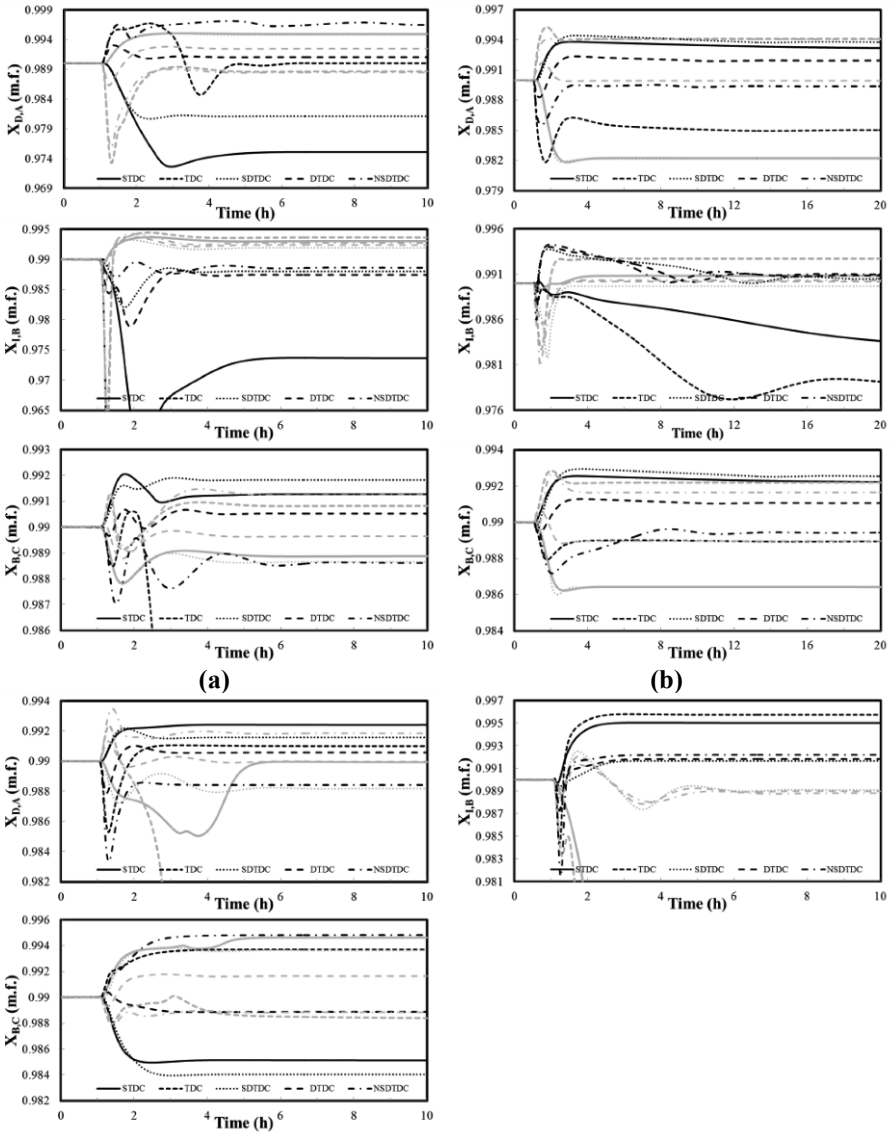

Figure 2. Comparison of various temperature difference control schemes in face of a ±30 % step change in feed compositions of components A, B, and C: (a) component A, (b) component B, (c) component C

In Figure 2, the comparisons of the closed-loop responses of the DWDCs, controlled, respectively, with the TDC, STDC, DTDC, and SDTDC schemes are depicted after the processes have been subjected to a ±30 % step change in feed compositions of components A, B, and C. While the dark lines indicate the responses to the positive changes, the gray lines to the negative ones. The TDC scheme is failed to suppress the disturbances in the cases of positive change in feed compositions of components A and B and negative change in feed compositions of component C. The STDC scheme is unable to reject the disturbances in the case of positive change in feed compositions of component B and negative change in feed compositions of component C. With the inclusion of 4 and 2 temperature measurements, the DTDC and SDTDC schemes can do a better job because they can now suppress a ±30% step change in feed compositions of components A, B, and C. In particular, the DTDC scheme displays smaller steady-state deviations in the three products for step change in feed compositions of components A and C but slightly bigger ones for step change in feed compositions of component B than the SDTDC scheme. Table 3 shows the relative static errors in more detail.

Table 3. Relative Static Errors for a ±30 % Step Change in Feed Compositions of Components A, B, and C

Scenario	Product	Relative static error (%)				
		STDC	TDC	SDTDC	DTDC	NSDTDC

5. Discussions

Generally speaking, the SDTDC scheme can be described to lead to comparable regulatory control performance with the DTDC scheme for a ±30 % disturbance in feed compositions of components A, B, and C. Luan et al. (2013) once demonstrated that the STDC scheme could achieve similar regulatory control performances with the TDC scheme for a ±20 % step change in feed compositions of components A, B, and C. These combined results indicate that for the effective operation of the DWDC it is

extremely important to give strict control of the two sections along the dividing wall and it should be ranked as the top priority in control system synthesis and design. Note the fact that the SDTDC scheme is superior to the STDC scheme coincides also with this interpretation. In case of employing four or more temperature measurements to the two sections along the dividing wall, little enhancement can, however, be secured. Therefore, the DTDC loop should be the best option here.

In Table 3, it can be further observed that the relative static errors in the three products of the DTDC/TDC schemes are smaller than those of the SDTDC/STDC schemes. The result reminds us of the fact that controlling strictly the rectifying and stripping sections helps to improve system performance and it should be taken into account if further improvement is expected from the control system performance of the SDTDC scheme. A novel SDTDC scheme (NSDTDC) with two TDC loops in the rectifying and stripping sections is thus derived as shown in Figure 1f. It yields slight improvement in control system performance in comparison with the SDTDC scheme and the detailed relative static errors are listed also in Table 3.

6. Conclusions

In the current study, the operation of a DWDC separating an ideal ternary mixture of hypothetical components A, B, and C has been examined with the TDC, STDC, DTDC, and SDTDC schemes, respectively. Two conclusions have been drawn on the synthesis and design of the control schemes for the DWDC. Firstly, top priority should be given to the control of the two sections along the dividing wall and usually the DTDC loops should be employed to yield tight control outcomes. Secondly, tightening the operations of the rectifying and stripping sections should then be considered if further improvement in control performance has been required. With the replacement the two TC loops in the SDTDC scheme by two TDC loops, a novel SDTDC scheme has been derived. It enriches the potential alternatives to control the DWDC.

Abstract

The rising interest in heat and power cogeneration, especially in the residential sector, the cost-effectiveness of its operation and environmentally friendly characteristics require attention from both an operational and a design optimisation point of view. In this work, a decentralised control optimisation approach is presented and applied on a natural gas powered, internal combustion engine equipped, domestic cogeneration plant. The approach allows us to not only capture the behaviour of the overall system but also take into account its different operational objectives in terms of either heat or power generation driven production.

Keywords: Decentralised control, multi-parametric Model Predictive Control, Residential scale cogeneration

1. Introduction

Combined Heat and Power (CHP) systems have been receiving a lot of interest as a substitute of traditional power and heat generation resources in residential applications according to Allen et al. (2008) and Ren et al. (2008). Their decentralized production characteristics, cost effective nature and small environmental footprint have added towards that direction. The use of CHP systems aims to reduce the system emissions and increase its operational efficiency via the simultaneous production of usable heat and power in a single process, consuming the same amount of fuel Diangelakis et al. (2014b). Depending on the utilisation of the CHP system, the usable heat is most commonly in the form of high temperature water in liquid or gas form of high pressure and heat bodies of the like. The afore-mentioned heat bodies can be used for a variety of purposes such as (i) heating purposes in other processes, (ii) steam for other process, (iii) space heating, (iv) hot utility water and the like. The basic idea of a cogeneration system is based on the ability of an engine[1] to transform the chemical energy of a fuel into heat and power, most commonly electricity, through a chemical process (i.e. internal/external combustion, etc.). The heat is a byproduct of the power generation process, therefore a heat recovery system, coupled with the prime mover is responsible for transforming the byproduct heat into usable heat. Substantial work has been performed over the last years in the field of cogeneration, employing systems of various scales and power production technologies, focusing on both operational and design aspects, Li et al.

[1]The engine is commonly referred to as the prime mover in such context. An analysis of the most commonly used prime movers can be found in Diangelakis et al. (2014b)

(2010); Wu and Wang (2006); Konstantinidis et al. (2010); Diangelakis et al. (2014a,b); Mehleri et al. (2012). Further attention on this systems is required both on the operational and design level.

The objective of this paper is to introduce a decentralised, multi-parametric Model Predictive Control approach for the operation of a natural gas powered, internal combustion engine equipped, domestic CHP system that exploits its dual operational objectives, namely the electrical power and hot water production. The procedure followed for that purpose is described below, followed by its application in section 2. The full PAROC framework (Figure 1) and the principles presented in Pistikopoulos et al. (2014) are followed in a step-by-step basis. The major difference in this decentralised case is the consideration of a multiple subsystems within the system at hand in order to handle the additional complexity. The 4 steps of the framework are presented below.

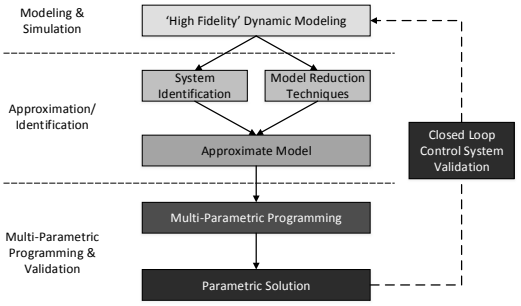

Figure 1: The PAROC Framework.

Step 1: "High Fidelity" Dynamic Modeling – The development of the "high fidelity model", its quality and robustness determine the validity of the framework. The modeling of the system takes place in gPROMS® Process Systems Enterprise (1997-2014).

Step 2: Model Approximation – The resulting highly complex dynamic models of the subsystems of the first step (most commonly DAE or PDAE programs), although sufficiently accurate compared to the real process, are far from ideal in terms of multi-parametric programming utilisation. Therefore, reduction techniques (Lambert et al. (2013) and Lambert (2013)) and identification methods (System Identification Toolbox of MATLAB®) are employed for to (i) reduce the model complexity while (ii) preserving the model accuracy.

Step 3: Design of the Multi-Parametric Model Predictive Controllers – The design of the controllers is based on the validated procedure described in Pistikopoulos et al. (2012) and Bemporad et al. (2002). The resulting multi-parametric program is solved via the POP® toolbox in MATLAB®, thus acquiring the map of optimal control actions.

Step 4: Closed-Loop Validation – The procedure is validated through a closed loop procedure, where the controllers are tested against the original model of Step 1. This can happen either via the interoperability between software tools such as gPROMS® and MATLAB® via gO:MATLAB or via the straight implementation of the controllers in the gPROMS® simulation via the use of C++ programming and the creation of Dynamic Link Libraries.

2. Decentralised mp-MPC for a domestic scale CHP plant

The afore-described framework is put into use on a domestic cogeneration plant utilised to produce electrical power and usable heat in the form of hot water of a certain temperature, in order to cover the electricity and space heating needs of a 10-house district.

2.1. High Fidelity Modeling

The dynamic model of the CHP system is represented in Figure 2 and a full description can be found in Diangelakis et al. (2014b). The mathematical model comprises of a total of 379

equations, 15 of which are differential, with 6 degrees of freedom, 4 of which are dynamic. The model is treated as the interactions between distinct subsystems, namely the power generation subsystem and the heat recovery subsystem. The power generation subsystem comprises the throttle valve, the inlet and exhaust manifolds, the reciprocating internal combustion engine coupled with the crankshaft and the power generator. On the other hand, the heat recovery subsystem comprises of two heat exchangers that facilitate the heat transfer between the high temperature cooling fluid of the internal combustion engine and the exhaust gases towards an external cold water stream.

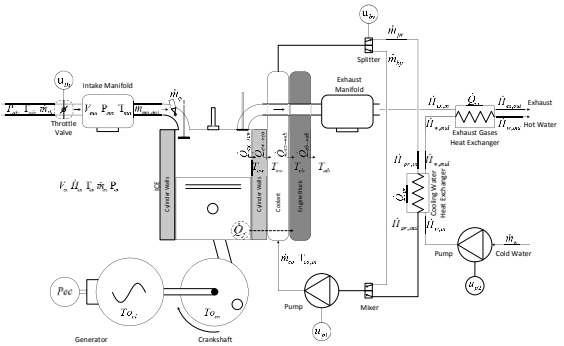

Figure 2: Graphical representation of the CHP System (Acquired from Diangelakis et al. (2014b)).

2.2. Model Approximation

Three subsystems are identified with the use of the System Identification Toolbox of MATLAB®. The first subsystem comprises of the power generation part of the CHP system, including the internal combustion engine, the electrical power generator and their supportive equipment. The approximate model of subsystem 1 is built using the throttle valve position and the electrical power generation output as input-output (I/O) data. The second subsystem comprises of the heat recovery subsystem, including the two heat exchangers and the interaction of the external water stream and the generated heat from the prime mover. The I/O data used for the identification purposes are the electrical power output, the water flowrate in the heat recovery system and the temperature of the water at the outlet of the system. A third subsystem is identified that correlates the inlet water flowrate to the outlet water flowrate of the heat recovery system which for brevity reason won't be thoroughly addressed. Overal 2 single input - single output subsystems and 1 multiple input - single output subsystem are identified. The three sets of equations (Equations 1 to 9) describe the approximate models for the power generation subsystem, the heat recovery subsystem and the flowrate correlation subsystem, respectively.

$$x_{k+1} = 0.9913\,x_k + 0.0044\,u_k \tag{1}$$
$$y_k = 3.5927\,x_k \tag{2}$$
$$T_s = 0.1s \tag{3}$$

$$x_{k+1} = \begin{bmatrix} 0.9712 & -0.0207 & -0.0529 \\ 0.0012 & 0.8169 & -0.0524 \\ -0.0099 & -0.0302 & 0.9551 \end{bmatrix} x_k + \begin{bmatrix} -0.0245 & -0.0079 \\ -0.1009 & 0.0593 \\ -0.02457 & 0.0125 \end{bmatrix} u_k \tag{4}$$
$$y_k = \begin{bmatrix} -158.5 & -9.306 & -155 \end{bmatrix} x_k \tag{5}$$
$$T_s = 0.1s \tag{6}$$

$$x_{k+1} = 0.99\,x_k + 0.01\,u_k \tag{7}$$
$$y_k = 1\,x_k \tag{8}$$
$$T_s = 0.1s \tag{9}$$

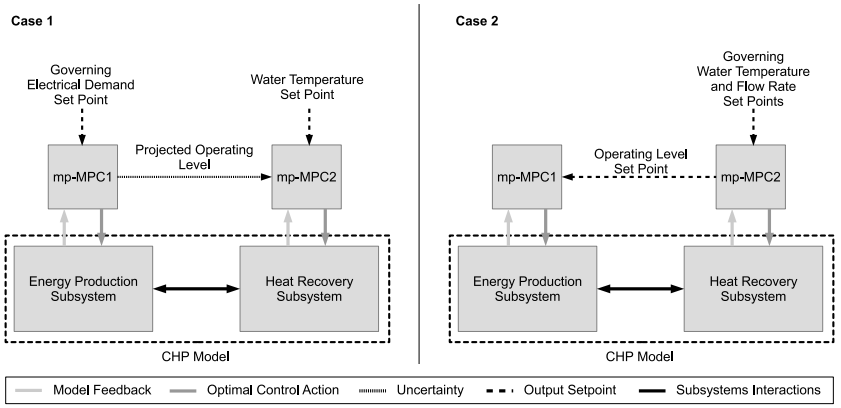

Figure 3: The two distinct control policies.

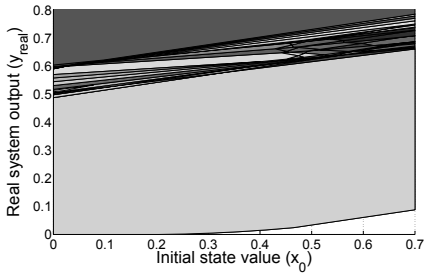

Figure 4: figure
Power generation subsystem mp-MPC

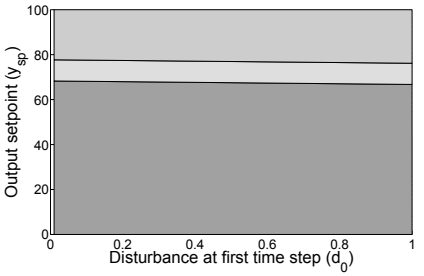

Figure 5: figure
Heat recovery subsystem mp-MPC

2.3. Multi-parametric Programming and Control

The approximate models identified in the model approximation step are the basis for the design of three multi-parametric controllers. The operation of the CHP system though, is governed by either the demand of electrical power (Case 1) or the demand of hot water (Case 2). To serve both cases, a two stage approach has been adopted for the design of the heat recovery system control. In Case 1, the system attempts to (i) cover the electrical power demand and (ii) produce water of a predefined temperature, regardless of the flow rate. In order for this to happen, the controller of the heat recovery subsystem controls the temperature of the water at the outlet of the heat recovery system via the manipulation of the water flow rate while treating the operational level of the energy generation subsystem as a measured uncertainty. Therefore, for Case 1, only two out of the three sub-suystems ad respective controllers are utilised, rendering the third subsystem In Case 2, the system attempts to produce water at predefined temperature and flowrate values. This is translated into treating both the water temperature and flow rate as control variables while the flow rate set point and the operational level of the electrical power generation subsystem are treated as manipulated variables of subsystem 2 and subsystem 3 respectively. The latter is treated as a power output set point for the energy generation subsystem. A schematic representation of the two control cases is presented in figure 3.

The parameters of the quadratic optimisation problems consist of the initial values of the states, the measured disturbances, the previous control action, the output setpoints and the output setpoint mismatch against the original high fidelity system. A 2-D projection of the critical regions for the

power generation and heat recovery subsystems is presented in figures 4 and 5.

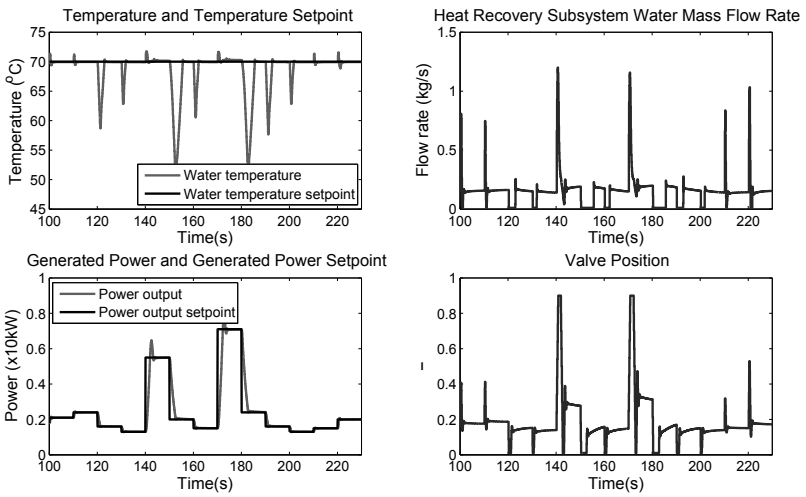

Figure 6: mp-MPC Results for Case 1.

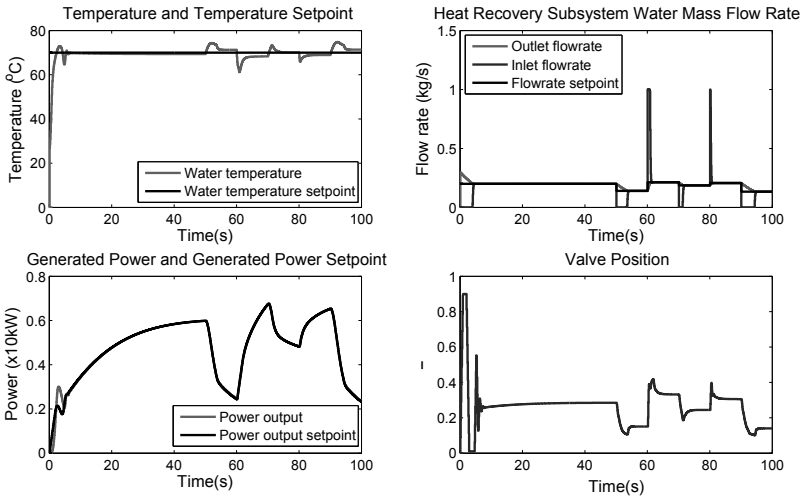

Figure 7: mp-MPC Results for Case 2.

2.4. Closed-Loop Validation and Results

The closed-loop validation takes place for the two cases individually. For the first case, the electrical power generation level is set. The controller of the power generation subsystem follows the pre-set set point while the controller of the heat recovery subsystem treats the electrical power output as a disturbance. The objective of the latter is to maintain the temperature of the water at the outlet of the heat recovery subsystem at 70^oC by manipulating the water flowrate (Figure 6). In the second case, both the flowrate of the water of the heat recovery system and its temperature need to be maintained to a pre-defined level. Therefore, the power generation output is treated as the

manipulated variable of the heat recovery subsystem controller and the setpoint for the electrical power generation controller (Figure 7).

3. Conclusions

Following the procedure described in the Framework we designed two distinct cases for the decentralised control of a domestic CHP system. This scheme decomposes the original system into two major parts thus enabling a more effective approach while ensuring that the operation of the CHP can cover both the heat generation and electrical generation setpoints. In both cases, the controller schemes manage to accurately capture the dynamics of the system and drive it to the desired operational setpoints. This then forms the basis for further exploring the interactions between process design, operational scheduling and model predictive control in a multi-parametric fashion Kopanos and Pistikopoulos (2014); Diangelakis et al. (2014a).

Abstract

In this work we present advanced multi-parametric control strategies for the "Multicolumn Countercurrent Solvent Gradient Purification" (MCSGP) process, which is a continuous chromatographic separation process, governed by a periodic operation profile, linked to the intensification of monoclonal antibody production. We demonstrate a seamless, step-by-step procedure for the development of multi-parametric controllers as part of our recently introduced PAROC framework and software platform. The designed controller assures optimal operating conditions, avoiding pertubations, under continuous operation, while capturing the periodic nature of the process.

Keywords: periodic systems, mp-MPC, chromatography

1. Introduction

Periodic systems form a challenging class of control problems that has been addressed in the open literature (Engell and Toumi, 2005, Kawajiri and Biegler, 2006, Grossmann et al., 2010). Contributions in the field have suggested 'cycle-to-cycle' control approaches (Grossmann et al., 2010), solving a Model Predictive Control (MPC) problem at every cycle. However, ensuring periodic input profiles that can lead to cyclic steady state (CSS) still remains an open challenge. In addition, the development of advanced control strategies for such systems includes handling of complex Partial Differential and Algebraic Equations (PDAEs) models that usually involve nonlinear terms.

In this work, we investigate the design and application of advanced control strategies for the twin-column MCSGP process that is a semi-continuous chromatographic process, described by a nonlinear PDAE model. We demonstrate the seamless development of multiparametric-MPC (mp-MPC)controllers for such systems through the application of the PAROC framework & software platform (Pistikopoulos et al., 2014, PAROC, 2013-2014) that comprises four major steps: (i) the development of a 'high-fidelity' mathematical model, (ii) a model approximation step, (iii) the design and solution of the multi-parametric programming problem and (iv) a 'closed-loop' in silico system

validation step. The steps are described through the application of the framework to a chromatographic system.

2. The System

The development of a multi-parametric control strategy for the twin-column MCSGP is examined. MCSGP (Figure 1a) is a periodic process comprising 2 chromatographic columns that operate in countercurrent mode (Krättli et al., 2011). Both columns are alternated between a batch and interconnected state. The two columns are characterized by the same technical details (e.g. length, diameter, resin material) and are operated in the same way with half a cycle delay. Here we reduce the system to a 5x3 single-column configuration (Figure 1b), considering the modifier concentration, the flow rate and the component concentrations in the feed stream as inputs, while the output set includes: the concentrations of the three mixture components (Weak impurities (W), Product (P) and Strong impurities (S)). MCSGP process aims to separate the product from the early eluting impurity W and the later eluting impurity S, while recycling overlapping regions of the chromatogram. Therefore the control objective is to maintain a high purity of the product stream, while optimizing the recovery yield.

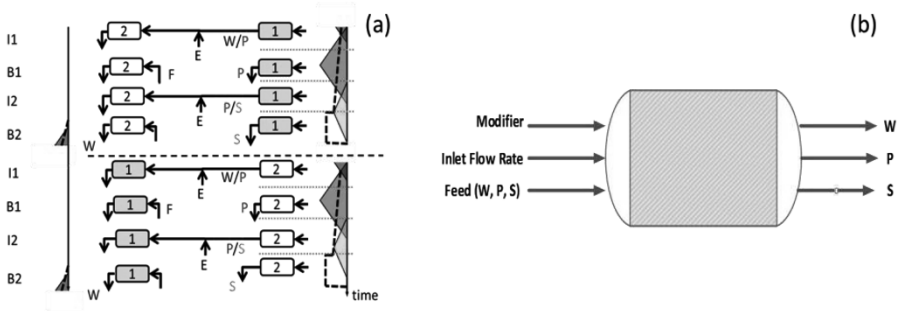

Figure 1 (a) Twin-column MCSGP setup, (b) Input/ Output single-column system based on the principles of the MCSGP process (5x3 system).

2.1 The High-Fidelity Process Model

The system is described by a Partial Differential Algebraic Equation (PDAE) model (Müller-Späth et al., 2008) that was modeled in gPROMS ModelBuilder ® v 4.0.0 (PSE, 1997-2014). The objective is to maintain the process under optimal operating conditions that will ensure high product purity and yield, which are functions of the average concentrations of the three mixture components in the outlet streams (Grossmann et al., 2010).

In this work we track the integral of the outlet concentration of the three mixture components aiming to overcome difficulties with online measurements, as well as to be able to monitor continuous outputs. In that way the controller can operate throughout the process cycle and possibly result in better process monitoring, compared to 'cycle-to-cycle' control. Tracking of the integral of the outlet concentration allows seamless post-calculation of purity and yield. The significance of the inputs was evaluated by the application of a pulse input strategy. As shown in Figure 2, four of the inputs were maintained constant, while the fifth one was varied within the range of interest.

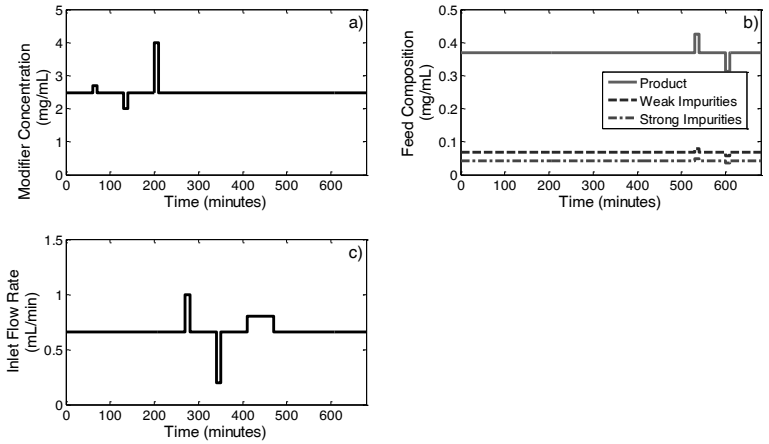

Figure 2 Pulse input strategy as applied for the sensitivity tests for (a) the modifier concentration (mg/mL), (b) feed composition (mg/mL) and (c) the inlet flow rate (mL/min).

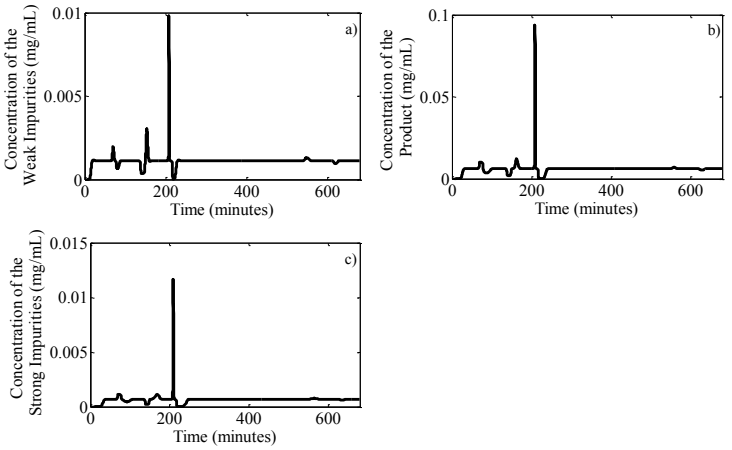

Figure 3 Output profiles as resulted from the sensitivity tests for the outlet concentration of (a) the weak impurities, (b) the product and (c) the strong impurities.

It can be observed that the modifier concentration has the most significant effect on the monitored outputs (Figures 2 & 3), followed by changes in the feed composition. On the contrary, changes in the flow rate values seem have no considerable effect (synergetic and/or antagonistic effects are not considered here). Based on these profiles, we reduce the system to a Single-Input Multiple-Output configuration (Figure 4), considering the modifier concentration as the sole input. This is also in accordance with the process physicochemical properties as the modifier concentration affects greatly the separation performance (Müller-Späth et al., 2008). It is known, however, that the value of the flow rate controls the speed that the components travel through the column and therefore the extraction times. Also, it should be underlined that in reality, the feed composition of the upstream mixture cannot be controlled and should be therefore treated as a disturbance. However, for the purposes of this work disturbances will not be considered.

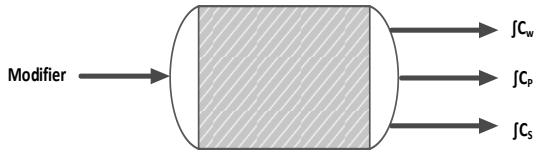

Figure 4 The three Single Input - Multiple Output (SIMO) system, considering the modifier concentration as input and the integral of the three outlet concentrations as outputs

2.2 Model Reduction/System Identification

The process model describing the 1x3 system (Figure 4) is characterized by a large set of PDAEs, involving highly nonlinear terms. Therefore it needs to be simplified in order to be used for control studies (Rivotti et al., 2012, Lambert et al., 2013). The process model was simulated under a random pulse input strategy, ensuring that the system is adequately excited within the range of interest. The input-output (modifier concentration – integral of the outlet concentrations) data set is used for the design of linear, state space model using the identification toolbox in MATLAB®. The reduced models were tested against various sets of inputs and their response and fitting was evaluated. For the selection of the model, the number of states was also considered. The selected reduced model comprises 6 states, 1 input (modifier concentration) and 3 outputs (integrals of the outlet concentrations) and was characterized by the best fit and a relatively small number of states that reduces the computational force needed.

2.3 Design of multi-parametric controllers & 'Closed-loop', in-silico validation

The state space model described above was used for the design of a multi-parametric controller for the nominal single-column design case (Figure 4). The problem was solved for an output horizon of 4 and a control horizon of 2 (using the PAROC software platform (PAROC, 2013-2014)) and the map of solutions comprises a set of 6 critical regions in total. The designed controller was tested in-silico against the original process model and the output behavior was monitored, using the gO:MATLAB interface in gPROMS ModelBuilder® (PSE, 1997-2014). Figure 6 illustrates the comparison between the output and the output setpoint as generated for the input strategy indicated by the controller (Figure 5).

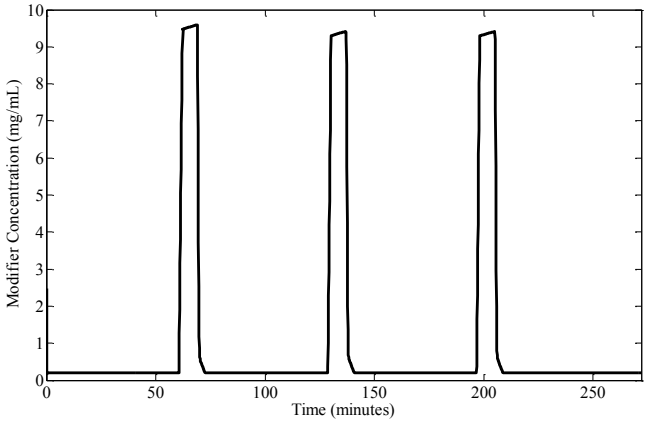

Figure 5. Input profile for the modifier concentration as indicated by the controller during the 'closed-loop' validation.

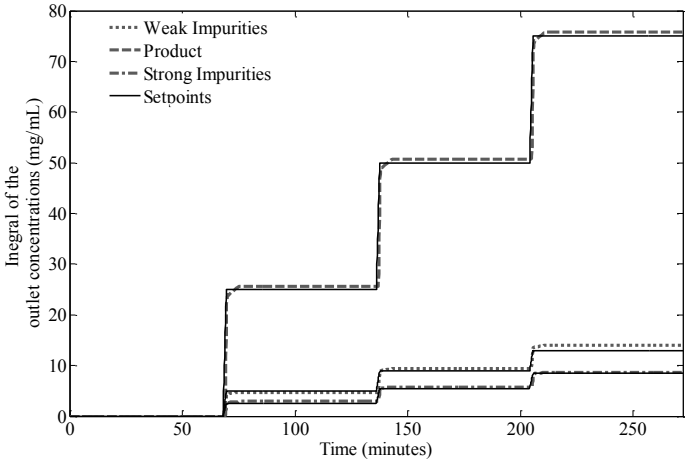

Figure 6 Comparison of the setpoint and the output model output as resulted from the controller closed-loop validation for weak impurities, product and strong impurities over time.

A fairly good agreement between the monitored outputs and the assigned setpoints can be observed (Figure 6), without significant offset (< 3%). However, even this deviation can be tackled by incorporating an integral state that will lead to more efficient setpoint tracking (Sakizlis et al., 2004). Moreover, it can be seen that the controller indicates a cyclic input profile (Figure 5). The latter implies that the design of both the state space and the controller capture the periodic nature of the system and will effectively ensure cyclic steady state (CSS). The results presented are also in agreement with the physicochemical laws that govern the system. In chromatography, elution can only take place with the addition of modifier. This behavior is efficiently captured by the controller, as we observe increase in the modifier concentration (Figure 5) whenever an increase in the setpoint is encountered (Figure 6). A periodic profile is also observed in the selection of critical regions (Figure 7a, 7b). This can be translated into period control laws that could force the system to reach CSS.

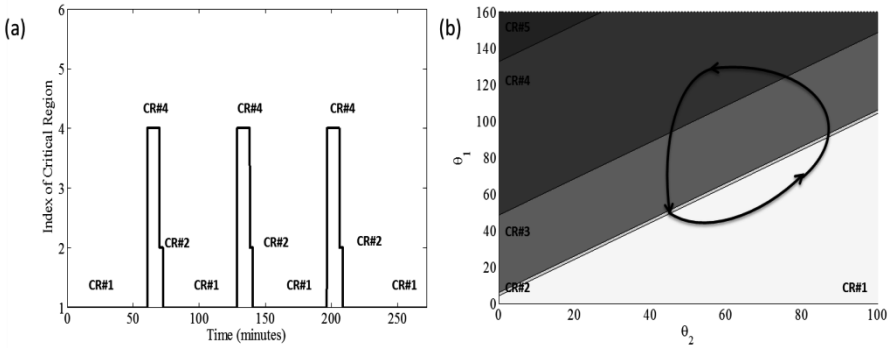

Figure 7 Evolution of the critical regions during the 'closed-loop' controller validation over time: (a) index of critical region, (b) Two-dimensional projection of the critical region polyhedral corresponding to the six state space model.

3. Conclusions

This works presents a detailed approach for the development of model-based multi-parametric controllers for a periodic, chromatographic process. Following the PAROC framework (Pistikopoulos et al., 2014) we demonstrate both the development of the mp-MPC controller and the 'closed-loop' validation against the original process model. We also suggest tracking of the integral of the output concentrations that could result into continuous outputs and effectively continuous process monitoring. The in-silico validation results demonstrate that the controller can efficiently capture the periodic nature of the process by indicating a cyclic input profile that results in cyclic steady state (CSS).

The proposed Single Input – Multiple Output (SIMO) controller could be further robustified against various values of flow rates and disturbances, to account for variations in the composition of the feed stream. Additionally, the addition of an integral state could lead to tighter output monitoring thus eliminating the offsets (Sakizlis et al., 2004).

Abstract

A methodology for combining multiparametric programming and NCO tracking is presented in the case of linear dynamic systems. The resulting parametric controller contains information regarding the solution structure provided by multiparametric programming and the corresponding feedback control laws for tracking optimality conditions, thus avoiding the need for repetitively solving optimization problems in online real time control. An example of a constrained linear quadratic optimal control problem with initial conditions as parameters is presented to illustrate the approach.

Keywords: multiparametric programming, NCO tracking, feedback control

1. Introduction

On-line optimization and real-time control have been receiving a lot of attention especially driven by the need to reduce economic costs and improve system performance. Many industrial applications are fast dynamic systems operated under constraints, typically reflecting physical operation bounds and/or safety requirements. The optimal control action is obtained by solving the optimization problem based on dynamic model of the system without violating the constraints. One major challenge in such systems is how to effectively deal with uncertainty stemming from model mismatch and process disturbances, where optimal operation needs to be decided online based on real-time feedback. Such optimal control actions can be obtained by solving dynamic optimization problems repeatedly. This is the strategy employed in Model Predictive Control (Rawlings and Mayne, 2009), where uncertainties can be handled by repeatedly solving the optimization problem online to obtain optimal inputs, a quite computationally demanding task. For systems with fast dynamics, this may often cause serious delays, leading to suboptimal performance or even infeasibility. Several approaches have been proposed in the literature to avoid the need for repeatedly solving optimization problems online. One is based on multiparametric programming and control (Pistikopoulos, 2012). Here, optimization problems are solved offline, resulting in priori computations of explicit mapping of solutions, effectively control strategies, as a function of measurable quantities. Another approach is tracking the Necessary Conditions of Optimality (NCO-tracking) (Kadam et al, 2007). Here, feedback control laws are derived in order to track the NCOs along each arc of the nominal optimal solution, as obtained off-line, thereby converting an optimal control problem into a self-optimizing feedback control problem.

The objectives of the work are to combine multiparametric programming and NCO-tracking in unified framework, thereby paving the path towards a theoretical justification for NCO-tracking based on multiparametric programming. A constrained linear quadratic

optimal control problem with parametric initial conditions is presented to illustrate the approach.

2. Multiparametric dynamic optimization

2.1. Problem formulation

Consider the following dynamic optimization problem with linear dynamic system

$$\begin{aligned}&\phi = \min_{u(t)} \tfrac{1}{2}{x_f}^T Q_f x_f + \int_{t_o}^{t_f} \tfrac{1}{2} x(t)^T Q x(t) + \tfrac{1}{2} u(t)^T R u(t) dt \\ &s.t. \quad \dot{x}(t) = Ax(t) + Bu(t), \;\; x(t_0) = x_o, \;\; t_0 \le t \le t_f \\ &\qquad g(x,u) = C_1 x(t) + C_2 u(t) + b_1 \le 0, \;\; e(x_f) = E_1 x_f + b_2 \le 0\end{aligned} \tag{1}$$

where ϕ is the scalar objective function; x and u are the differential state variables and control variables, x_f is the final state variable; t_0, t_f are the initial and final times; g and e are the path and terminal constraints; and $Q_f \succ 0, R \succ 0, Q \succcurlyeq 0$ are the weighting matrix, hence the problem is non-singular.

2.2. Parametric optimal solution structure

For each initial value x_o, treated as parameters, the optimal solution contains a unique sequence of interior and boundary arcs. We define this sequence as the *optimal solution structure*, denoted by $S(x_o)$. Also the entry and exit times for the k-th constraint are denoted by $t_{ken}(x_o)$ and $t_{kex}(x_o)$.

The optimal control and state trajectories should satisfy the following necessary conditions (Kreindler, 1982)

$$\partial\Psi/\partial u = 0, \quad \partial\Psi/\partial x = 0, \quad \partial\Psi/\partial x_f = p_f, \quad \mu^T g = 0, \quad \nu^T e = 0, \quad \mu, \nu \ge 0 \tag{2}$$

Here, $\Psi = \frac{1}{2}{x_f}^T Q_f x_f + \nu^T e(x_f) + \int_{t_0}^{t_f} H(t)dt$ is the Augmented Lagrange function, $H(t), p(t), \mu(t)$ and ν are the corresponding Hamiltonian function, costate variables, path constraints and terminal constraints, respectively.

By applying the above conditions, an optimal pair $(x(t), p(t))$ for (1) can be obtained by solving the following boundary value problem:

$$\begin{bmatrix} x(t) \\ p(t) \end{bmatrix} = e^{G(t-t_k)} \left(\begin{bmatrix} x(t_k) \\ p(t_k) \end{bmatrix} + b \right) - G^{-1} b$$

$$G = \begin{bmatrix} A - BR^{-1}\hat{C}_2^T \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \hat{C}_1 & -BR^{-1}B^T + BR^{-1}\hat{C}_2^T \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \hat{C}_2 R^{-1} B^T \\ -Q - \hat{C}_1^T \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \hat{C}_1 & -A^T + \hat{C}_1^T (\hat{C}_2^T)^{-1} B^T \end{bmatrix}$$

$$b = \begin{bmatrix} -BR^{-1}\hat{C}_2^T \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \hat{b}_1 \\ -\hat{C}_1^T \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \hat{b}_1 \end{bmatrix}, \quad \hat{\mu}(t) = \left(\hat{C}_2 R^{-1} \hat{C}_2^T\right)^{-1} \left(\hat{C}_1 x(t) - \hat{C}_2 R^{-1} B^T p(t) + \hat{b}_1\right)$$

Here, $\hat{C}_1, \hat{C}_2, \hat{b}_1$ are defined for the active constraints $\hat{g} = \hat{C}_1 x + \hat{C}_2 u + \hat{b}_1$ that explicitly contain u and $\hat{\mu}(t)$ are the Lagrange multipliers for $\hat{g}$. For the case with active state constraints, solution with similar form can be obtained by taking derivatives of the constraints, one can refer to (Vinter and Zheng, 1998) for details.

Initial costate function $p(t_0, x_0)$ is linear in x_0, for details one can refer to (Sakizlis et al, 2005). The switching times $t_k(x_0)$ can be computed from the continuity conditions $H(t_{ken}^+) = H(t_{ken}^-)$ and $H(t_{kex}^+) = H(t_{kex}^-)$.

Optimal input $u(t) = -R^{-1}B^T p(t) - R^{-1}\hat{C}_2{}^T \hat{\mu}(t)$.
In particular, solution structure can be completely determined by parameter x_0.

Critical regions are defined such that each region corresponds to certain optimal solution structure, which is characterized by a unique sequence of arcs in time domain. For details about how to define the critical regions and the boundaries, one can refer to (Sakizlis et al, 2005). Each critical region contains a set of parameters x_0 with same solution structure. Thus, the solution structure can be a function of parameters, denoted as multiparametric solution structure, providing a mapping for $x_0 \rightarrow S(x_0)$.

3. NCO tracking

3.1. Concept of NCO tracking

The measurement-based method of NCO tracking enforces optimality by directly tracking the necessary conditions of optimality in the presence of uncertainty, thus transforming a dynamic optimization problem into a feedback control problem (Kadam et al, 2007). The optimal control profile of dynamic optimization problem consists of a sequence of arcs, and along each arc, decision variables are linked to different types of NCO, namely, path constraints, terminal constraints and sensitivities conditions, as shown in Equation (2). The adaption laws for constraints and sensitivities is to force NCO variations to be zero (François et al, 2004). Therefore, measurements are used to directly update the inputs by tracking the NCOs at zero.

A restriction for this approach in practise lies in the fact that the solution structure is assumed to remain unchanged in the presence of disturbances. This can be avoided by the use of multiparametric solution structure, as described in section 2.2.

3.2. Solution model

For each solution structure, a feedback controller can be designed based on the corresponding solution model, which includes information about the sequence and types of arcs, input parameterization and adaption for each kind of arcs (Bonvin and Srinivasan, 2013). Such a solution model enforces optimality by defining feedback laws along each arc and switching logic between different arcs. The active constraints can be directly enforced to reach optimality. For sensitivity-seeking arcs input profiles can be parameterized by simple functions and more efforts should be made by pairing the decision variables with control variables (NCOs). It should be noticed that the sequence of arcs in each solution model matches exactly the switching structure for critical regions in the context of multiparametric programming.

4. Multiparametric NCO tracking controller

4.1. Multiparametric solution model

By resorting to the critical regions for optimal solution structure, the general theory of NCO tracking can be extended, where solution structure does not remain unchanged but is determined according to critical regions.

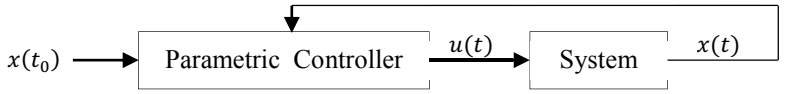

Figure 1 Schematic representation of the algorithm

The parametric controller follows a two-layer online measurement-based control scheme, multiparametric solution structure and input adaption based on NCO conditions, which can be referred to as multiparametric solution model. Here, define the above two-level method as multiparametric NCO tracking.

4.2. Steps for generating controller

The main steps to define feedback control laws in parametric controller are the following:

(1) Define initial feasible region and solve the multiparametric dynamic optimization problem, to find critical regions and their unique solution structures.

(2) Exploit input adaption for NCO conditions of all kinds of arcs in solution structure.

(3) Apply feedback tracking laws according to this multiparametric solution model.

4.3. Application in receding moving horizon control

If the time horizon for the multiparametric dynamic problem is taken as the receding horizon in MPC (Rawlings and Mayne, 2009), multiparametric solution for certain time interval from initial time can be applied as the control action, which is usually the input for first time interval.

During the selected first time interval, tracking method can be used to compute input, thus multiparametric NCO tracking control law is applied in a receding horizon manner. Estimates of states and model parameters can be obtained by online identification approach, enabling solution structure to be updated.

5. Examples

Multiparametric solution model is to be computed for the following problem

$$\min_{x(t),u(t)} \frac{1}{2}{x_f}^T P x_f + \int_0^1 \frac{1}{2}x(t)^T Q x(t) + \frac{1}{2}u(t)^T R\, u(t)$$

$$s.t. \quad \dot{x}(t) = Ax(t) + Bu(t)$$

$$x(0) = x_0$$

$$-2 \le u \le 2$$

$$A = \begin{bmatrix} -3 & -2 \\ 1 & 0 \end{bmatrix}, B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, R = 0.2$$

$$Q = \begin{bmatrix} 20 & 0 \\ 0 & 20 \end{bmatrix}, P = \begin{bmatrix} 1.6396 & 1.6396 \\ 1.6396 & 21.64 \end{bmatrix}$$

5.1. Solution structure obtained from mpDO

Solving this mpDO by using the method described in Section 2, critical regions are shown in Figure 2. Here, $x_{0,1} \in [-2,2], x_{0,2} \in [-2,2]$ is chosen as the initial region, which can be expanded with critical regions split by same interior boundary definition. It can be found that there are three critical regions, which denote different kinds of structure of optimal inputs. For initial states in CR01, there is no active constraint, which means that the optimal solution needs to only satisfy the sensitivity conditions. Therefore, the optimal control can be obtained the same as in classical LQR problem. For initial states in CR02, the optimal solution is constituted of two arcs, where the first arc corresponds to input reaching its lower bound followed by a sensitivity arc, sharing the same feedback control law as in CR01. For initial states in CR03, reaching its upper bound in first arc following by a sensitivity arc. For any given x_0, there exists an exact optimal solution structure and control profile $u(x_0, t)$.

Select $x_{0\_a} = (1, -0.8) \in$ CR01 and $x_{0\_b} = (1, 1) \in$ CR02, the open-loop optimal trajectories are shown in Figure 3. It can be seen that for x_{0_a}, there is one single arc. While for x_{0_b}, there are two arcs, the first constraint arc $u = -2$ from beginning to switching time around $t_1 = 0.44$, followed by a sensitivity arc.

5.2. Comparison with multiparametric programming

By discretising the continuous time system, the optimization problem can be formulated as conventional multiparametric programming problem (Pistikopoulos, 2012). Critical regions can be obtained by solving mpQP, where input is assumed constant for each time interval, are shown in Figure 4. Critical regions for mpQP are approximations of the regions for mpDO, the smaller the sample time, the more closely the critical regions approach to the exact solutions in Figure 2. A special region in both cases is the middle one, namely CR08 (a) or CR15 (b), which represents the case that no constraint is active. The others are all with the first couple of time intervals containing active constrains, with same solution structure as CR02 or CR03 in Figure 2. This unifies the definition of critical regions for different branches of multiparametric programing and also provides a way to explore the solution structures of mpDO by solving approximate mpQP.

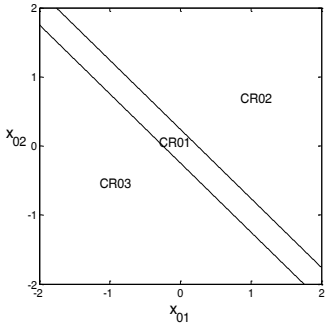

Figure 2 Critical Regions

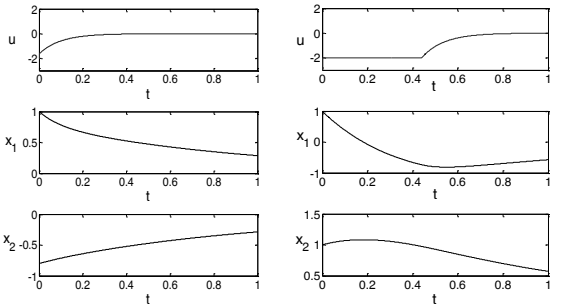

Figure 3 Optimal trajectory from solving mpDO

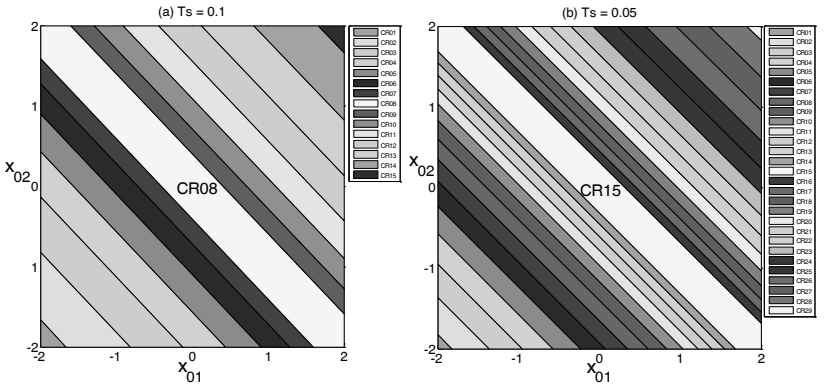

Figure 4 Critical Regions with sampling time (a) Ts = 0.1 and (b) Ts = 0.05.

5.3. Closed-loop simulations with NCO tracking

System response of initial condition x_{0_b} by mp-NCO-tracking as well as the optimal exact solution are shown in Figure 5, two curves coincide. For the first arc, input is kept at its lower bound. And for the second arc, sensitivity condition based on system model is used to force optimality, with feedback control law $u(t) = [-8.198 \ -8.198]\, x(t)$.

Results by applying mp-NCO-tracking in receding horizon scheme, as in section 4.3, coincide with the results shown in Figure 5, with receding time horizon T=1 and first time interval dt = 0.01. It can be seen that multiparametric controller has steered system to its optimal trajectory.

6. Conclusions

The integral framework of multiparametric NCO tracking is justified in the paper by exploiting the multiparametric solution model. An algorithm is proposed to make extension of NCO tracking for linear dynamic systems, which involves computing the multiparametric solution structure mapping via multiparametric dynamic optimization and using it as tracking policy for online feedback control. Critical regions that define the solution structures are determined as a function of uncertain parameters, whereby, the assumption that solution structure remains unchanged in the presence of uncertainty is no longer needed. A constrained linear quadratic optimal control problem is illustrated to show whole application of the algorithm. Critical regions for solution structures are compared with those obtained from solving mpQP, which are in fact approximations of the exact continuous time solution. Multiparametric NCO tracking is implemented for closed-loop control as well as in MPC control scheme, illustrating the use of the parametric controller.

Abstract

A new performance-oriented approach to robust real-time optimization and/or optimal control is developed. It relies on a scenario-based framework and ensures attainment of the robustness of the worst-case approach while allowing significant reduction in the loss in process performance measures, such as profitability. The effectiveness of the proposed robust strategy is demonstrated on the Williams-Otto fed-batch reactor and its profitability is shown to be superior to that of the worst-case approach.

Keywords: robust optimal control, robust dynamic optimization, multi-scenario programming.

1. Introduction

Discontinuous systems are typically employed in the production of high value-added but sensitive products, such as active pharmaceutical ingredients, bio-based chemicals, special polymers and ultra-pure materials for microelectronics. Due to the importance of these products, research is continuing on the development of efficient and reliable optimization and control methodologies for these types of dynamic operations. Among the various proposed options, real-time model-based frameworks, such as DRTO and NMPC, seem to be receiving the most attention in the literature. For example, (Greaves et al., 2003) addresses the DRTO of a batch distillation column and (Joly and Pinto, 2004) investigates the optimal quality control of a Nylon-6,6 production process. In addition, an unconventional optimal control system, aimed at safely reducing the batch cycle time in polymerization processes, has also been proposed in (Finkler et al., 2013). Finally, a screening of the most suitable control laws to be coupled with DRTO for discontinuous systems can be found in (Pahija et al., 2014).
DRTO/NMPC-like approaches are very promising but need a reliable model of the system to be managed, often referred to as a controlled system model (CSM). However, it can be difficult to meet this requirement due to the presence of uncertain parameters in the CSM, such as heat transfer coefficients, kinetic constants and fouling factors. Therefore, there is also a need for robust optimization and control strategies, which are effective even with uncertain parameters in the CSM. This is the goal of the current work. At present, the most common strategy for insuring robustness of DRTO/NMPC-like algorithms in the presence of uncertainties is the so-called worst-case approach (WCA). Worst-case scenario based DRTO/NMPC-like algorithms have been reported in several papers: a bioreactor study (Logist et al., 2011), a reactor for E. Coli bacteria

growth (Santos et al., 2012) and a study of a Siemens process (Vallerio et al., 2014). Moreover, efficient numerical implementations of these methods have also been studied (Diehl et al., 2008). Other strategies for the robust DRTO/NMPC exist but are rarely applicable. Among them, those using online measurements to compensate the CSM uncertainties (Gros et al., 2006, Kadam et al., 2007) are the most common.
The main drawback of the WCA and the typical strategies for insuring robustness lies in the associated optimization/control performance loss. Thus, this work is aimed at proposing a novel scenario-based approach to achieving robustness (SBA), whose main novelty resides in its own structure/configuration, that reduces this performance loss.
In the rest of the paper the SBA structure is outlined and its integration within an NMPC/DRTO-like approach, the BSMBO&C (Rossi et al., 2014a) is demonstrated. The BSMBO&C method is briefly described in section [2]. Subsequently, the combined SBA-BSMBO&C strategy is applied to the Williams-Otto fed-batch reactor and its performance is compared to that resulting from the WCA-BSMBO&C approach, i.e. the BSMBO&C method coupled with the WCA.

2. BSMBO&C schematic structure

BSMBO&C (Batch Simultaneous Model-Based Optimization and Control) is a strategy for the simultaneous dynamic optimization and optimal control of discontinuous systems. The merits of this combined approach are that it is able to: (I) optimally manage a (fed-)batch system by simultaneously adjusting both its manipulated variables and its batch cycle time; and (II) employ a general user-defined objective function. It was first proposed in (Rossi et al., 2014b) and fully elaborated in (Rossi et al., 2014a).
BSMBO&C proceeds by first performing an initialization and then iteratively executing a sequence of operations (*basic step*) until a stopping condition is fulfilled (Figure 1). The initialization is used to provide the algorithm with the user-defined inputs: the CSM, the objective function, the upper/lower bounds and the tuning parameters. The *basic step* consists of three phases: (I) an optimization to compute the next optimal control action; (II) the implementation of this control action on the controlled system; and (III) the measurement of the system response and check of the stopping condition.
BSMBO&C employs BzzMath integrators and optimizers (Buzzi-Ferraris and Manenti, 2012), which are capable of handling strongly non-linear systems. Therefore, it can be applied to almost any kind of system. Moreover, by belonging to the DRTO/NMPC-like methods, BSMBO&C lends itself to be easily integrated with both the SBA and WCA, thus being suitable for the aims of this work.

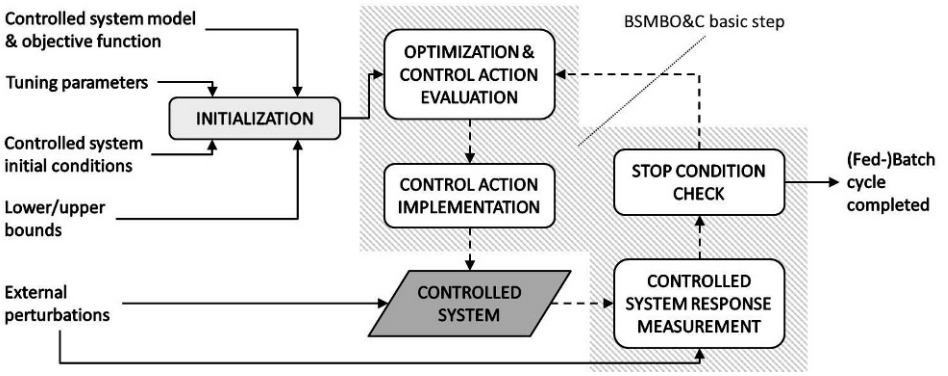

Figure 1. BSMBO&C method simplified scheme

3. The scenario-based robustness strategy

While the SBA is a general strategy for achieving robustness that can be applied within any NMPC/DRTO-like method, in this work we will discuss its application within the BSMBO&C framework. It is based on multiple scenarios and uses four steps in series: (I) definition of a finite space of scenarios; (II) identification of two scenarios, referred to as the nominal and worst case; (III) definition of the number and nature of the additional scenarios to be included; (IV) construction of the multi-scenario CSM and the multi-scenario based performance indicators to be provided to the BSMBO&C.

The identification of the finite space from which to draw scenarios can be readily done, assuming that the probability density function (PDF) of the CSM uncertain parameters is known. It is only necessary to identify the region of the uncertain parameters space corresponding to a cumulative probability that equals a certain confidence threshold.

The identification of the nominal case is straightforward as it corresponds to the maximum of the PDF of the CSM uncertain parameters. Instead, the worst case can be found via sensitivity analysis, performed on the controlled system uncertain parameters and manipulated variables. Indeed, the scenarios space can be mapped, using either Monte-Carlo methods or a uniform grid search, for the scenario that minimizes the distances between the related controlled system states and their upper/lower bounds.

The number of scenarios to be included should be selected in order to ensure the online applicability of the SBA-BSMBO&C. The specific scenarios can be chosen based on a mapping of the level surfaces of the PDF of the CSM uncertain parameters. Once again, either Monte-Carlo or a uniform grid can be employed for this mapping.

Notice that each of the scenarios selected in phases (II) and (III) will be associated with a weighting factor (p_s) that defines its discrete probability density (the p_s sum is one).

For the SBA final step, the multi-scenario CSM is constructed by combining the single-scenario CSMs (Eq. (1)), including the nominal and worst cases, found in step (II), and the other additional scenarios, selected in step (III).

$$\begin{cases} \mathbf{I}_M^s \dfrac{d\mathbf{w}^s}{dt} = \mathbf{h}^s\left(\mathbf{w}^s, \mathbf{m}, \mathbf{d}^*; \boldsymbol{\mu}^s\right) \\ \mathbf{w}^s(t^*) = \mathbf{w}^{s,*} \end{cases} \xrightarrow[\mathbf{h}^R = \{\mathbf{h}^1 \ldots \mathbf{h}^s \ldots \mathbf{h}^{N_s}\}]{\substack{\mathbf{I}_M^R = \{\mathbf{I}_M^1 \ldots \mathbf{I}_M^s \ldots \mathbf{I}_M^{N_s}\} \\ \mathbf{w}^R = \{\mathbf{w}^1 \ldots \mathbf{w}^s \ldots \mathbf{w}^{N_s}\}}} \begin{cases} \mathbf{I}_M^R \dfrac{d\mathbf{w}^R}{dt} = \mathbf{h}^R\left(\mathbf{w}^R, \mathbf{m}, \mathbf{d}^*\right) \\ \mathbf{w}^R(t^*) = \mathbf{w}^{R,*} \end{cases} \quad (1)$$

Moreover, the multi-scenario performance indicators of the controlled system are given as a weighted sum of the single-scenarios performance indicators, where the weighting factors are the p_s values (Eq. (2)). Notice that two performance indicators are needed (f and g) since the BSMBO&C method requires both. Indicators f and g must be chosen so that the product fg measures the controlled system profitability.

$$\begin{cases} f^s \\ g^s \end{cases} \rightarrow \begin{cases} f^R = \sum_{s=1}^{N_s} p_s f^s \\ g^R = \sum_{s=1}^{N_s} p_s g^s \end{cases} \quad (2)$$

In Eq. (1) and Eq. (2), $\mathbf{I_M^R}$ is a diagonal singular/non-singular identity-like matrix, $\mathbf{w}$, $\mathbf{m}$ and $\mathbf{d}$ represent the states, manipulated variables and external perturbations relating to the controlled system, $\boldsymbol{\mu}$ identifies the CSM uncertain parameters and N_s is the total number of included scenarios. In addition, superscript/subscript s refers to the generic scenario while superscript R refers to the entire set of scenarios.

Once steps (I) to (IV) are completed, the SBA can be merged into the BSMBO&C to build the SBA-BSMBO&C by simply setting the multi-scenario CSM and the multi-scenario performance indicators (f^R and g^R) as BSMBO&C input data.

4. The case study: Williams-Otto fed-batch reactor

In this section, the performance obtained via the SBA is tested against that resulting from the WCA and, for the sake of completeness, against that achieved with no attempt to ensure robustness (NCA, i.e. the nominal case approach). Specifically, the results of the online simultaneous optimization and control of a Williams-Otto fed-batch reactor, using the SBA-BSMBO&C, WCA-BSMBO&C and standard BSMBO&C, are reported. Note that the WCA-BSMBO&C is configured by incorporating into the BSMBO&C the CSM and controlled system performance indicators for the worst case while the standard BSMBO&C is configured in the same way but for the nominal case. The SBA-BSMBO&C is set up as described in section [3].

For these illustrative cases, the only CSM uncertain parameter is the overall heat transfer coefficient, which is assumed to be normally distributed. Moreover, the fed-batch reactor model is taken from (Rossi et al., 2014a) and the single-scenario controlled system performance indicators (f^s and g^s) are formulated similarly to those reported in the same reference and test case II. Therefore, the pseudo-scheduling problem is addressed. Finally, the confidence threshold for the SBA step (I) is set to 99.9 % and the SBA steps (II) and (III) are performed based on a uniform search grid. Additional input data for the case study are summarized in Table 1.

Table 1. Case study essential input data

Kinetic scheme, rate equations and kinetic parameters	A + B → C	(1)	$R_1 = k_1^0 \exp\left(-\frac{E_1}{T_R}\right) C_A C_B$	k_1^0 = 2.76650E+5 E_1 = 6.65E+3
	B + C → P + + E	(2)	$R_2 = k_2^0 \exp\left(-\frac{E_2}{T_R}\right) C_B C_C$	k_2^0 = 1.20195E+8 E_2 = 9.05E+3
	C + P → G	(3)	$R_3 = k_3^0 \exp\left(-\frac{E_3}{T_R}\right) C_C C_P$	k_3^0 = 4.45750E+11 E_3 = 1.15E+4
Heats of reaction	$\Delta H_{R,1}$ = -1.095E+5; $\Delta H_{R,2}$ = -1.5425E+5; $\Delta H_{R,3}$ = -3.085E+5			
Thermodynamic properties (reacting mixture and coolant)	Cp_A = 321.204; Cp_B = 127.14; Cp_C = 352.288; Cp_E = 166.212; Cp_G = 844.132; Cp_P = 426.617; Cp_j = 4.186; ρ_j = 1E+3			
Molecular weights (reacting mixture) and reactor structure	PM_A = 142; PM_B = 60; PM_C = 202; PM_E = 81; PM_G = 383; PM_P = 181; D_R = 1; H_R = 3.5; V_j = 0.8236			
Global heat transfer coefficient	U_{ave} = 0.8; $U_{std\ dev}$ = 0.1 (U is normally distributed)			
Relevant lower/upper bounds	$F^{IN,MAX}$ = 1E-3; F_j^{MAX} = 1E-2; T_R^{MAX} = 335; V_R^{MAX} = 2.15;			
Initial conditions	C_A^0 = 1; C_B^0 = 0.5; $C_{i\neq A,B}^0$ = 0; V_R^0 = 1.5; T_R^0 = 308; $T_j^{OUT,0}$ = 308;			
Feed conditions and coolant inlet temperature	C_B^{IN} = 1; $C_{i\neq B}^{IN}$ = 0; T^{IN} = 298; T_j^{IN} = 308;			
Reactants/products price	EV_A = 25; EV_B = 75; EV_C = 200; EV_E = 0; EV_G = 0; EV_P = 40			
Campaign time, dead time and number of selected scenarios	$t_{campaign}$ = 8.64E+4; t_{dead} = 420; N_s = 7;			
Units of measure	amount of substance [kmol]; mass [kg]; length/area/volume [m]/[m^2]/[m^3]; time [s]; temperature [K]; energy [kJ]; prices [€]			

The key results achieved in the case study are reported in Figure 2 and Figure 3. In detail, Figure 2 shows the typical optimal profiles of the reactor temperature (T_R) and manipulated variables (the feed (F^{IN}) and coolant (F_j) flows) observed when the only external perturbation (the coolant inlet temperature (T_j^{IN})) is a step-wise function. Notice that T_R approaches T_R^{MAX}, thus there may be feasibility problems since the reactor model is uncertain. Therefore, this case study is meaningful to test the robustness strategies.

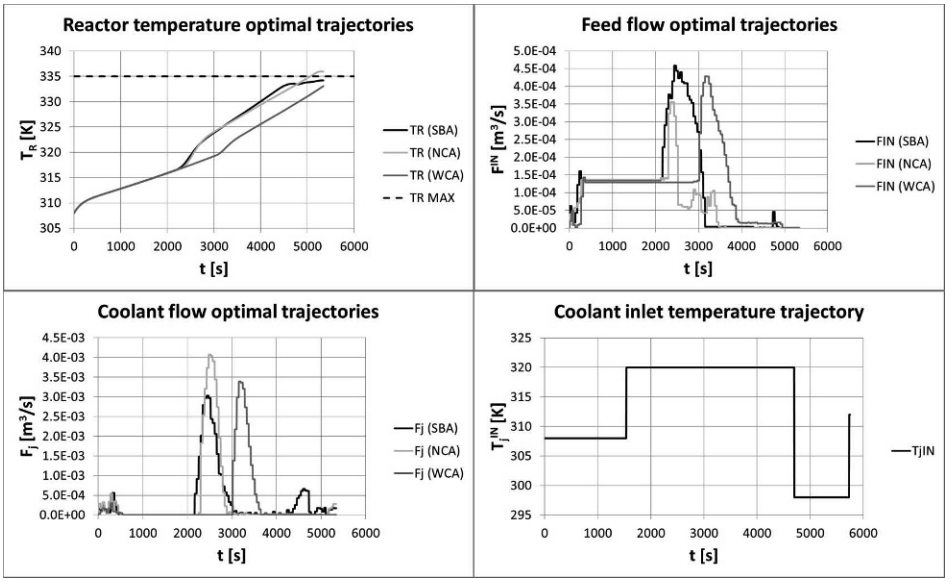

Figure 2. Reactor optimal operation achieved with the SBA-BSMBO&C (SBA), standard BSMBO&C (NCA) and WCA-BSMBO&C (WCA) (U_{real} = 0.625 kW/m^2/K)

Figure 3, shows the performance comparison between the SBA and WCA. It is evident that the SBA is typically much more profitable than the WCA while ensuring the same degree of robustness (both the SBA and WCA allow no bounds violation). In addition, the SBA is more profitable both locally (chart on the left) and globally (chart on the right) and tends to reach almost the same economic performance as the NCA. There is only a very limited zone where the SBA and WCA achieve similar performances. This is probably due to the concurrence of the T_j^{IN} and U_{real} variation along with the linear dependence of the derivatives of the reactor states on the heat transfer coefficient.

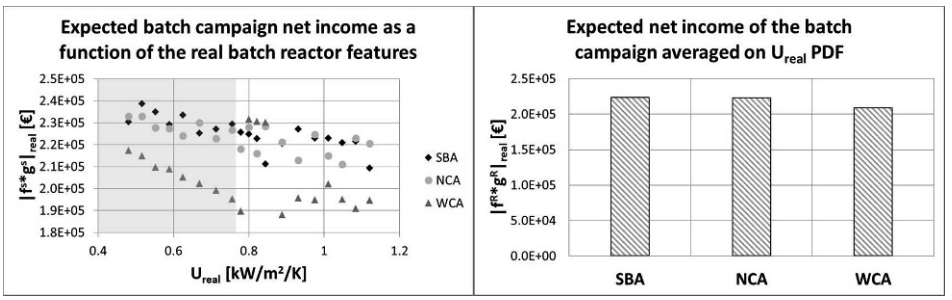

Figure 3. Performance comparison among the SBA-BSMBO&C (SBA), standard BSMBO&C (NCA) and WCA-BSMBO&C (WCA) (Note that the standard BSMBO&C takes the reactor to infeasible operation when U_{real} falls within the shaded region)

We offer two final observations about the SBA. First, it is able to achieve the same robustness as the WCA since the worst case is included in its scenarios set. Moreover, it provides better optimization/control performance because it relies on a more sophisticated objective functions set (Eq. (2)). Secondly, the SBA is suitable for full parallelization because each scenario is independent of the others. This is an additional useful feature and advantage of the SBA over the WCA.

5. Conclusions

A new performance-oriented scenario-based strategy for a robust NMPC/DRTO-like approach, the SBA, is proposed. Its effectiveness is tested against that of the worst-case approach (WCA), the most common conventional alternative. The comparison demonstrates that SBA achieves same robustness as WCA but also an average increase of 6.8 % in the optimization/control performance. Finally, the SBA is also suitable to full parallelization, thus allowing exploitation of multi-core platforms.

Abstract

For absorption processes with fluctuating feed gas compositions it is vital to continuously adjust the operation point to achieve energy efficiency. In this contribution a Raman-based advanced process control (APC) is introduced for the absorption of carbon dioxide (CO_2) using an aqueous solution of monoethanolamine (MEA). The APC is based on a Raman spectroscopic analysis of the composition and CO_2 load of the scrubbing liquid and a non-linear model predictive control (NMPC) to adjust the scrubbing liquid cycle. In addition, an outer real-time optimization loop is set in place to update the set points for the absorption process depending on the current feed gas composition minimizing the energy consumption of the process. Implementation and testing of the APC have been carried out in a mini-plant at TU Berlin. During a plant operation of more than 160 hours robustness and stability of the APC were shown.

Keywords: Raman Spectroscopy, Advanced Process Control, CO_2 Absorption

1. Motivation and Introduction

Process control of steady state systems with fluctuating feeds still is a challenge to date. Both model predictive control and real-time optimization have been applied in industry to improve the performance of such processes with internal or external disturbances (Camacho and Bordons, 2013). The largest challenges still lie in solving the underlying models with greater non-linear parts. This is especially the case for reactive systems such as reactive distillation columns investigated by Kawathekar and Riggs (2007).

1.1. CO_2 Separation

In this contribution, the carbon dioxide removal section of a mini-plant for the oxidative coupling of methane is discussed (Stünkel et al., 2011, 2012). The mini-plant consists of a 4 cm wide absorption column featuring Rombopak 12 M of 6 m of packing height by Sulzer. The desorption column is 10 cm wide and holds Rombopak 9 M of 5 m of packing height. The absorption is carried out at pressures from 5 to 32 bar with a gas flow rate of 10 Nm^3/h. Afterwards the loaded scrubbing liquid is flashed to atmospheric pressure and desorbed in the desorption column by electrically heating the liquid to temperatures around 130 °C at 2.5 bar.

Due to catalyst degradation and general cyclic behavior of the reactors, fluctuations can be observed in the feed to the product purification sections. For the design of this part of the overall

process, two aspects have to be taken into consideration. The first is the minimization of the product loss, namely ethene, the second is the minimization of the energy used to separate the required amount of carbon dioxide. The former is usually mostly achieved by reducing the absorption pressure, but also by using as little scrubbing liquid as possible for removing the carbon dioxide. The latter on the other hand cannot be ensured as straight forward. A model is required to find the optimal combination of desorption heating duty, scrubbing liquid flow rate, etc.

1.2. Optimal Operation

As motivated above, a fixed operation point for the absorption desorption section would not lead to an overall optimal performance. A repetitive reoptimization of the entire system depending on the current reaction conditions is required. For this purpose a model has already been developed to model the performance of the absorption desorption section of the mini-plant and to optimize its performance (Esche et al., 2014b).

In this contribution an overall real-time optimization (RTO) scheme is proposed for the absorption desorption section. The RTO uses the previously mentioned model for the update of the set points. Those are then controlled by nonlinear model predictive control (NMPC). To facilitate the RTO-NPMC structure Raman spectroscopy is applied as fast and reliable process control equipment.

The purpose of this contribution is to highlight the specifics of this new RTO-NMPC-based control scheme with an emphasis on the actual mini-plant implementation.

2. Control Structure Modification

Recently, in (Esche et al., 2014a) an advanced control structure for an amine-based absorption desorption process has been proposed to control the removal of CO_2 from a product gas stream by scrubbing with MEA.

Key aspects of the control structure, shown in Fig. 1, are a Raman spectroscopy-based analysis of the desorbed liquid and an IR analysis of the outlet gas. Raman spectroscopy can be applied to measure both the amine to water ratio as well as the carbon dioxide liquid load (Esche et al., 2014a). The Raman measurement is hence used to control the water to amine ratio by adding fresh amine solution ("QIC 02") and the CO_2 load of the scrubbing liquid at the outlet of the desorption column ("QIC 03") by manipulating the electrical heating of the desorption column. The IR analysis of the outlet gas of the absorption column returns the concentrations of all main gas components, i.e. CO_2, C_2H_4, CH_4, C_2H_6, and N_2. The controller "QIC 01" is able to manipulate the scrubbing liquid flow rate to keep the CO_2 outlet gas concentration at the required minimum level.

Whilst a static set point of 30 wt.-% MEA in water is applied for "QIC 02", deriving an optimal set-point for "QIC 03" and defining the range in which the scrubbing liquid flow may be changed by "QIC 01" can only be done based on the model of the entire process mentioned above.

As part of this contribution, the control structure shown above is applied on the existing mini-plant at TU Berlin.

Raman Spectroscopy: The measurements of the desorbed liquid for "QIC 02" and "03" are carried out using Raman spectroscopy. The calibration of the Raman spectrometer has already been discussed in previous publications (Esche et al., 2014a; Vogt et al., 2011). At this point only a couple of remarks will be made about the applied equipment, measurement positions, and the calibration models. Raman spectroscopy can measure several of the molecular and ionic components appearing in the aqueous technical systems. In this application the components of interest are MEA, CO_2, H_2O, $MEACOO^-$, H_3O^+, OH^-, HCO_3^-, CO_3^{2-}, and $MEAH^+$. Most of them have direct or indirect influences on the Raman spectrum due to changes in functional groups. Here, a

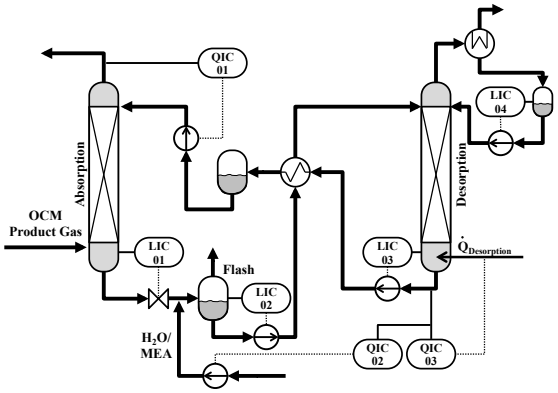

Figure 1: Sketch of the absorption desorption process and all major control loops.

Raman spectrometer RXN1 of Kaiser Optical Systems inc. with an Invictus^{TM} Laser (785 nm) is used covering the spectral range between 400 and 3 400 cm^{-1}. An inflow probe with a half inch diameter is inserted into the piping using a standard T-piece. Calibration models for measuring the CO_2 liquid load as well as the MEA in water concentration were developed. Laboratory calibration experiments based on quantitative NMR spectroscopy as reference method were carried out covering the range between 10 to 50 wt.-% MEA and 0.0 to 0.7 mol CO_2 / mol MEA. These models show a root mean square error of cross validation of below 3 %. First applications in a mini-plant process environment showed, that the transfer of the laboratory based models was successful with respect to robustness and dynamics. Further details may be found in (Esche et al., 2014a).

3. Modeling

To calculate the optimal set-points a model is used to minimize the energy consumption of the process. At a lower level, moving horizon estimation and non-linear model predictive control are employed to ensure a quick return to a steady state to guarantee the validity of the steady state model used for the higher level optimization.

3.1. Mini-plant Process Model

The RTO-NMPC scheme is based on two fundamentally different models for the real-time and the model-predictive control sections. For the RTO part an experimentally validated, steady state model is employed, which contains all necessary information on the most important operation conditions and the required energy inputs. For the NMPC part on the other hand, a dynamic process model is developed, which disregards all chemical compounds and formulates mass balances for all tanks, columns, and actuators of the liquid absorption cycle.

Steady State Model for Real-time Optimization: The steady state model is derived in detail in (Esche et al., 2014b). It has been specifically formulated for the absorption mini-plant at Technische Universität Berlin, but could easily been adapted to different plants. The general idea of the model is a reduction of the amine liquid system to three pseudo components: CO_2, MEA, and water. All ionic components are neglected. Correlations are introduced which relate temperature, CO_2 partial pressure, the amine liquid load α [mol CO_2 / mol MEA], and the heat of absorption based on equilibrium data published by Shen and Li (1992) and Kim and Svendsen (2007). The equilibrium stage model is fitted to experimental data of the mini-plant contained in (Stünkel,

2013) by introducing equilibrium efficiencies and heat loss.

The model allows for a specification of feed volume flow and CO_2 mole fraction, desired degree of CO_2 removal, absorption pressure and is implemented in AMPL using IPOPT (Wächter and Biegler, 2006) as a solver to return the optimal combination of scrubbing liquid flow and scrubbing liquid regeneration to minimize the required energy input.

Dynamic Model for Control: The model for the NMPC part consists of dynamic mass balances for absorption column, flash, desorption column, absorption feed tank, and partial condenser. The liquid content of the packings inside absorption and desorption columns is described by semi-empiric equations by Engel (1999). The correlations are fitted to experimental data obtained from the mini-plant at TU Berlin. In addition, characteristic curves of all control valves and pumps are included. In contrast to most NMPC implementations, the PID controlers are part of the NMPC's dynamic process model. The main reason for this step, is the heightened stability in case of non-convergence of the NMPC (Ławryńczuk, 2014). Consequently, the NMPC's dynamic model consists of a differential algebraic integral equation system (DAIE system).

3.2. Discretization of Differential Algebraic Integral Equation Systems

Instead of refering to the standard solution of employing a DAE solver with a step-integrator for solving the DAIE system, a new approach is tested here. A major disadvantage of the step-integration approach is that it prevents the use of simultaneous optimization schemes, which are often faster than sequential approaches. Here, the whole NMPC process model is fully discretized using fourth order Lagrangian collocation on finite elements. Therefore, the approximation of the offset integration of the PID controllers is performed by the integration of Lagrangian polynomials, which shows a reliable integration estimation within the scope of this contribution. This way, a computationally expensive integration of the differential integral algebraic equation system can be avoided and is replaced by an algebraic equation system with only one finite element per 300 seconds, within similar levels of accuracy as the step-integration method. The approximation of the integral of a function f using Lagrangian orthogonal collocation on finite elements is sketched in Eq. (1):

$$\int_0^{t_{fe,cp}} f(\theta)d\theta \approx fdt_{fe,cp} = fdt_{fe-1,cp=4} + \sum_{pol=0}^{4} a_{fe,cp=pol} \cdot Ldt_{pol,cp} \cdot \Delta t_{fe}, \tag{1}$$

wherein fe denotes the current finite element, cp the collocation position, fdt represents the value of the integral, a is the vector of collocation coefficients, Δt_{fe} the length of the current finite element, and $Ldt_{pol,cp}$ is the value of the integral of Lagrange polynome pol at position cp.

4. Implementation

The actual implementation of the RTO-NMPC scheme features a moving horizon estimation (MHE), which consists of a combined data reconciliation and parameter estimation section as well as the estimation of the states. Fig. 2 shows a schematic of the entire implementation. At the topmost level the Real-Time Optimizer minimizes the specific energy required per kilogram of CO_2 removed from the feed stream. The steady state model discussed above make up the bulk of the constraints for the RTO. A few additional constraints are added to keep the optimizer within the valid range of the model and to require the desired CO_2 separation. From the OPC Server, the RTO level acquires the current gas volume flow and feed concentrations to the absorption column. The optimal set points calculated by the RTO, i.e. CO_2 liquid load at the desorption column outlet α_{Des} and scrubbing liquid flow $\dot{m}$ are written to a "File 1", whenever a new optimal solution is found. This file is accessed by both the NMPC level as well as the process control system. For the

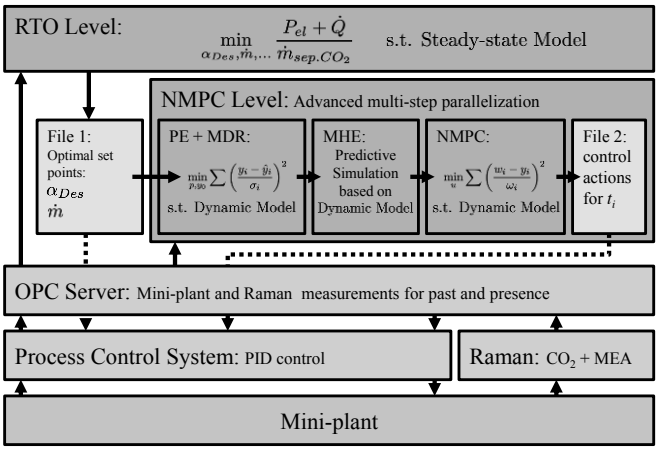

Figure 2: Implementation of the Raman-based RTO-NMPC scheme in the OCM mini-plant.

former $\dot{m}$ sets the window to adjust the liquid feed to the absorption column, for the latter α_{Des} is employed directly as the set-point for the process control system's control circuit "QIC 03".

The NMPC level consists of three separate parts. The first is a combined parameter estimation (PE) and measurement data reconciliation (MDR) section, the second a moving horizon estimation (MHE), and the third the actual nonlinear model predictive control (NMPC). The PE and MDR section has two goals: generate a consistent set of initial conditions for the MHE and further reduce the plant model mismatch by allowing adjustments of model parameters. Among these are the parameters of the correlations describing liquid hold-up of the packings. Based on these results the state of the plant at a time point in the future is estimated using the MHE to reserve time for the solution of the NMPC problem, which in turn minimizes the control offset by plotting a trajectory for the liquid cycle, which is saved in "File 2". The PE and MDR section operates on a time window of 1500 s, the MHE gives an estimation for a time point 300 s later, and the NMPC calculates a trajectory for the next 1200 s. To ensure stability of the entire control scheme, the PID controlers are kept inside the process control system. In addition, redundancy is created at the NMPC level. Every 300 s a new instance of the NMPC level is created as described by Yang and Biegler (2012) and the new control actions are accepted in case the NMPC converges successfully and further reduces the offset.

The content of "File 2" is also read by the process control system and directly translated into control actions for the actuators inside the mini-plant. The Raman spectra are evaluated on an external computer and the results of both carbon dioxide liquid load and MEA concentration model are transferred to RTO and Process Control System via the OPC server. Both "QIC 01" and "QIC 02" run independently from both RTO and NMPC as standard PID control loops on the process control system.

5. Case Study

Parts of the RTO-NMPC implementation discussed above are tested in a mini-plant operation of more than 160 hours. During that time the feed concentrations to the absorption is varied between 5 and 25 mol.-% CO_2, the absorption pressure is set to 5, 10, and 20 bar, and the scrubbing liquid cycle is varied from 30 to 60 kg/h.

The entire process shows a stable performance. Both Raman and IR spectroscopy necessary for

the APC scheme show a robust performance and the feedback time between adjustment of the desorption heating and change in the measured CO_2 liquid load is brief. The NMPC converges within the given time frame and the results of the RTO model show a validity within a range of $\pm$ 5 %. The communication between RTO, NMPC, Process Control System, Raman, and mini-plant is stable, except for a brief crash of the OPC Server, which could quickly be reinitialized. The only other issues, which appeared were a drift of the gas IR used for "QIC 01" and the stability of the parameter estimation inside the NMPC. The drift steadily increased over the operation time to an offset of 10 % of the nitrogen concentration at the gas outlet. The stability of the parameter estimation had to be ensured by quite tight bounds on the parameter values.

6. Conclusions and Outlook

In conclusion, the Raman-based APC has been successfully implemented and shows a robust behavior with respect to the desired minimization of the energy intake. The remaining challenges shall be tackled by improvements to the OPC server scripts and an identifiability analysis of the parameters using a subset selection algorithm. In future work, the Raman measurements shall be extended to more complex amine systems, such as piperazine-activated methyldiethanolamine (aMDEA).

Abstract

The main challenge of the hydrogen production study for the MEC reactor is to obtain a good automatic control system due to the nonlinearity and complexity of the microbial interactions. To address this issue an integrated approach involving process modeling, optimization and advanced control has to be implemented. This work focus on the controller's performance in the control system; neural network (NN)-based and Adaptive-PID controllers. The study has been carried out under optimal condition for the production of bio-hydrogen gas wherein the controller output are based on the correlation of the optimal current and voltage to the MEC. A Ziegler–Nichols tuning method and an adaptive gain technique have been used to design the PID controller, while the neural network controller has been designed from the inverse response of the MEC neural network model.

Keywords: **B**io-hydrogen gas, microbial electrolysis cell, neural network-based controller, adaptive-PID controller.

1. Introduction

Microbial electrolysis cells (MEC) is part of the microbial electrochemical cell technology which is one of the renewable energy alternatives today. MEC operation is based on the fundamental of a bio-electrochemical process and is a promising renewable energy technology that produce hydrogen gas. Anodophilic microorganisms in the anaerobic MEC bioreactor is capable of oxidizing substrates containing organic materials in the cell compartment into electrical energy. Anodophilic microorganisms is able to break the organic material and wastewater that has been diluted at low concentrations of organic compounds. In the MEC system, due to the addition of voltage into the cathode of the anaerobic-bioreactor, the reaction between protons and electrons occur leading to the formation of hydrogen gas (Rozendal et al., 2006 and Logan, 2010).

Bio-hydrogen production process in the MEC is a nonlinear and highly complex system due to microbial interaction. Its complexity makes MEC system difficult to operate and control under optimal conditions. However, these problems can be alleviated using an integrated process system engineering approach, which involves process modelling, optimization and control simultaneously. Artificial neural network (ANN) is an effective technique and a powerful tools to be used in modeling of complex processes and unknown systems. ANNs are able to cope with non-linear process between input and output variables without the requirement of explicit mathematical representation. In process control system, ANNs have been widely used when conventional control techniques did not give good performance (Wang and Wan, 2009; Sridevi et al., 2014).

A novel application of using advanced controller including neural network with adaptive PID has been carried out in the MEC bioreactor. This type of controller has not been reported yet in any MEC reactor application especially on control system performance investigation. This study focuses on the performance of the advanced controller in a feedback control system for controlling the MEC reactor. The comparative study including PID, Adaptive-PID, and neural network model-based controller has been discussed. The controller's performance assessment for regulator and servo cases has been investigated. The analysis was conducted in the presence of noise to imitate the real environment in the process system.

2. MEC Model

This section presents a model for the MEC in a fed-batch reactor, which is a modified model from Pinto et al. (2010). The mathematical models presented here aim to simulate the competition of microbial in the MEC. The model represents competition between anodophilic, acetoclastic methanogenic and hydrogenotrophic methanogenic microorganisms for the substrate (Pinto et al., 2011). The dynamic mass balance equations in the reactor system are given below as follows:

$$\frac{dS}{dt} = -q_{max,a}\frac{S}{K_{S,a}+S}\frac{M_{ox}}{K_M+M_{ox}}x_a - q_{max,m}\frac{S}{K_{S,m}+S} \quad (1)$$

$$\frac{dx_a}{dt} = \mu_{max,a}\frac{S}{K_{A,a}+S}\frac{M_{ox}}{K_M+M_{ox}}x_a - K_{d,a}x_a - \alpha_1 x_a \quad (2)$$

$$\frac{dx_m}{dt} = \mu_{max,m}\frac{S}{K_{A,m}+S} - K_{d,m}x_m - \alpha_1 x_m \quad (3)$$

$$\frac{dx_h}{dt} = \mu_{max,h}\frac{H_2}{K_h+H_2} - K_{d,h}x_h - \alpha_2 x_h \quad (4)$$

$$Q_{H_2} = Y_{H_2}\left(\frac{I_{MEC}}{mF}\frac{RT}{P}\right) - Y_h\mu_h x_h V_r \quad (5)$$

$$-E_{applied} = E_{CEF} - \eta_{ohm} - \eta_{conc} - \eta_{act} \quad (6)$$

$$I_{MEC} = \frac{E_{CEF}+E_{applied}-\frac{RT}{mF}ln\left(\frac{M_{Total}}{M_{red}}\right)-\eta_{act,C}(I_{MEC})}{R_{int}} \quad (7)$$

where S is the substrate concentration; x_a, x_m, and x_h are the concentration of the anodophilic, acetoclastic, and hydrogenotrophic microorganisms, respectively; Q_{H_2} is the hydrogen production rate (mL/day); $E_{applied}$ is the electrode potentials (V) and I_{MEC} is the MEC current (A).

3. Controller Design

3.1 Adaptive-PID controllers

Adaptive-PID controller is able to control the system dynamics in the event of a non-nominal process condition. Consider the MEC process model given by:

$$y(k) = A_1 x(k-1) + A_2 x(k-2) + [B_1 u(k-1) + B_2 u(k-2)]u(k) \quad (8)$$

For the case at nominal condition, A_i and B_i for i = 1, 2, and 3 are known through least-square regression technique. The control action is derived as:

$$u(k) = \frac{K_P\left[e(k)+\frac{1}{\tau_I}\int_0^t e(k)dt+\tau_D\frac{d}{dt}e(k)\right]- A_1 x(k-1)+ A_2 x(k-2)}{B_1 u(k-1)+ B_2 u(k-2)} \quad (9)$$

The block diagrams show the method of adaptive PID as in Figure 1.

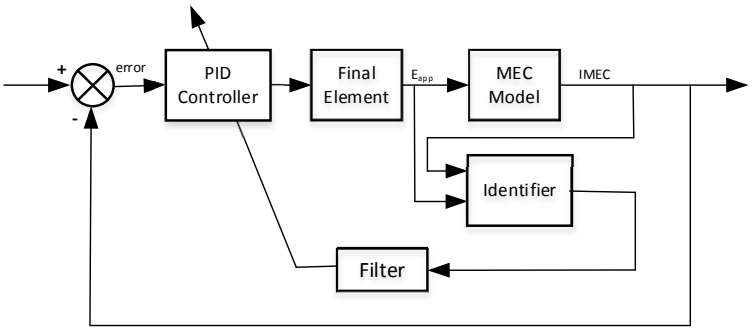

Figure 1. Block diagram of PID-Adaptive gain closed loop design

3.2 Neural network controllers

The NNs controller concept refers to the inverse response of the open loop MEC process. The diagram of the controller and control strategy are shown in Figure 2. In this case, the neural network model is trained to predict the required manipulated variable, Electrode potential $(\mathrm{E_{applied}})$ with the given desire of set-point, MEC current $(\mathrm{I_{MEC}})$.

3.3 Training and Forward Modelling

The forward NNs modeling refers to the open loop response of the MEC process. The networks have been trained to obtain the weights of every node and map the dynamic response of the input-output open loop dataset. The dataset is collected through a moving window approach. The model is made of 14 input nodes; the input nodes consist of data for substrate (S), anodophilic microorganisms (x_a), acetoclastic microorganism (x_m), ammonium nitrogen (x_h), oxidized mediator fraction (M_{ox}), MEC current (I_{MEC}) and the single output node is electrode potentials ($\mathrm{E_{applied}}$).

3.4 Inverse modelling and NNs Controller

However, inverse NNs modelling are the opposite of open loop response which can be used as an ideal controller inside the control system. Inverse model is designed similar to the forward modeling approach. The 14 inputs node and single manipulated output

variable has been selected; $S_{(t)}$, $S_{(t-1)}$; x_a *i.e.* $x_{a(t)}$, $x_{a(t-1)}$; x_m *i.e.* $x_{m(t)}$, $x_{m(t-1)}$; x_h *i.e.* $x_{h(t)}$, $x_{h(t-1)}$; M_{ox} *i.e.* $M_{ox(t)}$, $M_{ox(t-1)}$; I_{MEC} *i.e.* $I_{MEC(t)}$, $I_{MEC(t+1)}$, $I_{MEC(t-1)}$ and output node is the electrode potentials ($E_{applied}$) respectively. The detail network architecture for NNs controller development can refer to Hussain and Mujtaba, 2001.

4. Neural Network Controller Scheme

4.1 Multiple set-point tracking study

In this work, we perform multiple set-point tracking study when the I_{MEC} current has been maintained at the optimal operation value of 0.16 A. Figure 2 shows the comparison of conventional PID, adaptive-PID, and neural networks model-based controllers. Figure 2 shows good tracking performance for neural network controllers. The controlled variable follows the given set points and the result show reasonable control performance. Neural networks controller gives no overshoot compare to the others controller. However, PID controller shows the largest overshoot and longest settling time which indicates the conventional controller is not suitable to be applied in the MEC process. Meanwhile, adaptive-PID controller shows an adaptation progress which the overshoot and settling time performance are improving over time.

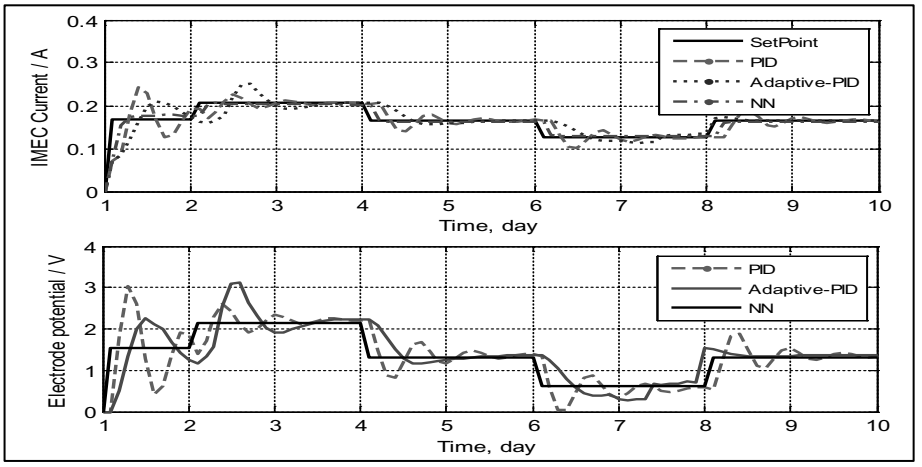

Figure 2**.** Comparison of controlling for set point tracking

The neural network model-based controller can provide better control for the MEC system compared with the conventional PID and adaptive-PID controller.

4.2 Disturbance rejection

Figure 3 shows the control performance comparison of the conventional PID, adaptive-PID and neural network model-based controllers for servo and regulator cases. The disturbance has been generated by changing the counter-electromotive force from the nominal value (from 0.15 V to 0.35 V). Based on Figure 3, all controllers show good performance but the neural network model-based controller is better compare to the rest. However, small offset has been observed from NNs controller and this offset can be compensated by introducing integral effect inside the NNs structure.

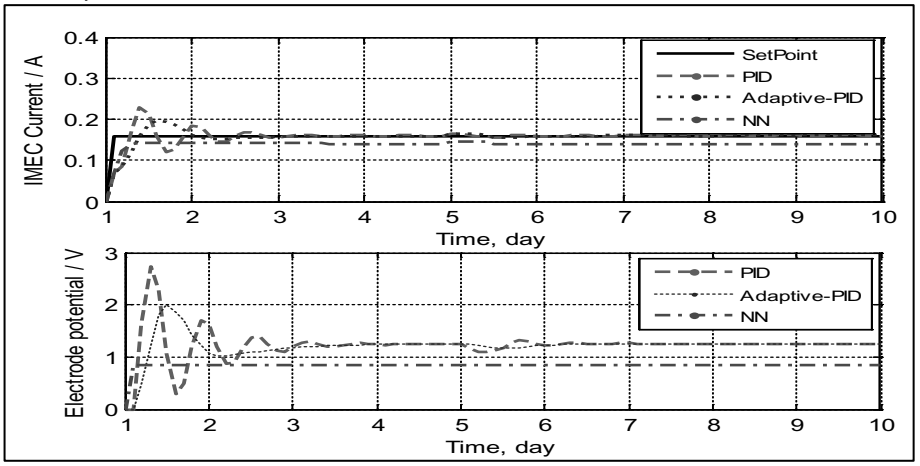

Figure 3. Control performance under disturnabce rejection

4.3 Measurement noise

Figure 4 shows the controller performance with the presence of noise under nominal operating conditions. The noises source are assumed from measurement element inside MEC system. NNs controller responses are more stable with less oscillations compared to the conventional PID and adaptive-PID gain controllers.

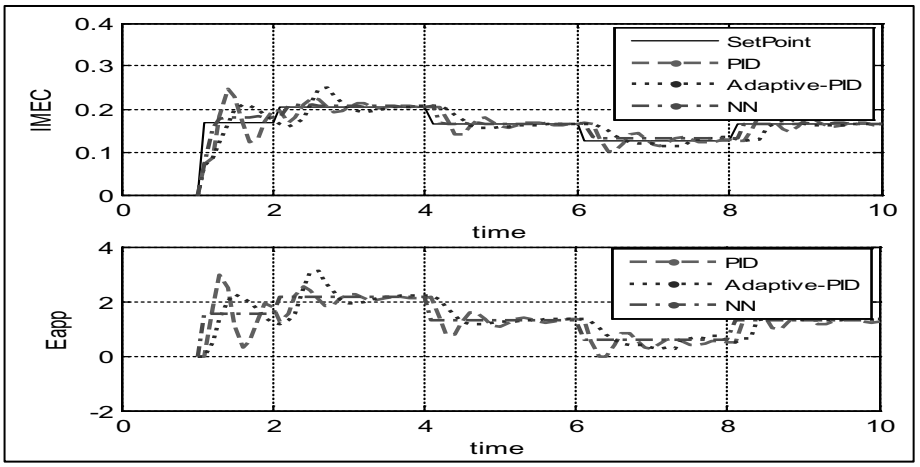

Figure 4. Control performance with measurement noise

In summary, the MEC reactor can be controlled to give an optimum current set-point (simultaneously an optimal hydrogen production rate) using the conventional PID, adaptive-PID and neural network model-based controller. However, the NNs model-based controller is able to give more robust performance compared to this PID and adaptive-PID gain controllers.

5. Conclusions

In this paper, a novel approach for implementing an advanced (NNs) controller for MEC system has been carried out. A comparative study for MEC with various simulation cases involving multiple set-point, disturbance rejection and noise measurement has been achieved. The NNs controller gives fast settling time response, less overshoots, and minimal offset. Thus, NNs controller performances surpass the other types of controller and performs better in all the simulation cases.

Abstract

In this work, methods for on-line monitoring of the setting reaction of magnesium potassium phosphate ceramic (MKPC) were developed. To this aim, multivariate statistical techniques combined with *in-situ* synchrotron X-ray powder diffraction (XRPD) enabled a fast, real time and reliable analysis of the phenomena occurring even in complex systems as investigated here. Thus, Multivariate Curve Resolution - Alternating Least Squares (MCR-ALS) was employed together with Evolving Factor Analysis (EFA). Comparison with conventional methods for describing reaction kinetic, namely, integrated area of selected diffraction peak for the crystalline phases, show that compounds involved in the process can be correctly distinguished and the main reaction steps, such as reactants consumption, occurrence of intermediate amorphous phase and finally MKPC formation can be clearly identified.

Keywords: reaction monitoring, Multivariate Curve Resolution, ceramic materials.

1. Introduction

Recently, on-line monitoring has become essential for process understanding, particularly in the case of evolving systems where reaction mechanisms and physical phenomena are not completely understood. With this regard, spectroscopic measurements represent a powerful tool for the on-line process monitoring that can provide more information about specific chemical features of the process, such as concentration changes of reacting species. The main drawback in most of the cases is the need of mathematical recipes capable of correlating the raw data gathered in the experiment to informative data. Here, multivariate procedures were implemented to investigate reaction and setting mechanism of MKPC. MKPC is a chemically-bonded ceramic (Wagh, 2004) attractive for applications like waste encapsulation, bone repair, natural fibre composites. When MgO reacts with potassium di-hydrogen phosphate (KDP) in solution, formation of K-struvite (MKP) occurs: $MgO + KH_2PO_4 + 5H_2O = MgKPO_4 \cdot 6H_2O$. Several mechanisms for this reaction have been proposed, but kinetic studies are scarce and none of them provided quantitative data (Ding et al., 2012). Moreover, there are experimental evidences that, besides crystalline MKP, an amorphous phase also forms which can be considered as a precursor of the crystalline

MKP. At the current state of knowledge, the nature of this amorphous phase remains unexplained. Recent kinetic synchrotron diffraction experiments (Viani et al., 2014b) allowed for the description of the reaction as being initially controlled by the dissolution of MgO in aqueous solution to form an intermediate product accumulating at the grain surface. This thickening layer hindered further diffusion of water shifting the mechanism towards a diffusion control one. MKP crystallization reaction was modeled using an Avrami model followed by a first order chemical reaction, as water is available at the interface of the intermediate layer, and K+ and PO_4^{3-} ions readily migrate through the open structure of elongated MKP crystals. Such interpretation should be supported by further evidences since, conventional analysis of X-rays diffraction data allows to evaluate only the crystalline components.
In this work, we propose a procedure based on multivariate techniques, namely the MCR-ALS combined with the EFA algorithm, in order to enable the interpretation and the investigation of the reaction mechanisms and detect the different species involved.

2. Experimental

2.1. Sample preparation

MgO powder obtained by calcination of $MgCO_3$ at 1400°C was mixed with KDP by hand in agate mortar at unity molar ratio and then placed in a capillary 0.7 mm in diameter opened on both ends. The powder was laterally confined between 2 small layers of quartz wool, allowing for the water to flow through the capillary. The capillary was mounted on a goniometric head for data collection with one end connected to a vacuum pump. Water was introduced on the other end, but initially not in contact with the powders. After starting data collection, operating the vacuum pump, the water was gently allowed to flow through the capillary wetting the powder and defining the start of the experiment. The whole process was followed through a high resolution camera. The advantage of such experimental setup, described in more detail elsewhere (Conterosito et al., 2013), is that the reaction can be monitored from the very beginning. The downside was that no exact control on the water/solid ratio was possible.

2.2. XRPD measurements

Data were collected at 20 °C at the beamline BM01a, European Synchrotron Radiation Facility (ESRF), Grenoble (France), employing a wavelength of 0.6895 Å with the pilatus 2M detector (Dectris). The reaction was followed for 111.23 min collecting four scans/min allowing the capillary to swing on its axis of 60 °. Each spectrum was recorded covering a 2θ range 0.97 ° - 43.82 ° with a resolution of 0.0146 °2θ. Eventually, each spectrum $\mathbf{d}^{i}_{(1\times J)}$ recorded at the i-th time (i = 1,… I) can be arranged into a matrix $\mathbf{D}_{(I\times J)}$ representing the I experimental patterns collected at the different J diffraction angles 2θ.

3. Methods

The classical approach to the analysis of decomposition of the reactants and crystallization of MKP implies the integration of the area under Bragg reflection peaks for each one of the phases, their normalization to phase fraction (α) and plot as α vs. time curves. This procedure is time consuming, and is thus usually limited to only one peak for each phase. Furthermore, it requires the preliminary knowledge of each powder pattern in order to exclude the overlap of peaks from different phases that otherwise adversely affects the kinetic interpretation.

Here, the MCR-ALS approach is investigated as a viable alternative to the conventional one. Such technique decomposes the experimental $\mathbf{D}_{(I\times J)}$ matrix in two matrices $\mathbf{C}_{(I\times M)}$ and $\mathbf{S}^{T}_{(M\times J)}$ (de Juan et al., 2009) according to equation (1).

$$\underset{(I\times J)}{\boldsymbol{D}} = \underset{(I\times M)}{\boldsymbol{C}} \cdot \underset{(M\times J)}{\boldsymbol{S^T}} + \underset{(I\times J)}{\boldsymbol{E}} \quad (1)$$

Equation (1) can be considered as the extension of the Lambert–Beer's law in matrix form: **C** is the estimated concentration profile for *M* components; **S** is the matrix representing the estimated spectra for the *M* components. The goal of MCR-ALS is to find iteratively the proper matrices **C** and **S** through the Alternating Least Squares optimization procedure starting from a suitable initial guess $\mathbf{C}^0$ for **C** (or alternatively **S**). During the ALS optimization, several (physical) constraints (e.g. non-negativity, unimodality, mass balance closure) should be applied in order to convey the algorithm towards the most proper estimation of the **C** and **S** profiles. A drawback of MCR-ALS is the lack of ability to separate compounds that behave together (kinetically) in the same manner (e.g. more reactants that decrease together over the time and/or unreacted compounds). Therefore, the method could not lead to the detection of the actual chemicals but may represent a mixture of chemicals appearing in each estimated spectrum $\mathbf{s}^{m}_{(1\times J)}$ (m=1,…,*M*).

In order to improve the performance of the procedure for a more effective separation of the different real compounds in the system, a novel procedure was here adopted and briefly described in the following:

1. EFA algorithm was implemented in order to find the initial estimate $\mathbf{C}^0$ of matrix **C** (De Juan et al., 2004);
2. MCR-ALS was performed and matrices $\mathbf{C}^1$ and $\mathbf{S}^1$ were evaluated.
3. The *pure compounds* diffractograms $\mathbf{S}^2$, were then estimated again with the MCR-ALS procedure by considering an initial guess spectra matrix $\mathbf{S}^{20}$ obtained in the following way: (i) the matrix $\mathbf{S}^1$ is decomposed taking into account the theoretical patterns available from database and (ii) a baseline correction was applied on the resulting diffractograms;

The procedure was implemented with a in-house written Matlab® code and MCR-ALS and EFA algorithms developed by Jaumot et al. (2005).

4. Results and discussion

4.1. Experimental spectra

By comparing XRPD patterns over the time with theoretical ones, three significant changes were identified (dissolution of reactants, amorphous phase formation and growth of MKP crystals) as depicted in figure 1: (i) at t= 0 the spectrum is characterized by a linear combination of the MgO and KDP patterns (Figure 1.a); (ii) at $t\approx$2.6 min broad peaks appear at 1.4 and 13 ° 2θ (Figure 1.b), probably due to the presence of an amorphous phase, in the meantime KDP and MgO begin to dissociate in solution; (iii) at $t\approx$5 min, contribution of the KDP spectra disappears and only magnesia and amorphous phase are present (Figure 1.c); (iv) at $t\approx$15 min MKP crystals start to grow (Figure 1.d); (v) from $t\approx$30 to 111 min (end of the experiment) spectra do not exhibit important changes (Figure 1.e). It should be noticed that MgO is not completely consumed since the reaction is controlled by diffusion as already mentioned in the introduction.

For the forthcoming analysis, data collected in the angular region 1-6 ° 2θ are removed because of the strong contribution coming from incoherent scattering from water. Furthermore spectra collected after 35 min will be not considered because they do not show significant changes. Thus the final data set will be arranged in a matrix $\mathbf{D}_{(80\times 1295)}$.

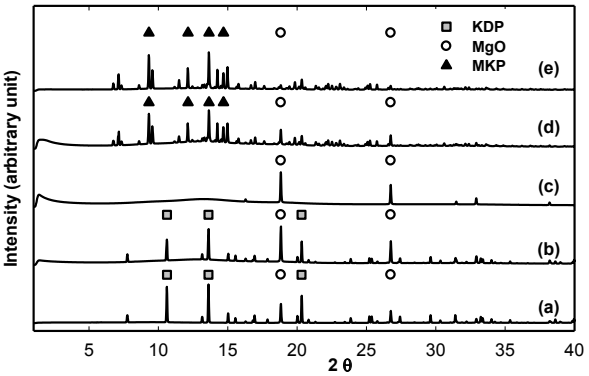

Figure 1. Representative raw spectra at different times: (a) 0 min, (b) 2.6 min, (c) 5 min, (d) 15 min and (e) 30 min. White circles, gray squares and black triangles represent the main characteristic patterns of MgO, KDP, MKP, respectively.

4.2. Data processing

Data processing was performed according to the recipe introduced in section 3.

Step 1: initial estimate $\mathbf{C}^0$ was calculated with the EFA algorithm and reported in Figure 2. It was found that three components adequately capture most of the variance of the matrix **D** and they might be reasonably associated to the following three steps: (i) reactants consumption, (ii) development of intermediate species, (iii) product formation;

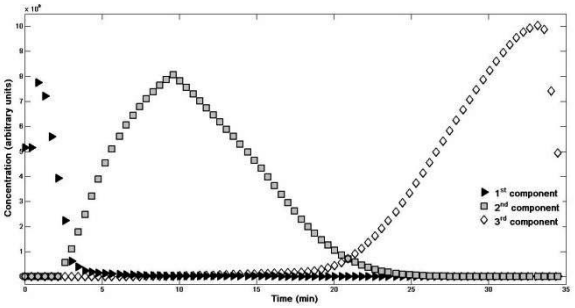

Figure 2. Concentration profiles estimated through EFA algorithm. First component: (►); second component: (■); third component: (◊).

Step (2) matrices $\mathbf{S}^1_{(1295\times3)}$ and $\mathbf{C}^1_{(80\times3)}$ are then evaluated through the MCR-ALS algorithm;

Step (3): spectra $\mathbf{S}^1$ evaluated by MCR, were compared with the theoretical patterns of the pure compounds. It was found that the three spectra correspond to: (i) MgO plus KDP; (ii) MgO and an undefined intermediate species (likely corresponding to the amorphous phase); (iii) MKP and MgO. Therefore, MgO contribution was present in all the $\mathbf{S}^1$ spectra, since it does not react completely. Eventually, four compounds spectra were determined and arranged in the matrix $\mathbf{S}^{20}$.

However, the protocol requires further refinements because of the presence of unreacted species (for the case at hand MgO) that may degrade the effectiveness of the MCR-ALS procedure. For this purpose, the contribution of unreacted MgO diffractogram $\mathbf{d}_{\mathbf{MgO}}$ observed at the end of the experiment was subtracted from the raw matrix **D**. The goal is to obtain a new data set $\mathbf{D}^R$ where $\mathbf{d}^{\mathbf{R}}_{\mathbf{i}}=\mathbf{d}_{\mathbf{i}}-\mathbf{d}_{\mathbf{MgO}}$ (i=1,..,80) where unreacted species are filtered out from the analysis. The matrix $\mathbf{D}^R$ and $\mathbf{S}^{20}$ are then used as input in the MCR-ALS that provides eventually the estimation of the spectra $\mathbf{S}^2$ and $\mathbf{C}^2$. Figure 3 shows

the $\mathbf{S}^2$ spectra together with the main theoretical patterns of the MgO, KDP and MKP. It can be concluded that the first three estimated spectra agree very well with the theoretical patterns of MgO (Figure 3.a), KDP (Figure 3.b), MKP (Figure 3.c), respectively. In addition a spectrum for the intermediate phase is also provided (Figure 3.d). Nevertheless, a perfect separation among the compounds had not been achieved, and this may affect the prediction of the related concentration.

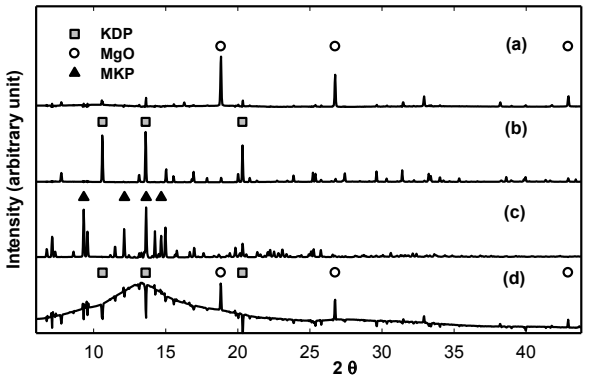

Figure 3. Evaluation of $\mathbf{S}^2$ spectra. White circles, gray squares and black triangles indicate MgO, KDP, MKP main patterns respectively.

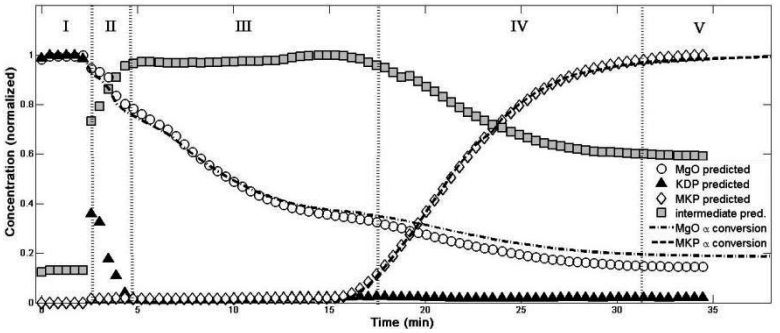

Figure 4. Normalized concentration profiles: MgO (○), KDP (▲), MKP (◊) and amorphous phase (■) are reported. Dashed and dashed-dotted lines represent the estimated α conversion of MKP and MgO, respectively.

Figure 4 shows the concentrations $\mathbf{c}_m^2$ (m=1,…,4) calculated with the proposed procedure and normalized with respect to its maximum value. Moreover the α conversion values obtained from the conventional kinetic analysis (Banford et al., 1980) are also reported for sake of comparison. It is observed a really good agreement between the concentration profiles estimated with the MCR-ALS procedure and the conventional one. It's worth noting that MCR-ALS provides an additional third component, whose contribution comes from the non-crystalline fraction. Its behavior is coherent with previous observations showing a quick formation of an amorphous fraction at the initial stage of the reaction with the subsequent conversion into crystalline MKP (Viani et al., 2014a). Thus, a reliable description of reaction dynamics is achieved. In fact, according to spectra analysis in section 4.1, five regions can be identified in figure 4:

1. *t*= 0÷2.6 min: MgO and KDP are at the maximum values, while the amorphous phase starts from value greater than zero, likely due to the water scattering;
2. *t*=2.6÷5 min: KDP rapidly disappears as dissolves in solution, meanwhile the amorphous phase quickly increases reaching its maximum;
3. *t*=5÷15 min: amorphous phase concentration stays constant, in the meantime MgO keeps dissolving in solution;
4. *t*=15÷30 min: at t=15 min the onset of MKP crystallization and decrease of the amorphous phase are evident;
5. *t*>30 min: a flattening out of the amorphous decay and crystal growth rate is observed and no significant changes in the system are appreciated. This is probably due to a change in mechanism or a diffusion barrier emerging as reaction progresses.

5. Conclusions

In this paper *in situ* x-ray diffraction measurements are used to monitor the K-struvite formation. A procedure based on the MCR-ALS method combined with the EFA algorithm is here proposed to analyse the XRPD data. The main benefits of the algorithm with respect to the traditional analysis are summarized below: (i) it exploits the whole information gathered from data rather than focusing on a limited number of peaks; (ii) it appears less time consuming; (iii) it allows for the detection of the non-crystalline component, otherwise not considered. Thus, the reaction processes are well described and identified. The results here reported demonstrate that the MCR-ALS-EFA method could be a promising framework for generalized treatment of X ray diffraction data and encourage its implementation for the on-line process monitoring. The goals might be: (i) to ensure the achievement of the optimal end-product specifications and (ii) to detect in real time deviations from the nominal process conditions.

Abstract

In multivariate statistical process monitoring (MSPC), isolation of faulty variables is a critical step to discover the source of the detected fault. Although fault detection methods have been intensively investigated, studies on fault isolation are relatively limited, due to the difficulty in analyzing the influences of multiple variables on monitoring statistics. To solve the problems of the existing methods, this paper proposes to conduct fault isolation via a lasso-based penalized discriminant analysis technique. Instead of just offering a suggested set of faulty variables, the proposed method provides more information on the relevance of process variables to the detected fault, which facilitates the subsequent root cause diagnosis step after isolation. The benchmark Tennessee Eastman (TE) process is used as a case study to illustrate the effectiveness of the proposed method.

Keywords: fault isolation, multivariate statistical process monitoring, lasso, discriminant analysis, variable selection.

1. Introduction

For ensuring the safe and efficient operation of manufacturing and chemical industries, multivariate statistical process monitoring (MSPM), which extracts process information from historical operating data, is becoming increasingly important. According to (Chiang *et al.*, 2004), the procedure of MSPM can be summarized into four steps: fault detection, fault isolation, fault diagnosis, and process recovery. The purpose of fault detection is to recognize process abnormality, while fault isolation is for the identification of the variables contributing most to the process faults. Although fault detection methods have been intensively investigated, studies on fault isolation are relatively limited, due to the difficulty in analyzing the influences of multiple variables on monitoring statistics.

For the isolation of faulty variables, contribution plots (Westerhuis *et al.*, 2000) are the most popular tools. Although easy to use, contribution plots often suffer from the "smearing" effect, i.e. the influence of faulty variables on the contributions of non-faulty variables, yielding misleading results (Qin, 2003). The reconstruction-based approaches are also widely used, which re-calculate the values of process variables and monitoring statistics along certain candidate "fault directions" (Dunia and Qin, 1998). A critical assumption for fault reconstruction is that the candidate fault directions are assumed to be known or estimated from sufficient historical fault data, which may not be realistic in real industries. In addition, the unknown faults cannot be handled well by

the reconstruction-based approaches. The reconstruction-based contribution (RBC) was proposed to deal with both known and unknown faults (Alcala and Qin, 2009). However, the smearing effect can still be observed in the RBC plots. To overcome the drawbacks of the reconstruction-based approaches, the branch and bound (BAB) algorithm was combined with the missing variable approach to address the fault isolation problem by solving a combinatorial optimization problem (He *et al.*, 2012). Although BAB is relatively efficient in solving the combinatorial optimization problem, the computational burden of this approach is still heavy, especially for a process with a massive number of variables. As a result, it is difficult to be applied in online process monitoring. In addition to the methods mentioned above, discriminant analysis methods, such as Fisher discriminant analysis (FDA) and support vector machine (SVM), have also been utilized for fault classification, e.g. (Chiang *et al.*, 2004). After a fault is detected, the fault type can be determined by calculating the similarity between the new data and each group of known event data, if sufficient fault data are available in historical database. However, it is unusually to have a complete dataset containing all types of faults. In such situation, the unknown fault may not be isolated.

To solve the mentioned problems of the existing methods, this paper proposes to conduct fault isolation via a lasso-based penalized discriminant analysis technique. Unlike the conventional fault classification, the historical information about the process faults is not needed in the proposed method. Instead, the variables contributing most to the detected fault are automatically selected by solving a penalized discriminant analysis problem formulated in a form of the least absolute shrinkage and selection operator (lasso) (Tibshirani, 1996). Since the lasso can be solved efficiently using state-of-the-art algorithms, heavy computational burden is avoided. In addition, as discussed in (Liu *et al.*, 2014), although the contribution values of process variables follow a certain distribution in the normal operating condition (NOC), the contributions of fault-free variables usually not following the same distribution when a fault occurs. Therefore, it is improper to offer a suggested set of faulty variables based on the control limits derived from normal operating data. In this paper, the proposed method provides more information on the relevance of process variables to the detected fault, which facilitates the subsequent root cause diagnosis step after isolation.

2. Lasso-based penalized discriminant analysis for fault isolation

2.1. Motivations

The basic idea of this paper can be expressed roughly as follows. As mentioned in previous, the goal of fault isolation is to identify variables responsible for the detected process abnormality. In other words, the variables to be isolated are those discriminating the normal process measurements and the fault samples. In a sense, isolating faulty variables is equivalent to identifying discriminating variables in a two-class problem, with the normal operation data regarded as belonging to one class and the data associated with the detected fault as belonging to the other class. Therefore, the task of fault isolation can be transformed into a variable selection problem in discriminant analysis.

In the following of this paper, such problem illustrated using the famous Fisher Discriminant analysis (FDA) technique and solved in a framework of penalized optimization. In previous research, it has been well established that an FDA model can be transformed identically to a least squares regression model with predictors and

response variable chosen properly (Duda *et al.*, 2012). Consequently, the task of identifying discriminating variables is accomplished by doing variable selection for a regression model. In the field of variable selection, the lasso is a promising technique, which minimizes the residual sum of squares under a constraint on the L1-norm of the coefficient vector. By doing so, the lasso tends to produce a number of zero coefficients enforcing sparsity in the solution, and thereby conducts parameter estimation and variable selection simultaneously. The lasso problem can be solved efficiently using a least-angle regression (LARS) algorithm (Efron *et al.*, 2004).

2.2. Relationship between Fisher's linear discriminant and regression analysis

Suppose $\Xi_1 = \{\mathbf{x}_1^1, \cdots, \mathbf{x}_{n_1}^1\}$ and $\Xi_2 = \{\mathbf{x}_1^2, \cdots, \mathbf{x}_{n_2}^2\}$ contain samples from two different classes and $\Xi = \Xi_1 \cup \Xi_2 = \{\mathbf{x}_1, \cdots, \mathbf{x}_n\}$. Fisher's linear discriminant is defined by the vector $\boldsymbol{\omega}$ which maximizes

$$J(\boldsymbol{\omega}) = \frac{\boldsymbol{\omega}^T \mathbf{S}_B \boldsymbol{\omega}}{\boldsymbol{\omega}^T \mathbf{S}_W \boldsymbol{\omega}}, \tag{1}$$

where

$$\mathbf{S}_B = (\mathbf{m}_1 - \mathbf{m}_2)(\mathbf{m}_1 - \mathbf{m}_2)^T, \tag{2}$$

$$\mathbf{S}_W = \sum_{i=1,2} \sum_{\mathbf{x} \in \Xi_i} (\mathbf{x} - \mathbf{m}_i)(\mathbf{x} - \mathbf{m}_i)^T \tag{3}$$

are the between and within class scatter matrices respectively and $\mathbf{m}_i = \frac{1}{n_i} \sum_{j=1}^{n_i} \mathbf{x}_j^i$ are the sample means. By solving the objective function, FDA finds a projection direction maximizing the separation of class means while minimizing the within-class variance, where

$$\boldsymbol{\omega} \propto \mathbf{S}_W^{-1}(\mathbf{m}_1 - \mathbf{m}_2). \tag{4}$$

In order to link the least squares regression solution to FDA, define a predictor matrix

$$\mathbf{X} = \begin{bmatrix} \mathbf{1}_1 & \mathbf{X}_1 \\ -\mathbf{1}_2 & -\mathbf{X}_2 \end{bmatrix}, \tag{5}$$

where $\mathbf{1}_i$ is a column vector containing n_i ones, and $\mathbf{X}_i$ is a matrix whose rows are the samples belonging to Ξ_i. Define a response vector $\mathbf{y}$ as

$$\mathbf{y} = \begin{bmatrix} \frac{n}{n_1}\mathbf{1}_1 \\ \frac{n}{n_2}\mathbf{1}_2 \end{bmatrix}. \tag{6}$$

For a least squares regression problem $\mathbf{X}\boldsymbol{\beta} = \mathbf{y}$, the regression coefficient vector $\boldsymbol{\beta}$ can be obtained by minimizing the residual sum of squares (RSS). Denote $\boldsymbol{\beta} = \begin{bmatrix} W_0 \\ \boldsymbol{\omega} \end{bmatrix}$, where W_0

is the coefficient corresponding to the first column in **X** and the vector **ω** contains the remaining coefficients. Then, it can be proved that **ω** has the same form as in Eq.(4), i.e. the solution of the least squares regression problem is identical to that of FDA.

2.3. Lasso for fault isolation

Since an FDA model can be transformed identically to a least squares regression model, the lasso, which is a penalized regression method, can be adopted to solve the variable selection problem in discriminant analysis. Different from the ordinary least squares (OLS), the lasso minimizes a penalized RSS by introducing an L1 penalty term into the objective function:

$$\min_{\boldsymbol{\beta}}((\mathbf{y}-\mathbf{X}\boldsymbol{\beta})^T(\mathbf{y}-\mathbf{X}\boldsymbol{\beta})+\lambda\|\boldsymbol{\beta}\|_1), \tag{7}$$

where $\|\boldsymbol{\beta}\|_1$ represents the L1-norm of $\boldsymbol{\beta}$ and λ is a tuning parameter. A larger λ usually results in fewer non-zero predictors. There exists a finite sequence: $\lambda_0 > \lambda_1 > \cdots > \lambda_K = 0$. For $\lambda > \lambda_0$, all regression coefficients β_j^λ are shrunk to zero, where β_j^λ is the j-th entry of $\boldsymbol{\beta}$ calculated by solving the optimization problem in Eq.(7). In each interval $(\lambda_{k+1}, \lambda_k)$, the active set $\Gamma(\lambda)=\{j:\mathrm{sgn}[\beta_j^\lambda]\neq 0\}$ and the sign vector $S(\lambda)=\{\mathrm{sgn}[\beta_1^\lambda],...,\mathrm{sgn}[\beta_m^\lambda]\}$ do not change with the value of λ, where $0 \le k \le K-1$ and m is total number of predictors. These λ_k are called transition points. The LARS algorithm (Efron *et al.*, 2004) can be adopted to produce the transition points step by step and obtain the lasso solutions with a similar computational cost to that of OLS.

On the basis of the lasso, the proposed fault isolation procedure is summarized as follows.

1. After a fault is detected, the process data associated with the fault are stored in Ξ_2, while Ξ_1 consists of the historical normal operating data. Without loss of generality, it is assumed that the data have been normalized properly.
2. Construct the predictor matrix **X** and the response vector **y** according to Eq.(5) and Eq.(6).
3. Start with $k = 0$.
4. Set $\lambda = \lambda_k$ and solve the penalized optimization problem described in Eq.(7). The active set $\Gamma(\lambda)$ is achieved.
5. Update $k = k + 1$ and return to step 4, until $\lambda = \lambda_K = 0$.

The order of the process variables appearing in the active set indicates the relevance of the variables to the detected fault. The earlier a variable enters the active set, the more relevant it is. Such information is useful for the subsequent root cause diagnosis step.

3. Case study

In this section, the effectiveness of the proposed fault isolation method is illustrated using the Tennessee Eastman (TE) benchmark process. In the TE process, process data are collected from 41 measured variables and 11 manipulated variables. 20 different types of faults can be simulated. In each fault dataset, the abnormal event is triggered after the 160th sampling interval. More details about the TE process can be found in (Downs and Vogel, 1993).

For illustration, the isolation results of Fault 4 and Fault 5 are introduced. Fault 4 was caused by a step change in the reactor cooling water inlet temperature, which would directly influence the reactor temperature x_9. When the fault occurred, a sudden temperature increase happened in the reactor. Then the feedback controller actioned by adjusting the reactor cooling water flow rate x_{51}. Since such control action is efficient, x_9 returned towards its normal state as shown in Fig. 1, while x_{51} reached a new steady-state value. Other process variables were not affected. Since the steady-state fault signature is informative for root-cause diagnosis, the fault isolation was conducted based on the last 25 observations. Fig. 2 shows the regression coefficients changing with the tuning factor λ, which indicates the isolation results. It is clear that x_{51} is the variable entering the active set first, i.e. the variable most responsible to the fault. The second important variable is x_9.

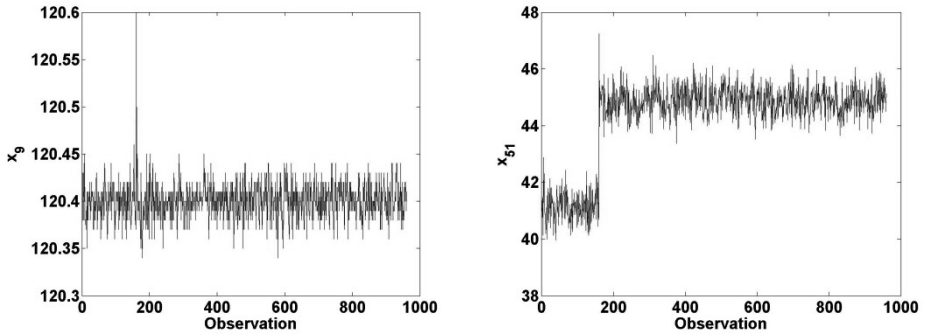

Figure 1. Process variable trajectories for Fault 4

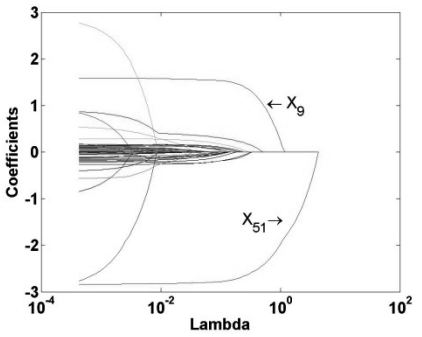

Figure 2. The isolation result for fault 4

Fault 5 was due to a step change in the condenser cooling water inlet temperature. To compensate the effect of such change, the condenser cooling water flow rate x_{52} would be adjusted by the feedback controller. Therefore, when the process reached a new steady-state, x_{52} would not return to its original state. Fig. 3 displays the trajectory of such variable, while Fig. 4 shows the regression coefficients changing with the tuning factor λ. Again, such results are obtained based on the steady-state fault data. According to Fig. 4, x_{52} is considered as the most indicative faulty variable, which is consistent with the process knowledge. The missing data analysis approach based on BAB (He *et al.*, 2012) was also conducted for comparison, which cannot reveal the abnormal variable x_{52}. The second potential faulty variable is x_{18}, which is found to be normal

after further investigation. Therefore, x_{52} is the only abnormal variable in this case, which should be analyzed carefully to reveal the root cause of the fault.

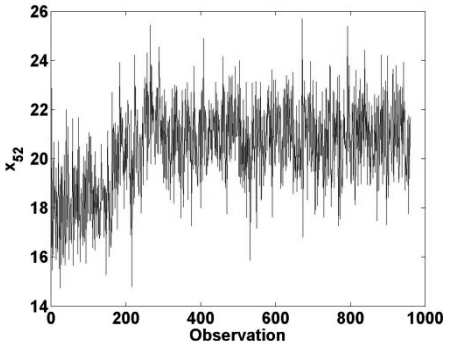

Figure 3. Variable trajectory for Fault 5

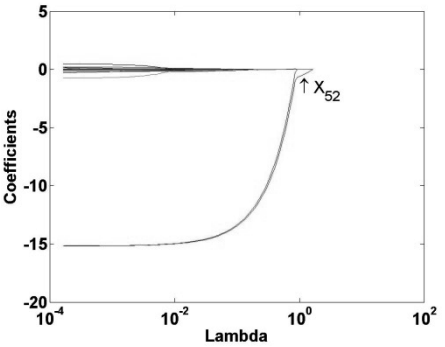

Figure 4. The isolation result for fault 5

4. Conclusions

Isolating faulty variables is a critical step to discover the source of the detected fault. In this paper, the task of fault isolation is transformed to a variable selection problem in discriminant analysis. The lasso approach is adopted to solve such problem. The proposed method does not need any historical fault data or known fault directions, and provides richer information than the conventional methods.

Abstract

In this work, a dynamic rate-base model is used to describe CO_2 capture process in aqueous solution of MEA. The model has been implemented in the Matlab/Simulink software in order to do a part-load analysis and elaboration of control strategies of carbon capture process to be used within a power plant. The experimental results published in literature for Esbjerg CESAR pilot plant are used to validate the developed model. A good correlation between absorber's temperature profiles obtained by simulation and experiment was observed, R-squared value is of 0.936 in case of liquid's temperature and of 0.965 for gas's temperature. From environmental protection perspective, the primary control objective for the absorption column is the control of the carbon dioxide concentration in the sweet gas stream. Typical disturbances have been investigated, such as the step/ramp/sinusoidal increment in the flue gas flow rate with respect to its nominal operating point. Two different scenarios have been investigated using both the classical and the advanced control strategy approaches. The simulation results revealed that both PI and MPC controllers were capable to maintain the controlled gaseous mixture close to its imposed set point, rejecting the flue gas flow rate disturbance. Moreover, the MPC is capable to perform efficient control while conforming to constraints imposed on the maximum allowed value of the outlet CO_2 gas concentration and improving the CO_2 capture efficiency.

Keywords: CO_2 capture process, Dynamic rate-base model, Part-load analysis, MPC and PI control strategy.

1. Introduction

In order to reduce CO_2 emissions from flue gases produced by the power generation or other energy-intensive sectors, chemical gas-liquid absorption is an attractive option to be implemented in practice after a well-established scale-up procedure.
CO_2 removal with alkanolamine solvent is the most advanced technology to be deployed on large scale, as worldwide, the CO_2 capture pilot plants had already demonstrated the feasibility of this technology. The use of monoethanolamine (MEA) has considerable interest and led to significant progress in post-combustion CO_2 capture. The advantages of CO_2 capture with alkanolamine are the ability to treat flue gas flows from power stations (CO_2 concentration is of 10–15 vol % for coal and of 3–5 vol % for natural gas) and its suitability for retrofitting existing power plants. The obtained CO_2 product can be made available for chemical and food manufacturing industries (Bui et al., 2014).

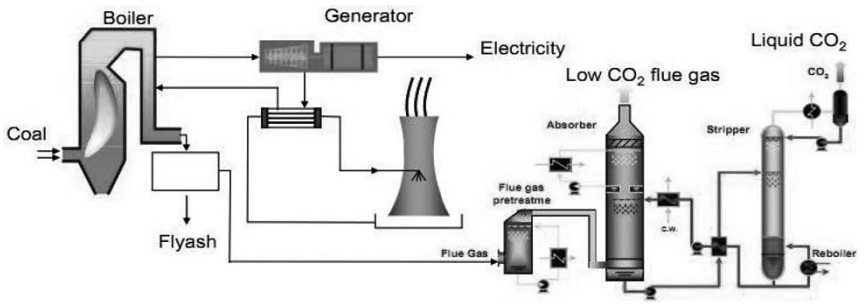

Figure 1. Schematic diagram of CO_2 capture from power station flue gases (http://www.energy-without-carbon.org)

CO_2 capture from power station flue gases using the amine-based process consists in two main packed columns, an absorber and striper (Figure 1). In the absorber, the CO_2 is absorbed from the flue gas by lean amine solvent, being counter-currently contacted. The rich solvent is regenerated in the striper using heat from the steam extracted during the power generation process. A major disadvantage of this technology is the large energy requirement for solvent regeneration. In order to reduce the energy penalty during peak periods of electricity demand, a flexible operation of post-combustion CO_2 capture has been proposed (Bui et al., 2014). Dynamic flexible operation of carbon capture plant is fundamental to successfully implement the process at industrial scale, since full-time continuous CO_2 capture might not be economically feasible. Very few examples of dynamic cases relevant to flexible carbon capture process operation exist in literature at the present time. Dynamic CO_2 capture model simulations have only analysed very small disturbances (Bui et al., 2014).
In this paper, a scale-up dynamic model (for 17 m high absortion column) is used to describe the CO_2 capture process in aqueous solution of MEA. Implemented in Matlab/Simulink software, the model offers the instrument to perform part-load analysis and control strategy design for the carbon capture process to be used within a power plant.

2. Model development and validation

In present work, a dynamic model (previously developed within de group) is scale-up to describe CO_2 capture process in a 17 m high absorption column. The model equations are presented, in detail, in previous works (Gaspar and Cormos, 2011, 2012). The model contain partial differential equations (PDE) to describe the total mass, component and energy balance equations of liquid and gas phases, and algebraic equations for the physical and chemical properties calculation (diffusion coefficients, CO_2 solubility in amine solution, densities, viscosities, specific heat capacities, etc). Two-film theory was used to determine mass and heat transfer processes. Mass transfer coefficient, effective interfacial area and liquid hold up are calculated from Rocha, Bravo and Fair (1996) empirical correlations. The effect of the chemical reaction on the transfer rate is built-in in the transfer equations by the enhancement factor. The reaction mechanism implemented in the model is based on data revised by Versteeg et al. (1996).

The experimental results published in literature for Esbjerg CESAR pilot plant (pilot plant parameters: absorbent 30wt% MEA; packing type: Sulzer Mellapak 2X; absorber diameter 1.1 m, packed height 17 m) are used to validate the developed model. The model parameters are presented in table 1 (Razi et al., 2013).

Table1. Parameter of CESAR pilot plant

Parameters	Value
Packing type	Sulzer Mellapak 2X
Absorber diameter (m)	1.1
Absorber packed height (m)	17
Removal efficiency (%)	87
Flow gas flow (Nm3/h)	50
Lean MEA flow (m3/h)	24
Flue gas temperature (°C)	50
MEA temperature (°C)	40
Lean amine loading	0.2-0.3

The simulation results were used to assess the overall process parameters such as chemical species concentration profiles, liquid and gas flow profiles, temperature profile in the liquid and gas phase along the absorption column. The gas phase CO_2 concentration decreases from the bottom to the top of absorber as it reacts with the solvent (monoethanolamine). The CO_2 removal efficiency to its nominal operating point obtained by simulation is of 83.5 % (experimental is of 87 %). A good correlation between absorber's temperature profiles obtained by simulation and experiment was observed, the R-squared is of 0.936 for the temperature of the liquid and of 0.965 for the temperature of the gas. The temperature profile along the packed column height obtained by simulation and experiment is presented in Figure 2 (Razi et al., 2013).

3. Part-load analysis

Usually, the power plant is operated at full capacity during the day and part-load or even shut down during the night, due to the timely variation of the grid demand. Generally during periods of high electricity demand and, hence spot price, energy penalty of carbon capture process can have a negative impact on the technical and economic performance of the power plant. Flexible operation can significantly reduce the financial impact of integrating carbon capture unit into power plants. The post-combustion CO_2 capture unit is affected by the need of load-following operation imposed by the power block. A complete understanding of the dynamic operability of the power plant with CO_2 capture using amine-based solvents is fundamental to successfully implement this process in commercial scale power plants. The developed dynamic model is used to simulate the transient behavior of the CO_2 capture plant due to changes in the flue gas flow rate, in order to study the effect of the power plants operating conditions on the CO_2 capture process. The CO_2 removal capacity has been studied using step, ramp and sinusoidal input tests to highlight the transient response.

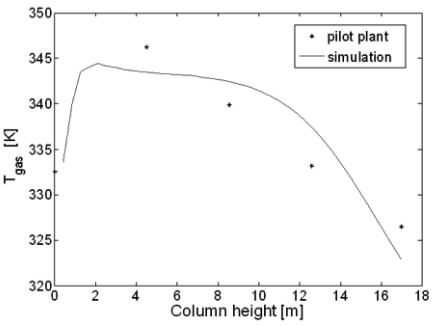

Figure 2. Gas temperature profile

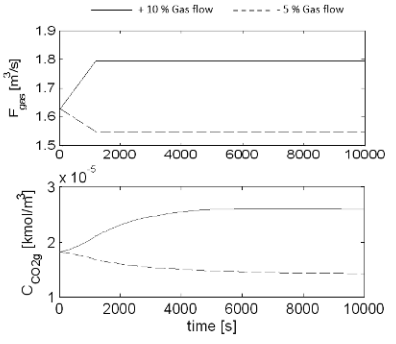

Figure 3. Flue gas flow rate and CO_2 capture rate during the ramp test

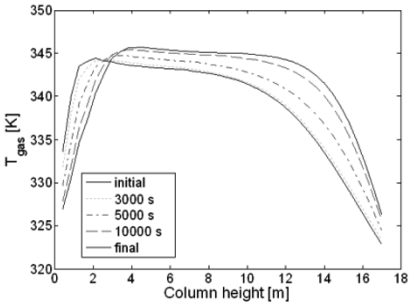

Figure 4. Gas temperature profile during the step test (-20 % in the flue gas flow)

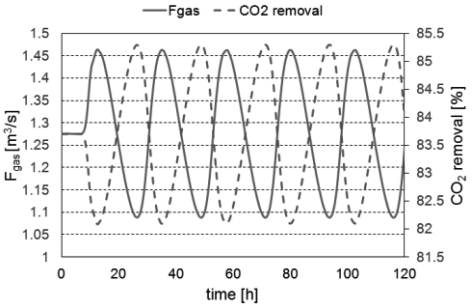

Figure 5. Output gas flow and CO_2 removal percentage during sinusoidal change

The dynamic behavior study of the CO_2 capture process demonstrates that plant performance is reduced significantly with excessive increase of the absorber load and a decrease of FG/FL allowed an increase of CO_2 capture rate. The CO_2 removal capacity of the carbonator was studied during a ramp test which included the increasing/decreasing of inlet gas flow within a 10 % / 5 % range (with respect to its nominal operating point), followed by a constant type disturbance (Figure 3). Figure 4 shows the change of the gas temperature to a typical disturbance, a step increment of -20 % in the inlet gas flow. The response of CO_2 removal efficiency is fast; therefore it is hardly noticeable in an hour scale, as presented in Figure 3 and 4.

The sinusoidal test was introduced in the process model to study the oscillatory behavior of this process, which is ~~a~~ typical for power plant outputs. Consequently, this case study was carried out considering that the amplitude of the sinusoidal function has a change of 15% with respect to the flue gas input base case value. The sinusoidal input was set to complete one cycle within a day. The simulation was performed for five days, as Figure 5 shows. The percentage of CO_2 removal reached a minimal value of 82.2 % when the flue gas flow rate was at its maximum and a maximal value of 85.3 % at the minimum of flue gas flow rate. The changes on CO_2 capture rate are due that the disturbance propagates with delay from beginning to the column end and the absorber are not stabilizes at the new steady-state value. Future studies should provide a dynamic model validated with dynamic pilot plant data.

4. Elaboration of control strategies

Control of the carbon dioxide quantity in the sweet gas stream is the most important objective for flexible operation configuration of post combustion capture plant. In this work, simulations of different control scenarios have been performed using both classical control strategy (proportional-integral controller, PI) and advance control strategy (model predictive control, MPC) (Cristea, et al. 2003; Leonard, et al. 2013).

The two considered control approaches have been investigated in the presence of typical disturbances, such as the step change of the inlet flue gas flow rate, having an increase of 10% with respect to its nominal operating point. The manipulated variable was the liquid flow, adjusted by the controllers to maintain the output CO_2 gas concentration at the setpoint value of 1.81 10^{-5} Kmol/m^3, the latter providing removal of at least 85% CO_2 from the gaseous mixture. As shown in Figure 6, both PI and MPC controllers succeed to reject the effect of the inlet flue gas flow rate change, bringing the output CO_2 gas concentration at the desired value. The advantage of the unconstrained MPC over PI consists in the duration of the time period the controlled CO_2 gas concentration

is exceeding the imposed setpoint. For the MPC case this period is smaller compared to the PI control approach, as shown in Figure 6. This fact has a direct impact on the CO_2 capture increase of efficiency and results in decreased CO_2 emissions. Additionally, the slightly smaller overshoot of the controlled CO_2 gas concentration for the MPC case, compared to the PI case, is emphasizing the same favourable impact. The PI tuning has been based on a trial and error procedure. The control loop with a P controller was brought to oscillation by increasing the proportional gain. The oscillation gain was later halved and the integral gain was increased until the offset was rejected in sufficiently small period of time.

One of the most appreciated features of MPC consists in its optimal characteristic and ability to handle constraints. This may offer flexibility for operation. As an example, this capability is presented in Figure 7 where an upper constraint on the controlled CO_2 gas concentration, at the value of 2.3 10^{-5} Kmol/m^3, was imposed and the results revealed the potential of the constrained MPC to reject the same disturbance while bringing the controlled variable to the desired setpoint. The constraint MPC approach is substantiating the incentives of the unconstrained MPC by further reducing both the period of exceeding the imposed setpoint and the overshoot. The computation of the MPC control law relies on the constrained minimisation of a cost function consisting in the summation of two weighted terms. The first one is the square difference between the desired setpoint and the predicted output, considered over the future prediction horizon, while the second one is the square change of the manipulated variable, considered over the future input horizon. The weighting factors in the cost function have been used for MPC tuning. They have been initially chosen based on the maximum allowed change of the output and respectively, the manipulated variable, values that have been further adjusted until the offset was rejected and the time of return under the setpoint value was minimal.

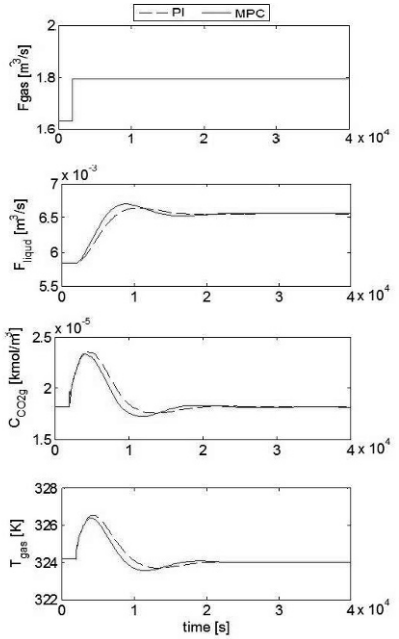

Figure 6. PI vs MPC performance

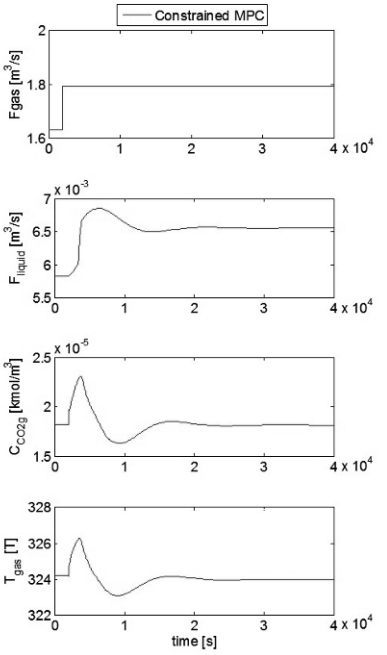

Figure 7. Constrained MPC performance

5. Conclusions

A consistent dynamic rate-base model has been implemented in the Matlab/Simulink in order to do a part-load analysis and design of control strategies of carbon capture process to be used within a power plant. A good correlation between absorber's temperature profiles obtained by simulation and experimental (published in literature for Esbjerg CESAR pilot plant) was observed.

The CO_2 removal capacity has been studied using step, ramp and sinusoidal input tests in order to highlight the transient response of CO_2 capture for a typical load following the behavior of power generation plants. The amount of liquid flow was adjusted to provide absorption of at least 85 % CO_2 of the gaseous mixture.

Two different control strategies have been tested based on the classical PI and the advanced MPC control, in order to enhance the flexibility of the plant operation. The results revealed that the PI and MPC controllers were capable to maintain the concentration of the CO_2 gaseous mixture close to the desired set point, despite the upset produced by the inlet gas flow rate disturbance. Furthermore, the MPC demonstrated to have the very valued potential to perform efficient control by efficiently bringing back the CO_2 concentration under the setpoint imposed limit and reduce overshoot, while complying with operation constraints. This ability results in the improvement of the CO_2 capture efficiency.

Abstract

For several systems of interest, inputs to the system may be unknown. Thus, one may be interested in estimating the unknown inputs alongwith the states. In this work, we modify the approach proposed by Madapusi and Bernstein (2007) for estimating the states and the unknown inputs. The approach, applicable to systems with feedthrough, obtains a minimum variance unbiased estimate of the states. The inputs are estimated after the filtered states are obtained and do not require any restrictive assumptions about the dynamic variation of the inputs. Compared to Madapusi and Bernstein (2007), our approach differs in the prediction step. In particular, we use the estimated input in the prediction step while it has not been considered in the work of Madapusi and Bernstein (2007). Our proposed modification reduces the number of constraints that need to be satisfied by the filter gain thereby increasing the applicability of the approach. The efficacy of the approach is demonstrated by applying it to estimate unknown inputs and states in a self powered neutron detector, that is widely used in nuclear reactors to monitor the neutron flux.

Keywords: State estimation, unknown input estimation, minimum variance estimation, self powered neutron detector.

1. Introduction

The problem of state estimation is to estimate the states of the system using an uncertain process model and noisy measurements. Most of the state estimation approaches available in literature assume that the inputs to the process are exactly known. However, in several systems of interest the inputs are not directly measured and hence their exact values are unknown. Relatively less attention has been given to problem of state estimation under this scenario. One approach for addressing such problems would be to consider the unknown input to be an unknown parameter and assume a dynamic model (typically random walk) for its variation. The problem is to then estimate the augmented states with this parameter as an additional state. However, arbitrary assumptions about the dynamic variation of the unknown input may be poorly justified specially for inputs varying over a wide range in a deterministic manner.

There are relatively fewer approaches that don't assume any model for the variation of the unknown input. In particular, Kitanidis (1987) developed an unbiased minimum variance estimator for the states in the presence of unknown inputs. Their approach requires the filter gain to satisfy a constraint that ensures that the effect of the unknown input is not felt on the estimated state. However, the focus of their work is on state estimation only and they did not discuss estimation of the unknown inputs. Sanyal and Shen (1974) have considered the problem of state and input estimation but assume the input to be a series of impulses of unknown magnitudes occurring after significant time lapses. Glover (1969) consider mainly estimation of unknown inputs and not the

states themselves. But they assume the initial state to be zero. Madapusi and Bernstein (2007) have presented observability conditions for estimating both states and unknown inputs. They also extend the work of Kitanidis (1987) to deal with feedthrough systems. In both the approaches of Kitanidis (1987) and Madapusi and Bernstein (2007), the prediction step in the filter implicitly assumes the unknown input to be zero.

In this work, we focus on the problem of simultaneous state and unknown input estimation. Our work is applicable to linear systems with feedthrough, namely where the unknown inputs directly affect the measurements. In particular, we modify the approach of Madapusi and Bernstein (2007) in that we use the estimated value of the unknown input in the state prediction step at the next time instant. We show that this modification enables application of the approach to a larger class of systems by reducing the constraints to be satisfied by filter gain to ensure unbiased state estimates. It also results in better (lower variance) state estimates. The approach is thus a modification of traditional Kalman filter and ensures unbiased, minimum variance state estimates while using the estimated values of unmeasured inputs in the state prediction step. The utility of the approach is demonstrated by applying it to the problem of estimating neutron flux in a nuclear reactor. The rest of the paper is structured as follows: in section 2 we present the problem statement and summarize the existing relevant work. The proposed extension is presented in section 3. The approach is applied to a neutron flux estimation problem in section 4. The paper is concluded in section 5.

2. Problem Statement and Existing Approaches

Consider a discrete-time linear system with a linear measurement function,

$$x_{k+1} = A_k x_k + H_k e_k + w_k \tag{1}$$
$$y_k = C_k x_k + G_k e_k + v_k \tag{2}$$

where, $x_k \in \mathbb{R}^n, y_k \in \mathbb{R}^m, e_k \in \mathbb{R}^p, w_k \in \mathbb{R}^n, v_k \in \mathbb{R}^m$ are respectively the states, measurements, unknown inputs, process noise and measurement noise, respectively. w_k and v_k are usually considered to be white, Gaussian discrete time stochastic processes with mean 0 and covariances Q_k and R_k respectively. The subscript k for the various quantities indicates the time instant t_k. The problem in joint state and unknown input estimation is to obtain the best estimates of x_k and e_k given the measurements upto time t_k. Note that while writing the measurement equation above, we have assumed direct feedthrough namely that the unmeasured inputs e_k directly affect the measurements y_k. Further, for simplicity of notation we have not considered known inputs in either the state evolution or measurement equation. Incase some known inputs are present, the proposed methodology can easily be modified to accommodate them. We now summarize the existing relevant technique (Madapusi and Bernstein, 2007) for simultaneous state and unknown input estimation.

2.1. Simultaneous State and Input Estimation

We assume the conditional state density at time t_k to be Gaussian with mean $\hat{x}_{k|k}$ and covariance $P_{k|k}$. In the approach proposed by Kitanidis (1987) and Madapusi and Bernstein (2007), the filter takes the following form:

$$\hat{x}_{k+1|k} = A_k \hat{x}_{k|k} \tag{3}$$
$$\hat{x}_{k+1|k+1} = \hat{x}_{k+1|k} + L_{k+1}(y_{k+1} - C_{k+1}\hat{x}_{k+1|k}) \tag{4}$$

where $\hat{x}_{k+1|k+1}$ is the required filtered (estimated or updated) state while L_{k+1} is the filter gain and $\hat{x}_{k+1|k}$ is the model predicted state based on measurements till time instant k. An important thing to note in the prediction equation (Eq. 3) is that the effect of the unknown input has been ignored while predicting the state.

Define the state estimation error as: $\varepsilon_{k+1|k+1} \triangleq x_{k+1} - \hat{x}_{k+1|k+1}$. Requiring the state estimation error to be 0 mean, leads to the following constraints on the filter gain (Madapusi and Bernstein, 2007):

$$(I - L_{k+1}C_{k+1})H_k = 0 \tag{5}$$

$$L_{k+1}G_{k+1} = 0 \tag{6}$$

The updated error covariance matrix $P_{k+1|k+1}$ is given by,

$$P_{k+1|k+1} \triangleq \mathbb{E}[\varepsilon_{k+1|k+1}\varepsilon_{k+1|k+1}^T] = L_{k+1}\tilde{R}_{k+1}L_{k+1}^T - F_{k+1}L_{k+1}^T - L_{k+1}F_{k+1}^T + P_{k+1|k} \tag{7}$$

$$\text{where, } P_{k+1|k} = A_kP_{k|k}A_k^T + Q_k,\ \tilde{R}_{k+1} = C_{k+1}P_{k+1|k}C_{k+1}^T + R_{k+1},\ F_{k+1} = P_{k+1|k}C_{k+1}^T \tag{8}$$

The unbiased minimum-variance gain L_{k+1} is calculated by minimizing the trace of the error covariance matrix $P_{k+1|k+1}$ subject to the constraints in Eq. 5 and 6 and is given by,

$$L_{k+1} = (F_{k+1} + \Omega_{k+1}(\Phi_{k+1}^T\tilde{R}_{k+1}^{-1}\Phi_{K+1})^{-1}\Phi_{K+1}^T)\tilde{R}_{k+1}^{-1} \tag{9}$$

where,

$$\Phi_{k+1} = [-G_{k+1} \quad V_{k+1}],\ V_{k+1} = C_{k+1}H_k,\ \Omega_{k+1} = [0_{n\times p} \quad H_k] - F_{k+1}\tilde{R}_{k+1}^{-1}\Phi_{k+1} \tag{10}$$

This completes the state estimation step. The estimate $\hat{e}_k$ of the unknown input is subsequently obtained as (Madapusi and Bernstein, 2007),

$$\hat{e}_{k+1|k+1} = G_{k+1}^{\dagger}(y_{k+1} - C_{k+1}\hat{x}_{k+1|k+1}) \tag{11}$$

where, $G^{\dagger}$ is Moore-Penrose generalized inverse, given as $G^{\dagger} = (G^TG)^{-1}G^T$. Note that the presence of the unknown input $e(k)$ in the measurement equation (Eq. 2) enables its estimation using the above expression. Further, it can be shown (Madapusi and Bernstein, 2007) that Eq. 11 provides an unbiased estimate of the unknown input i.e. $\mathbb{E}[\bar{e}_{k+1|k+1}] = 0$ where $\bar{e}_{k+1|k+1} \triangleq e_{k+1} - \hat{e}_{k+1|k+1}$ is the error in estimating the unknown input. The approach in this section is labeled as input reconstruction (InpR) approach.

3. Proposed Approach

In this work, we propose the following filter form,

$$\hat{x}_{k+1|k} = A_k\hat{x}_{k|k} + H_k\hat{e}_{k|k} \tag{12}$$

$$\hat{x}_{k+1|k+1} = \hat{x}_{k+1|k} + L_{k+1}(y_{k+1} - C_{k+1}\hat{x}_{k+1|k}) \tag{13}$$

Comparing with Eqs. 3 and 4, it can be seen that our approach does not ignore the unknown input while predicting the states. Instead, we use the estimated value of the unknown input $\hat{e}_{k|k}$ in the prediction equation. The expected value of the state estimation error $\varepsilon_{k+1|k+1}$ can then be derived to be,

$$\begin{aligned}\mathbb{E}[\varepsilon_{k+1|k+1}] = \mathbb{E}[&(I - L_{k+1}C_{k+1})A_k\varepsilon_{k|k} + (I - L_{k+1}C_{k+1})H_k(e_k - \hat{e}_{k|k}) + (I - L_{k+1}C_{k+1})w_k \\ &- L_{k+1}G_{k+1}e_{k+1} - L_{k+1}v_{k+1}]\end{aligned} \tag{14}$$

Now the filter gain can be derived using a similar procedure as in Kitanidis (1987); Madapusi and Bernstein (2007). If the estimated inputs and the estimated states at previous time step are unbiased, we have $\mathbb{E}[e_k - \hat{e}_{k|k}] = 0$ and $\mathbb{E}[\varepsilon_{k|k}] = 0$. Further, since the unknown input e_k is arbitrary, the following condition needs to hold for obtaining unbiased state estimates at time t_{k+1}:

$$L_{k+1}G_{k+1} = 0 \tag{15}$$

Comparing this condition to Eqs. 5 and 6, it can be seen that the proposed approach results in less restrictive conditions on the filter gain. Further, it can be noted that for the filter gain to exist, the matrix G_{k+1} should have a non-empty left null space i.e. the number of measurements should be more than the number of unknown inputs. Using constraint 15, the state estimation error is,

$$\varepsilon_{k+1|k+1} = (I - L_{k+1}C_{k+1})(A_k\varepsilon_k + H_k\bar{e}_{k|k} + w_k) - L_{k+1}v_{k+1}$$

Thus, the covariance matrix $P_{k+1|k+1}$ of state estimation errors can be derived to be,

$$P_{k+1|k+1} = \mathbb{E}\left[\varepsilon_{k+1|k+1}\varepsilon_{k+1|k+1}^T\right] = P_{k+1|k} - L_{k+1}F_{k+1}^T - F_{k+1}L_{k+1}^T + L_{k+1}\tilde{R}_{k+1}L_{k+1}^T \tag{16}$$

where,

$$P_{k+1|k} = A_kP_{k|k}A_k^T + H_k\xi_{k+1}H_k^T + A_k\sigma_{k+1}H_k^T + H_k\sigma_{k+1}^TA_k^T + Q_k \tag{17}$$

$$\xi_{k+1} = \mathbb{E}[\bar{e}_{k|k}\bar{e}_{k|k}^T] = G_k^\dagger(C_kP_{k|k}C_k^T + R_k - C_kL_kR_k - R_kL_k^TC_k^T)(G_k^\dagger)^T \tag{18}$$

$$\sigma_{k+1} = \mathbb{E}[\varepsilon_{k|k}\bar{e}_k^T] = (-P_{k|k}C_k^T + L_kR_k)(G_k^\dagger)^T \tag{19}$$

$$\tilde{R}_{k+1} = C_{k+1}P_{k+1|k}C_{k+1}^T + R_{k+1}, \quad F_{k+1} = P_{k+1|k}C_{k+1}^T \tag{20}$$

As in the previous section, the optimal filter gain is now computed by minimizing the trace of the estimation error covariance matrix, i.e. trace$(P_{k+1|k+1})$, subject to constraint in Eq. 15 and is derived to be (details are in Baranwal (2012)):

$$L_{k+1} = F_{k+1}(I - \tilde{R}_{k+1}^{-1}G_{k+1}(G_{k+1}^T\tilde{R}_{k+1}^{-1}G_{k+1})^{-1}G_{k+1}^T)\tilde{R}_{k+1}^{-1} \tag{21}$$

Once the state is estimated, the estimate of the unknown input can be computed as,

$$\hat{e}_{k+1|k+1} = G_{k+1}^\dagger(y_{k+1} - C_{k+1}\hat{x}_{k+1|k+1}) \tag{22}$$

It can be shown that this is an unbiased estimate of the unknown input. We label our approach as modified input reconstruction (MInpR) approach to distinguish it from the input reconstruction approach presented in the last section.

4. Case Study

We now implement the proposed approach on a self powered neutron detector (SPND) which is a sensor widely used in nuclear reactors for incore neutron flux estimation. An SPND operates on the principle of activation by neutron interaction, namely that it generates current upon absorption of neutrons. A dynamic model of Vanadium SPND is (Srinivasarengan et al., 2012):

$$\frac{d}{dt}N_{52}(t) = -\lambda_{52}N_{52}(t) + \sigma_{51}N_{51}\phi(t) \tag{23}$$

$$I(t) = k_{pv}\sigma_{51}N_{51}(t)\phi(t) + k_{gv}\lambda_{52}N_{52}(t) \tag{24}$$

where state N_{52} denotes the concentration (atoms.cm^{-3}) of the isotope ^{52}V, while ϕ denotes the neutron flux (neutrons.cm^{-2}.sec^{-1}) which is the unknown input of interest. The measurement $I(t)$ is of the current generated by the SPND. Note that while writing this model, the concentration N_{51} of the stable isotope ^{51}V has been assumed to be a constant. The various parameters occurring in the above equations are listed in Table 1. The constants k_{gv}, k_{pv} reported in this Table are subsequently multiplied by a factor of 1×10^9 to scale the measurement. The sampling interval for the measurements is 1 second. It can be seen that the above is a direct feedthrough linear state space model since the input $\phi(t)$ directly appears in the measurement equation as well. However, the size of the G matrix (Eq. 2) is 1×1. From Eq. 15, this directly leads to filter gain being

zero and the proposed approach (Sec. 3) or the existing approach in literature (Sec. 2) cannot be applied. We thus consider two Vanadium SPNDs with the same, but unknown input. In a nuclear reactor, such a scenario is possible since a typical nuclear reactor has several SPNDs some of which are highly correlated (Razak et al., 2014). The parameters of both the SPNDs are assumed to be the same as given in Table 1. While the proposed modified input reconstruction approach can be applied to estimate states and the unknown input, an analysis of Eqs. 5 and 6 reveals that these constraints cannot be simultaneously satisfied and hence the existing input reconstruction approach cannot be applied. We thus apply the proposed MInpR approach and compare its results with a covariance-reset based Kalman Filter (KF) approach presented in Srinivasarengan et al. (2012). The latter assumes a random walk model for the unknown flux and applies a traditional Kalman filter to the augmented system. However to track sudden changes in the flux, it heuristically resets the variance of the estimated flux to a large value when the mean of norm of the innovations in a moving window exceeds a predefined threshold. Thus, tuning parameters related to the length of the window, the threshold and the value to which the variance is reset, need to be suitably chosen for the approach to work properly.

Three types of input (flux) profiles are generated. The corresponding inputs estimated by the covariance-reset approach and the proposed MInpR approach are shown in Fig. 1 alongwith the true input profiles. The mean squared errors (MSE) corresponding to the estimated fluxes and the estimated states are reported in Table 2. From this table it can be seen the state estimation accuracy is higher (i.e. MSE is lower) with the proposed approach for all the three flux profiles. The accuracy of estimated flux profiles is higher for the covariance-reset approach for first two flux profiles while it is higher for the proposed approach for the third flux profile.

Table 1: Model Parameters

Parameter	Values	Unit
N_{51}	6.86×10^{22}	cm^{-3}
σ_{51}	4.9×10^{-24}	cm^{2}
λ_{52}	3.6×10^{-3}	sec^{-1}
k_{gv}	3.846×10^{-20}	$Amperes.sec$
k_{pv}	3.487×10^{-12}	$Amperes.sec$

Table 2: MSE for Estimated States and Inputs

Flux Profile	Variable	KF (Cov Reset)	MInpR
Flux 1	State: SPND 1	1.1068×10^{14}	1.0590×10^{14}

	Flux	8.6614×10^{12}	7.1141×10^{12}

5. Conclusions

In this work, we present a technique for estimating states and unknown inputs for linear systems with feedthrough. The technique, labeled modified input reconstruction approach, modifies an existing (Madapusi and Bernstein, 2007) technique from literature. The modification is in the prediction step and reduces the number of constraints to be satisfied by the filter gain while obtaining unbiased, minimum variance estimates of the states. The approach is applied to estimate states and the unknown input for a self powered neutron detector, which are widely used in nuclear reactors.

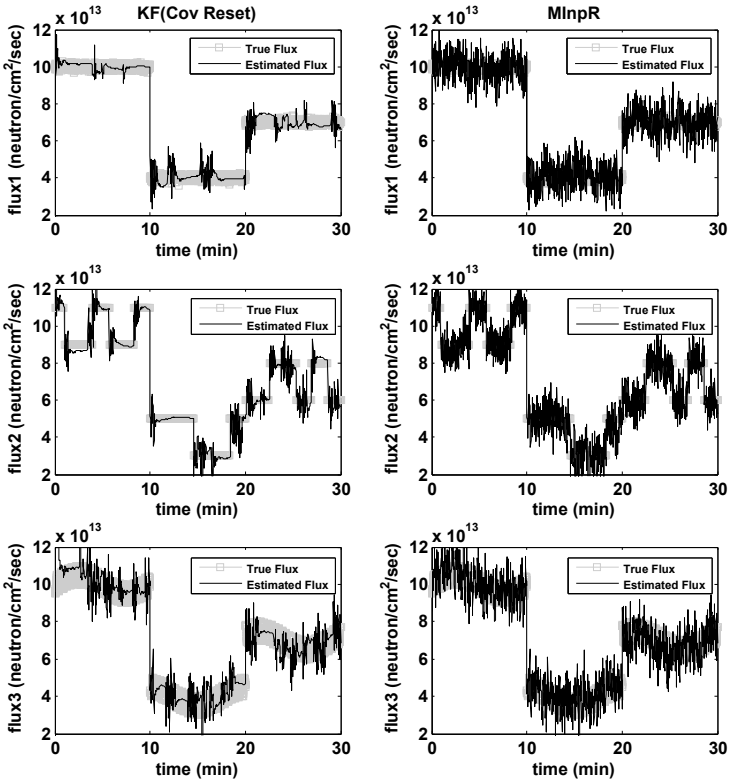

Figure 1: Flux Estimation for Vanadium SPND

The results demonstrate superior quality of state estimation when compared to traditional estimation approach that assumes a dynamic model for the variation of the unknown input, while the quality of estimated inputs is comparable. However, unlike the traditional approach, the proposed approach does not involve any tuning parameters.

A New Software Development Methodology for Controllability Analysis of Forced Circulation Evaporator System

Afshin Sadrieh, Parisa A. Bahri[a]

[a]*Murdoch University, 90 south street, Perth 6150, Australia*

Abstract

Modern chemical process plants are becoming more and more complex due to tighter economic and environmental limitations. As a result, achieving well-controllable process system designs becomes a tedious task. Using software products to evaluate designs in early stages is beneficial in order to reduce the human error and increase the efficiency. However, developing software tools for controllability problems using traditional software development methods is inefficient due to complexity and scale of these problems as well as considerable differences between them. In this work, a graphical domain-specific language (DSL) is introduced for measuring RGA index, to assess the controllability of a process plant with an application to a forced-circulation evaporator system.

Keywords: Domain-specific languages, Forced circulation evaporator, Controllability analysis

1. Introduction

Maintaining controllability measure of modern chemical plants in a safe margin is not only beneficial from economical point of view, but also crucial for safety concerns. A research suggested that Chernobyl disaster could have been prevented if controllability issues of that plant were addressed.

Controllability concept has been defined in various forms, depending on the scope it is being used in. Originally, Ziegler and Nichols defined it back in 1943 and since then it has been emphasized that controllability index of a process system design is dependent on the process design itself, not the controller. As a result, controllability analysis should be conducted during the design stage (Yuan et al, 2011).

However, although the need for controllability evaluation of process systems at design stage was bolded out before, surprisingly, there are only very few software tools dedicated for this purpose and they never became commercialised (Fararooy and Perkins, 1992). This may be due to the fact that controllability problems are complex and sophisticated and also vary significantly from case to case. Therefore, implementing software tools specific to each case becomes inefficient and expensive.

In this work, a new methodology based on graphical domain-specific language (DSL) is introduced to develop software tools to measure controllability index of process system design. The structure of this paper is as follows: first, the proposed methodology and its advantages and disadvantages are discussed followed by introducing the structure of the proposed software product. The product is then tested against a forced-circulation evaporator system case study. The results from evaluating the case study as well as the effort needed to develop the software tool are presented. Finally, the effort needed to

develop this DSL framework is compared with the effort required to develop a DSL framework for a simpler case study.

2. Background

Software development procedures evolved dramatically over the past few years. Novel methodologies are proposed and improvements in traditional procedures are made. domain-specific language (DSL) is a new software development methodology defined as "a computer programming language of limited expressiveness focused on a particular domain" (Fowler and Parsons 2010). In other words, DSL product is a programming language designed and developed for a clearly defined and narrowed down domain. Providing loosely coupled structure and elements, DSL offers a pathway to address complex problems. Moreover, because each DSL product is specially designed for a particular domain, familiar symbols and notations in that domain will be used by the DSL to ease the communication between the programmer and the domain expert. Apart from that, DSL products are relatively small programming languages, which means the symbols and syntax that can be used by them are limited, consequently DSL are often easy to learn and use.

As mentioned above, using DSL methodology in software development process has several advantages; however, it has some drawbacks as well. Similar to any other software tool, it is time consuming to develop, maintain and learn them. This issue is magnified especially when its borders and scope of the domain, on which the DSL is defined, are not clear.

However, one of the reasons that gained attention to DSL is the extensive tool support it requires. In fact, using these tools can reduce the effort of designing, developing, maintaining and using the programming languages by far (Sadrieh and Bahri, 2014). Language workbench is the general term for this category of software and according to Fowler and Parsons (2010), language workbenches can be the "corner stone" of the new software development era.

3. Methodology

In this section the major elements of the proposed framework as well as the procedure of evolution are described.

3.1. DSL Elements

This framework consists of five major elements: Solver, Graphical User Interface (GUI), Semantic model, Code generator and Code generator controller. In the following section, the process of developing framework elements will be explained. It should be noted that MetaEdit+ is used as the language workbench toolbox to generate the DSL framework.

Solver: This part of the framework is responsible for performing the linear and non-linear calculations, which are necessary to evaluate the controllability index of the process system design. The first step for developing the DSL framework is to develop the desired code in the solver environment to generate the final result. In this case, the expected result from the framework is the controllability index of the process system design and the solver is MATLAB software. The input to this element is the state-space model of the process system. During the solver development, the feasibility of solving the problem will be examined via development of a prototype solution, a MATLAB script in this case. This will help to isolate and decouple development of the other elements of the framework.

Graphical User Interface (GUI): DSL notations and rules are designed and used within GUI element. It is essential to use familiar notations in the domain to ensure the software product fits within the definition of a DSL. Moreover, the GUI should be able to gather all the information required to fully describe the process system design. The necessary data from the design is the non-linear model of the process system and the nominal values of the variables. The output of the GUI element is an XML file which contains all the information collected from the user. The structure of the output file depends on how DSL objects and the relationship among the objects are defined.

Semantic model: Based on the properties, relationships and connections among the objects in the DSL, a data structure is implemented. The semantic model is responsible for keeping track of the process system model specification and it should be designed and implemented so that the specifications of process system model can be accessed by other elements of the framework. In this study, a set of classes is chosen as the backbone of the semantic model. Because of the object-oriented nature of the semantic model, an object-oriented programming language is used to parse and analyse the output data from the DSL elements.

As the next sub-element, a parser should be developed to fetch the output data from the DSL element and set it in the semantic model. In this study, to make the evaluation process simpler and more traceable, an XML file is used as an intermediate media and then parsed into the semantic model. However, in real-time cases, where the performance is a concern, it is possible to link the DSL element to the semantic model directly, so that the data from process system model flows straight into the semantic model.

Code generator: The code generator acts as a system which takes the semantic model as the input and generates a set of instructions, which are valid in the solver environment as the output. If run by the solver, this set of instructions calculates the final result.

The crucial role of the prototype, which was generated along with the solver, will be visible in developing the code generator. If the structure of the output of the code generator is similar to solver script prototype, it is guaranteed that the results from running the generated code within the solver environment will also lead to the desirable results.

Code generator controller: So far the framework is capable of assessing single process system design, without any modification in the flow-sheet. However, it is desirable to be able to apply relatively small changes in the process model and the framework to be still capable of analysing it. In this study, the semantic model can be changed based on the disturbances entering the process system. The code generator is then run based on the new semantic model, leading to different generated scripts and different controllability values.

3.2. Assessment procedure

The procedure of assessing the process system design using DSL framework in this study consists of three phases: 1) fetching system information from the user input and calculating the steady state values of state variables, 2) generating the linear model using steady-state values and nonlinear equations and 3) using the linear model to calculate RGA index of the process system design (Figure 1).

In this study, the first phase is carried out autonomously to illustrate this methodology is applicable to any controllability problem, regardless of the complexity and size of process system model. The symbolic math toolbox in MATLAB is used for this task.

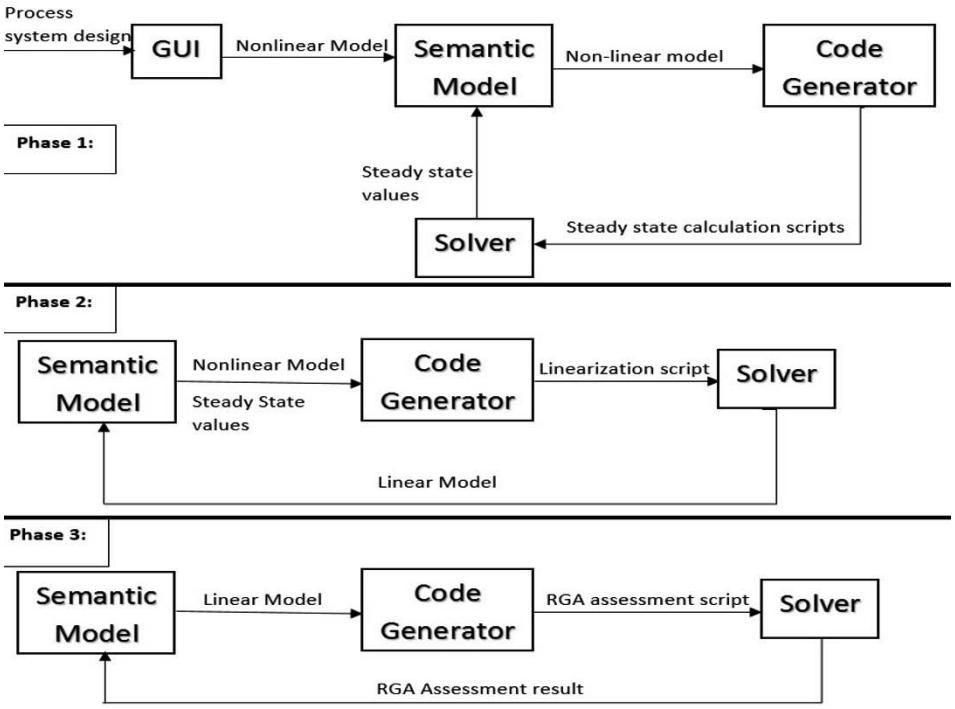

Figure 1 Analyzing process. Phase 1: Fetching process system model data and calculating steady state values. Phase 2: Calculating Linear Model. Phase 3: Calculating RGA Index

4. Case study

In order to verify the scalability of the proposed methodology, an evaporation system is used as a case study. The forced circulation evaporative (FCE) system used in this case study consists of a heat exchanger, a separator, a condenser and a pump (Figure 2). The liquid is circulated at a high rate through the heat exchanger, boiling being prevented within the unit by virtue of a hydrostatic head maintained above the top tube plate. As the liquid enters the separator where the absolute pressure is slightly less than in the tube bundle, the liquid flashes to form a vapour. This process is modelled by Newell and Lee (1989). Table 1 shows the model variables, their types and nominal values.

Table 1. FCE model variable types and nominal steady state values.

Variables	Type	Nominal steady state values
F3, F1, T1, X1, T200,	Disturbance	F1=10 (kg/min), T1=40 (°C), X1=5 (%), F3=50 (kg/min)
L2, X2, P2	Controlled	L2=1 (m), X2=25 (%), P2=50 (kPa)
F2, P100, F200	Manipulated	F2= 2 (kg/min), P100=194 (kPa)

As the FCE behaves relatively linear around its steady state, a controllability measure based on Relative Gain Array (RGA) (Garcia and Morari. 1982), which is a linear

measure, is defined and used in this study. The controllability measure (R) is calculated using Eq.1:

$$R = \sum (\lambda_i - 1)^2 \text{ for each positive } \lambda_i \quad (1)$$

5. Results

The FCE process system is modelled using the proposed DSL framework (Figure 2) and the resulted λ (relative gain) and R values are presented in Table 2. Each row of the table represents the controllability index of the specified conditions of the FCE problem. In each set, a defined value of disturbance (i.e.±7, ±10) is applied to two disturbance variables (T1 and F1) and the RGA index of that configuration is evaluated automatically.

Table 3 illustrates the time needed to implement each element of the two DSL frameworks; one is FCE case study, which is presented in this work, and also another DSL framework which was designed to calculate the same controllability index, but for a different case study consisting of two CSTRs ordered in parallel mode (Sadrieh and Bahri, 2014).

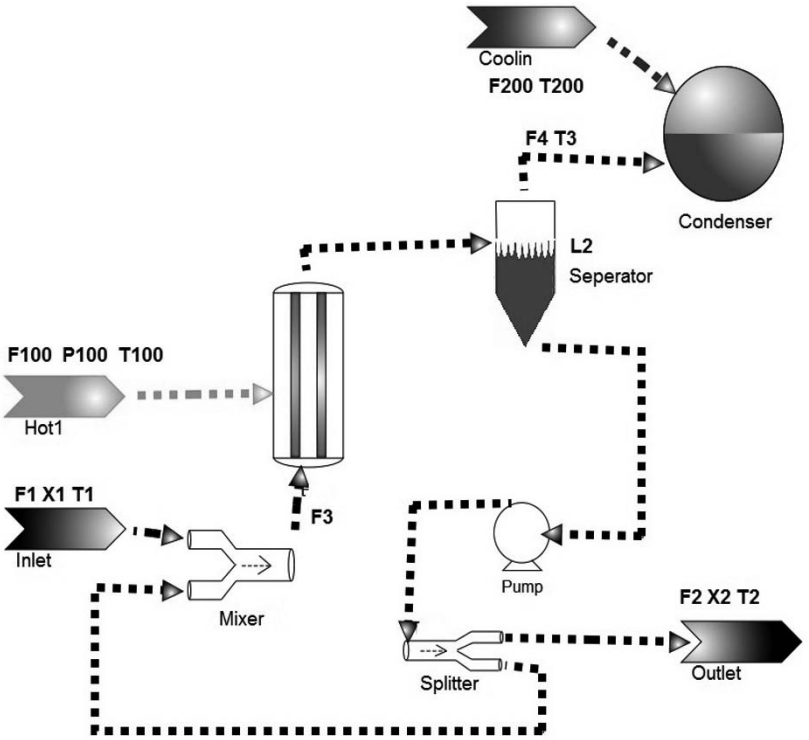

Figure 2. The DSL representation of the FCE case study

6. Conclusion

This study describes a new methodology to produce software tools for controllability analysis of process systems. The product is tested using a Forced Circulation Evaporator (FCE) case study and the results are presented. Moreover, it is concluded that different process model sizes (FCE with 26 equations and CSTR with 4 equations) slightly affect

the effort needed to develop the DSL products. This proves that this methodology is efficient, regardless of the complexity of the process system model.
This is mainly because of the structure of the framework, which isolates the mathematical process from the rest of the framework, and therefore, the size of the model has very little effect on the total effort.

A nonlinear quasi-unknown input observer for the chemostat Droop model

Alexander Schaum[a] and Thomas Meurer[a]

[a]*Chair of Automatic Control, Christian-Albrechts-University Kiel, Germany*
alsc@tf.uni-kiel.de

Abstract

An unknown input observer is designed for the Droop model for microalgae growth in the chemostat considering the feed concentration as unknown input. Based on a biomass measurement, the nutrient quota and substrate are estimated together with the unknown (piecewise constant) feed concentration using a nonlinear observation scheme with PI-like correction mechanism. The estimation performance is illustrated with numerical simulations.

Keywords: Microalgae growth, Droop model, unknown-input observability, state and input estimation

1. Introduction

Microalgae processes have received increasing attention in recent years due to the fact that these microorganisms produce high-value compounds like fatty-acids, vitamins or pigments and have a great potential use in the production of energy sources like hydrogen and biofuels (Havlik et al., 2013). Furthermore, microalgae show a comparatively rapid growth, making them even more interesting from a production point of view.

Nevertheless, like all biological processes, microalgae growth processes have to face the complex interaction of (possibly unmeasured) dynamically evolving states, like the extracellular and intracellular nutrient, the biomass and potentially others. This leads to the need of monitoring devices, commonly known as software sensors or observers (Bastin and Dochain, 1990; Havlik et al., 2013). The design of a software sensor is based on a mathematical model for the underlying biological process, which, in combination with a measurement injection mechanism, is used to reconstruct the actual process state from the knowledge of the measurements and the actual (known) inputs. The most commonly used model for microalgae growth is the Droop model (Droop, 1968), which gives a quantitative relation between the dynamics of the biomass growth and nitrogen uptake from an extracellular resource. Several approaches to software sensor design for microalgae production processes have been presented so far, like high-gain observers (Bernard et al., 2001), interval observers (Goffaux et al., 2009a,b), and Lipschitz observers (Toroghi et al., 2013). In the case of unknown inputs, like the dilution rate or the feed concentration, these observation schemes can not achieve exact state reconstruction. When some structural properties of the input are known, e.g. for piecewise constant inputs, so-called quasi-unknown input observers can be designed (Moreno, 2001a,b; Rocha-Cozatl and Vande Wouwer, 2011). The structural property associated to the possibility of observing the state of a system with unknown input is called strong observability and in case of estimating both state and input, state and unknown input observability (Hautus, 1983; Moreno et al., 2014). Classically, the existence of a state observer for the (complete) unknown input case relies on the condition that the unknown input has relative degree one

with respect to the measured output – a property leading to the strong*-detectability concept – (Hautus, 1983; Moreno et al., 2014; Rocha and Moreno, 2010; Rocha-Cozatl and Vande Wouwer, 2011). For this case, recently, a local quasi-unkown input observer based on the linearized Droop model has been proposed for estimating both state and unknown feed flow rate in (Rocha-Cozatl and Vande Wouwer, 2011). The results of this study are quite convincing and highlight the possibility of reconstructing unknown feed perturbations in the Droop model.

In the present study a different scenario is addressed: the biomass is measured and the (piecewise constant) feed concentration is considered as (quasi) unknown input. This leads to the underlying structural burden of having an unknown input with relative degree three, making it impossible to design a complete unknown input observer for the system. Nevertheless, it is shown that for the case of piecewise constant (or slowly varying) feed concentrations that a nonlinear quasi-unknown input estimator can be designed to reconstruct both the state and the unknown feed input. For this purpose, a nonlinear model plus PI-like observation scheme is employed and the observer convergence is rigorously established in the sense of semi-global asymptotic stability using Lyapunov's direct method. Numerical simulations illustrate the estimator performance.

2. Droop's microalgae growth model

Consider Droop's model for microalgae growth (Droop, 1968) in the chemostat

$$\begin{array}{ll} \dot{b} = -db + \mu(q)b, & b(0) = b_0 \\ \dot{q} = \rho(s) - \mu(q)q, & q(0) = q_0 \\ \dot{s} = d(s_{in} - s) - \rho(s)b, & s(0) = s_0 \\ y = b & \end{array} \tag{1}$$

where b is the biomass concentration, q is the internal nutrient quota (i.e. the intracellular nutrient concentration per biomass unit), s is the extracellular nutrient concentration, s_{in} is the *piecewise constant, unknown* feed concentration, μ is the growth rate, ρ is the uptake rate, d is the dilution rate (i.e. the flow-colume quotient q/V), and y is the biomass measurement.

The growth and uptake rates are given by the monotonic functions

$$\mu(q) = \bar{\mu}\left(1 - \frac{k_q}{q}\right), \quad \rho(s) = \frac{k_0 s}{K_s + s}, \tag{2}$$

where $\bar{\mu}$ is the hypothetic maximum growth at infinite quota, k_q is the minimum quota necessary for biomass growth, k_0 is the maximum uptake rate $\rho(s)$, and K_s is the half-saturation constant.

By the change of variables

$$\theta = q - k_q$$

the growth rate μ can be written in the standard Monod form

$$\nu(\theta) := \mu(\theta + k_q) = \frac{\bar{\mu}\theta}{k_q + \theta}. \tag{3}$$

and the dynamics (1) become

$$\begin{array}{ll} \dot{b} = -db + \nu(\theta)b, & b(0) = b_0 \\ \dot{\theta} = \rho(s) - \bar{\mu}\theta, & \theta(0) = q_0 - k_q \\ \dot{s} = d(s_{in} - s) - \rho(s)b, & s(0) = s_0 \\ y = b & \end{array} \tag{4}$$

In vector notation the preceding dynamics are written as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, u, s_{in}), \quad y = \mathbf{c}^T \mathbf{x}. \tag{5}$$

with

$$\mathbf{x} = [b, \theta, s]^T, \quad h(\mathbf{x}) = x_1.$$

It can be directly verified that the $\mathbb{R}^3_+$ is a positively invariant set for the dynamics (4), given that $x_i = 0$ implies $\dot{x}_i \geq 0$, $i = 1,2,3$. For the purpose at hand the following analysis and design are based on the model (4).

3. Observability analysis and observer design

In this section, it is shown that the model (4) is state and unknown input observable with respect to the unknown piecewise constant feed concentration s_{in} and a nonlinear observer with PI-like innovation scheme is designed for the simultanous estimation of the state $\mathbf{x}$ and exogeneous input s_{in}. For this purpose, the extended state vector

$$\mathbf{x}_e = \left[b, \theta, s, s_{in}\right]^T \tag{6}$$

is introduced.

3.1. Unknown input observability

Here, the approach for the analysis of state and unknown-input (or strong) observability discussed in (Schaum and Moreno, 2007; Moreno et al., 2014) is followed. Before going into detail on the observability analysis, it should be recalled from (Lemesle and Mailleret, 2008) that for $d < \max \nu$ the washout $\mathbf{x}_w = [0, \theta_w, s_{in}]'$ with $\theta_w = \rho(s_{in})/\bar{\mu}$ is a repulsor. Based on this property it can be shown that $\mathbf{x}$ moves within a subset $\mathscr{X} \subset \mathbb{R}^3_+$ and in particular that $b > 0$ for $b_0 > 0$.

Proposition 1 *The Droop model* (4) *with $y = b$ and unknown input s_{in} is state and unknown-input (or strongly) observable.*

Proof: Let the claim be false. Then there exist two indistinguishable extended trajectories $\mathbf{x}_{e1} \neq \mathbf{x}_{e2}$ (driven by the same input $d(t)$) satisfying $b_1(t) \equiv b_2(t)$ over some time interval. Let $\varepsilon_b = b_2 - b_1$, $\varepsilon_q = \theta_2 - \theta_1$, $\varepsilon_s = s_2 - s_1$ and $\varepsilon_i = s_{in2} - s_{in1}$ denote the differences between the two trajectories and introduce $\varepsilon = [\varepsilon_b, \varepsilon_q, \varepsilon_s, \varepsilon_i]^T$. From $b_1 \equiv b_2$ it follows directly that $\varepsilon_b = 0$. Furthermore,

$$\dot{\varepsilon}_b \equiv 0 = -d\varepsilon_b + [\nu(\theta_1 + \varepsilon_q)(b_1 + \varepsilon_b) - \nu(\theta_1)b_1] = \nu(\theta_1 + \varepsilon_q)b_1 - \nu(\theta_1)b_1$$

Given that $b_1 > 0$ this holds only if $\nu(\theta_1 + \varepsilon_q) \equiv \nu(\theta_1)$ and, given the monotonicity feature of the growth rate ν, this implies $\varepsilon_q \equiv 0$. Next, it holds that

$$\dot{\varepsilon}_q \equiv 0 = \rho(s_1 + \varepsilon_s) - \rho(s_1) - \bar{\mu}\varepsilon_q = \rho(s_1 + \varepsilon_s) - \rho(s_1)$$

which means that $\varepsilon_s \equiv 0$ due to the monotonicity of the uptake rate ρ. Finally,

$$\dot{\varepsilon}_s \equiv 0 = d(\varepsilon_i - \varepsilon_s) - [\rho(s_1 + \varepsilon_s)(b_1 + \varepsilon_b) - \rho(s_1)b_1] = d\varepsilon_i$$

implying that $\varepsilon_i \equiv 0$. This shows that $\mathbf{x}_{e2} = \mathbf{x}_{e1} + \varepsilon = \mathbf{x}_{e1}$ which contradicts the initial assumption. Thus, model (4) is unknown-input (or strongly) observable. Q.E.D.

3.2. Unknown-input observer

Based on the state and unknown-input observability property derived in the preceding section a nonlinear unknown-input observer is designed for the Droop model (4). For this purpose, the following (full order) nonlinear observer with PI-like correction scheme is considered

$$\begin{aligned}
&\dot{\hat{b}} = -d\hat{b} + \nu(\hat{\theta})\hat{b} - l_b(\hat{b}-y), && \hat{b}(0) = \hat{b}_0\\
&\dot{\hat{\theta}} = \rho(\hat{s}) - \bar{\mu}\hat{\theta} - l_q(\hat{b}-y), && \hat{\theta}(0) = \hat{\theta}_0\\
&\dot{\hat{s}} = d(\hat{s}_{in}-\hat{s}) - \rho(\hat{s})\hat{b} - l_s(\hat{b}-y), && \hat{s}(0) = \hat{s}_0\\
&\hat{s}_{in} = \hat{s}_{in,0} - l_i\int_0^t (\hat{b}(\tau)-y(\tau))d\tau\\
&\hat{q} = \hat{\theta} + k_q.
\end{aligned} \tag{7}$$

with observer gains l_b, l_q, l_s and l_i.

The following proposition states the semi-global asymptotic convergence of the observer over a domain of interest $\hat{\mathscr{X}_e}$.

Proposition 2 *For a piecewise constant input s_{in}, and a given domain of interest $\hat{\mathscr{X}_e} \subset \mathbb{R}^4_+$, the observer gains l_b, l_q, l_s and l_i can be chosen so that*

$$\forall \hat{\mathbf{x}}_e \in \hat{\mathscr{X}_e}: \quad \lim_{t\to\infty} ||\hat{\mathbf{x}}_e - \mathbf{x}_e|| = 0.$$

Proof: Introducing the estimation error

$$e_b = \hat{b} - b, \quad e_q = \hat{\theta} - \theta, \quad e_s = \hat{s} - s, \quad e_i = \hat{s}_{in} - s_{in}, \quad \mathbf{e} = \left[e_b, e_q, e_s, e_i\right]^T$$

the associated observation error dynamics are given by

$$\begin{aligned}
\dot{e}_b &= -(d + l_b - \nu(\hat{\theta}))e_b + [\nu(\theta+e_q)b - \nu(\theta)b]\\
\dot{e}_q &= -l_q e_b - \bar{\mu}e_q + [\rho(s+e_s) - \rho(s)]\\
\dot{e}_s &= -(l_s + \rho(\hat{s}))e_b - de_s + de_i - [\rho(s+e_s)b - \rho(s)b]\\
\dot{e}_i &= -l_i e_b
\end{aligned} \tag{8}$$

or equivalently (summing and subtracting $-e_i$ in the last line) in vector notation

$$\dot{\mathbf{e}} = (\hat{A} - \mathbf{l}\mathbf{c}_e^T)\mathbf{e} + G(y)\left(\varphi(\mathbf{x}_e+\mathbf{e}) - \varphi(\mathbf{x}_e)\right), \quad \mathbf{e} = \left[e_b, e_q, e_s, e_i\right]^T, \quad \mathbf{c}_e = \left[\mathbf{c}^T, 0\right] \tag{9}$$

with

$$\hat{A} - \mathbf{l}\mathbf{c}_e^T = \begin{bmatrix} -(d + l_b + \nu(\hat{\theta})) & 0 & 0 & 0\\ -l_q & -\bar{\mu} & 0 & 0\\ -(l_s + \rho(\hat{s})) & 0 & -d & d\\ -l_i & 0 & 0 & -1 \end{bmatrix}, \quad G(y) = \begin{bmatrix} y & 0 & 0\\ 0 & 1 & 0\\ 0 & -y & 0\\ 0 & 0 & 1 \end{bmatrix}, \quad \varphi(\mathbf{x}_e) = \begin{bmatrix} \nu(\theta)\\ \rho(s)\\ s_{in} \end{bmatrix}$$

Introduce the Lyapunov fuction

$$V(\mathbf{e}) = \mathbf{e}^T P\mathbf{e}, \quad P = P^T > 0 \tag{10}$$

set $\hat{A}_\mathbf{l} = \hat{A} - \mathbf{l}\mathbf{c}_e^T$ and take the time derivative of V

$$\dot{V}(\mathbf{e}) = \mathbf{e}^T\left(\hat{A}_\mathbf{l}^T P + P\hat{A}_\mathbf{l}\right)\mathbf{e} + \mathbf{e}^T PG(y)\left(\varphi(\mathbf{x}_e+\mathbf{e}) - \varphi(\mathbf{x}_e)\right) + \left(\varphi(\mathbf{x}_e+\mathbf{e}) - \varphi(\mathbf{x}_e)\right)^T G^T(y)P\mathbf{e}$$

Due to the Lipschitz continuity of ν and ρ over $\mathbb{R}_+$ there exists a matrix-valued function $M(y)$ such that

$$\mathbf{e}^T PG(y)\left(\varphi(\mathbf{x}_e+\mathbf{e}) - \varphi(\mathbf{x}_e)\right) = \mathbf{e}^T PG(y)\left(\int_0^1 \frac{\partial\varphi}{\partial\mathbf{x}_e}(\mathbf{x}_e + \eta\mathbf{e})d\eta\right)\mathbf{e} \le \mathbf{e}^T PM(y)\mathbf{e}. \tag{11}$$

By the particular observability structure of the pair $(\hat{A}, \mathbf{c}_e^T)$ (for any $\hat{x}_e \in \hat{\mathscr{X}_e}$ the eigenvalues of $\hat{A}_\mathbf{l}$ can be arbitrarily assigned) it holds that $\mathbf{l}$ can be chosen such that the Lyapunov inequality

$$(\hat{A}_\mathbf{l}^T + M^T(y))P + P(\hat{A}_\mathbf{l} + M(y)) < 0 \tag{12}$$

is satisfied for all pairs $(\mathbf{x}_e, \hat{\mathbf{x}}_e) \in \mathscr{X}_e \times \hat{\mathscr{X}_e}$. This means that $\dot{V} < 0$ over $\mathscr{X}_e \times \hat{\mathscr{X}_e}$, implying the observer convergence. Q.E.D.

Note that this result also implies that in presence of (zero-mean) measurement noise the observed trajectories will move within bounded tubes (with size depending on the observer gain) around the actual reactor trajectories.

4. Simulations

In order to verify the theoretic assessment, numerical simulations have been carried out for the parameter set (taken from (Toroghi et al., 2013)) $K_s = 0.105$, $\bar{\mu} = 2$, $k_q = 1.8$, $k_0 = 9.3$ using MATLAB with *ode15s*, and the unknown feed concentration input was set to $s_{in}(t) = 100 + 10\sigma(10) - 20\sigma(20)$ where $\sigma(T)$ is the unit step at T.

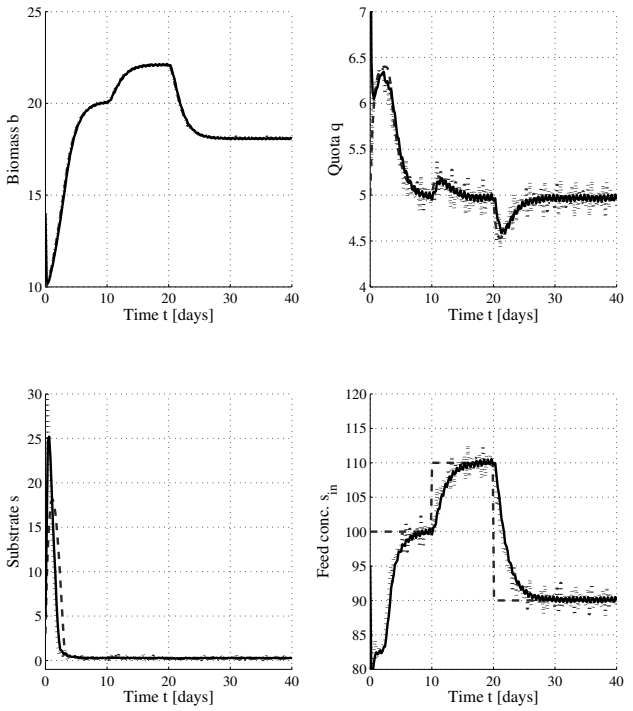

Figure 1: Time response of the Droop model (4) and the state and unknown-input estimator (7): actual plant (dashed lines), estimated state (dotted lines) and filtered state estimates (continuous line).

The measurement was perturbed by a high frequency noise with 1% amplitude. The dilution rate input is set to $d = 1.275$ and the initial condition of the system is given by

$$\mathbf{x}_0 = [10, 5, 3]^T$$

and for the extended state-input observer

$$\hat{\mathbf{x}}_{e0} = [14, 7, 5, 95]^T.$$

The observer gains are chosen as $l_b = 20$, $l_q = 45$, $l_s = 400$, and $l_i = 700$. Given that due to the measurement noise the observed state is noisy, a filtered version of the state estimate is obtained using a simple first-order low-pass filter. Note that the convergence of the filtered estimates is ensured by the convergence (in mean) of the observer state to the actual reactor trajectory.

In Figure 1 the reactor response is shown by the dashed line, the observed (noisy) state by the dotted line, and a filtered version of the observed state by the continuous line. It can be seen that the observed state (dotted line) and its filtered version (continuous line) recover the actual value of the extended state vector $\mathbf{x}_e = [b, q, s, s_{in}]^T$ (dashed line) despite of the unknown feed input.

5. Conclusions

The Droop model for microalgae growth is analyzed with respect to its observability with unknown feed input and it is shown that the model is state and unknown input observable. A nonlinear state-unknown input observer is designed with PI-like innovation scheme and ensured asymptotic stability over a sufficiently large domain of interest. Numerical simulations illustrate the observer performance for constant and time-varying feed flows.

PAT for Reactive Crystallization Process Optimization for Phosphorus Recovery from Sewage Sludge

Yi Liu, Haiyan Qu*

Department of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, Campusvej 55, DK-5230, Odense, Denmark.
haq@kbm.sdu.dk

Abstract

Recovery of high-purity phosphorus product from sewage sludge ash requires the production of crystals with optimized particulate properties, which will significantly facilitate the down-stream filtration operation and therefore ensure a high purity of the final products. Our previous study has demonstrated that there is a great potential to recover high-purity $CaClH_2PO_4 \cdot H_2O$ crystals from sewage sludge ash that contains high concentration of iron and aluminum. However, $CaClH_2PO_4 \cdot H_2O$ crystals produced from the reactive crystallization process possess poor particulate properties (e.g. small particle size and wide size distribution). In the present work, the effects of different operation parameters on the reactive crystallization of $CaClH_2PO_4 \cdot H_2O$ have been studied in a pure artificial system ($CaCl_2$ + H_3PO_4). The quality of $CaClH_2PO_4 \cdot H_2O$ crystals varied with changing temperature and pH of the solution. It has been found that increasing the processing temperature (>50 ^oC) and the pH of solution will improve the particle size distribution of the crystalline products.

Keywords: Reactive crystallization, Phosphorus recovery, monocalcium chlorophosphate.

1. Introduction

Phosphorus is an essential element for ecosystem, because the function of phosphorus as a nutrient for plants can not be replaced by any other substance (Steen, 1998). Currently, the phosphorus fertilizers are produced from the processing of phosphate rock, which is a natural source with limited deposits. However, as the demand of population and agricultural increases, it is predicted that the current exploitable reserves of phosphate rock will run out within 60-130 years (Steen, 1998). The production of phosphorus is rather concentrated; China, Morocco and the United States occupy almost two-thirds of global phosphate (Steen, 1998). European has only very limited resources (in Finland) and is largely dependent on imports. Therefore, recovery of phosphorus from sewage sludge ash provides an opportunity of supplying phosphorus with sustainable development.

The sewage sludge ash may contain high concentrations of iron and aluminum since iron and aluminum salts are frequently used to precipitate phosphate at wastewater treatment plants (WWTPs). The crude products containing phosphorus can be obtained from the ash in an acidic environment (Tan and Lagerkvist, 2011) (Schaum et al., 2007), and then they can be further processed with reactive crystallization to obtain a purer product in the form of monocalcium chlorophosphate ($CaClH_2PO_4 \cdot H_2O$). 75 years ago,

Fox (1939) observed that $CaClH_2PO_4 \cdot H_2O$ can be precipitated by treating the phosphate rock (CaO/P_2O_5) with hydrochloric and phosphoric acid. The further growth of $CaClH_2PO_4 \cdot H_2O$ crystals took place when the suspension was kept at or near its boiling point. However, the growth of $CaClH_2PO_4 \cdot H_2O$ was very slow and the resulted fine particles led to a very difficult solid-liquid separation via filtration. The poor filterability of the crystals also caused a significant reduction of the final products purity due to the high residual of mother liquor in the filter cake. This poor particle size hinders the application of this process to the large-scale production of phosphorus in industry. In order to improve the filterability of the $CaClH_2PO_4 \cdot H_2O$ crystals, the mechanism of the reactive crystallization process needs to be understood and the key operation parameters that significantly influence the growth kinetics of the $CaClH_2PO_4 \cdot H_2O$ crystals have to be identified.

The objective of this work is to gain insight into the mechanism of reactive crystallization of $CaClH_2PO_4 \cdot H_2O$ in an artificial system of calcium chloride and phosphoric acid. The properties of the produced crystals were characterized with various process analytical technologies, such as Laser Diffraction Particle Size Analyzer, Raman Spectroscopy, X-ray Powder Diffraction (XRPD). The effects of different operation parameters (reactants concentration, temperature, pH) on the reactive crystallization process and the properties of the crystal products have been investigated. Key operation parameters for the optimization of the process have been identified.

2. Experimental Methods

2.1. Reactive crystallization

The solid calcium chloride was purchased from Sigma-Aldrich and the 85 % wt ortho-phosphoric acid was purchased from Merck. $CaClH_2PO_4 \cdot H_2O$ crystals can be produced through the reactive crystallization described in Eq. (1) (Fox, 1939) as follows:

$$CaCl_2+H_3PO_4+H_2O=CaClH_2PO_4 \cdot H_2O+HCl\uparrow \quad (1)$$

The calcium chloride was firstly dissolved in distilled water and then mixed with diluted phosphoric acid in 1:1 ratio of molal quantities. The feed speeds of calcium chloride solution and phosphoric acid were controlled by two peristaltic pumps (Ole Dich Instrumentmakers, Denmark), respectively, assuring to mix calcium chloride and phosphoric acid in equimolecular amounts. An IKA C-MAG HS7 magnetic stirrer (IKA, Denmark) was applied to stir and to heat the mixture up during crystallization. The temperature of the mixture solution was monitored with a thermometer. After the crystallization process, the crystals were separated by vacuum filtration from the mother liquor through a glass fiber filter paper (ADVANTEC GC-50). The whole procedure was carried out in a fume hood.

2.2. X-ray Powder Diffraction (XRPD) Analysis

The products obtained in the present work were analyzed with an X´Pert Pro diffractometer by using Cu $K\alpha_1$ (λ=1.5406 Å) radiation, operating at 40 mA, 45 kV, at room temperature. The pattern were recorded in the range of $2\theta = 5^o - 60^o$ with a step size $2\theta=0.02^o$ and the scan step time was 100 s. Phase of $CaClH_2PO_4 \cdot H_2O$ was identified by using the standard PDF card No. 00-044-0746.

2.3. Raman Analysis

The Raman analysis of crystals was carried out with a SENTERRA/ Dispersive Raman Spectrometer (Bruker, Germany) with a 785 nm laser at 100 mW.

2.4. Particles Size Distribution

The particle size distribution of the solids obtained from the reactive crystallization was measured with a LS13320 Laser Diffraction Particle Size Analyzer (Beckman Coulter). Because $CaClH_2PO_4 \cdot H_2O$ is highly soluble in water, a saturated solution of the testing solids in 70 % (v/v) ethanol (VWR) was chosen as the background solution for analyzing.

3. Results and Discussion

3.1. The effects of temperature

When calcium chloride and phosphoric acid were mixed in an equal molar concentration of higher than 2.9 mol/L, $CaClH_2PO_4 \cdot H_2O$ tends to crystallize as white crystals from the liquid phase at room temperature (22-25 ^oC). It was found that the filterability of the crystals produced at a higher temperature (>50 ^oC) was much better than that of the crystals processed at room temperature (22-25 ^oC). Figure 1 shows the particle size distribution of the crystals prepared at 25 ^oC and at 54 ^oC, respectively. It is evident that the crystals formed at 54 ^oC possess larger sizes, most of which are 200~400 μm, while the particle sizes of the crystals formed at 25 ^oC mainly are 50~200 μm. The micrographs of such $CaClH_2PO_4 \cdot H_2O$ crystals formed at 25 ^oC (upper) and 54 ^oC (down) inset in Figure 1 also demonstrates that the crystals formed at 54 ^oC possess bigger sizes.

The purity of $CaClH_2PO_4 \cdot H_2O$ crystals increases with increasing processing temperature, which is proved by the XRPD analysis,as shown in Figure 2. The solid line in Figure 2 represents the pattern of crystals formed at 25 ^oC and the dash line indicates the pattern of crystals formed at 54 ^oC. Besides the characteristic peaks attributed to the $CaClH_2PO_4 \cdot H_2O$ crystals, it still exists other sharp peaks which are assigned to calcium phosphate hydrate ($Ca_2P_2O_7 \cdot 2H_2O$, $2\theta=7.720^o$, highlighted with ♣) and calcium hydrogen phosphate hydrate ($Ca(H_2PO_4)_2 \cdot H_2O$, $2\theta=22.902^o$ and $2\theta=24.098^o$, highlighted with ♥) in the pattern regarding crystals formed at 25 ^oC. It is obvious that such typical peaks related to impurities are much weaker in the pattern of crystals formed at 54 ^oC. Thus, it demonstrates that a higher processing temperature ($\geq$ 54 ^oC) will be of great benefit to increase the purity of $CaClH_2PO_4 \cdot H_2O$ crystals.

The two crystals prepared at 25 ^oC and 54 ^oC were also checked by Raman spectroscopy, respectively. The results are shown in Figure 3. The crystals prepared at 54 ^oC yields two single significant peaks at the position of 900 cm^{-1} and 1105 cm^{-1}, respectively (dash line, in Figure 3). By comparison, the crystals formed at 25 ^oC shows a single sharp peak at 1110 cm^{-1}, a broad peak at 1014 cm^{-1} and a double peak at 902 cm^{-1} and 913 cm^{-1} (solid line, in Figure 3).The pure $Ca(H_2PO_4)_2$ solid contains such three peaks at similar positions (dash-dot line, in Figure 3), which are the signals assigned to the $H_2PO_4^-$ species. This result reveals that the crystals formed at 25 ^oC contain major impurity of $Ca(H_2PO_4)_2$.

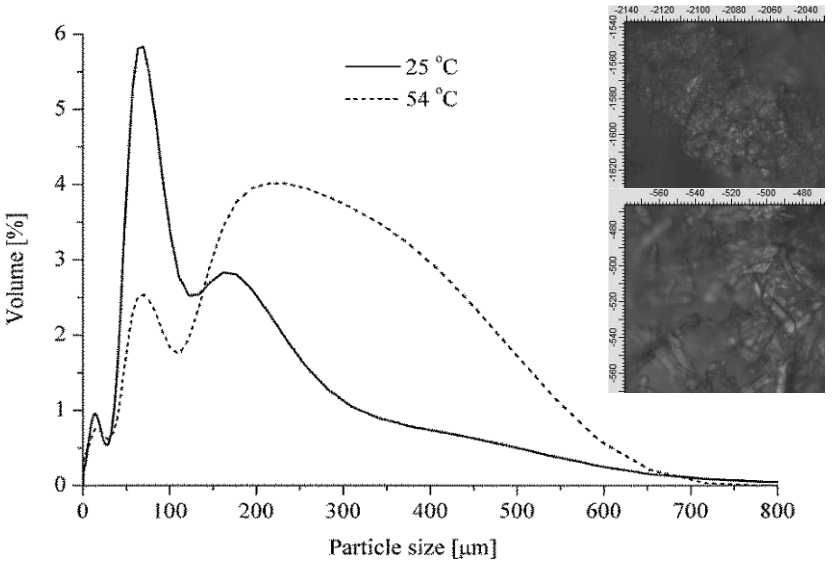

Figure 1: Particle size distribution of $CaClH_2PO_4 \cdot H_2O$ crystals produced at different temperatures. The original concentrations of $CaCl_2$ and H_3PO_4 were both 3.1 mol/L. The attached two photos are the micrographs (×20) of $CaClH_2PO_4 \cdot H_2O$ crystals formed at 25 °C (upper) and at 54 °C (down).

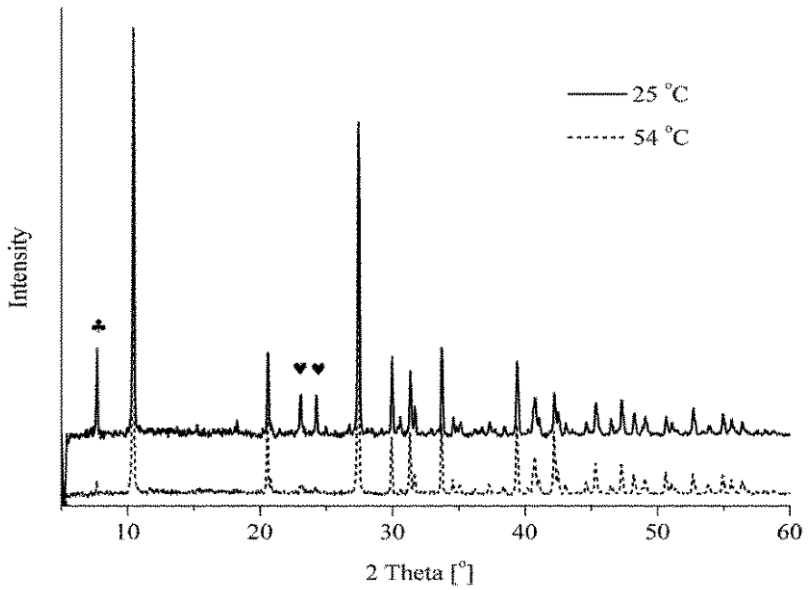

Figure 2: XRPD pattern of $CaClH_2PO_4 \cdot H_2O$ crystals produced at 25 °C (solid line) and at 54 °C (dash line). The original concentrations of $CaCl_2$ and H_3PO_4 were both 3.1 mol/L. ♣ - peak for $Ca_2P_2O_7 \cdot 2H_2O$at $2\theta=7.720^o$; ♥- peaks for $Ca(H_2PO_4)_2 \cdot H_2O$ at $2\theta=22.902^o$ and $2\theta=24.098^o$.

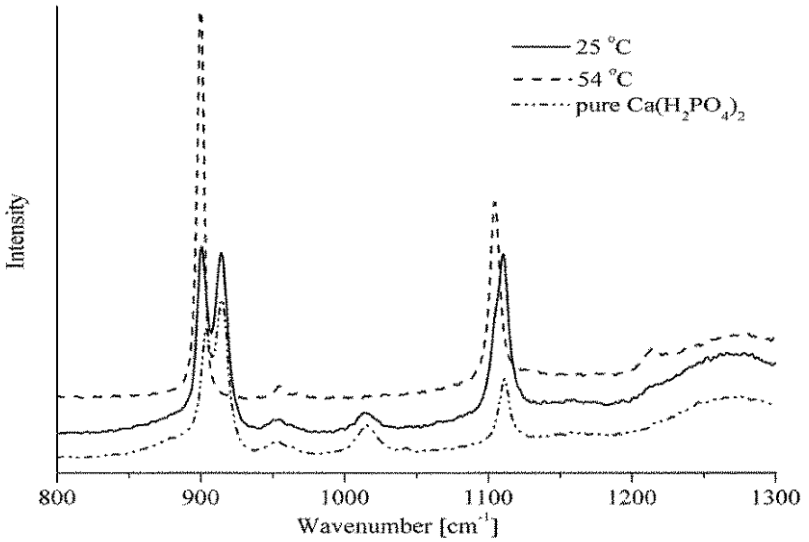

Figure 3: Raman spectra of $CaClH_2PO_4 \cdot H_2O$ crystals produced at 25 °C (solid line), at 54 °C (dash line) and the pure solid of $Ca(H_2PO_4)_2$ (dash-dot line). The original concentrations of $CaCl_2$ and H_3PO_4 were both 3.1 mol/L.

3.2. The effects of pH values

The pH of the mixture solution ($CaCl_2$ + H_3PO_4) in this work is always minus. The relative fraction of the dissociated species of phosphoric acid in water as a function of pH is illustrated in Figure 4 (Wolfe-Simon et al., 2009). The relative concentration of $H_2PO_4^-$ reaches a maximum around pH 4-5. Although the high concentration of $H_2PO_4^-$ will facilitate the formation of $CaClH_2PO_4 \cdot H_2O$ crystals, the other heavy metals (such as Fe and Al) in the sewage sludge ash will precipitated out at pH ≥3 (Schaum et al., 2007). In order to obtain the $CaClH_2PO_4 \cdot H_2O$ crystals without Fe and Al, the pH of the solution must be kept below 3.

In the present work, the pH of the mixture solution was adjusted by adding saturated $Ca(OH)_2$ solution. Since the phosphoric acid can exist as different species, changing the pH of the solution, might lead to the formation of other intermedia phases during the crystallization process, such as dicalcium phosphate dihydrate (DCPD), octacalcium phosphate (OCP), tricalcium phosphate (TCP) and hydroxyapatite (HAP) (Johnsson and Nancollas, 1992). Therefore, it is necessary to check if changing pH will influence the composition of the product.

The XRPD pattern of $CaClH_2PO_4 \cdot H_2O$ crystals prepared at different original pH have been compared and it has been observed that increasing the pH up to 0.42 didn't cause the formation of the phosphate products other than $CaClH_2PO_4 \cdot H_2O$. Meanwhile, the filterability of the crystals has been improved probably due to the higher concentration of $H_2PO_4^-$, which favored the growth of $CaClH_2PO_4 \cdot H_2O$ crystals.

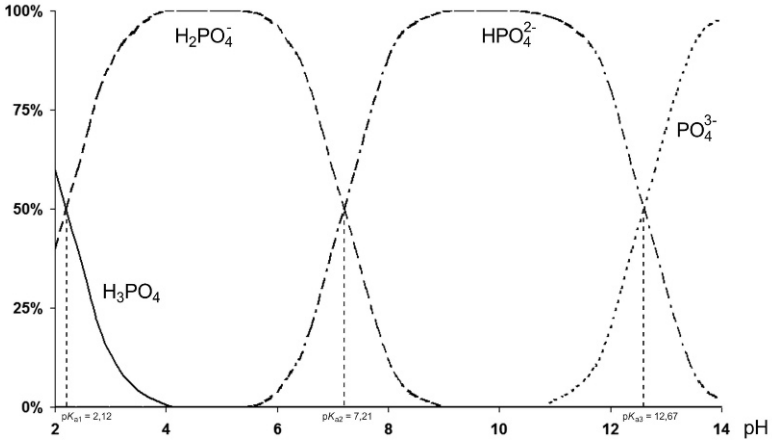

Figure 4: The relative fraction of phosphoric acid in water as a function of pH (Wolfe-Simon et al. 2009).

4. Conclusions

$CaClH_2PO_4 \cdot H_2O$ crystals were produced with a reactive crystallization by mixing calcium chloride solution and diluted phosphoric acid solution in equimolal proportions. The properties of the obtained products have been characterized with different process analytical technologies, such as XRPD, Raman spectroscopy and particle size analyzer. It can be concluded that increasing the processing temperature (>50 ^oC) and pH of the crystallization solution promote $CaClH_2PO_4 \cdot H_2O$ product properties in terms of high purity and larger particle size. The increased particle size will improve the filterability of the crystals and thus lead to a better solid-liquid separation in the down-stream filtration operations. Results obtained in the present work provide guidance for the development and optimization of reactive crystallization process for recovery of phosphorus product from sewage sludge ash that is heavily contaminated by ferrum and aluminum.

Abstract

This paper deals with time-optimal operation of a batch diafiltration process in the presence of membrane fouling. Fouling causes a decrease in membrane area and hence, a decrease in permeate flux. Pontryagin's minimum principle is applied to characterize the structure of the optimal operation. Due to the specific structure of the problem, it is possible to derive and verify an explicit analytic solution. Obtained results are used in a case study where we provide a comparison between traditional operation and the herein developed time-optimal operation.

Keywords: optimal control, membrane fouling, Pontryagin's minimum principle, diafiltration.

1. Introduction

Diafiltration (DF) is a unique membrane process for separation of two or more solutes in a solution, used in the pharmaceutical, food and biotechnological industry. The process is designed to increase the concentration of high molecular weight components (macro-solute) and to decrease the concentration of low molecular weight components (micro-solute).

One of the major problems encountered in membrane separation processes is the fouling of the membrane. Fouling causes a decrease in effective membrane area resulting in reduction of permeate flow, and hence the increase of the processing time. Hermia (1982) provided a unified fouling model, from which four different standard fouling models can be derived considering different ways the solutes deposit on the membrane surface. These models are expressed in the terms of decrease in effective membrane area or the permeate flux (Bolton et al., 2006; Vela et al., 2008).

In the recent years, several papers (Foley, 1999; Paulen et al., 2012) have discussed the optimization of the diafiltration processes. They exploited several ways to efficiently run the diafiltration process in minimum time, but have not considered any fouling behavior. In the paper by Jelemenský et al. (2014b) a time-optimal operation in the presence of fouling has been proposed. It considers that the fouling causes a gradual decrease in the effective membrane area. Pontryagin' minimum principle is applied and optimal operation combines analytic structure with numerical optimization. In this paper we assume explicit dependency of permeate flux on processing time as proposed by Vela et al. (2008). The optimal operation derived in this paper is improved and completely given by simple rules and avoids any on-line optimization. A comparison between the proposed time-optimal operation and the traditionally used control strategy is presented further by means of a case study.

2. Problem Formulation

2.1. Process Description

A diafiltration process consists of a feed tank and a membrane unit. The solution from the feed tank consisting of a solvent and solutes is brought to the membrane unit by means of mechanical energy. The membrane is designed to retain the macro-solute and to allow the passage of micro-solute. Part of the filtered solution rejected by the membrane (retentate) returns back to the feed tank. Permeate stream leaves the system at a flowrate $q = A \cdot J$, where A represents the effective membrane area and J is the concentration- and time-depedent permeate flux subjected to unit membrane area.

The process control is achieved by adjusting the flowrate of solute-free diluant into the feed tank. The control variable α is defined as a ratio between the inflow of diluant into the feed tank, and the outflow of the permeate q. There are several control strategies according to the rate of the diluant utilization: (a) concentration (C) mode with α = 0; (b) constant-volume diafiltration (CVD) mode with α = 1; (c) dilution (D) mode with $\alpha \in (1, \infty)$, where $\alpha \to \infty$ represents an instantaneous dilution that maintains the ratio of solutes concentrations. One of the widely used control strategy in industry is a two-step operation, wherein the first step uses concentration mode (C) to increase the concentration of the product, and the second step is CVD to decrease the concentration of impurities (i.e. C-CVD). The mathematical model of the process is given by material balances of solutes and the overall material balance (Fikar et al., 2010):

$$\frac{dc_i}{dt} = \frac{c_i}{V} \cdot A \cdot J \cdot (R_i - 1), \qquad c_i(0) = c_{i,0}, \qquad i = 1,2,\dots,n \tag{1a}$$

$$\frac{dV}{dt} = A \cdot J \cdot (\alpha - 1), \qquad V(0) = V_0, \tag{2b}$$

where c_i represents the concentration of the *i*th solute, V is the volume of the processedsolution. R_i represents the rejection coefficient for the *i*th solute defined as $R_i = 1 - c_i/c_{p,i}$ where $c_{p,i}$ is concentration of component *i* in permeate.

2.2. Membrane Fouling

Membrane fouling causes decrease of the permeate flux in time as a consequence of the effective membrane area being reduced due to the deposit of the solutes on or in the membrane pores. In Hermia (1982); Vela et al. (2008) a unified model is provided from which four standard fouling models can be derived.The permeate fluxes in these models can be characterized as:

$$\text{(a)complete fouling model: } \ln J = \ln J_0 - K_c \cdot t, \tag{2a}$$

$$\text{(b)intermediate fouling model: } \frac{1}{J} = \frac{1}{J_0} + K_i \cdot t, \tag{2b}$$

$$\text{(c)standard (internal)fouling model: } \frac{1}{\sqrt{J}} = \frac{1}{\sqrt{J_0}} + K_s \cdot t, \tag{2c}$$

$$\text{(d)cake fouling model: } \frac{1}{J^2} = \frac{1}{{J_0}^2} + K_g \cdot t, \tag{2d}$$

where J_0 is the initial flux and K is a fouling constant. These results were obtained for dead-end filtration. We will use the intermediate model (2b) in the subsequent sections for cross-flow regime and J_0 will represent the permeate flow of unfouled membrane.

2.3. Optimization Problem

The optimization goal is to find such time-dependent function $\alpha(t)$ which guarantees transition from given initial to final concentrations in minimum time. We assume that the membrane is absolutely impermeable to macro-solute (c_1), the permeability of micro-solute (c_2) changes as a function of concentrations, and is expressed using rejection coefficient $R_2 = R_2(c_1, c_2)$. Consequently, the optimization problem reads as:

$$\min_{\alpha\in[0,\infty)} \int_0^{t_f} 1 \cdot dt \tag{3a}$$

$$\text{s.t.} \quad \frac{dc_1}{dt} = {c_1}^2 \cdot \frac{A \cdot J}{c_{1,0} \cdot V_0} \cdot (1-\alpha), \qquad c_1(0) = c_{1,0}, \qquad c_1(t_f) = c_{1,f}, \tag{3b}$$

$$\frac{dc_2}{dt} = c_1 \cdot c_2 \cdot \frac{A \cdot J}{c_{1,0} \cdot V_0} \cdot (R_2 - \alpha), \qquad c_2(0) = c_{2,0}, \qquad c_2(t_f) = c_{2,f}, \tag{3c}$$

where we use the fact that $V = c_{10} \cdot V_0 / c_1$, since $R_1 = 1$.

3. Optimal Operation

We use Pontryagin's minimum principle (PMP) (Pontryagin et al., 1962; Bryson, Jr. and Ho, 1975) to identify the candidates for optimal control. A care has to be taken as the process model depends explicitly on time, thus the problem is non-autonomous. There are two possible approaches to handle optimal control of non-autonomous systems. The first approach considers time explicitly in the process model. Then, the optimal Hamiltonian function is zero only at final time. Therefore, there are two variables (concentrations) and PMP has to supply two equations for optimality. The second approach adds a third state variable $\dot{x}_3 = 1$ with initial condition $x_3(0) = 0$ and replaces t with x_3. Therefore, the new problem is autonomous with increased number of variables. In this case, Hamiltonian function is zero along the optimal trajectory and this fact can be used to provide additional equations for finding an optimal solution. When we consider the first approach, the process model can be written as

$$\dot{x} = f(t,x) + g(t,x) \cdot \alpha, \tag{4}$$

where $x = (c_1, c_2)^T$. The Hamiltonian function can then be constructed as

$$H(t,x,\lambda,\alpha) = 1 + f^T(t,x) \cdot \lambda + g^T(t,x) \cdot \lambda \cdot \alpha = H_0(t,x,\lambda) + H_\alpha(t,x,\lambda) \cdot \alpha, \tag{5}$$

where $\lambda = (\lambda_1, \lambda_2)^T$ is the vector of adjoint variables defined from

$$\dot{\lambda} = -\,\partial H/\partial x = -(f_x + g_x \cdot \alpha) \cdot \lambda\,, \quad f_x(t,x) = \frac{\partial f^T(t,x)}{\partial x}, \quad g_x(t,x) = \frac{\partial g^T(t,x)}{\partial x}. \tag{6}$$

Since the Hamiltonian is affine in α, its minimum is attained with α on its boundaries as

$$\alpha = \begin{cases} 0 & \text{if } H_\alpha > 0, \\ \infty & \text{if } H_\alpha < 0. \end{cases} \tag{7}$$

If Hamiltonian is singular in α, the singular case is characterized by equations $H_\alpha = 0$, $\dot{H}_\alpha = 0$. This gives a set of equations which are linear in λ

$$H_\alpha(t,x,\lambda) = g^T \cdot \lambda = 0, \tag{8}$$

$$\dot{H}_\alpha(t,x,\lambda) = h^T \cdot \lambda = (g_x \cdot f - f_x \cdot g + \partial H_\alpha/\partial t)^T \cdot \lambda = 0 \tag{9}$$

Elimination of λ from (8) and (9) results in characterization of the singular surface:

$$S(t, c_1, c_2) = (R_2 - 1) \cdot \left(J + \sum_{i=1}^{2} c_i \cdot \partial J / \partial c_i \right) + J \cdot \left(\sum_{i=1}^{2} c_i \cdot \partial R_2 / \partial c_i \right) = 0 \quad (10)$$

Note that the expression (10) is actually identical to the one without fouling, as derived in Paulen et al. (2012). The only difference lies in the fact that J (and thus S) is not only a function of concentrations but also of time. To obtain the control which keeps the states on the singular surface, we differentiate the singular surface (10) w.r.t. to time. The obtained singular control is:

$$\alpha(t, c_1, c_2) = \frac{c_1 \cdot \partial S / \partial c_1 + c_2 \cdot R_2 \, \partial S / \partial c_2}{\sum_{i=1}^{2} c_i \cdot \partial S / \partial c_i} + \frac{\partial S / \partial t}{c_1 \cdot J / c_{10} \cdot V_0 \cdot (\sum_{i=1}^{2} c_i \cdot \partial S / \partial c_i)}. \quad (11)$$

The optimal operation hence deduced, consists of following three steps:

1. In the first step, depending on the initial concentrations, we use either concentration mode or pure dilution mode until the condition $S(t, c_1, c_2) = 0$ is met.
2. During the second step we stay on singular surface where the singular control (11) is used.
3. The last step is characterized by saturated control until the final conditions for concentrations are met.

It is necessary to point out that any step can be missing from the optimal operation. This depends solely on the initial and final conditions. For instance, if there does not exist any three-step strategy fulfilling the final conditions, the middle step is skipped, and the optimal control is saturated on constraints. It is also worth mentioning that the developed optimal operation can be applied to a general batch diafiltration process with arbitrary type of membrane module and nature of filtered species.

4. Case Study

A case study on the separation of lactose (with concentration c_2) from proteins (with concentration c_1) originally formulated in Rajagopalan and Cheryan (1991) is solved here. The authors experimentally obtained a model for the permeate flux as,

$$J_0(c_1, c_2) = b_0 + b_1 \cdot \ln c_1 + b_2 \cdot \ln c_2 = 63.42 - 12.439 \cdot \ln c_1 - 7.836 \cdot \ln c_2. \quad (12)$$

The fouling model for the permeate flux (2b) is used here. Goal is to drive the concentrations from initial point $[c_{1,0}, c_{2,0}] = [3.3\ \text{g/dL}, 5.5\ \text{g/dL}]$ to final point $[c_{1,f}, c_{2,f}] = [9.04\ \text{g/dL}, 0.64\ \text{g/dL}]$ for 100dL of solution. Further on, we consider that the membrane is absolutely permeable to lactose ($R_2 = 0$), and the membrane area is 1 m^2. The analytic results for singular surface (10) and singular control (11) are

$$S(t, c_1, c_2) = b_1 + b_2 + J_0 + K_i \cdot t \cdot [b_0(b_0 + 2 \cdot F) + F^2] = 0, \quad (13)$$

where $F = b_1 \cdot \ln c_1 + b_2 \cdot \ln c_2$, and (14)

$$\alpha(t, c_1, c_2) = \frac{b_1}{b_1 + b_2} + \frac{c_{10} \cdot V_0 \cdot K_i \cdot J_0 \cdot (K_i \cdot J_0 \cdot t + 1)}{A \cdot K \cdot c_1 \cdot (b_1 + b_2) \cdot (2 \cdot K_i \cdot J_0 \cdot t + 1)}, \quad (15)$$

respectively, with V_0 as the initial volume. We can observe that besides concentrations, singular surface and control also depend on fouling rate and time. From the results

above, time-optimal operation in the presence of fouling comprises a sequence of following three steps:

1. The first step is concentration mode ($\alpha = 0$) till the singular surface (13) is reached.
2. Then, in the second step, the states reside on the singular surface with the singular control (15). This step is performed until the condition $c_1(t)/c_2(t) = c_{1,f}/c_{2,f}$ is satisfied.
3. In the last step we perform pure dilution mode with $\alpha = \infty$ until the final concentrations are reached.

Figure 1 depicts the optimal control strategy (states and control) for the minimum-time operation for different fouling rates. The control structure in all the cases is a three-step strategy, as mentioned above. In the state diagram the circle represents the initial concentrations and the cross depicts the final ones. We can observe that the switching concentration to singular surface (13) is changing with different fouling rates K_i. Furthermore we can observe that the increase of these values translates to longer processing time, as expected.

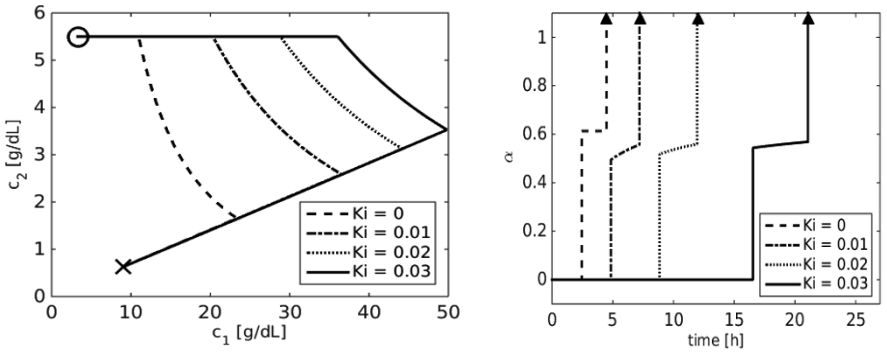

Figure 1: Comparison of different control strategies (left – state space, right – control profiles).

Table 1 presents a comparison of the final processing time in case of minimum-time operation, derived in this paper, and the traditionally used operation (C-CVD). The differences in the duration of the respective operations get more significant as the fouling rate increases. For the highest rate of fouling considered here, the savings in terms of processing time are more than threefold. Therefore we can conclude that it would be substantially beneficial to employ the time-optimal operation for reducing the costs in the separation of macro-solute in this case study.

A care must be taken when applying this optimal operation on a real process. The traditional C-CVD operation and model (11) operate with concentration $c_1 < 10$ g/dL.The proposed optimal operation uses much higher concentrations, up to 50 g/dL. Therefore, a new model has to be estimated that also covers this area.

Table 1: Time-optimal operation compared to traditional operation for different fouling rates.

K_i [10^{-3} m^{-1}]	minimum time t_f [h]	C-CVD t_f [h]	Δ[%]
0	4.49	4.74	5.57
10	7.24	10.52	45.30
20	12.02	26.70	122.13
30	21.27	75.57	255.29

Such high concentrations can cause strong polarization effects and necessity to move the operation in lower-concentration region. In that case, the singular surface would not be attained and constraint-based operation would be applied, as in Jelemenský et al. (2014a).

5. Conclusions

In this paper we studied the time-optimal control of a batch diafiltration process in the presence of fouling. The fouling behavior was described by the reduction of the permeate flux caused by the deposit of the solutes on the membrane. Using Pontryagin's minimum principle we derived the candidates for optimal control. The derived optimal operation is completely analytic, and consists of three steps with singular control being the second one. The developed theory was applied on an example for separating proteins and lactose. The obtained results indicate that by using advanced control strategy we can reduce the production costs compared to traditionally used operations.

Abstract

This paper presents computer-based analysis and design of control systems for centrifugal compressors when the operating fluid is supercritical CO_2. It demonstrates that the design of the control system of the compressor must take into account the state of the fluid. It also evaluates if the plant configuration allows compressor operation within a given surge margin. The results show the impact of the operating conditions of the compression station on surge prevention, their effect on the energy consumption, and suggest ways of dealing with supercritical fluid while controlling a compressor.
Keywords: supercritical, compressor, control, CO_2, recycle.

1. Introduction

The compression of carbon dioxide for transportation and storage has increased in recent years. This is due to its importance within carbon capture and storage technology with large-scale transportation via pipelines (Zhang et al., 2006).
In order to increase the gas density while reducing the pressure drop along the pipeline, the gas is compressed to supercritical phase via multistage centrifugal compressors. However, practical problems can arise in the operation of such a compressor, especially when dealing with gas recycle for antisurge protection. Prior work on transcritical CO_2 compression operation is found from other research areas such as refrigeration plants and power generation based on a supercritical CO_2 Brayton cycle. However in the refrigeration industry the research goal is the thermal optimization of the cycle and positive displacement machines are employed (Conboy et al., 2013, Salazar and Mendez, 2014). On the other hand, technology involving rotating dynamic compressors, such as power generation based on a supercritical CO_2 gas turbine, is still in the early stage of development (Lettieri et al., 2014). Therefore in the future it will need a suitable control system able to deal with the recycle of supercritical CO_2.
This paper reports on the analysis of supercritical gas recycle with the purpose of surge prevention. It compares different recycle configurations during boundary disturbances in order to evaluate the effect of the recycle temperature on surge occurrence and power consumption.

2. Model of the compression system

The model of the compression system consists of a fully validated non-linear dynamic model based on a model present in the literature (Greitzer, 1976) that has been modified by other authors in order to include the shaft dynamics (Fink et al., 1992) and the equations for the torque of the compressor and of the electric driver (Gravdahl et al., 2002). The main equations of the model include the mass and momentum balance for

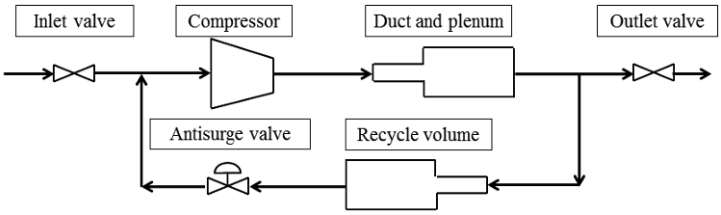

Figure 1. Sketch of the compression system

the compressor and the moment of momentum balance for the rotating shaft. The model of the compression system also includes the equations of the mass flow rate through inlet, outlet and recycle antisurge valve. The mass flow rate has been defined as a function of the upstream density according to Morini et al. (2007). The density of the gas as a function of its temperature and pressure is estimated using the Span and Wagner equation of state (Anwar and Carroll, 2010).

3. Simulation scenarios and control system

Two different configuration scenarios have been modelled. The first scenario includes a cold gas recycle where the recycled gas is cooled from the outlet temperature of the compressor T_{02} to the same temperature as the freshly fed gas T_{in}. The second scenario includes a hot gas recycle where the gas is not cooled before being recycled and therefore affects the inlet temperature of the compressor T_{01}. These two configuration scenarios have been compared during disturbances consisting of step changes of the opening position of the boundary valves. The response of the two systems has been recorded and compared via graphic representation and also by means of dimensionless indicators representing respectively the amount of gas recycled, the energy requested by the system and the performance of the pressure controller, according to the equations (1) - (3). m_r is the recycle mass flow rate, m is the compressor mass flow rate, t_{final} is the time period under analysis, P is the power consumption due to gas compression, Q is the power consumption due to heat removal in the cold gas recycle configuration, p is the compressor outlet pressure and p_{sp} its set point. Equation (4) expresses the corrected mass flow rate as a function of the inlet conditions of the gas (Boyce, 2003). m_{corr} is the corrected mass flow rate while m_{act} is the actual mass flow rate. p_{01} and T_{01} are respectively the compressor inlet pressure and temperature while p_{ref} and T_{ref} are respectively the reference pressure and temperature.

$$M = \frac{\int_{t=0}^{t_{final}} m_r dt}{\int_{t=0}^{t=1h} m dt} \tag{1}$$

$$E = \frac{\int_{t=0}^{t_{final}} (P+Q) dt}{\int_{t=0}^{t=1h} P dt} \tag{2}$$

$$ISE_p = \int_{t=0}^{t_{final}} (p(t) - p_{SP}(t))^2 dt \tag{3}$$

$$m_{corr} = \frac{m_{act}\sqrt{T_{01}/T_{ref}}}{p_{01}/p_{ref}} \tag{4}$$

Finally supercritical gas recycle has been compared with subcritical gas recycle.
A standard control system has been proposed and implemented. It consists of a cascade pressure controller and an antisurge controller. The interaction between these two controllers is a known issue in industrial application. However this is still the most employed control system for compressors and therefore it has been selected for the analysis. In the cascade control structure, the slave loop is a speed controller while the master loop is a pressure controller. The driver torque τ_d is the manipulated variable. The antisurge controller opens the recycle valve ASV when the inlet flow rate of the compressor m falls below the control flow rate m_{ctrl}. A margin of 20 % between the surge flow rate m_{surge} and m_{ctrl} has been imposed.
All the variables reported in the paper have been scaled according to their design value at the inlet of the compressor. This is due to non-disclosure agreement with the partner of the project that has provided the industrial case study. It consists of a multistage centrifugal compressor driven by an electric motor and mounted in a single shaft configuration. The fourth and last stage of compression has been the reference for the supercritical compression case while the third stage has been the reference for the subcritical compression case, and the two machines have the same model.

4. Dynamic simulations and results

4.1. Cold gas recycle

The opening position of the inlet and of the outlet boundary valves has been modified according to negative step changes from the fully open position OP=100 % to the opening positions specified in Table 1. Step disturbances took place at time t=100s and simulations were performed for 30 minutes. Performance indexes for some representative cases have been reported in the table below. For inlet boundary disturbances, four cases have been reported. The first case is the steady state simulation and then the other three cases represent three different step changes. For the second and third case where OP is equal respectively to 80 % and 50 % the compressor does not

Table 1. Performance indexes for inlet and outlet disturbances (cold gas recycle)

	Inlet valve V_{in}				Outlet valve V_{out}				
OP (%)	100	80	50	20	100	80	78	75	72
M	0.00	0.00	0.00	1.35	0.00	0.00	0.00	0.35	5.23
ISE_p	0.00	0.02	0.51	3869.70	0.00	7.75	9.43	12.35	16.01
E	0.50	0.50	0.52	0.63	0.50	0.40	0.39	0.41	0.88

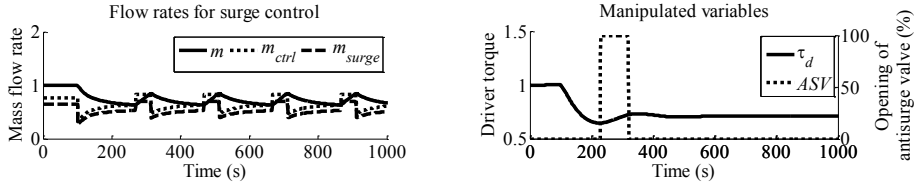

Figure 2. Cold gas recycle. a.Inlet valve step change from fully open position to 20 % (left) – b.Outlet valve step change from fully open position to 75 % (right)

recycle gas as its inlet flow rate m is still above the control flow rate m_{ctrl}. Therefore for these two cases M is equal to zero and E depends only on the compression process. As expected ISE_p increases with the disturbance magnitude. When m and m_{ctrl} cross each other at OP=20 % the antisurge controller opens ASV in order to increase m. However this action influences the value of m_{surge}, according to equation (4). The actual value of m_{surge} increases if p_{01} increases and for this reason m and m_{surge} cross right after the opening of ASV. The operating point of the compressor goes below the surge value and the response of the system starts oscillating as represented in Figure 2.a. The overall control system is not able to stabilise the system. The control over pressure is poor (ISE_p=3869.7). This is due to the saturation of the pressure controller, when the rotating shaft speed achieves its upper boundary.

Negative step disturbances have been performed for V_{out} as well. As it happened for inlet disturbances, until ASV is closed M is equal to zero and ISE_p increases. In this case E decreases because of the decrease of m. When m crosses m_{ctrl} at V_{out}=75 % part of the gas is recycled back to the inlet of the compressor and this case has been represented Figure 2.b. The ASV opens for a short period until m goes above m_{ctrl}. M and therefore E increase with the magnitude of the disturbance.

4.2. Hot gas recycle

The same disturbances as above have been tested in the hot gas recycle configuration. Results have been summarised in Table 2. Until ASV is closed the system behaves as did the cold gas recycle configuration, as the recycle line is not engaged in the process operation. However when ASV opens the system responds in a different way. For the case V_{in}=20 %, the compressor does not go into surge however the response of the system oscillates. This is due to the recycle of hot gas that causes T_{01} to increase and therefore m_{surge} to decreases, according to equation (4), as represented in Figure 3.a. Moreover in this case the power consumption decreases and this is due to both the reduction of m and the missing cost due to gas cooling.

Similarly for the output boundary valve, in the case when OP is equal to 75 % ASV oscillates because of the effect of the hot gas recycle on T_{01} and therefore m_{ctrl}. The time series for the manipulated variables has been represented in Figure 3.b. For this

Table 2. Performance indexes for inlet and outlet disturbances (hot gas recycle)

	Inlet valve V_{in}				Outlet valve V_{out}				
OP (%)	100	80	50	20	100	80	78	75	72
M	0.00	0.00	0.00	0.21	0.00	0.00	0.00	0.04	0.19
ISE_p	0.00	0.02	0.51	6578.80	0.00	7.72	9.39	12.85	17.69
E	0.50	0.50	0.52	0.40	0.50	0.40	0.39	0.38	0.36

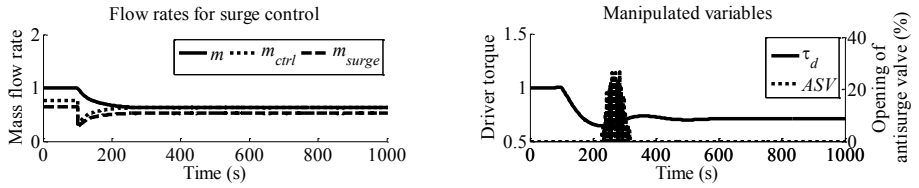

Figure 3. Hot gas recycle. a.Inlet valve step change from fully open position to 20 % (left) – b.Outlet valve step change from fully open position to 75 % (right)

specific case M was higher while ISE_p and E lower. Therefore the hot gas recycle configuration has prevented the surge of the compression system during inlet disturbances and has a lower energy consumption. However it has caused a very strong oscillation of the antisurge valve. This oscillation is caused by the effect of the recycled hot gas on the location of the surge region.

In order to further clarify this point, Figure 4 shows the surge flow rate and the opening of the antisurge valve for the cold gas recycle configuration and for the hot gas recycle configuration. For both inlet and outlet disturbances, the results demonstrate that in the cold gas recycle configuration the opening of the antisurge valve causes the increase of the surge flow rate. This is due to the increase of p_{01} caused by the opening of the recycle valve itself. In the hot gas recycle configuration, the opening of the antisurge valve decreases the surge flow rate. In this case both T_{01} and p_{01} increase because of the gas recycle. However the rate of change of T_{01} is higher than the rate of change of p_{01} and therefore m_{surge} decreases, according to equation (4). In conclusion this behaviour causes the oscillation of ASV, as m and m_{ctrl} keep crossing each other every time the antisurge valve moves towards the opening or closing position.

4.3. Comparison between supercritical and subcritical compression

Additional analyses have been performed in order to compare supercritical gas recycle with subcritical gas recycle for surge prevention. In the selection between cold and hot gas recycle the process parameters that are usually considered include time delay in the process response and machine integrity (Botros, 2011). However when dealing with supercritical compression operation it is also important to take into account the amount of gas recycled. In the present case study, results show that the subcritical compressor operating in full recycle mode is able to recycle 22.64 % more gas by means of a cold gas recycle rather than a hot gas recycle. However in the supercritical compressor this amount rises to 81.50 %. This is due to the dramatic change of density of a supercritical gas especially when it is cooled down toward its critical point. This result is decisive

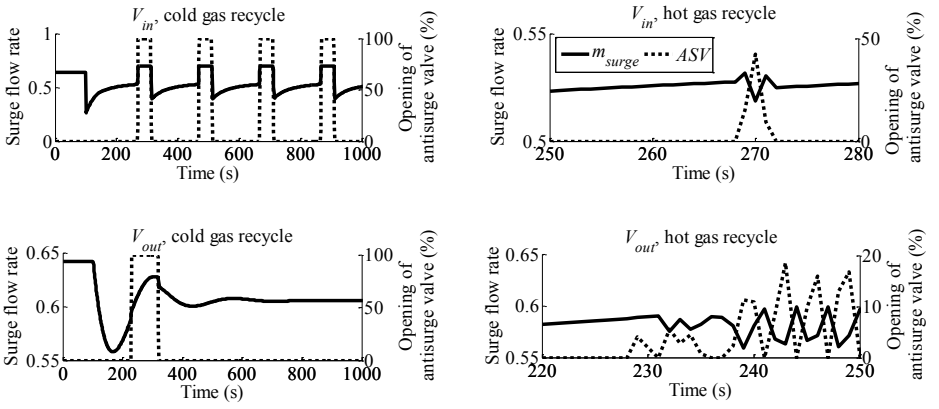

Figure 4. Surge flow rate and opening of the antisurge valve for input (top) and output (bottom) valve disturbances, in cold (left) and hot (right, zoomed views) gas recycle configurations

when full recycle is needed and a hot gas recycle configuration may not provide a sufficient amount of gas for surge protection.

5. Conclusion

This paper reports on the effect of the gas recycle configuration for surge protection on the compression system when dealing with supercritical fluid. Results demonstrate that a hot gas recycle configuration protects the system from boundary disturbances and has a lower energy request. However the response of the antisurge control system and therefore the antisurge valve oscillates. This is due to the effect of the recycle temperature on the location of the surge region. Moreover the amount of gas recycled must be taken into account especially when full recycle is needed. In fact, a supercritical compression station is able to recycle more than three times more gas in a cold gas recycle configuration than a subcritical compression station.

Abstract

In this paper, a couple of software sensors were designed for CSTR processes and they were tested in the esterification of grease trap wastes which is a low-cost feedstock for biodiesel production. Both software sensors were designed for the estimation of the concentration of Free Fatty Acids (FFAs) from discrete CSTR's temperature measurements. One of these software sensors, called asymptotic observer, is recognized for its capacity to provide estimates without the knowledge of the process kinetics. It has been also designed an estimation algorithm known as reset fuzzy observer. This approach has been recently proposed and is able to update the estimated states at each instant when discrete measurements are available. Both observers were built regarding the structure of a validated dynamical model for the esterification of grease trap wastes and they were tested considering experimental data. The results show that the asymptotic observer offers a very poor performance when some process's disturbances (e.g. input concentration of FFAs, jacket temperature) are carried out, whereas the reset fuzzy observer is able to reconstruct satisfactorily the concentration of FFAs in the presence of such disturbances. Therefore, this fuzzy observer can be selected as reliable monitoring approach that could be further used as a key part of robust control schemes conceived for this specific biodiesel production process.

Keywords: software sensors, biodiesel, grease trap wastes

1. Introduction

An observer (i.e. software sensor) is an algorithm derived from a mathematical model which is able to reconstruct state variables (whose measurement is technically difficult or relatively expensive) from variables that can be captured constantly from common instruments such as thermocouples, phmeters, etc. An Asymptotic Observer (AO) is able to handle uncertainties in reaction kinetics. Probably, this characteristic has allowed the successful implementation of the asymptotic observer in chemical and biotechnological processes. There exists another class of observer which is known as Fuzzy Reset Observer (FRO) because its structure is derived from the Takagi-Sugeno fuzzy representation of a dynamical model and besides, is able to update the estimation scheme at every instant where measurements are available. This observer has been been successfully applied in biotechnological processes.

On the other hand, biodiesel is a renewable blend of organic esters that has received attention recently due to its ability of reducing CO_2 emissions in comparison to the petroleum diesel fuel. The main barrier for the commercialization of biodiesel is the relatively high cost of this biofuel when it is produced from refined oils (Wen et al., 2010). This economical issue can be improved if biodiesel is produced from cheaper, lower quality feedstock (e.g. waste cooking oils or grease

trap wastes) that is characterized by their high content of Free Fatty Acids (FFAs) (Canakci and Van Gerpen, 2001). In this case, biodiesel is usually produced by the esterification of FFAs with methanol in the presence of sulfuric acid as an homogeneous catalyst.

To the best of our knowledge, little attention has been paid to the design of software sensors in biodiesel production processes, with the remarkable exception of the work conducted by Price et al. (2014). In the present contribution, an AO and a FRO are proposed as monitoring tools for the esterification of a very complex blend of FFAs known as grease trap wastes that are abundantly and routinely collected from grease interceptors before entering the sanitary sewer lines (Park et al., 2010; Canakci, 2007). Specifically, these observers are designed in order to estimate the concentration of FFAs from reactor's temperature measurements.

2. Material and methods

2.1. Materials

Grease tap wastes were provided by Solución Ambiental de México (Guadalajara, Jalisco, México) containing 83.61% FFAs. Industrial reagent grade methanol (0.3% moisture content) and H_2SO_4 were supplied by Pochteca and Químicos Marquez (Mexico), respectively.

2.2. Esterification of grease trap wastes and its dynamical model

The esterification of grease trap wastes was conducted in a three necked glass Continuous Stirred Tank Reactor (1L, 200rpm) that was immersed in a water bath at temperature T_J. The CSTR's temperature, T, was recorded *every minute*. In addition, the methanol and the FFAs' molar ratio was around 20:1. Grease trap wastes and a reagent mixture of methanol/H_2SO_4were pumped to the reactor with volumetric flows F_{FFA} and F_{mix}, respectively, while the output flow F was adjusted to avoid any total mass accumulation within the reactor. The dynamical model for this esterification process is given in (Aguilar-Garnica et al., 2014):

$$\frac{dC_A}{dt} = \frac{F_{FFA}C_{Ai}}{V} - \frac{FC_A}{V} - k_1 C_M(0)\left(C_A - \frac{C_E C_W}{K_{eq} C_M(0)}\right) \tag{1}$$

$$\frac{dT}{dt} = \frac{F_{FFA}\rho_{FFA}\gamma_{FFA}}{\rho V \gamma_P}(T_{AG} - T) + \frac{F_{Mix}\rho_{Mix}\gamma_{Mix}}{\rho V \gamma_P}(T_{Mix} - T) + \frac{U}{\rho V \gamma_P}(T_J - T) - \frac{\Delta H}{\rho \gamma_P} k_1 C_M(0)\left(C_A - \frac{C_E C_W}{K_{eq} C_M(0)}\right) \tag{2}$$

$$\frac{dC_E}{dt} = -\frac{FC_E}{V} + k_1 C_M(0)\left(C_A - \frac{C_E C_W}{K_{eq} C_M(0)}\right) \tag{3}$$

$$\frac{dC_W}{dt} = -\frac{FC_W}{V} + k_1 C_M(0)\left(C_A - \frac{C_E C_W}{K_{eq} C_M(0)}\right) \tag{4}$$

In this model, t is time, while T_{AG} and T_{mix} denote the input temperature for the grease trap wastes and the mixture methanol/H_2SO_4, respectively. Besides, V is the (known) effective volume of the reaction medium, ρ_{FFA}, ρ_{Mix}, ρ, γ_{FFA}, γ_{Mix} and γ_P represent the densities and heat capacities of the grease trap wastes, the reagent mixture methanol/H_2SO_4 and the reaction products, respectively. In addition, U is the overall heat transfer coefficient, ΔH is the entalphy of the reaction and C_{Ai} is the inflow concentration of FFAs. The state variables C_A, C_E and C_W represent the concentration of FFAs, organic esters (i.e. biodiesel) and water, respectively, whereas $C_M(0)$ is the initial concentration of the methanol, that is considered as a constant because it is the reagent in excess. Besides, k_1 and K_{eq} are described by Arrhenius and Van't Hoff expressions, respectively. The dynamical model represented by equations (1)-(4) has been experimentally validated

with the numerical values for densities, heat capacities, kinetic parameters, operating conditions and disturbances that are described in (Aguilar-Garnica et al., 2014).

2.3. Model Fuzzification

Let us define the following premise variables: $z_1(t) = k_1 C_M(0)$, $z_2(t) = k_1 \frac{C_E}{K_{eq}}$ and $z_3(t) = k_1 \frac{C_W}{K_{eq}}$ that remain bounded as follows: $a_1 \leq z_1(t) < a_2$, $b_1 \leq z_2(t) < b_2$ and $c_1 \leq z_3(t) < c_2$. Then, the dynamical model given by equations (1)-(4) can be alternatively expressed as

$$\frac{dx}{dt} = A\left(z_1(t), z_2(t), z_3(t)\right)x + Bu \tag{5}$$

In equation (5) $x = \left[\begin{array}{cccc} C_A & T & C_E & C_W \end{array}\right]^T$, $u = \left[\begin{array}{cccc} C_{Ai} & T_{AG} & T_{Mix} & T_J \end{array}\right]^T$ and

$$A\left(z_1(t), z_2(t), z_3(t)\right) = \begin{pmatrix} -\frac{F_{FFA}}{V} - z_1(t) & 0 & z_3(t) & 0 \\ -\frac{\Delta H}{\rho \gamma_P} z_1(t) & -A_{22} & 0 & \frac{\Delta H}{\rho \gamma_P} z_2(t) \\ z_1(t) & 0 & -\frac{F}{V} - z_3(t) & 0 \\ z_1(t) & 0 & 0 & -\frac{F}{V} - z_2(t) \end{pmatrix} \tag{6}$$

$$B = \begin{pmatrix} \frac{F_{FFA}}{V} & 0 & 0 & 0 \\ 0 & \frac{F_{FFA}\rho_{FFA}\gamma_{FFA}}{\rho V \gamma_P} & \frac{F_{Mix}\rho_{Mix}\gamma_{Mix}}{\rho V \gamma_P} & U \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix} \tag{7}$$

Here $A_{22} = \left(\frac{F_{FFA}\rho_{FFA}\gamma_{FFA}}{\rho V \gamma_P} + \frac{F_{Mix}\rho_{Mix}\gamma_{Mix}}{\rho V \gamma_P} + \frac{U}{\rho V \gamma_P}\right)$ is an element of matrix A given by equation (6) Now, let us define the following membership functions $E_1 = \frac{z_1(t)-a_2}{a_1-a_2}$, $E_2 = \frac{a_1-z_1(t)}{a_1-a_2}$, $N_1 = \frac{z_2(t)-b_2}{b_1-b_2}$, $N_2 = \frac{b_1-z_2(t)}{b_1-b_2}$, $M_1 = \frac{z_3(t)-c_2}{c_1-c_2}$ and $M_2 = \frac{c_1-z_3(t)}{c_1-c_2}$ that make possible to propose the following Tagaki-Sugeno fuzzy model for the esterification process (see further details in Guillén-Flores et al., 2013):

$$\frac{dx}{dt} = \sum_{i=1}^{8} h_i \left(A_i x + Bu\right) \tag{8}$$

where $h_i = E_{\phi(i,1)} N_{\phi(i,2)} M_{\phi(i,3)}$, $A_i = A\left(a_{\phi(i,1)}, b_{\phi(i,2)}, c_{\phi(i,3)}\right)$, B is given by equation (7) and

$$\begin{aligned} 2^4 \phi(i,j) = {} & 3 \cdot 2^{j-1}\left(3 + (-1)^j\right) - 2^j \sin\left(\frac{j\pi}{2}\right)(-1)^{i+1} \\ & + \sqrt{2}\left(-1 + 5(-1)^j + 2j\right)\cos\left(\frac{(2i+1)\pi}{4}\right) + \left(5 - (-1)^j - 2j\right) i \end{aligned} \tag{9}$$

This fuzzy model represents exactly the nonlinear dynamical model described by equations (1)-(4) in the local region defined by the bounds of $z_1(t)$, $z_2(t)$ and $z_3(t)$ according to an approach known as sector nonlinearity (Tanaka and Wang, 2001).

2.4. Observers design

2.4.1. Asymptotic observer

A state variable partition is necessary to design the AO . The variables to be estimated are gathered in ξ_1 $\left(i.e.,\ \xi_1 = \left[\begin{array}{ccc} C_A & C_E & C_W \end{array}\right]^T\right)$ and the measured variables in ξ_2 (i.e. $\xi_2 = T$). Thus, the dynamical model for the esterification process can be partitioned into: $\frac{d\xi_1}{dt} = K_1 f + D_{11}\xi_1 + D_{12}\xi_2 + H_1$ and $\frac{d\xi_2}{dt} = K_2 f + D_{21}\xi_1 + D_{22}\xi_2 + H_2$ where $f = k_1 C_M(0)\left(C_A - \frac{C_E C_W}{K_{eq} C_M(0)}\right)$ is the nonlinear term, $K_1 = \left[\begin{array}{ccc} -1 & 1 & 1 \end{array}\right]^T$, $K_2 = -\frac{\Delta H}{\rho \gamma_P}$, $D_{11} = -\frac{F}{V} I_{3X3}$, $D_{12} = 0_{3X1}$, $D_{21} = 0_{1x3}$, $D_{22} = -A_{22}$, $H_1 = \left[\begin{array}{ccc} \frac{F_{FFA} C_{Ai}}{V} & 0 & 0 \end{array}\right]^T$ and

$$H_2 = \left(\frac{F_{FFA}\rho_{FFA}\gamma_{FFA}T_{AG}}{\rho V \gamma_P} + \frac{F_{Mix}\rho_{Mix}\gamma_{Mix}T_{mix}}{\rho V \gamma_P} + \frac{UT_J}{\rho V \gamma_P}\right) \tag{10}$$

In addition, it is possible to obtain a couple of matrices $\Lambda_1 = I_{3\times 3}$ and $\Lambda_2 = \left[\begin{array}{ccc} -\frac{\rho\gamma_P}{\Delta H} & \frac{\rho\gamma_P}{\Delta H} & \frac{\rho\gamma_P}{\Delta H} \end{array}\right]^T$ such that $\Lambda_1 K_1 + \Lambda_2 K_2 = 0$. The AO's structure remains as follows (Bastin and Dochain (1990)):

$$\frac{d\hat{w}}{dt} = W\hat{w} + ZT + \Lambda_1 H_1 + \Lambda_2 H_2 \tag{11}$$

$$\hat{w}(0) = \hat{\xi}_1(0) + \Lambda_2 T(0) \tag{12}$$

$$\hat{\xi}_1 = \hat{w} - \Lambda_2 T \tag{13}$$

Notice that this observer effectively does not require the knowledge of the nonlinear term f that is related with the process kinetics. Besides, $\hat{\xi}_1$ is the estimate provided by the AO for ξ_1 whereas $H_2$is given by equation (10) while W and Z have the following structure

$$W = Z\Lambda_1 D_{11} + \Lambda_2 D_{21} = -\frac{F}{V} I_{3X3} \qquad Z = \Lambda_1 D_{12} + \Lambda_2 D_{22} - W\Lambda_2 \left(\begin{array}{ccc} Z_{11} & 0 & 0 \\ 0 & Z_{22} & 0 \\ 0 & 0 & Z_{33} \end{array}\right)$$

with $Z_{11} = \frac{F_{FFA}\rho_{FFA}\gamma_{FFA} + F_{Mix}\rho_{Mix}\gamma_{Mix} + U + F\rho\gamma_P}{V\Delta H}$ and $Z_{22} = Z_{33} = -Z_{11}$.

2.4.2. Fuzzy reset observer with discrete measurements of T

A FRO can be derived for any process whose dynamical model might be expressed in terms of the fuzzy representation (8)-(9) (Guillén-Flores et al. (2013)). Since the dynamical model of the esterification process matches this fuzzy representation then it is possible to derive a FRO whose structure is given by

$$\frac{d\hat{x}}{dt} = \sum_{i=1}^{8} h_i\left(A_i\hat{x} + Bu\right) \quad t \neq k\delta \tag{14}$$

$$\hat{x}(k\delta^+) = \hat{x}(k\delta) - G_d\left(T(k\delta) - \hat{T}(k\delta)\right) \quad t = k\delta \tag{15}$$

where $\hat{x}$ is the estimate of x, δ is the sampling period, $k = 1, 2, 3, ..., x(k\delta^+)$ is the updated initial condition defined as $\hat{x}(k\delta^+) = \lim_{\varepsilon\to 0}\hat{x}(k\delta^+ + \varepsilon)$ and $G_d = Q^{-1}R$ is the observer's gain with matrices $Q > 0$, R and a constant ϑ derived from Linear Matrix Inequalities specified in (Guillén-Flores et al., 2013).

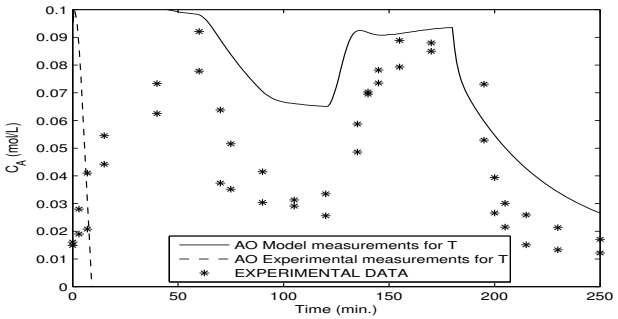

Figure 1: Experimental results for the concentration of FFAs and asymptotic observer performance

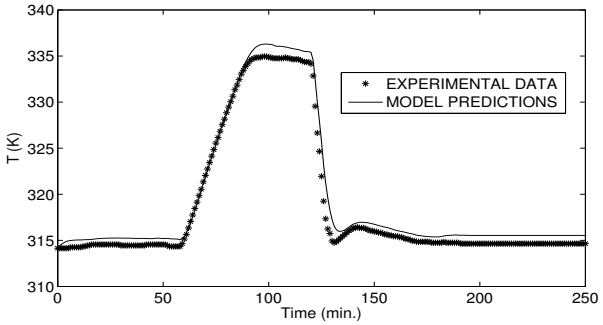

Figure 2: Experimental data and model predictions for the Reactor Temperature T

3. Results, discussion and conclusion

The esterification process was carried out in duplicate over a period of 250 minutes with disturbances on C_{Ai} and on T_J. Samples were analyzed in order to be determined the concentration of FFAs (i.e. C_A) considering the AOCS official method Ca 5a-40. The proposed observers are able to estimate C_A, C_E and C_W but for validation purposes it was decided to measure only C_A because it can be obtained by a very simple titration method compared with the tests to determine C_E and C_W. The experimental results of C_A and T are shown as star points in Figure 1 and Figure 2, respectively. In Figure 2, the solid line corresponds to the temperature that is obtained from the mathematical model eqs. (1)-(4). Note that the experimental results for T remain very close to the temperature described by the model.

The AO, which is described by equations (11)-(13), has been initialized with $\hat{C}_A(0) = 0.1 molL^{-1}$ and its performance is shown in Figure 1. The solid line corresponds to the AO with temperatures provided by the model and in this case, the AO's performance can be considered as satisfactory. Nevertheless, when the model measurements are replaced by the experimental measurements for T, the AO simply does not work well (see Figure 2, dashed line) in spite that both measurements and the model values for T remains very close. *The poor performance of the AO when actual temperature measurements are being used can be associated to a deficient model. This performance can also be due to the relatively high magnitude of the element Λ_2 that enhances slight variations on the measured variable when the estimated state is being computed (see eq. 13).* Thus, the AO can be considered as highly sensitive in temperature variations for this specific es-

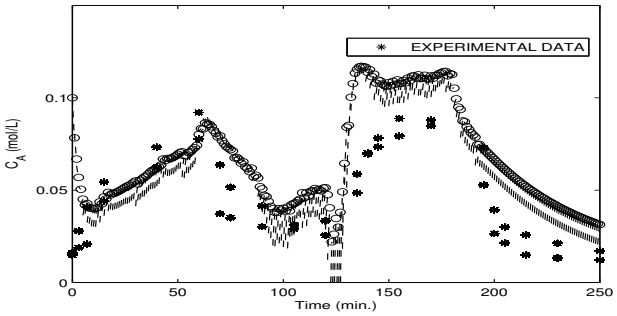

Figure 3: Fuzzy reset observer performance with sampling period $\delta = 1$ min

terification process and then, it is necessary to consider alternative estimation schemes such as the FRO. The performance of this fuzzy observer is shown in Figure 3. Is this case, the estimation scheme was updated according with equations (14)-(15) including experimental temperature measurements captured every minute (i.e. $\delta = 1min$). For $\delta = 1min$, the observer gain was determined to be $G_d = \begin{bmatrix} -0.046 & -1.8 & 0.062 & 0.056 \end{bmatrix}^T$. The FRO was initialized with the same initial condition than the AO and the discrete actualization is clearly visible every minute where a jump on the states estimation can be seen. The circles depict the reset observer result at $\delta = 1$, whereas the dashed lines describe the reset observer performance among sampling periods. It can be concluded that the FRO provides the best performance among the proposed monitoring tools for the esterification of grease trap wastes.

Improving Data Reliability for Process Monitoring with Fuzzy Outlier Detection

Harakhun Tanatavikorn[a] and Yoshiyuki Yamashita[a]

[a]*Department of Chemical Engineering; Tokyo University of Agriculture and Technology; Tokyo, Japan*
harakhun@hotmail.com

Abstract

To implement on-line process monitoring techniques that utilize principal component analysis (PCA) or partial least squares (PLS) models, it is important to use reliable data that represents normal process operation when constructing the models. In this paper, a novel flexible fuzzy treatment method is developed for the detection of outliers in process data. This method utilizes a combination of fuzzy C-means clustering algorithm to separate the data into clusters and a fuzzy inference engine to assign a degree of outlier to data points. The current iteration of the fuzzy inference engine performs an evaluation based on distance as a measure of standard deviation and fuzzy membership values to determine the degree of outlier. This method can be considered a hybrid method that incorporates statistical parameters into a fuzzy strategy. Decisions on how to handle the data can then be made based on the degree of outlier. This degree of outlier can be conveniently translated into a relative weight assigned to an outlier entering downstream data processes.

The fuzzy treatment method was applied to benchmark penicillin production process data containing artificial outliers data points. The proposed method was able to detect the outliers in the process data. Though data points in the transient region were prone to high degree of outlier. Additionally it is possible to modify the fuzzy inference engine to utilize different criteria, such as data density or spread to evaluate outlierness. The result is presented along with a discussion on the advantages of this method as a flexible treatment of process data. The methodology will be applied to future investigation on PCA based process monitoring.

1. Introduction

The advances in the field of sensors, computers, and informatics have exponentially increased the amount of available process data. Large plants record process variables, product quality, production, and maintenance information on a frequent basis. Reliable process data is a vital component in the implementation of on-line process monitoring techniques that control these large facilities. Data reliability, in this context, refers to the accuracy and completeness of data, given the intended purpose for use. Reliability does not mean that the data is error-free; it means that any errors present and found in the data are within a tolerable range. This tolerance is dependent upon evaluation that the associated risks have been assessed and determined that the errors are not significant enough to doubt the findings or conclusions based on the data.

Given a set of process data, an outlier is an element that deviates significantly from normal or

sometimes meaningful range. They represent either errors or interesting observations; such as mechanical faults, changes in system behavior, instrument error, or simply through human error. The presence of outliers may lead to inaccurate process models and wrong analytical conclusions. Therefore outlier detection is used to detect and, when appropriate, remove anomalous entries from process data to improve their reliability for process monitoring. Conventional outlier detection methods rely on statistical tests to perform a screening of a dataset. Classical test are the Grubbs (1950) and the Dixon (1950) ones; other similar tests have also been formulated by Quesenberry and David (1961), and Ferguson (1961). In essence, all these tests provide a statistic to be compared with a critical value in order to evaluate whether a data point is an outlier. Their difference is mainly construction of the statistic and the selection of critical value. Since ultimately outlier detection and analysis is a subjective exercise, classical methods are often rigid and sometime face limitations posed by their statistical nature.

In this paper, a novel flexible fuzzy treatment method is developed for the detection of outliers in process data. This method utilizes a combination of fuzzy C-means clustering algorithm to separate the data into clusters and a fuzzy inference engine to assign a degree of outlier to data points. The main advantage of the method is the flexibility of the inference engine where different evaluation criteria can be implemented. This provides a adjustable subjective framework for evaluating large size data sets. The organization of the paper is as follows: Section 2 describes the components and methodology of the fuzzy treatment method. Section 3 presents selected results of applying the fuzzy treatment method on simulated process data. Finally, Section 4 concludes the paper.

2. Methodology

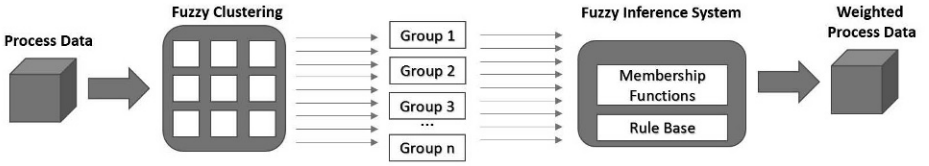

Figure 1: Fuzzy treatment method

2.1. Fuzzy c-means Clustering

The main purpose of fuzzy c-means clustering is the partitioning of data into a collection clusters, where each data point is assigned a membership value for each cluster. Fuzzy c-means clustering involves two processes: the calculation of cluster centers and the assignment of points to these centers using a form of Euclidian distance. These processes are repeated until the cluster centers stabilize. The algorithm is similar to crisp clustering, such as k-means clustering, in several aspects but incorporates fuzzy set concepts of partial memberships by allowing data points to belong to more than one cluster. This can be observed in the form of overlapping clusters. Additionally many crisp clustering techniques tend to have difficulties in handling extreme outliers but fuzzy clustering algorithms tend to give them small membership degree in surrounding clusters (Looney, 1999). The algorithm also needs a fuzzification parameter m which determines the degree of fuzziness in the clusters. When the value of m is 1 the algorithm works like crisp clustering, while larger values of m increases the fuzzification of the clustering algorithm thus allowing a higher degree cluster overlap.

Based on the clustering results, k different data groups are prepare from the initial data. The assignment of x_i to a data group depends it's membership value corresponding to each cluster, u_{ik}. x_i gets assigned to a cluster based on the following conditions:

- The highest value of u_{ik} denotes which group k the x_i is placed in;
- If the difference between highest u_{ik} and the next highest $u_{i(k-1)}$ is less than the threshold value, then x_i gets placed in both groups;
- Additionally if the highest valuest of u_{ik} is below 0.2 then the top 3 u_i are placed 3 groups.

It is important to note that, the selection of the threshold value δ depends on the selecting of the number of clusters n for the fuzzy clustering. In this work, a plot of the *within groups sum of squares* by number of clusters extracted is used to determine the appropriate number of clusters based on the bend in the plot (Everitt and Hothorn, 2006). This is often referred to as the "elbow" method.

2.2. Fuzzy Inference System

Fuzzy inference is the process of formulating the mapping from a given input to an output using fuzzy logic. The mapping then provides a basis from which decisions can be made, or patterns discerned. The FIS selected for implementation in this paper was proposed by D'Errico and Murru (2012) with modifications to the FIS rule base and input variables. The modified FIS includes two inputs (distance and grouping) and one output (degree of outlier). The inference engine is the basic Mamdani Model was constructed using the R Statistical Software 'frbs' package.

The fuzzy distance is obtained after a fuzzification of the crisp distance input $d = d(x_i, \mu)$, according to:

- if $d(x_i, \mu) \geq 4\sigma_{max}$, then distance is very long;
- if $3\sigma_{max} \leq d(x_i, \mu) \leq 5\sigma_{max}$, then distance is long;
- if $2\sigma_{max} \leq d(x_i, \mu) \leq 4\sigma_{max}$, then distance is medium;
- if $d(x_i, \mu) \leq 3\sigma_{max}$, then distance is short.

where
σ_{max} : is the highest observed standard deviation among the chosen variables of the in the corresponding group.
The fuzzy grouping is obtained after a fuzzification of the highest membership values $g = g(x_i, uik)$ from the results of the fuzzy clustering, according to:

- if $g(x_i, u_{ik}) \geq 0.4\sigma$, then grouping is grouped;
- if $0.25 \leq g(x_i, u_{ik}) \leq 0.45$, then grouping is moderate;
- if $0.2 \leq g(x_i, u_{ik})$, then grouping is spread;

where
u_{ik} : is the membership value of the data point i to the data group k.
As to outlierness:

- if $\rho \geq 0.5\sigma$, then outlierness is high;
- if $0.25 \leq \rho \leq 0.75$, then outlierness is intermediate;
- if $0.5 \leq \rho$, then outlierness is low;

The inference system is based on the following 11 rules:

1. if (distance is short) and (grouping is grouped), then outlierness is (low)
2. if (distance is short) and (grouping is moderate), then outlierness is (intermediate)
3. if (distance is short) and (grouping is spread), then outlierness is (intermediate)
4. if (distance is medium) and (grouping is grouped), then outlierness is (low)
5. if (distance is medium) and (grouping is moderate), then outlierness is (intermediate)
6. if (distance is medium) and (grouping is spread), then outlierness is (high)
7. if (distance is long) and (grouping is grouped), then outlierness is (intermediate)
8. if (distance is long) and (grouping is moderate), then outlierness is (intermediate)

9. if (distance is long) and (grouping is spread), then outlierness is (high)
10. if (distance is very long), then outlierness is (high)
11. if (grouping is spread), then outlierness is (high)

This degree of outlier can be conveniently translated into a relative weight that allows a fuzzy outlier to still contribute to a certain extent to any subsequent processes.

2.3. Simulation Example: Fed-batch Penicillin Cultivation Process

Birol et al. (2002) developed a simulation software based on a detailed unstructured model for penicillin production in a fed-batch fermentor. The model extends the mechanistic model of Bajpai and Reuß (1980) by adding input variables such as pH, temperature, aeration rate, agitation power, and feed flow rate of substrate along with introducing the CO2 evolution term. The model is used to generate process data for testing the fuzzy treatment method.

A batch was simulated based on an integration step size of 0.02 h and a sampling interval of 0.5 h. In the simulation, an initial batch culture is followed by a fed-batch operation depending on the depletion of the carbon source. The process switches to fed-batch mode of operation when the level of glucose concentration reaches 0.3 g/l. Fermenter Temperature and pH have a strong influence on product quality. They are controlled by PID controllers whose settings in the simulation software were left at default values for normal operation. The main variables extracted for fuzzy treatment were pH and fermenter temperature.

5 artificial outlier points based on standard deviations were inserted into the simulated data:

1. Outlier$[0.615\sigma_T, -2\sigma_{pH}]$ in Transient region of pH @ 20
2. Outlier $[3\sigma_T, 3\sigma_{pH}]$ (in Temperature and pH @ 200
3. Outlier $[3\sigma_T, -0.3925\sigma_{pH}]$in Temperature @ 400
4. Outlier $[-0.217\sigma_T, -3\sigma_{pH}]$ in pH @ 600
5. Outlier $[6\sigma_T, 6\sigma_{pH}]$ in Temperature and pH @ 800

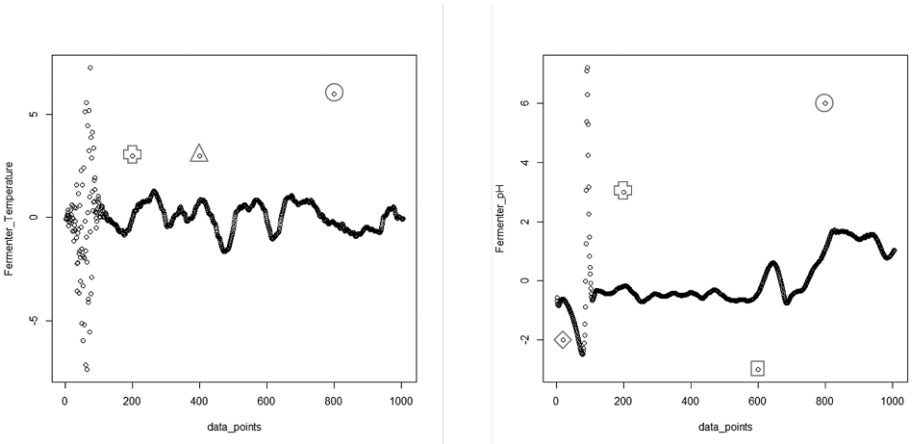

Figure 2: Fuzzy treatment method

3. Result and discussion

As previously mentioned, the elbow method was used to determine the number of cluster for the fuzzy c-means clustering. The number of clusters selected is 10. Additionally a corresponding

threshold value of $\delta = 0.2$ was chosen for the clustering. The group assignment and outlierness value for each artificial outlier point is presented in Table1.

The Fuzzy Treatment Method is able to evaluate and assign an appropriately high outlierness to the artificial outlier points. It is also observed, as seen in Table 2, that the method assigns high outlierness to extreme values, such as those found in the transition region (approx. $0 \leq$ index≤ 150). This is expected due to the fact that the 2 basic input criteria, distance and fuzzy c-means membership values, used to evaluate the outlierness of a data point are sensitive to extreme and/or isolated values. In particular it is interesting to note that a low fuzzy c-means membership value or an evenly spread out membership value distribution between the groups signifies that a data point is relatively isolated from data clusters.

The transient region, where large and rapid fluctuations occur, remain a challenge for the fuzzy treatment method. It is speculated that changing or increasing the numbers of input parameters will improve performance in the transient region. Integration of pattern based outlier detection methods, such as PLS or neural networks, may improve the performance in the transient region. Though this is subjected to further study.

Table 1: Group assignment and outlierness of artificial outliers

Data Point Index	**Group Assignment and Outlierness**			**Variable with Artifical Outlier**
20	3	5	7	pH
	0.583	0.583	0.583	
200	8	9	10	Temp. and pH
	0.75	0.75	0.75	
400	5	7		Temp.
	0.75	0.75		
600	1	2	3	pH
	0.75	0.75	0.75	
800	8	9	10	Temp. and pH
	0.75	0.75	0.75	

Table 2: Group assignment and outlierness of selected data points

Data Point Index	**Group Assignment and Outlierness**			**Remarks**
70	3	5	7	Transient Region
	0.75	0.75	0.75	
100	7	8		Transient Region
	0.583	0.75		
130	1	2		
	0.516	0.456		
300	1			
	0.25			
700	7			
	0.25			

A summary and comparison of the fuzzy treatment method can be seen in Table 3. It is compared to a multivariate outlier detection proposed by Filzmoser et al. (2005) and the Local Outlier Factor (LOF) proposed by Breunig et al. (2000). All three methods yield similar results and have difficulties in the transient region of the data; resulting in false positives or being unable to distinguish the artificial outlier from extreme data points. Though it is important to note that it is possible to integrate the outlier detections proposed by Filzmoser et al. (2005) and Breunig et al. (2000) into the fuzzy treatment methodology.

Table 3: Summary and comparison of fuzzy outlier treatment method

Data Point Index	**Fuzzy Treatment Method (Outlierness)**	**Robust mahalanobis distance based on the adjusted mcd estimator**	**Local Outlier Factor**
20	0.5833	Detected	1.02261 (rank 595/1005)
200	0.75	Detected	1.890222 (rank 43/1005)
400	0.75	Detected	1.822154 (rank 49/1005)
600	0.75	Detected	1.425353 (rank 107/1005)
800	0.75	Detected	2.619494 (rank 21/1005)

4. Conclusion

The presence of suspected outlier values in process data has been a long-standing problem. The difficulty of the problem is mainly due to the subjective nature of outlier detection. A single criteria to distinguish different types of outliers is generally insufficient and does not address the subjective nature of outlier detection. To overcome this issue a novel fuzzy logic approach has been proposed and a system has been implemented. The system performance has been manually tuned: optimization of input parameters along with investigation into automatic-tuning (self-learning) is envisaged for further developments.

The fuzzy treatment method utilizes fuzzy c-means clustering to separate multi-variate data into clusters. Data points can belong to more than a single cluster due to the nature of fuzzy clustering. The concept of fuzzy outlier is then adapted from D'Errico and Murru (2012) with modifications to FIS input parameters and rule-base. Utilizing individual cluster standard deviation and fuzzy c-means clustering membership values as inputs, the outlierness of a data point is computed as a result of a 2-input/1-output fuzzy inference system. The overall fuzzy treatment methodology is a generalize approach and can be modified to suit the application. It provides a flexible and highly subjective framework for outlier detection.

From the results of the research conducted so far, the following conclusions can be pointed out:

1. The fuzzy treatment method provides a subjective framework for integrating various outlier detection parameters.
2. The fuzzy c-means clustering membership values have correlation to extreme and isolated values. These values may potentially be outliers.

Inversion-based feedforward control design for the Droop model

Alexander Schaum[a] and Thomas Meurer[a]

[a]*Chair of Automatic Control, Christian-Albrechts-University Kiel, Germany*
alsc@tf.uni-kiel.de

Abstract

An inversion-based feedforward control for the Droop model for microalgae growth in the chemostat is presented. The dilution rate is manipulated in such a way that a desired biomass trajectory for set point changes is tracked. For this purpose a stable inversion technique is employed exploiting the asymptotic stability of the internal dynamics due to mass-conservation. The impact of unknown feed substrate step changes on the controller performance is analytically delimited using the mass-conservation-based bounded input-bounded output stability property. Numerical results show that the transition time can be significantly reduced by the proposed approach in comparison to a simple step change in the feed flow showing the bounded downgrade due to unknown variations in the feed concentration.

Keywords: Feedforward control, microalgae growth, Droop model, set point transition

1. Introduction

The production of high-value compound production like fatty-acids, vitamins, or pigments have great impact in the biotechnology market. Particularly usefull resources for these products with relatively rapid growth are microalgae. Additionally, microalgae are also of interest as sources for hydrogen and biofuel production (Havlik et al., 2013).

Typically process control is used to improve the process response times and robustness with respect to unknown (and unpredictable) perturbations in the feed variables, etc. In several process control application examples (Graichen et al., 2009; Hagenmeyer and Nohr, 2008; Kleinert et al., 2010) it has been numerically and experimentally shown that substantial improvement can be achieved using model-based feedforward control. This motivates the design of a feedforward control strategy for microalgae growth processes to reduce the time requirements for set-point changes. Furthermore, as such processes are typically subject to fluctuations, specially in the feed concentration, the effects of such variations has to be carefully delimited. This taks are addressed in the present paper, by exploiting the stable inversion technique (Chen and Paden, 1996; Devasia, 1999). For this purpose, using mass-conservation arguments and the reactor bifurcation behavior it is rigurously shown that bounded feed perturbation will lead to bounded deviations from the reference output. Numerical simulation results illustrate the obtained performance.

2. Droop's microalgae growth model

The Droop model for microalgae growth in the chemostat is given by (Droop, 1968; Lemesle and Mailleret, 2008)

$$\begin{aligned} \dot{b} &= -db + \mu(q)b, & b(0) &= b_0 \\ \dot{q} &= \rho(s) - \mu(q)q, & q(0) &= q_0 \\ \dot{s} &= d(s_{in} - s) - \rho(s)b, & s(0) &= s_0 \\ y &= b, \end{aligned} \tag{1}$$

where b is the biomass concentration, q is the internal nutrient quota (i.e. the intracellular nutrient concentration per biomass unit), s is the extracellular nutrient concentration, s_{in} is the *piecewise constant, unknown* feed concentration with nominal value $\bar{s}_{in}$, μ is the growth rate, ρ is the uptake rate, d is the dilution rate (i.e. the flow-colume quotient q/V), and y is the biomass measurement.

The growth and uptake rates are given by the monotonic relations

$$\mu(q) = \bar{\mu}\left(1 - \frac{k_q}{q}\right), \quad \rho(s) = \frac{k_0 s}{K_s + s}, \tag{2}$$

where $\bar{\mu}$ is the (hypothetic) maximum growth at infinite quota, k_q is the minimum quota necessary for biomass growth, k_0 is the maximum uptake rate $\rho(s)$, and K_s the half-saturation constant.

By the change of variables

$$\theta = q - k_q \tag{3}$$

the growth rate μ can be written in the standard Monod form

$$\nu(\theta) := \mu(\theta + k_q) = \frac{\bar{\mu}\theta}{k_q + \theta} \tag{4}$$

and the dynamics (1) become

$$\dot{b} = -db + \nu(\theta)b, \qquad b(0) = b_0 \tag{5a}$$

$$\dot{\theta} = \rho(s) - \bar{\mu}\theta, \qquad \theta(0) = q_0 - k_q \tag{5b}$$

$$\dot{s} = d(s_{in} - s) - \rho(s)b, \quad s(0) = s_0 \tag{5c}$$

$$y = b. \tag{5d}$$

In vector notation the preceding dynamics are written as

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, u, s_{in}), \quad y = h(\mathbf{x}). \tag{6}$$

with

$$\mathbf{x} = [b, \theta, s]', \quad h(\mathbf{x}) = x_1.$$

For the purpose at hand, the subsequent analysis and design are based on the model (5).

3. Reactor dynamics

In this section the reactor dynamics are characterized in terms of the input-output behavior including steady-state multiplicity, bifurcation and bounded-input-bounded-output stability properties, which are essential for the subsequent design of a feedforward control strategy. The discussion presented here verifies and complements the one reported in (Lemesle and Mailleret, 2008) and forms the basis of the subsequent characterization of the bounded-input bounded-output stability of the reactor with the feedforward controller designed in Section 4.

3.1. Bifurcation behavior

Consider the equilibrium conditions

$$0 = -db + \nu(\theta)b, \quad 0 = \rho(s) - \bar{\mu}\theta, \quad 0 = d(s_{in} - s) - \rho(s)b \tag{7}$$

Clearly, the washout solution $\mathbf{x}_w = \begin{bmatrix} 0 & s_{in} & \rho(s_{in})/\bar{\mu} \end{bmatrix}^T$ is a solution. For $b > 0$ the following conclusion sequence is valid

$$d = \nu(\theta) \quad \Leftrightarrow \quad \theta = \nu^{-1}(d) = \frac{dk_q}{\bar{\mu} - d} = \sigma_\theta(d) \tag{8a}$$

$$s = \rho^{-1}(\bar{\mu}\theta) = \rho^{-1}(\bar{\mu}\nu^{-1}(d)) = \sigma_s(d) \tag{8b}$$

$$b = \frac{d(s_{in} - \sigma_s(d))}{\rho(\sigma_s(d))} = \sigma_b(d, s_{in}). \tag{8c}$$

In particular, these relations imply that for $d < \max \nu = d_*$ there are two biomass steady states, with the washout being an unstable saddle respulsor and the reactor operation point as asymptotically stable attractor node. At $d = d_*$ a transcritical bifurcation takes place, leading to the disappearance (in a physically feasible regime) of the operation point, and leaving the washout as unique global (in $\mathbb{R}^3_+$) attractor. The associated solution diagram is presented in Figure 1.

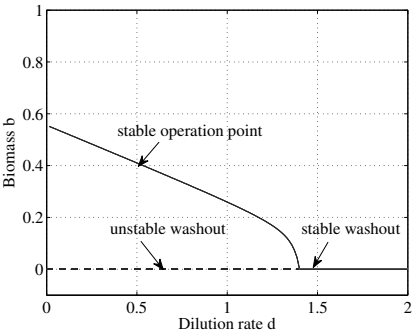

Figure 1: Solution diagram for the Droop model (5) showing the equilibrium dilution rate input-to-biomass output relation.

Note that the sensitivity of the bifurcation point d_* with respect to the feed concentration s_{in} satisfies for $s_{in} \gg k_s$

$$\frac{\partial d_*}{\partial s_{in}} = \frac{\partial d_*}{\partial \rho}\frac{\partial \rho}{\partial s}|_{s=s_{in}} \ll 1$$

given that the slope of $\rho(s)$ attains its minimum over $[0, s_{in}]$ at s_{in} which is much less than one.

3.2. Practical stability

The notion of practical stability (Salle and Lefschetz, 1961) ensures on the one hand asymptotic stability in the absence of perturbations and on the other hand bounded input bounded output stability with respect to perturbations. Mathematically, this can be formulated for the reactor (5) by the existence of a class-KL (increasing-decreasing) function α and a class-K (increasing) function β, so that

$$||\mathbf{x}(t) - \mathbf{x}_r(t)|| \leq \alpha(||\mathbf{x}_0 - \mathbf{x}_r(t)||, t) + \beta(|s_{in}(\cdot) - \bar{s}_{in}|), \tag{9}$$

where $\mathbf{x}_r$ is the reference trajectory for the state $\mathbf{x}$. Typical examples are $\alpha(||\mathbf{z}||, t) = ||\mathbf{z}||e^{-t}$ for some vector $\mathbf{z}$ and $\beta(|s_f(\cdot) - \bar{s}_f|) = \sup_{t \geq 0}|s_f(t) - \bar{s}_f|$. This property will be analyzed in the sequel.

Notice that from (5b) it follows that $\theta \in [0, \theta^+]$ where $\theta^+ = \rho(s_{in}^+)/\bar{\mu}$ and s_{in}^+ are the maximum nutrient quota and feed concentration, respectively. Similarly, from (5c) it follows that $s \in [0, s_{in}^+]$. Furthermore, $\theta = 0$ corresponds to a repulsor set as well as $s = 0$. Now, introduce the total substrate content in the reactor at time t

$$\mathfrak{S} = s + (\theta + k_q)b, \quad \dot{\mathfrak{S}} = d(s_{in} - \mathfrak{S}), \quad \mathfrak{S}(0) = s_0 + (\theta_0 + k_q)b_0. \tag{10}$$

It follows that $\mathfrak{S} \in [0, s_{in}^+]$ and thus $b \in [0, b^+]$ with $b^+ = s_{in}^+/k_q$ in consequence of (10). This shows that the compact pyramidal set (see Figure 2)

$$\mathscr{X} = \left\{ \mathbf{x} \in \mathbb{R}^3 | 0 \le x_2 \le \theta^+, 0 \le x_3 \le s_{in}^+, 0 \le x_3 + (x_2 + k_q)x_1 \le s_{in}^+ \right\} \subset \mathbb{R}_+^3 \tag{11}$$

is a positively invariant set for (5). The face corresponding to $b = 0$ (washout) is an invariant subset of $\mathscr{X}$.

The compact set $\mathscr{X}$ contains the planar compact set

$$\Sigma = \left\{ \mathbf{x} \in \mathbb{R}^3 | \mathfrak{S} = \bar{s}_{in} \right\} \tag{12}$$

which separates $\mathscr{X}$. For $s_{in}(t) = \bar{s}_{in}$ the set Σ is an attractor set for $\mathscr{X}$ and in Σ the operation point $\bar{\mathbf{x}}$ is the unique attractor. Actually, the dynamics in Σ are given by

$$\begin{aligned} \dot{b} &= \left[(\bar{\mu} - d) - \frac{k_q b}{s_{in} - s} \right] b, \\ \dot{s} &= d(s_{in} - s) - \rho(s) b \end{aligned}$$

and have $\bar{\mathbf{x}}$ as unique attractor node for $d < d_*$ accompanied by the repulsor washout $\mathbf{x}_w$, as follows from Poincaré-Bendixson's theorem over the positively invariant compact state set Σ. Note that for a general feed input $s_{in}(t)$ the response is given by

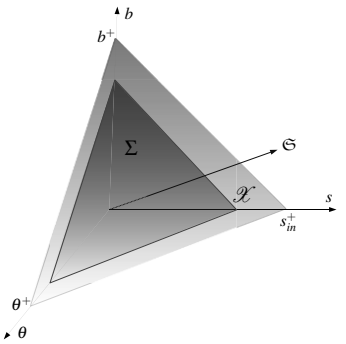

Figure 2: Compact state space sets $\mathscr{X}$ and Σ.

$$\mathfrak{S}(t) = e^{-\int_0^t d(\tau)d\tau} \mathfrak{S}(0) + \int_0^t e^{-\int_0^t d(\vartheta)d\vartheta + \int_0^\tau d(\vartheta)d\vartheta} d(\tau) s_{in}(\tau) d\tau$$

which for $s_{in}(t) = \bar{s}_{in}$ reduces to the nominal one $\bar{\mathfrak{S}}(t) = \bar{s}_{in} + e^{-\int_0^t d(\tau)d\tau}(\mathfrak{S}_0 - \bar{s}_{in})$. Thus for $|s_{in}(t) - \bar{s}_{in}| \le \delta_{in}/2$ it holds that $|\mathfrak{S}(t) - \bar{\mathfrak{S}}(t)| \le \delta_{in}/2$, meaning that the trajectories converge towards a set $\tilde{\Sigma} \supset \Sigma$ of thickness δ_{in}. Hence, for $\tilde{s}_{in}(t) \neq 0$ the reactor trajectories move within a δ_{in}-tube around the nominal one and converge towards an δ_{in} neighborhood of $\bar{x}$ (for $d < d_*$). This implies the practical stability of the reactor with respect to feed perturbations.

4. Feedforward control

In this section a feedforward control is designed to achieve trajectory tracking for operation-point changes in the Droop model. For this puropse, the stable inversion technique (Chen and Paden, 1996; Devasia, 1999) is employed. Having the biomass as output variable, denote the reference trajectory by $y^*(t) = b^*(t)$ with dynamics

$$\dot{y}^*(t) = -d^*(t)y^*(t) + \nu(\theta^*(t))y^*(t), \quad y^*(0) = y_0^*. \tag{13}$$

The requirement of transition between the two steady-states corresponding to $y(0) = b_0$ to $y(T) = b_T$ yields four boundary conditions for the reference trajectory y^*, i.e.

$$\begin{aligned} y^*(0) &= b_0, \quad y^*(T) = b_T \\ \dot{y}^*(0) &= 0, \quad \dot{y}^*(T) = 0 \end{aligned} \tag{14}$$

which are satisfied by the reference trajectory

$$y^*(t) = b_0 + (b_T - b_0)\left(3\left(\frac{t}{T}\right)^2 - 2\left(\frac{t}{T}\right)^3 \right). \tag{15}$$

The corresponding input $d^*(t)$ is thus given at each time instant by (having in mind $y = b > 0$)

$$d^*(t) = \frac{\nu(\theta^*(t))y^*(t) - \dot{y}^*(t)}{y^*(t)} \qquad (16)$$

with $\theta^*(t)$ being the solution of the reference internal dynamics

$$\dot{\theta}^*(t) = \rho(s^*(t)) - \bar{\mu}\theta^*(t)$$
$$\dot{s}^*(t) = d^*(t)(\bar{s}_{in} - s^*(t)) - \rho(s^*(t))y^*(t),$$

with $d^*(t)$ being defined in (16). This equation can be solved numerically for the pair $(\theta^*(\cdot), s^*(\cdot))$, so that $d^*(\cdot)$ can be completely determined *off-line*.

It should be noted that for arbitrary s_{in}, using the coordinate change (10), the internal dynamics can be written as

$$\dot{\mathfrak{S}} = d(s_{in} - \mathfrak{S}), \quad \dot{s} = d(s_{in} - s) - \rho(s)b$$

which, according to the analysis in Section 3, are bounded-input bounded-output stable with respect to the feed concentration.

From the preceding analysis of the reactor dynamics, it follows immediately, that due to mass conservation the reference trajectory will be exactly tracked for the nominal feed concentration $\bar{s}_{in}$ using the feedforward control (16), while for bounded perturbations in s_{in} of size δ_{in}, the reactor trajectories will move within an δ_{in}-tube around the reference trajectory, in the sense of practical stability (cp. eq. (9)).

5. Numerical simulations

In order to verify the theoretic assessment, numerical simulations using MATLAB with *ode15s* have been carried out for the parameter set (taken from (Toroghi et al., 2013)) $K_s = 0.105$, $\bar{\mu} = 2$, $k_q = 1.8$, $k_0 = 9.3$.

In Figure 3 the reactor response for the biomass set-point change from $b_0 = 52.78$ to $b_T = 27.76$ in $T = 1$ day is illustrated. The nominal trajectory is represented by the thin grey continuous line and the reactor feedforward response by the dashed green line.

For comparison purposes the open-loop response for a simple step change in the dilution rate is shown by the dash-dotted line.

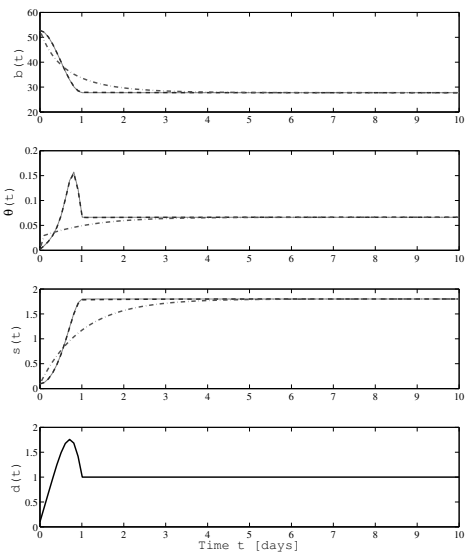

Figure 3: Nominal time response of the Droop model for a biomass set point change from $b_0 = 52.78$ to $b_T = 27.76$ in $T = 1$ day: reference trajectory (thin continuous line), FF response (dashed line), Step response (dash-dotted line).

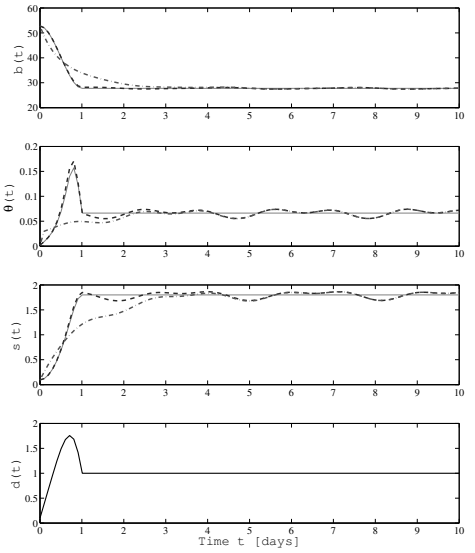

Figure 4: Time response for a biomass set point change from $b_0 = 52.78$ to $b_T = 27.76$ in $T = 1$ day with feed perturbation: reference trajectory (thin continuous line), FF response (dashed line), Step response (dash-dotted line).

It can be seen that the biomass reference trajectory is exactly followed leading to a significant improvement in convergence speed of about a factor of four in comparison to a simple step change.

In Figure 4 the corresponding behavior with a periodic feed perturbation with 10% amplitude according to $s_{in}(t) = \bar{s}_{in} + 10\sin(t)\sin(3t)$ is shown. It can be seen that the improvement in convergence speed is maintained and the deviations from the nominal trajectories lie entirely within a bounded neighborhood of this, verifying the practical stability property.

6. Conclusions

An inversion-based feedforward control for the Droop model for microalgae growth in the chemostat is presented. The dilution rate is manipulated in such a way that biomass set point changes are followed in finite time with practical stability with respect to feed perturbations. The asymptotic stability of the internal dynamics due to mass-conservation is exploited to show this property. Numerical results show that the steady-state to steady-state transition time can be significantly reduced by a factor of four using the proposed approach in comparison to a simple step change in the feed flow, and show the robustness with respect to unknown feed perturbations.

Av. Aprígio Veloso, 882, Bodocongó, Campina Grande – Brazil.

Abstract

This paper arose from a new approach to evaluating separation and energy consumption of extractive distillation columns using as primary analysis parameter the solvent content throughout the column. This new approach allows to find a range of possible solutions that contemplates the global optimal point of operation. In view of this, the objective of this paper is to investigate the influence of the solvent content throughout the column and the size (number of stages) of the column on controllability. The results showed that the columns with smaller number of stages operating with lower solvent content have a better controllability when applied disturbances in the composition of the azeotropic mixture that feeds the column. The production of anhydrous ethanol by extractive distillation using ethylene glycol as solvent was used as a case study for this work.

Keywords: Extractive distillation, Solvent content, Dehydration of anhydrous ethanol, Controllability.

1. Introduction and Problem Definition

Considering that the design of an extractive distillation column is fixed, the variables that result in major impact on energy consumption are the reflux ratio and solvent flowrate (Bruggemann and Marquardt et al., 2004). Recently, a paper published by Figueiredo et al. (2014) included a new parameter in the analysis of extractive distillation, the solvent content in the extractive section. When evaluating the solvent content, the reflux ratio and solvent flowrate are considered simultaneously. According to the authors, the use of this parameter allows to find the range of possible solutions that will necessarily include the global optimum operating point. The specification of the solvent content in the feed stage of the extractive column together with product specifications represent a new phase for the understanding and search for optimal operating conditions of this process as it eliminates one of the main problems of extractive distillation: the existence of various local optimums.

On the results from the analysis procedure suggested by Figueiredo et al. (2014), it was observed that the operating point with higher solvent content in the extractive section provides lower energy consumption by the reboiler of the extractive column. The results also indicate that increasing the solvent content causes the energy consumption to become independent of the number of stages of the column.

However, the idea of using the solvent content in the search for the global optimum operation point is recent and still requires additional studies to support its use in extractive distillation problems. The analysis of the dynamic behavior and controllability of the extractive distillation process is very important for the usefulness

of this separation process in an industrial plant. In view of the non-approach in the literature about the influence of the solvent content in the dynamic and controllability of the extractive distillation process and the intention to complement the study of Figueiredo et al. (2014) based on the analysis of the solvent content, this paper proposes to investigate this aspect, more specifically, answer the following question: Is a column with higher number of stages operating at lower EG content easier to control than a column with smaller number of stages operating at higher levels of EG?

2. Dynamic and Control

Obtaining anhydrous ethanol by extractive distillation using ethylene glycol (EG) as solvent is the case study of this work. The modeling and simulations at steady state, using Aspen Plus®, were based on Figueiredo et al. (2014). By following the procedure suggested by the authors, the Aspen® *design spec* tool was used to obtain ethanol in the distillate with the desired specification of 99.5 mol% and recovery fraction of 99.99%. As specification of the solvent content in the solvent feed stage ($x_{EG}^{\#solv}$), two values were used: 20 % and 75 %, these spoken by the authors as the minimum and maximum solvent content, respectively, that guarantee the specifications of the required product.

In addition, the simulations were performed considering two sizes of the column, 24 and 50 stages, in order to be able to respond to the questions that arose from the sequencing of study of the authors. It totaled in four simulated cases, these described in Table 1. The variables that were manipulated to achieve these specifications were: solvent flowrate (S) and reflux ratio (R) in the extractive column. Table 1 also shows the values of the main variables that resulted in lower specific energy consumption (SEC) for the four simulated cases where it can be seen that the lowest specific energy consumption occurs in a column with a higher content of solvent.

The simulations (Case I, II, III, IV) were exported to Aspen Dynamics® using the pressure-driven mode. Pump head and valve pressure drops (usually 3 atm) were specified to provide reasonable rangeability so that a 20 % increase in transfer rate is handled without valve saturation. The reflux drum and the sump height of the columns, for all cases, were sized to provide 5 min of holdup when 50 % full, at steady state.

Table 1 - Optimal results for minimum specific energy consumption for extractive distillation columns.

Case study	Case I	Case II	Case III	Case IV
Parameter	Values			
Number of stages	24	24	50	50
Ethylene glycol content (mole fraction): $x_{EG}^{\#solv}$	0.2	0.75	0.2	0.75
Solvent flowrate, kmol/h	48.86	78.08	33.81	74.36
Reflux ratio	2.6040	1.4504	1.7892	0.2906
Number of stages of the extractive section	15	15	30	30
Specific energy consumption, kW/kmol	42.67	19.41	33.24	19.21
Internal diameter, m	2.0	2.0	0.8	0.8

Figure 1 shows the basic control structure used for the water-ethanol-ethylene glycol system. All four cases use essentially the same structure with some modifications that account for different temperature profiles and sensitivities to disturbances.

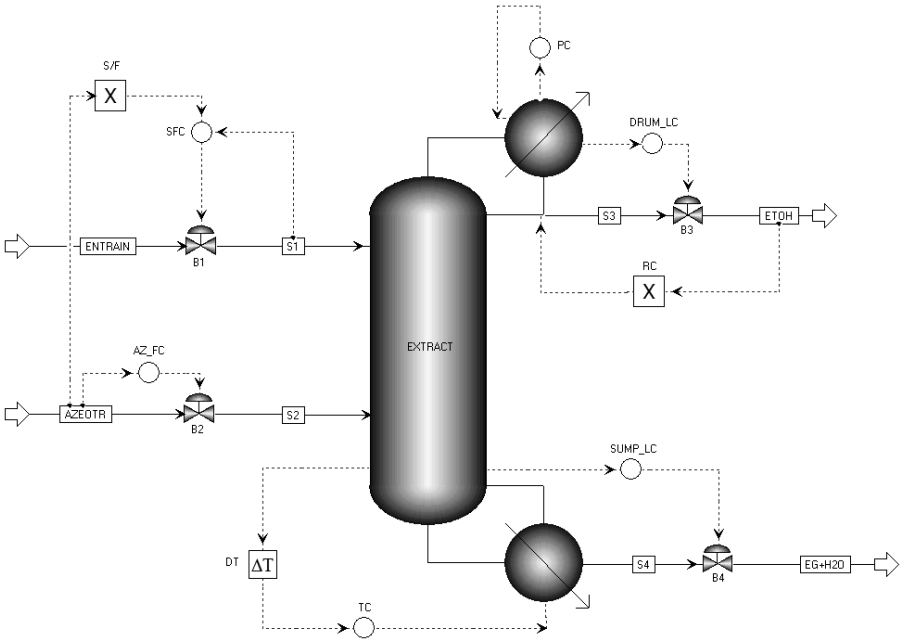

Figure 1. Control structure

The control strategy used in the 4 studied cases was established in accordance with the strategies proposed by Luyben (2008), Gil et al. (2012), Fan et al. (2013) and Tututi-Avila et al. (2014). The control structure consists of the following loops: (1) The sump level is controlled by manipulating the bottom flowrate; (2) The top pressure is controlled by manipulating the condenser duty; (3) The reflux drum level is controlled by manipulating the distillate flowrate; (4) The reflux ratio was kept constant while the disturbances were applied (Arifin and Chien, 2008; Luyben, 2008; Gil et al., 2012); (5) The ratio between the solvent feed flowrate and azeotropic mixture feed flowrate (S/F) is kept constant by using a multiplier together with a controller in cascade; (6) The temperature control is performed by manipulating the vapor flowrate of the reboiler; (7) A flow controller was added to the azeotropic feed stream in order to apply feed flowrate disturbances.

Two criteria were used to determine the best stage to have its temperature controlled: the stage that has the highest slope in the temperature profile, as well as the stage with the highest sensitivity to changes in heat duty, by manipulating the vapor flowrate in the reboiler in ± 0.1 %. It was observed that for the column with 24 stages, the stage 23 is the most suitable to have its temperature controlled for the two solvent contents analyzed. For the column with 50 stages, the results indicated the stage 49 for the column operating with 75 % EG content and stage 39 for the column operating at 20 % EG content.

The level controllers are Proportional olny, with Kc = 2 for the reflux drum level (Luyben, 2002) and Kc = 10 for the sump level (Gil et al., 2012). The pressure controller is Proportional-Integral with Kc = 20 and τ_I = 12 min (Aspen Dynamics default values). The flow controllers are Proportional-Integral with Kc = 0.5 and τ_I = 0.3 min and the filter time constant F = 0.1 min (Luyben, 2002). The parameters of the temperature controllers were tuned using the Tyreus-Luyben method (Tyreus and Luyben, 1992). The results are shown in Table 2. A dead time block was inserted before the temperature controllers with dead time of 1 minute.

2.1. Dynamic Performance

To analyze the effect of the solvent content in the controllability of the the extractive column, disturbances of ±10 % were applied, in the time equal to 2 hours, in the feed flowrate of azeotropic mixture by changing the setpoint of the AZ_FC controller. Disturbances in feed composition of the azeotropic mixture were also applied by changing the mole fraction of ethanol from 0.85 to 0.88 and 0.80.

Figure 2 shows the comparison between the dynamic responses to the disturbances in the azeotropic feed flowrate in the the column with 24 stages, for 20 % and 75 % solvent content in the extractive section, where it can be seen that the control system can maintain the purity of ethanol in the distillate close to the specification value for both EG content, with a slightly better performance when the column operates with 75% EG content. However, the column operating with 20 % EG content has reached the steady state faster, in about 2.5 hours, for disturbances in the feed flowrate and approximately 2 hours for disturbances in the composition.

Figure 3 shows the dynamic responses related to the temperature control of stage 23, where can be seen that the temperature has returned to its setpoint value in about 1 hour. Figure 4 shows the comparison between the dynamic responses to disturbances in the composition of the azeotropic mixture, where can be seen that the control is more efficient when the column operates with a lower solvent content.

The same disturbances were applied to the columns with 50 stages. Similar results were obtained for disturbances in the feed flowrate, as shown in Figures 6 and 7. For disturbances in the azeotropic feed composition, it was also observed that the column operating with lower solvent content has a better controllability (Figure 8). However comparing the results presented in Figures 4 and 8, it is noted that the column with 24 stages is able to better control the composition. The temperature control of the stages 39 and 49 proved to be efficient, as can be seen in Figures 7 and 9.

Table 2. Temperature controllers parameters.

	Case I	Case II	Case III	Case IV
Controlled variable	$T_{I,23}$ = 381.2 K	$T_{II,23}$ = 368.7 K	$T_{III,49}$ = 385.3 K	$T_{IV,39}$ = 371.4 K
Manipulated variable	Reboiler vapor flow	Reboiler vapor flow	Reboiler vapor flow	Reboiler vapor flow
Kc	1.9944	1.5767	0.7283	0.5141
τ_I	7.92 min	9.24 min	9.24 min	9.24 min

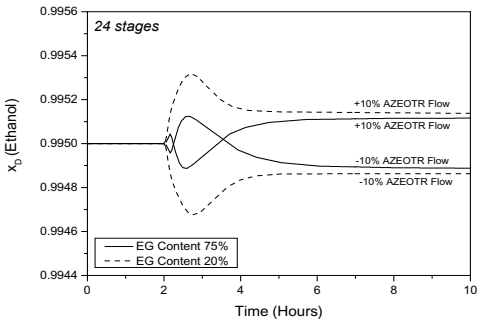

Figure 2. Comparison between the dynamic responses to disturbances in the azeotropic feed flowrate for 20% and 75% solvent content in the the extractive section.

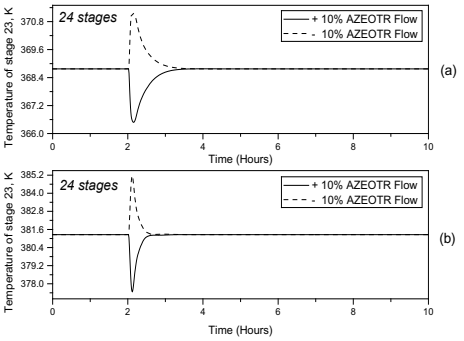

Figure 3. Dynamic responses to disturbances in the azeotropic feed flowrate for (a) 20 % EG content and (b) 75% EG content.

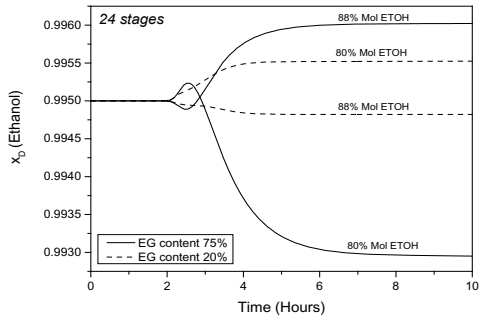

Figure 4. Comparison between the dynamic responses to disturbances in the composition of the azeotropic mixture for 20% and 75% solvent content in the extractive section.

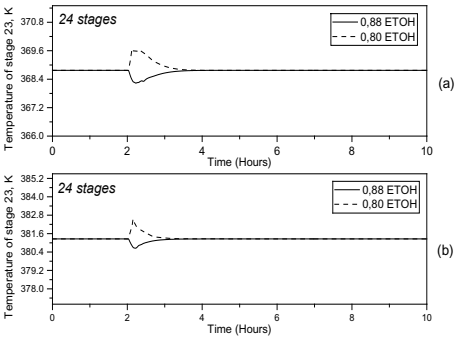

Figure 5. Dynamic responses to disturbances in the azeotropic feed composition for (a) 20% EG content and (b) 75% EG content.

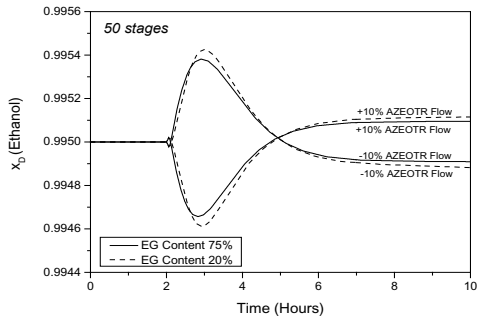

Figure 6. Comparison between the dynamic responses to disturbances in the azeotropic feed flowrate for 20% and 75% solvent content in the the extractive section

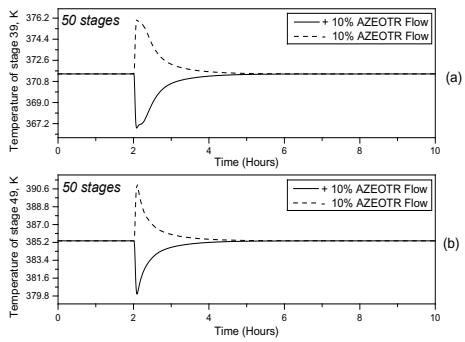

Figure 7. Dynamic responses to disturbances in the azeotropic feed flowrate for (a) 20 % EG content and (b) 75% EG content.

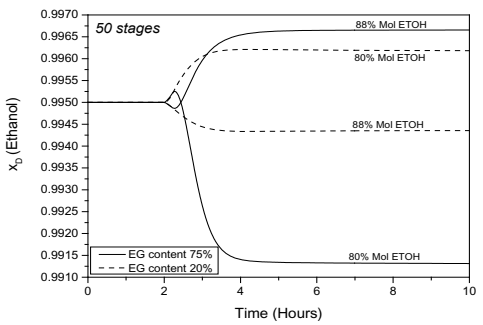

Figure 8. Comparison between the dynamic responses to disturbances in the composition of the azeotropic mixture for 20% and 75% solvent content in the extractive section.

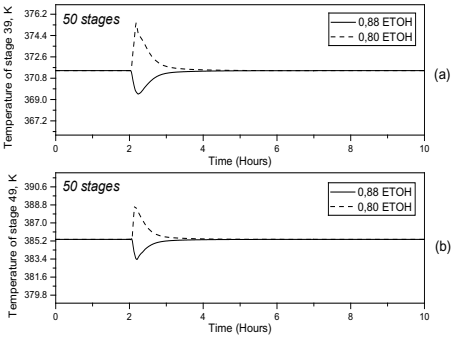

Figure 9. Dynamic responses to disturbances in the azeotropic feed composition for (a) 20% EG content and (b) 75% EG content.

3. Conclusions

Disturbances in the azeotropic feed composition caused poor performance in controlling the top product purity of the the extractive column operating with high solvent content; this poor performance is even sharper in columns with higher number of stages.

Disturbances in the azeotropic feed flowrate had small impact on the control of the top product composition in the four studied cases, however the column with higher number of stages took longer to reach steady state.

These results showed that controlling smaller extractive distillation columns is easier than controlling columns with higher numbers of stages, especially columns operating with low solvent content.

Abstract

High purity distillation is a well-established area of research. In an industrial setting most columns are operated at high recovery rate due to economic factors. However, most research work in this area overlooks high recovery as well as the fact many operations have multi-component feeds. In high-purity ($<$ 10ppm) multi-component methanol distillation the columns are typically operated at a recovery of 97.5%. Despite this relatively high value, even a 1% increase in recovery carries a significant financial incentive. In this work a validated model of a methanol distillation column was built in a commercial process simulator and used to study the dynamic behaviour of a real column operating high recovery levels. Based on the analysis the a novel control scheme has been developed and tested for 99.5% recovery: The control scheme extracts flow and composition information from feed, product and side draw streams to dynamically calculate the mass and energy requirements. The information is then used to set reboiler duty, and to manipulate the set points of the decentralized product ethanol composition controller and side draw flow controller. These actions manage the energy requirement, methanol and ethanol mass balances respectively.

Keywords: High purity, High Recovery Distillation, Industrial distillation

1. Introduction and Background

The determination of control system structure is an important step in process control design. The selection of control system structure is based on the type of control used for the process/plant. A centralized multi-input multi-output (MIMO) controller or a set of single-input single-output (SISO) controllers can be used to control a distributed or decentralized process. A decentralized type of control system is more common than the centralized control system in the process industry, as it has more captivating advantages: it is easy to understand, uses uncomplicated hardware, and employs simple working algorithms Morari and Evanghelos (1989); Marlin (2000); Svrcek et al. (2014). On the other hand, centralized type of control (e.g. Model Predictive controllers (MPC)) has many limitations such as: 1) higher maintenance cost, 2) difficulties in operation, 3) complicated structure, and 4) lack of flexibility that can result in fragile controller that is not profitable (Camacho and Alba , 2013). However, centralized controllers have the potential to operate systems at optimal levels, that can potentially have noticeable economic benefits. Distillation columns are an example of a process with sever nonlinear behaviour when their operations lie in the high-purity region. As a result they are challenging to control. Furthermore, gain directionality also becomes more severe near the high purity region (i.e. $x_D > 95\%$ and $x_B < 5\%$). Directionality issues of high-purity distillation columns makes the process response dominated by the higher gain direction (i.e. one product composition can be made further purified), which significantly

limits the performance of linear SISO controllers for dual composition control. A MIMO controller, such as MPC, is often used to address this directionality issue however MPC has its own challenges as discussed. Non-linear behaviour of high-purity distillation columns also results in different dynamics as a result of a small deviation from the operation point. This emphasises that a linear process model and linear SISO controller are insufficient to describe the system dynamics and control respectively over changing operating conditions (Fuentes and Luyben , 1983; Carcia et al. , 1989). The control of industrial multi-component methanol distillation columns is complex due to high product purity specifications ($<$ 10 ppm ethanol in products), and the need to achieve 97.5% product recovery rates or higher. In addition a strict bottoms composition ($x_B < 5$ ppm) needs to be maintained. In current operations producers employ basic control loops together with continuous human intervention to keep the columns operating at these specifications. This operating strategy results in notable financial loses. Thus, there is an industrial requirement for a robust, practical control scheme that can regulate industrial methanol distillation columns both at high recovery and high purity. A MPC can serve most of these purposes, but will require a complex model and mathematical execution algorithms to capture the highly non-linear behaviours at high purity and high recovery. In an industrial setting the MPC will also incur high installation cost and the requirement of a dedicated MPC expert on site, making MPC unviable. This manuscript will attempt to employ constraint based control on a real industrial distillation column (Figure 1 & Table 1) to create a robust control scheme that can optimize recovery and maintain purity, without the complexity of MPC.

2. Control Scheme Developments

2.1. Control Objectives

The main objective of this control scheme is to optimize the economic performance of methanol distillation columns. To achieve this objective the following parameters were found to be important from both previous work (Udugama et al. , 2014) as well as initial analysis:

- Real time management of the ethanol inventory
- Maintaining an average product ethanol specification of $<$ 10 ppm
- Real time tracking of methanol inventory
- Managing reboiler duty to meet the heat requirement for incoming feed disturbances

2.2. Control scheme

Based on the control objectives and initial analysis, the control scheme in Figure 1 has been designed. Table 1 gives the average industrial mass and energy balance data for this type of column in normal operation. In this particular type of methanol refining column, marginal savings in reboiler duty does not carry any financial benefits. The control scheme displayed in Figue 1 consists of a basic PID reboiler level controller and a condenser pressure controller. The set points to the fusel flow rate the distillate flow rate controllers are set by the Recovery constraint controller (RCC), while the steam to the reboiler (reboiler duty) is controlled by a feed-forward controller (FF).

2.3. FF controller

The feed forward controller is a simple static feed forward controller that increases or decreases reboiler duty based on the feed flow rate. Equation (1) has been empirically derived based on both plant performance and model output to achieve 99.5% recovery.

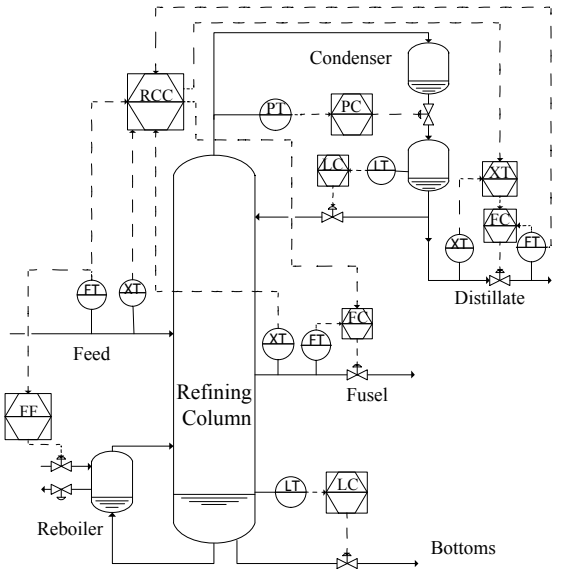

Figure 1: Proposed control scheme

Table 1: Distillation column flow and composition information

		Plant data	Units
Feed	Flow	142500	kg/h
	Methanol	0.82	Mass Frac (%)
	Ethanol	150	ppm
	Water	0.18	Mass Frac (%)
Distillate	Flow	115000	kg/h
	Methanol	99.99	Mass Frac (%)
	Ethanol	8	ppm
	Water	0.1	ppm
Bottom	Flow	25485	kg/h
	Methanol	5	ppm
	Ethanol	0	ppm
	Water	100	Mass Frac(%)
Fusel	Flow	3015	kg/hr
	Methanol	84	Mass Frac (%)
	Ethanol	0.61	Mass Frac (%)
	Water	16	Mass Frac (%)
Reflux ratio		1.687	-
Reboiler duty		88.25	MW
Methanol recovery		97.5	%

$$\text{Power (kW)} = 0.6707 \times \text{feed mass flow rate (in kg/h)} - 801 \tag{1}$$

The simple nature of the control algorithm means it can be easily auto calibrated on a daily / weekly basis to prevent the control scheme from drifting by changing the gradient and constant

values. This is a common practice in many advanced process control (APC) applications (Taube , 2014).

2.4. RCC controller

This recovery constraint controller acts as a central controller that influences the mass flow rate of the distillate and fusel draw to keep both ethanol and methanol inventories at acceptable levels.

The required fusel flow rate is calculated based on the hourly average accumulation / depletion of ethanol and the current fusel ethanol composition. The set point for the fusel flow rate is then adjusted to ensure no accumulation or depletion occurs. A Maximum flow rate set point of 3700 kg/h has been enforced due to practical limitations of the disposal system. While a minimum flow rate set point of 2600 kg/h has been set to maintain column stability.

Comparatively, the calculation of the set point to the product ethanol controller is more complex. In this instance the product ethanol set point is manipulated (within limits) to increase the product recovery when it is $< 99.5\%$. The controller also manipulates the ethanol set point to decrease the product recovery when it is $> 100\%$, as initial analysis illustrate that exceeding 100% methanol recovery for long durations leads to poor column control, leading to poor finical performance.

In situations where the recovery is above 99.5% , the product ethanol set point should be reduced below the 8 ppm limit. Based on Eq. (2),

$$\text{High recovery SP} = 8ppm + 2 \times (99.5 - \text{Product Recovery}) \tag{2}$$

This will force the composition controller to reduce the distillate flow rate which in turn would reduce the recovery rate while taking advantage of the favourable conditions to make product with ≤ 8 ppm ethanol. In situations where the recovery is 99.5% or below the controller should attempt to bring the recovery back to 99.5% as soon as possible by increasing the product specification by the following Eq. (3) up to 10 ppm where a maximum limitation is set.

$$\text{Low recovery SP (LRSP)} = 8ppm + 6 \times (99.5 - \text{Product Recovery}) \tag{3}$$

Both these equations are linear equations. In these equations the constant value is set as the average product ethanol value the operators and plant management would set for steady state operations. The gradient value is set based on how aggressively the set point should be changed per 1% change in recovery. In this instance at lower product recovery the controller acts more aggressively in comparison to a high product recovery situation. The rate at which the controller can change the set point is limited to 0.5 ppm/minute to ensure stability and unwanted reaction to high frequency disturbances. Due to the simple nature equations, these constants and gradient value can be changed by a plant engineer if required. The output of this controller with the current parameters is displayed in Figure 2.

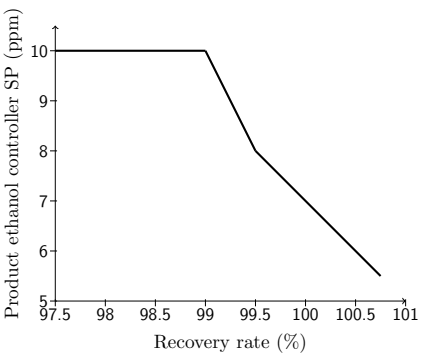

Figure 2: Ethanol controller SP Vs recovery rate

The conceptual frame work of this type of control structure has existed for some time (e.g Luyben (1992) preferred this type of constraint control over a MPC approach). In this paper this conceptual framework has been applied to a real world control situation, where all practical limitations and potential issues of introducing new control structure have been considered. The conceptual frame

work has been simplified to the point where all the supervisory/constraints equations used in the two centralized (RCC and FF) controllers can be manipulated by operators/plant engineers without the need for an expert control person.

In case of sensor faliure, the RCC control scheme can be simply switched off and the underlying control structure can provoide sufficent control to continue operations. In case of misleading/incorrect sensor signals the contraints in the RCC controller will garuntee reasonable operation. In the specific case of feed stream composition sensor failure, there is the possibility of not meeting both the product and bottoms specification. To counter this the FF Controller will be set to maximum. This will increase the refulx ratio as well as the energy cost.

3. Testing and comparison

In order to analyse the control schemes ability to produce AA grade (10ppm ethanol) methanol while keeping a high product recovery it is necessary to introduce process disturbances into the column. To test the column against feed disturbances performance against random flow disturbance sine waves with amplitude of 5 t/h was assessed. The period of the sine wave was changed between 50 minutes and 2000 minutes to simulate short process disturbances to long term process upsets. This also ensured that the designed control scheme does not create "resonance" at expected frequencies of disturbances.

To test the column for long term process upsets a sinusoidal feed disturbance that has a period of 2000 minutes (Left) and 50 minutes (Right) was introduced. The results from this test are displayed in Figure 3 (a)- (d) .

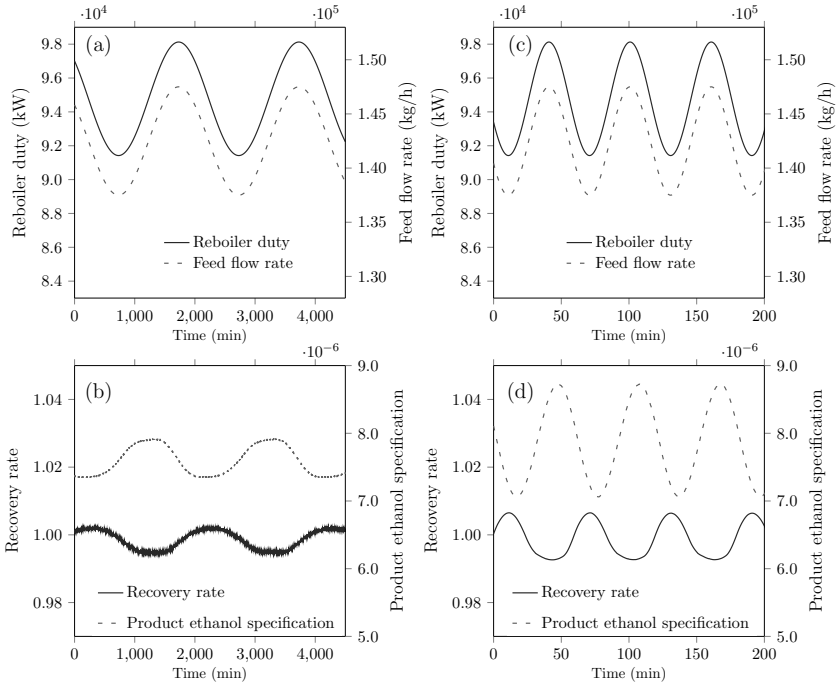

Figure 3: Controller performance for 2000 (min) and 50 (min) disturbances

Figure 3 (a) and (c) show that the reaction of reboiler duty to a fluctuating feed flow rate. In these cases the static feed forward controller has almost immediately adjusted the reboiler duty to maintain the energy balance. Figure 3 (b) and (d) show the behaviour of product recovery and product ethanol specification during the disturbances.

In the 2000 minutes case (Figure 3 (b)), as expected the product ethanol specification is fluctuating around 7 and 8 ppm which is acceptable. Despite significant changes the product recovery is stably tracking between 100.5 and 99.95% which in the long term will help column stability and profitability. Similar results can be observed in the 50 minute figures where the recovery fluctuated between 100.6 and 99.4% (Figure 3 (d)).

Overall the controller seems to be performing it objective of making AA grade methanol at improved level of recovery. To quantify the value of the new control scheme, a control scheme with a classic DV control arrangement was built and tested against similar disturbances. In this instance the average product recovery reached by the classic control for 50 minute fluctuation is scheme is 97.8% while the proposed control scheme reaches a recovery of 99.8%. For 2000 minute fluctuations the classic control scheme reached a recovery of 98.1% while the proposed control scheme reaches a recovery of 99.9%. On average this is an improvement of 1.5%. This will add up to 15000 (t) of extra methanol recovered per year per column which gives a significant financial incentive to implement such a system in the field. Similar results have been observed for other alternatives.

4. Conclusions

In this work an examination has been carried out to quantify the difficult of constantly operating an industrial methanol distillation column at a recovery of 99.5% or above. Based on this analysis a novel control scheme has been propose and tested that can achieve high recovery while being practical to implement. When compared to a classic DV control arrangement the proposed controlled outperformed the classic control scheme where on average it achieved a recovery $> 1.5\%$ than that of a classical DV controller. Considering the financial impact of this extra recovery, simplicity and robustness of the proposed control scheme will be well received in an industrial setting. Furthermore, even if a MPC perfectly control the process further gains in recovery would be limited to 0.15% as the proposed scheme is already operating at 99.85% (average). The only upside of a MPC would be savings made in reboiler duty consumed, which is this particular type of case study is irrelevant.

Abstract

Sulfur is an important pollutant that can severely prevent an implementation of all major pollution control strategies. Thus, to reduce air pollution and to comply with strict environmental regulations, sulfur content in all types of fuel produced is required to be lowered to a certain level. A selective desulfurization process is used to reduce sulfur content of fluidized catalytic cracked (FCC) naphtha, which is a blending component for gasoline product. Though, the desulfurization process can considerably lower sulfur content of the naphtha. Some undesirable olefin saturation reactions are also occurred, resulting in octane loss of the gasoline product. The octane loss depressingly influences economic performances of the plant. Thus, optimizing the operation in order to minimize the octane loss while still complying with sulfur specification and other process constraints is necessary. The operation optimization can be accomplished by implementing model predictive control (MPC). In this work, we focus on the implementation of MPC in the selective desulfurization process in order to strictly control sulfur content in the gasoline product while minimizing octane loss. A soft-sensor for on-line estimating sulfur content in gasoline product was designed and implemented. A series of step tests were performed to build empirical dynamic models. The models obtained were validated and used in MPC design. Analysis of benefit was performed with data collected before and after MPC implementation. The results showed that after MPC implementation, the control performances were improved by shifting mean of sulfur content in product close to the high limit operation. Thus, energy consumption was significantly decreased.

Keywords: model predictive control, desulfurization process, fluidized catalytic cracked naphtha.

1. Introduction

Sulfur is an important pollutant in transportation sector. It can severely prevent an implementation of all major pollution control strategies. Thus, to reduce air pollution and to comply with strict environmental regulations, sulfur content in all types of fuel produced is required to be lowered to a certain level.

Gasoline products are blended from various streams with different properties and sulphur contents. Fluidized catalytic cracked (FCC) naphtha is one of the blending components generally used. Unfortunately, without a pretreatment, FCC naphtha usually contains high sulfur content.

A selective desulfurization process can be used to significantly reduce sulfur content of fluidized catalytic cracked (FCC) naphtha. This process consists of three major units including selective hydrogenation unit, FCC-naphtha splitter unit, and hydrodesulfurization unit. Though, the desulfurization process can considerably lower sulfur content of the naphtha. Some undesirable olefin saturation reactions are occurred, resulting in octane loss of the gasoline product. The octane loss depressingly influences economic performances of the plant. Thus, optimizing the operation in order to minimize the octane loss while still complying with sulfur specification and other process constraints is necessary. The operation optimization can be accomplished by implementing model predictive control (MPC). MPC have been implemented in various industrial processes (Haktanir et al., 2013; Kemaloglu et al., 2009).

In this work, we focus on the implementation of MPC in the selective desulfurization unit of one oil refinery in Thailand. The control objective of the MPC implemented is to strictly control sulfur content in the gasoline product while minimizing octane loss. A soft-sensor for on-line estimating sulfur content in gasoline product was designed and implemented. A series of step tests were performed to build empirical dynamic models. The models obtained were validated and used in MPC design, Shell Multivariable Optimization Controller (SMOCPro). Analysis of benefit was performed with data collected before and after MPC implementation.

2. Selective desulfurization process

A selective desulfurization process composes of three major sections including selective hydrogenation unit (SHU), FCC-naphtha splitter unit, and hydrodesulfurization (HDS) unit. A simple flow diagram of this process is shown in Fig.1.

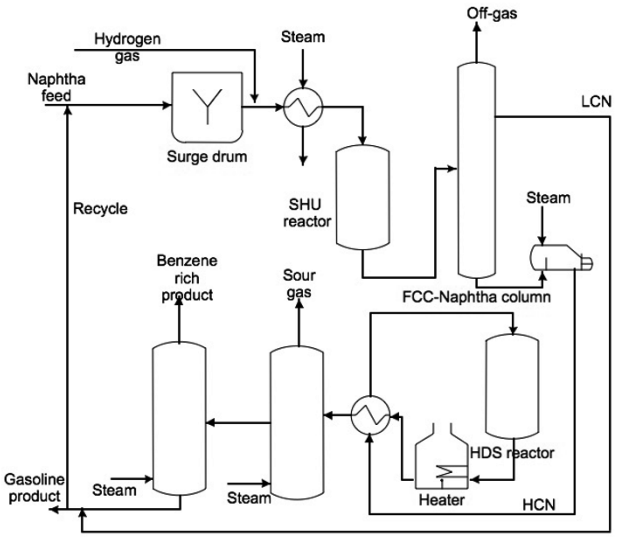

Figure 1. Process flow diagram of the selective desulfurization process.

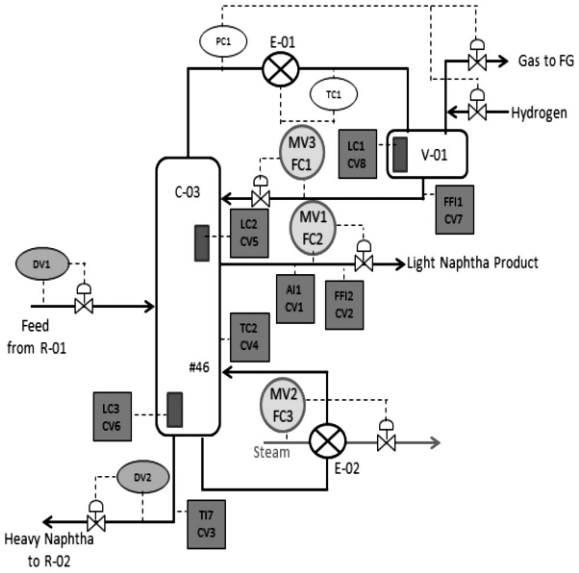

Figure 2. Control structure of the FCC-naphtha splitter unit.

FCC naphtha is fed to the selective desulfurization process through the SHU. In this unit, di-olefins are converted into olefins and light mercaptans are converted into heavier sulfur-containing compounds in the SHU reactor.

The effluent of the SHU reactor is then fed to FCC-naphtha splitter unit at tray #28 of the column, in which light-cut naphtha (LCN) and heavy-cut naphtha (HCN). LCN, which has low sulfur content and high octane number, is drawn from tray #7 in the column. In comparison, HCN, which contains high amount of sulfur and lower octane number, is drawn from the bottom of the column. The top stream of the column is condensed and collected in an overhead drum. The condensed liquid is fed back to the column as reflux. The non-condensable gas leaves the column as off-gas.

The HCN stream leaving from FCC-naphtha splitter unit is processed in the HDS unit. In the HDS reactor, heavy sulfur-containing compounds are converted into hydrogen sulfide. At the same time, undesirable olefin saturation reactions are occurred in the HDS reactor, resulting in octane loss of the gasoline product. The effluent of the HDS reactor is then fed to a stabilizer column to remove all gas by-products. Benzene is removed from the effluent in the benzene splitter column. The final HCN product is then combined with the LCN product drew from FCC-naphtha splitter unit, and sent to gasoline pool.

3. Control objectives and MPC design

The main control objectives of the desulfurization process include maximizing sulfur content in the final product within permissible limits. Thus, the upper limit of sulfur content is satisfied with Euro IV specifications, and octane loss minimization is also achieved. Other objectives are to minimize steam consumption in each column. To achieve these objectives, the main controller was decomposed into two sub controllers. The first controller regards the operation of the SHU, and the FCC-naphtha splitter unit. The other one regards the HDS unit, the stabilizer column, and the benzene splitter column. In this work, we considered the design of the first controller. However, the

Table 1. The effects of manipulated variables and disturbances on controlled variables.

	CV_1	CV_2	CV_3	CV_4	CV_5	CV_6	CV_7	CV_8
MV_1	+	+	+	+	-	-		
MV_2			+	+				
MV_3			-	-			+	-
DV_1		-					-	
DV_2						-		

+ represents positively proportional relation, - represents negatively proportional relation

di-olefin concentration in the SHU reactor cannot be measured online or predicted. Thus, the SHU reactor is excluded from our MPC design. Consequently, design of MPC for FCC-naphtha splitter unit was focused. Figure 2 shows the control structure of the FCC-naphtha splitter unit. Pressure of the column is maintained by adjusting off-gas or hydrogen gas streams. Column pressure must be kept constant. Thus, this loop was not included in the MPC design.

Sulfur content in LCN strongly depends on temperature of the column, and thus LCN draw. Before MPC implementation, a tray temperature is controlled by LCN draw. However, control of sulfur content in LCN was not implemented, as an online analyzer is not available. By utilizing an inferential property, sulfur content in LCN can be predicted from temperature of tray #45, temperature of LCN draw tray, and reflux-to-feed ratio. Real industrial data were collected and multiple linear regression was used to construct the prediction model. The prediction model is shown in Eq.(1).

$$CV_1 = 0.358T_{45} + 0.772T_{LCN} - 1.83r_{R/F} - 136 \quad (1)$$

CV_1 represents sulfur content in LCN. T_{45} and T_{LCN} are temperatures of tray #45 and LCN draw tray, respectively. $r_{R/F}$ is reflux-to-feed ratio. Model validation was done by using another set of industrial data. Good agreement between prediction and industrial data has been obtained.

The MPC designed targets sulfur content in LCN at 20 ppm. The higher sulfur contents lead to a violation of final product specification, while lower sulfur content increases octane loss and energy consumption.

The controlled variables of MPC designed included sulfur content in LCN (CV_1), LCN draw-to-feed ratio (CV_2), bottom column temperature (CV_3), temperature of tray #14 (CV_4), naphtha level at tray #7 (CV_5), naphtha level at bottom (CV_6), reflux-to-feed ratio (CV_7), and condenser level (CV_8). The manipulated variables of MPC designed included LCN draw (MV_1), reboiler steam (MV_2), and reflux flow (MV_3). The measurable disturbances were also included in MPC design. These disturbances were feed flow rate (DV_1), which is adjusted by upstream process, and HCN draw at the bottom (DV_2), which is manipulated by the HDS unit. Some of the CVs may not be maintained at the setpoint as the number of CVs is much greater than the number of

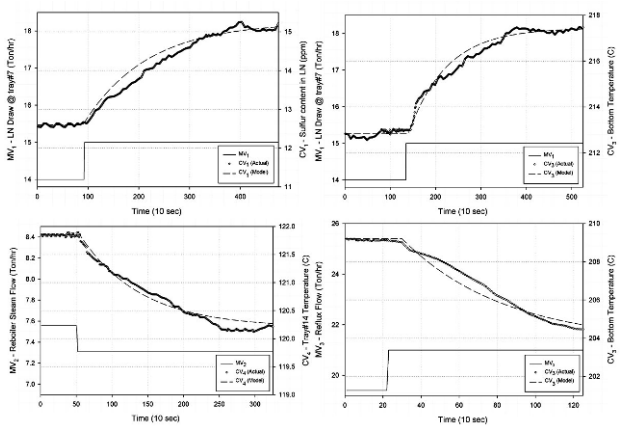

Figure 3. Some of the results from step response tests.

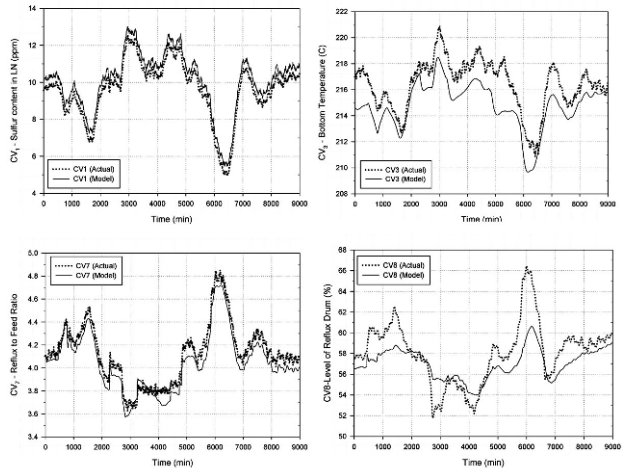

Figure 4. Some of the results from model validation.

MVs. Table 1 shows the effects of manipulated variables and disturbances on controlled variables.

A series of step test was performed, and each dynamic model was then identified as first order plus time delay system. Figure 3 shows some of the results from step response tests. The models obtained are omitted here for brevity.

These empirical models were then validated with another set of real operating data. The prediction data and real operating data were in good agreement as shown in Fig 4. Then, MPC was designed based on these models in SMOCPro.

The MPC uses optimization to minimize a cost function specified while satisfying constraints given. The objective function used was formulated as $\sum_{i=1}^{p} w_1 \| \hat{y}(n+i) - r(n+i) \|^2 + \sum_{j=1}^{c} w_2 \| \Delta u(n+j-1) \|^2$. Where $\hat{y}$, r, and u are a control

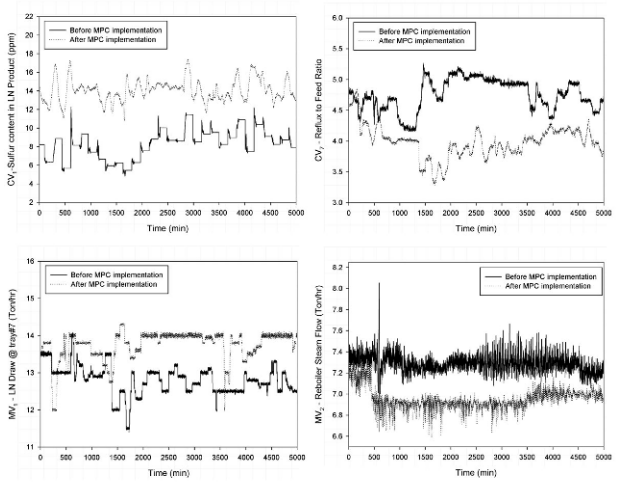

Figure 5. Performances of the process before and after MPC implementation.

vector predicted, a desired reference vector, and a manipulated vector, respectively. $\boldsymbol{p}$ and $\boldsymbol{c}$ are prediction and control horizons, respectively. $\boldsymbol{w_1}$ and $\boldsymbol{w_2}$ are adjustable weighting factors.

4. Results and discussion

Figure 5 shows the results of MPC implementation in normal operation, where disturbances were similar. By implementing MPC, the control performances were improved by shifting mean of sulfur content in product close to the high limit operation. The reflux flow was much lower than that of before MPC implementation. Thus, energy consumption was significantly decreased.

5. Conclusions

In this work, a model predictive control (MPC) was designed and implemented on a FCC-naphtha splitter unit of a selective desulfurization process. The results showed that after MPC implementation, the control performances were significantly improved. Further, reboiler steam consumption was drastically reduced.

Abstract

This work addresses the implementation of an online dynamic optimization cascaded with a dual mode PID control strategy for improving the product quality and profit of an autocatalytic esterification of Propionic Anhydride with 2-Butanol. An orthogonal collocation method is implemented to re-optimize the feed rate and temperature trajectories to compensate the deviation of end product due to disturbance (variation of feed concentration). The problem of dynamic optimization is formulated to maximize the profit. The spec of final product (±5% of conversion) constraint is denoted as an active constraint which is applied as the trigger for activating re-optimization. The simulation results show that the proposed strategy offers a large improvement in semi batch reactor performance if compared to the method which the optimal trajectories set point is pre-determined (offline). Moreover, the online dynamic optimization of temperature and feed flowrate trajectories obtained able to sustain the limiting reactant concentration within active constraint. Meanwhile, the offline optimization failed to handle the effect of disturbance thus the end concentration produced is off-spec and can lead to loss in profit.

Keywords: Online dynamic optimization; Semi batch; Autocatalytic esterification,

1 Introduction

To improve the batch processes performance, the dynamic optimization is preferable to be implemented due to its ability to capture the dynamic behavior of the process. Dynamic batch system is very sensitive to uncertainties and disturbances in the process operation. In semi batch esterification process, a disturbance such as variation concentration in the feed stream may cause the final product differs from the desired value. This discrepancy may risk the violation of safety constraints, production off-spec products, and more vitally the loss of invaluable profit. Under these circumstances it is desirable to implement online dynamic optimization strategy to desired trajectories to reach the optimal performances (Kadam and Marquadt, 2007). The aim of the online dynamic optimization for semi batch reactor is to generate the optimal trajectories of process variables such as flow rates of feeds and temperature, which are typically re-adjusted to optimize the objective function in the presence of significance disturbance (Würth et al., 2009). The cascaded-conditional based optimization is applied in this

study because it is found to be an effective technique for updating system with uncertainty. It is solving the optimization and control problem separately by decomposing the overall problem into two levels (Alonso et al., 2013). As the significance uncertainty and disturbance occurred, the re-optimizer will generate a new/modified optimal trajectory in order to ensure optimum performance is obtained. However, the existing techniques implements cascaded – conditional based optimization using a combination of sensitivity-based updates and adaptive control vector parameterization strategy which highly complex. Moreover, it also causes a slower rate of convergence if exact Hessian matrix is miscalculated (Kadam and Marquadt, 2007, Würth et al., 2009). Therefore, the development of effective way for activating the re-optimizer is a must which can lead to the more efficient optimal solution computation.

In this work, orthogonal collocation method (OC) is implemented for cascaded-conditional based optimization to optimize the feed flowrate and temperature reactor trajectories in the presence of disturbance. The process considered is Catalyzed Esterification of Propionic Anhydride with 2-Butanol in a semi batch reactor. The optimal trajectories obtained are based on maximum profit problem.

2. Modeling of autocatalytic esterification process

Esterification of propionic anhydride with 2-butanol is producing sec-butyl propionate and propionic acid. It exhibits a kind of autocatalytic behaviour when sulphuric acid is introduced. The reaction kinetics of this esterification has been investigated and the data of parameters is depicted from Zaldivar et al. (1993). The semi batch reactor model which consist of the mass and energy balances are represented by following equations:

$$\frac{dC_B}{dt} = -((k_1 + k_2 C_{cat1}) C_A C_B + k_3 C_{cat2} C_B) + \frac{F_o}{V}(C_{B0} - C_B) \tag{1}$$

$$\frac{dC_C}{dt} = \frac{dC_D}{dt} = ((k_1 + k_2 C_{cat1}) C_A C_B + k_3 C_{cat2} C_B) - \frac{F_0 C_C}{V} \tag{2}$$

$$\frac{dC_{cat1}}{dt} = -\frac{dC_{cat2}}{dt} = -(k_4 10^{-H} C_{cat1} C_A) - \frac{F_0 C_{cat1}}{V} \tag{3}$$

$$\frac{dT}{dt} = \frac{-\Delta Hr_{total}}{\rho C_p} + \frac{UA}{\rho C_p V}(T_j - T) + \frac{F_O}{V}(T_{feed} - T) \tag{4}$$

$$\frac{dT_j}{dt} = \frac{F_j}{V_j}(T_{jin} - T_j) + \frac{UA}{\rho_j V_j C_j}(T - T_j) \tag{5}$$

where C_A, C_B,C_C, C_{Cat1}, and C_{cat2} are the concentration of 2-butanol, propionic anhydride; propionic acid, sulphuric acid and mono-butyl sulphuric acid, respectively. F_o , V are the feed rate and the volume of solution within reactor. F_j is the jacket flowrate, T_j is the jacket temperature; T_{jin} is the inlet jacket temperature; T_{feed} is the feed temperature; A is the heat exchange area; V_j is the volume of jacket; U is the heat exchange coefficient; C_p, C_j is heat capacity of solution in the reactor and the jacket, respectively; H is the acidity function; ΔHr is the heat of reaction; ρ is density of solution in reactor; ρ_j is density of jacket solution. Those pertaining constant value is depicted from Ubrich et al. (1999). The initial value of C_A, C_B, C_C, C_D, C_{cat1}, C_{cat2} V, T and T_j is 3.4M, 0M, 0M, 0M, 1.02 x 10^{-2}M, 0M, 1L, 303K and 303K, respectively.

3. Design of online cascaded-conditional based optimization

The cascaded-conditional based optimization is constructed by the integration of process model, initial optimal control trajectory, estimator, controller and dynamic re-optimization mechanism which consists of trigger and dynamic re-optimizer. The framework of this strategy is adopted from the works of Alonso et al. (2013), Würth et al. (2009), and Kadam and Marquadt (2007) as shown in Figure 1.

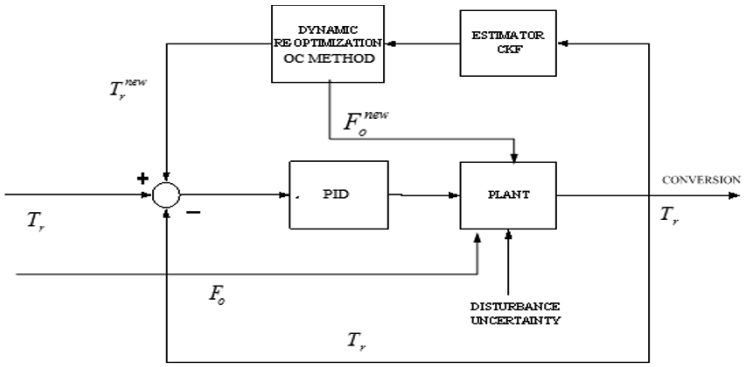

Figure 1: Scheme diagram of online dynamic optimization framework

The distinct of this research from the previous work on cascaded-conditional based optimization is the application of conventional controller and simple dynamic re-optimizer mechanism. Since the value of feed flowrate is assumed to be measurable, the temperature trajectory can be tracked by the dual mode of adaptive PID controller. The details of controller and its tuning can be found in Landau (1990). Meanwhile, the dynamic re-optimization mechanism uses the spec of final product (±5% of conversion) as the activator re-optimizer (trigger) for handling the significance disturbance. All the state variables presented in mass balance are required to calculate the updated values by using Cubature Kalman Filter technique which the algorithm code package is developed by Solin (2010). The measurements available which consider as the CKF input are C_A, jacket and reactor temperature. The noises incriminated in the states are maintained at low level.

The optimal feed flowrate and temperature trajectories were pre-determined from an offline dynamic optimization study. Meanwhile, online dynamic re-optimizer generates new optimal trajectories in order to re-optimize plant for rejecting impact on disturbance. Both offline optimal and online re-optimized trajectories are evaluated by OC method for maximizing profit. In this work, the OC was implemented within the MATLAB® environment by using the dynopt code package developed by Cizniar and co-workers (2005). The operation profit is derived from the price of the product. The operation profit (RM/min) expression is presented by Equation 6 (Aziz, 2001):

$$P = \frac{V\left(C_C P_C + C_D P_D\right) - \left(C_{A0} - C_A\right) P_A V - P_B \left(C_{BF} + C_B\right) V}{t} \tag{6}$$

where P_A, P_B, P_c and P_D, are the prices of A, B, C and D, E and F with numerical values [26.75, 34.39, 10.17, 339.1], respectively (Xingtai, 2014, Sigma-Aldrich, 2014). All values are in RM/mol.

In this study, volume of solution, the reactant, catalyst and product concentration were considered as states variables. The control variables considered were feed flowrate and temperature reactor. The objective function was to maximize profit. The inequality constraint associated was end concentration of limiting reactant and total volume reactor. The dynamic optimization formulations for both problems are shown as:

Problem:

$$\max_{T,F_0} \Im = P$$

Subject to semi batch dynamic model Eq.1-5;
Inequality constraints: $V \leq 2.2L$; Bounds: $0 \leq F_0 \leq 5x\ 10^{-4} L\ s^{-1}$ and $303K \leq T \leq 343K$.

4. Results and discussion

The simulation of cascaded-conditional based optimization was carried out in the SIMULINK® environment. The significance disturbance and parameter that can violate the active constraints and generate the off-spec product (±5% of conversion) was introduced in the plant. The alleviation of feed concentration C_{B0}, i.e. 1M, at 25-35 min of process time was considered as disturbance.

The conversion obtained in online dynamic optimization study is shown in Figure 2. The optimal temperature trajectories together with control response for tracking temperature trajectory obtained for maximizing profit problem under effect of disturbance is shown in Figure 3. Meanwhile, the optimal feed flowrate trajectories obtained are shown in Figures 4. From Figure 2, it is found that the decrease of the feed concentration decrease the amount of product. Therefore, the conversion obtained was also decrease when the disturbance occurs. When the conversion exceeded the active constraint, the dynamic re-optimization was activated to generate the new optimal feed flowrate and temperature trajectories as shown in Figure 3 and 4, respectively. The update mechanism in cascaded dynamic optimization was able to capture the effect of the disturbance by re-optimizing the optimal trajectories which bring the conversion back to the specified constraints region, i.e. conversion = 99.86%. Meanwhile, the offline mode (without the re-optimizing mechanism) produces an off-spec end conversion with value of 94.62%. The online strategy maintained the process to obtain profit at RM 12.89 RM/min. whereas the offline strategy only manages to give profit at 10.89 RM/min. From Figure.3, it is also found that the action of adaptive PID controller to track temperature trajectory is acceptable since the controller can drive the system from current set point value to a new one and maintain it at the set point. This observation signifies the feasibility of the conventional control implemented for the process considered.

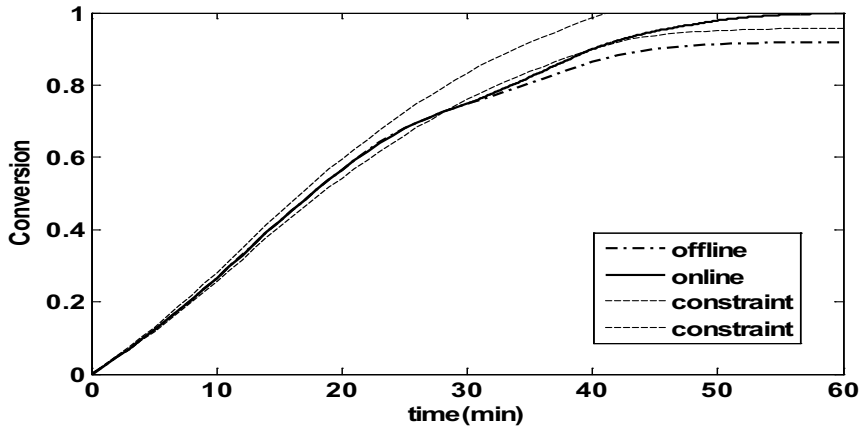

Figure 2: Conversion profile for dynamic optimization study

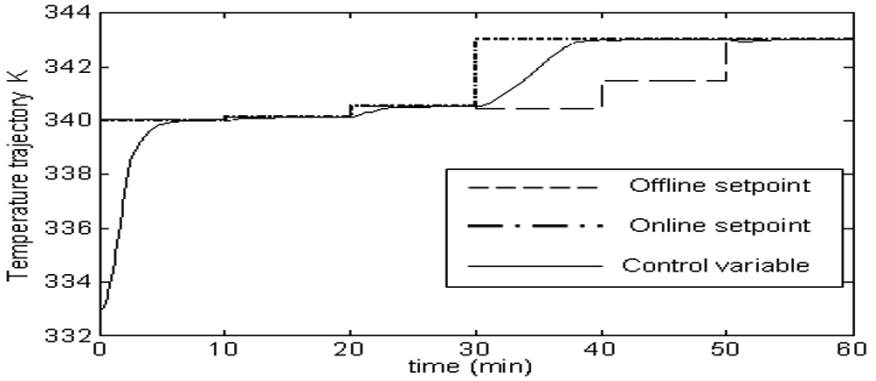

Figure 3: Optimal temperature trajectory for dynamic optimization study

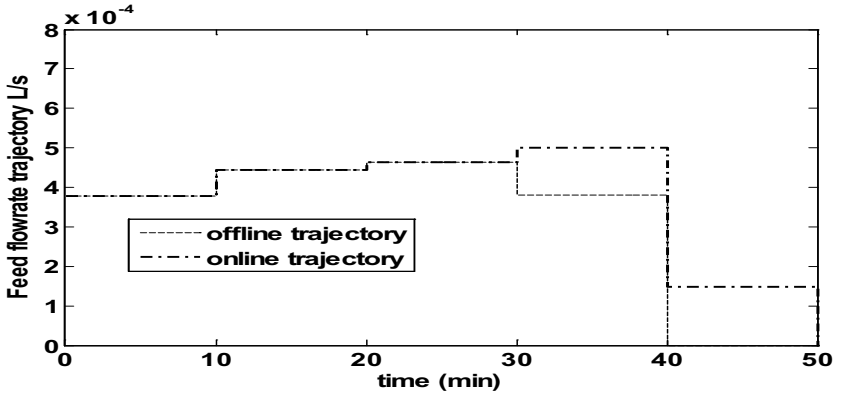

Figure 4: Optimal feed flowrate trajectory for dynamic optimization study

5. Conclusion

The online dynamic optimization of Catalyzed Esterification of Propionic Anhydride with 2-Butanol in semi batch has been carried out. The cascade optimization strategy was implemented to update the optimal trajectories when a significant disturbance occurs in the process. The re-optimized temperature and feed flowrate trajectories drove the conversion within the active constraint which maintains the profit of process. Meanwhile, the offline optimization mode cannot capture the effect disturbance which led to off-spec end product.

Abstract

MTBE is commonly produced using reactive distillation column which combine reactor and distillation column in single unit process. To achieve high MTBE purity and reactant conversion is a challenging task due to strong interaction between control variables and due its highly nonlinear behaviour of the process. In this work, nonlinear model predictive control (NMPC) is developed and applied to control tray temperature of MTBE reactive distillation. To increase the performance of NMPC, the Neural Wiener model and Simulated Annealing–Particle swarm optimization (SA-PSO) are chosen to be implemented in NMPC. In this work, the MTBE reactive distillation was modelled using Aspen dynamic, meanwhile the control study has been carried out using Simulink (Matlab) which is connected with Aspen dynamic model. The results obtained show that the multi input multi output (MIMO) Neural Wiener based model predictive control (NWMPC) using SA-PSO can successfully control the tray temperatures in MTBE reactive distillation. The NWMPC is able to track the set point change and to reject the disturbances very well with small value of error.

Keywords: Neural Wiener, NMPC, Simulated annealing, PSO, Nonlinear Optimisation

1. Introduction

Maximum production of the MTBE can be achieved using reactive distillation (RD) which the reaction and separation process are combined and run at the optimum operating conditions and column configuration. Meanwhile, to maintain the product purity at a specified range, a feasible controller is required. Control of RD is major problem in MTBE production due to its high degree of nonlinearity, steady state multiplicity, time delay, strong interactions, process uncertainties and the large number of possible control configurations (Satyanarayana and Saha, 2005). One of the advanced control system which can be applied in reactive distillation is a nonlinear model predictive control (NMPC). The NMPC consists of three main components namely the process, the nonlinear model and nonlinear optimizer (Konakom et al., 2011).

Neural Wiener Based MPC (NWMPC) is a relatively new scheme of NMPC which can be applied in a MTBE RD. Neural Wiener model is simple block oriented model that can be solved at lower computational time. It is also flexible in representing the nonlinear processes and can avoid the interactions among control variable thus make NWMPC more attractive for real application (Lawry´nczuk, 2011). The advanced

nonlinear optimization is proposed to increase the performance of NWMPC which must have ability to find both the global and local optimum result. Particle swarm optimization (PSO) is one of nonlinear optimizer which has good performance to find global optimum result but difficult to find a local minimum. Meanwhile, Simulated Annealing (SA) has a strong ability to find the local optimum result but less superior in finding the global optimum. Hence, the combination of SA and PSO will enhances the convergence and accuracy of the controller optimization. Wang et al. (2005) have used SA- PSO to solve the optimization problem in a single input and output (SISO) NMPC to control a thermal power unit load system. Meanwhile, in this work, a NWMPC combined with SA-PSO optimizer is designed and developed to control a reactive distillation for MTBE production.

2. Development MTBE reactive distillation model

The most promising technique of producing MTBE is from methanol and isobutene, where the liquid-phase reaction is catalyzed by ion exchange resin (heterogeneous reaction). The reaction scheme is:

$$\text{i-C4H8} + \text{CH3-OH} \rightleftharpoons \text{C5H12O} \qquad (1)$$

The specification MTBE RD considered here can be found in Fig. 1(Higler et al., 1999). In this work, MTBE reactive distillation model has been developed in Aspen dynamic .

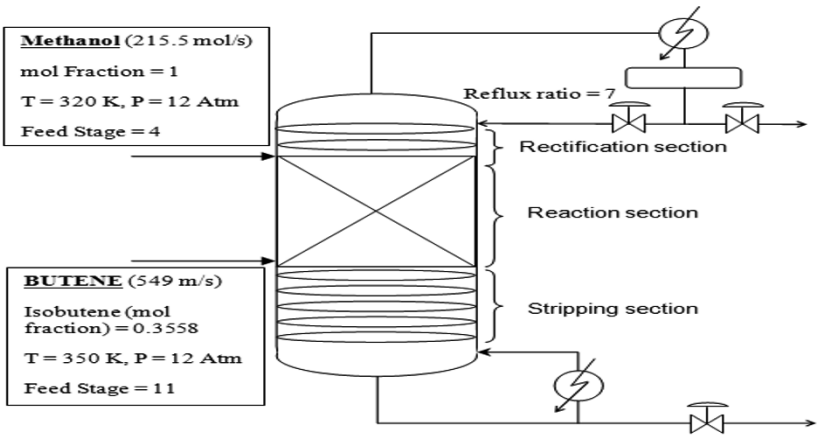

Fig. 1. MTBE Reactive Distillation Column

3. Neural Wiener model identification

Neural Wiener (N-W) model consist of linear block and nonlinear block as shown in Fig. 2. The N-W identification algorithm is begun by data generation in order to collect dynamic input-output data. Then, a linear model is identified to produce the intermediate variable of v(k) from the input data. The v(k) output is a linear dynamic part of state space model which consist of v1 and v2. Finally, neural network model is identified using intermediate variable as input variable. The N-W model block arrangement is shown in Fig. 3.

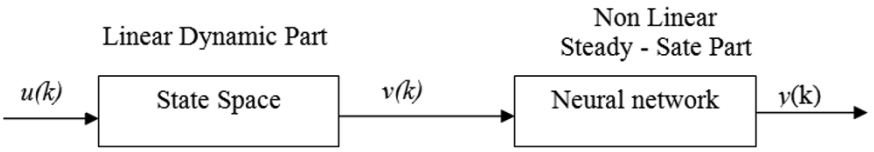

Fig. 2. Neural Wiener model configuration

In this work, state space model is used as the linear block and MIMO neural network model is used as the nonlinear block. The MIMO Neural network used is a feed forward neural network with 15 hidden nodes and 1 hidden layer. The output y(k) of the N-W model is described below:

$$y(k) = w_0 + \sum_{i=1}^{K} w_i^2 \varphi\{w_{i,0}^1 + w_{i,1}^1[C\,x(k) + D\,u(k) + e(k)]\} \quad (2)$$

where w_0 is the bias, $w_{i,j}$ is the weight of first layer, and w_i is the weight of second layer, φ is a nonlinear transfer function such as hyperbolic tangent sigmoid transfer function and tansig, K is the number of hidden nodes.

4. Development of simulated annealing–particle swarm optimization (SA-PSO)

The description of original PSO can be found in Shi and Eberhart (1999). In this research, the first modification done was the addition of weighting function (w) in the inertia of velocity equations shown below:

$$v_i^{t+1} = w.v_i^t + \varphi_1 U_1^t (Pb_i^t - x_i^t) + \varphi_2 U_2^t (gb_i^t - x_i^t) \quad (3)$$

where, v_i^{t+1} is velocity of agent i at iteration k, φ_1 and φ_2 is weighting factor, U_1^t and U_2^t is uniformly distributed random number between 0 and 1, x_i^t is the current position of agent i at iteration k, Pb_i^t is the best known position of particle i. Meanwhile, gb_i^t is the best known position of the entire swarm. The value of the inertia weight (w) is decreased automatically during a run as a proposed by Shi and Eberhart [11]. The combination of simulated annealing (SA) and PSO has been proposed by Wang et al. (2005). The combination of SA and PSO algorithm's have similar searching process which is also started from initializing a group of random particles. In the process of simulated annealing, the new individuals are given randomly around the original individuals. The changing range of original particles as a parameter r1, to each particle is given by following equation:

$$\text{Present} = \text{present} + r1 - r2.2.\ \text{rand}(1) \quad (4)$$

where rand (1) is a random number between 0 and 1, the parameter r1 here also reduces step by step as the generation increasing. The SA method which is activated using 50% of total particle. In SA calculation, the new individuals are given randomly around the original individuals and the changing range of original particles as a parameter r1, to each particle reduces step by step as the generation increasing, hence the SA formulation become:

$$r_1 = \left(\frac{(lb-ub)(0-(0-w_{max})}{(it_{min}-it_{max})(it_{max}-it)}\right) \quad (5)$$

$$x_{(i\to n)} = x_{(i\to n)} + r_1 - r_1 * 2 * \text{rand}\,(1) \quad (6)$$

Where lb = is lower bound, ub is upper bond, lb is lower bound and x is the final result and rand (1) is a random number between 0 and 1 (Wang and Xiao, 2005).

5. Development of Neural Wiener Based MPC (NWMPC)

The N-W model developed and the SA-PSO optimizer proposed are embedded in the Neural Wiener NMPC as shown in Fig. 3.

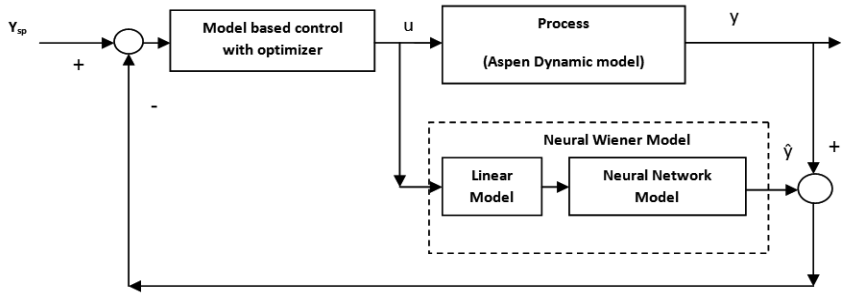

Fig. 3. General structure of Neural-Wiener Based model predictive control

The NWMPC objective function for the MIMO case consists of the quadratic error between each controlled variable and its set-point and the quadratic change of each manipulated variable. The control variables chosen are tray temperature no.3 (CV1) and no.8 (CV2). Meanwhile the manipulated variables are reboiler duty (MV1) and reflux flowrate (MV2). The control and manipulated variables are chosen based on SVD test (Sudibyo*et al*., 2012).The MPC objective function for the 2 × 2 system is defined as follows:

$$j_k = \sum_{i=1}^{P} \left((y_{f1|k+i} - y_{sp1|k+i})^2 Q_1 + (y_{f2|k+i} - y_{sp2|k+i})^2 . Q_2\right) + (\Delta u_{f1|k+i})^2 . R_1 + (\Delta u_{f2|k+i})^2 . R_2 \quad (6)$$

where y_f is predicted future output, y_{sp} is set point, Q is error penalty, R is input change penalty, Δu_f is future input change and k is current sampling time.

6. CONTROL STUDY

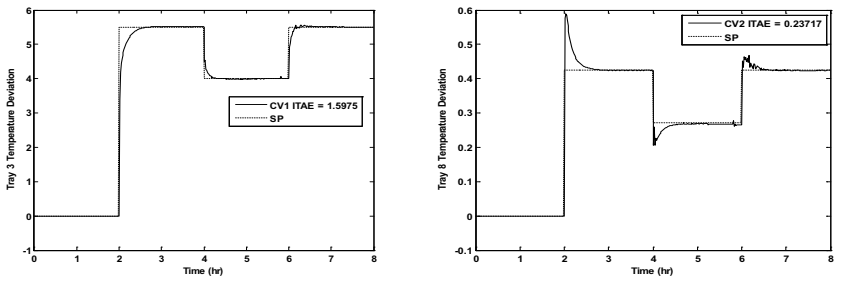
NWMPC using SA-PSO as a nonlinear optimizer was tuned to obtain the best control configuration. The NWMPC tuned parameters obtained are tabulated in Table 1.

Table 1.NWMPC and PSO Parameter after tuning

MPC Parameter	Value		PSO Parameter	Value
Prediction horizon	5		Number of particle	110
Control horizon	2		weight function minimum	0.4
Error penalty	1	1	weight function maximum	0.9
Input change penalty	98000	4500	Number of iteration	60
input constraint upper bounds	0.05;	0.05	Rho1 (weighing factor 1)	1.25
input constraint lower bounds	-0.05;	-0.05	Rho2 ((weighing factor 2)	1.25

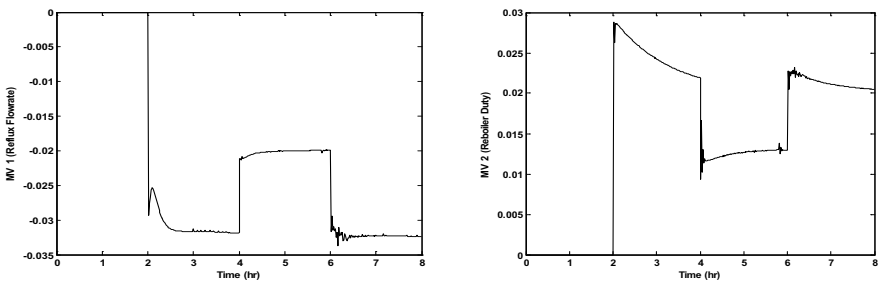
6.1 Set point change

In this test, the set point CV1 is set at value of 0, 5.4966, 4 and 5.4966, meanwhile set point CV2 is set at value of 0, 0.424, 0.2708 and 0.424 where the switching time of all changes is 2 hours. The changing of set point of tray temperatures in this test was aim to achieve the MTBE purity at 95%, 97.5% and 99%.The profiles of control variables (CV1 and CV2) obtained in this set point test are shown in Fig. 4a and 4b, respectively. Fig. 4a shows that the proposed NWMPC is able to track the set point change with a small amount of overshoot and error (the value ITAE is 1.59). Meanwhile, CV2 profile shows that the controller is also able to track the set point with the settling time less than 0.5 hour and small value of error (ITAE value is 0.237) as shown in Fig. 4b. The result achieved has managed to obtain more that 99% isobutene conversion.The respective MV1 and MV2 profiles achieved are shown in Fig. 5 which are within the specified range with acceptable pattern of changing.



(a) (b)

Fig. 4. Set point change (a) CV1 profile and (b) CV2 profile



(a) (b)

Fig. 5. Set point change (a) MV1 profile and (b) MV2 profile

6.2 Disturbances rejection test

In this test, +30% change in methanol feed flow rate was introduced as disturbance that occur from 3 until 3.2 hour. Using SA-PSO optimizer, the proposed controller is able to reject the effect of disturbance change after 0.5 and 0.7 hour for CV1 and CV2, respectively as shown in Fig. 6. The ITAE value for CV1 and CV2 are 0.71042 and 0.215, respectively. Meanwhile, the respective MV profiles are shown in Fig. 7.

7. Conclusion

NWMPC using SA-PSO has been successfully developed and applied to control tray temperatures in the MTBE reactive distillation model. The performance test of set point change and disturbance rejection showed that the proposed controller have good performance with small amount of overshoot, low settling time and small amount of error.

Abstract

This paper focuses on the design and implementation of on-line optimal control strategies of crystal properties for non-isothermal antisolvent crystallization processes. The one-dimensional Fokker-Planck equation (FPE) is used to represent the dynamic characteristics of the crystal growth and to generate iso-mean and iso-standard deviation curves. Using controllability tools it is shown that the system is ill conditioned in the operational range, posing limitations on the achievable control performance. A novel digital image texturing analysis approach is implemented to track crystal's size distribution along the experiment, thus providing the on-line information for further feedback control action. Subsequently, alternative control strategies are implemented and tested to achieve a desired crystal size distribution (CSD).

Keywords: Crystallization, Optimal control, image analysis

1. Introduction

Crystallization is a main physical separation process in many chemical industries. It is an old unit operation which can separate solids of high purity from liquids, and is widely applied in the production of food, pharmaceuticals and fine chemicals. There are significant properties of the final product in crystallization process such as purity and stability of crystalline particles, growth morphology and size distribution that affect downstream unit operations including filtration, granulation and drying. Hence, to fulfill the product specification it is important to properly control the process which necessitates understanding the dynamic of the system and underlying phenomena. For the control of CSD, one typical approach used is based on model-developed optimal profiles which are then implemented on-line with or without any feedback action. Recently, cooling has been combined with antisolvent crystallization and the joint process has been modeled (e.g., Lindenberg et al. 2009). In contrast to model-developed optimal profiles, there has been alternative ways to control anti-solvent processes. These have been supersaturation control (e.g., Sheikhzadeh et al., 2008). In supersaturation control, the aim is to control the supersaturation at a constant level to maximize crystal growth, while in indirect nucleation control the aim is to control the number of particle counts using an on line particle counter, such as the Lasentecs FBRMs (focused beam reflectance measurement). This prevents excessive nucleation, thus increasing the product crystal sizes. Various methods of robust optimal control have also been studied (e.g., Yang and Nagy, 2014).

Despite the described contributions, there are not publications that directly control the CSD in a feedback fashion. This is basically due to the lack of proper on-line

characterization of the crystal characteristics. This contribution proposes an online strategy to directly control crystal size distribution in joint cooling antisolvent crystallization processes. Crystallization of sodium chloride in water using ethanol as antisolvent is performed in an experimental bench-scale semi-batch crystallizer. Results demonstrate in some cases poor performance of the PIs control strategy, due to ill-conditioning of the process. On the other hand excellent behavior on the CSD control is achieved when the FF and the proposed FF/FB controllers are applied.

2. Theoretical background

The recent development of a stochastic approach to model the non-isothermal antisolvent crystallization processes (Grosso et al., 2010), allowed an accurate analysis on the controllability property of such system. In this novel approach the dynamics of a single crystal size L is described as

$$\frac{dL}{dt} = Lg(L,\theta) + L\,\eta(t) \tag{1}$$

Where g(L;θ) represents the growth rate with θ indicating the vector of model parameters, t is the time, and η(t) is the Langevin force including the growth fluctuation. The dynamic behavior of the probability density distribution of the crystal size (ψ) had been obtained by recurring to the Fokker-Planck equation after performing a nonlinear variable transformation y=ln (L) in Eq. (1):

$$\partial_t \psi = D\partial_{yy}\psi - \partial_y[g(y,t,\theta)\psi] \tag{2}$$

The growth rate function in the variable y, allowing the most simple and accurate representation of the crystallization system is the logistic equation:

$$g(y,\theta) = ry\left(1 - {}^{y}\!/_{K}\right) \tag{3}$$

Simple relationships had been developed to correlate the parameters r and K along with the noise intensity (D) to the antisolvent flow rate and temperature leading to a stochastic model that can be applied to the whole operating range of the experimental system.

The stochastic modeling approach provides a convenient way to analyze the input-output relationships in order to evaluate the process characteristics such as stability and transient response. In recent works it was shown that, representing the asymptotic mean and variance on an antisolvent (q) vs. temperature (T) plane, input multiplicities were obtained (Cogoni et al, 2014) for a certain window of operating conditions. This means that it is possible to obtain an asymptotic CSD, characterized by its mean and variance, by using two different sets of input values. This particular behavior has been corroborated experimentally (Cogoni et al., 2014), and it is due to the presence of competing effects of the process inputs. From a control perspective, input multiplicities implies that the steady-state gains of the system may change sign as the system moves from one operating point to another, therefore if a conventional feedback control is applied, it can lead to undesired output values, unstable or oscillatory responses (Kumar et al., 2005). For the problem at hand, it is possible to analytically solve Equation (2) at the stationary solution (Tronci et al., 2011) obtaining the expression of the asymptotic distribution. Choosing a mean size value, the analytical expressions can be iteratively solved in the domain of the operating conditions to calculate all the possible standard deviations for that specific mean size. This allows constructing the asymptotic iso-mean

(blue line) and iso-standard deviation (red line) curves reported in an antisolvent flowrate - temperature plane (Figure 1).

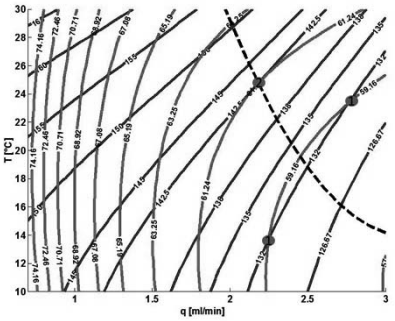

Figure 1: Asymptotic standard deviation (solid red lines) and the mean size (solid blue lines). The catastrophe locus is also reported (dashed black line)

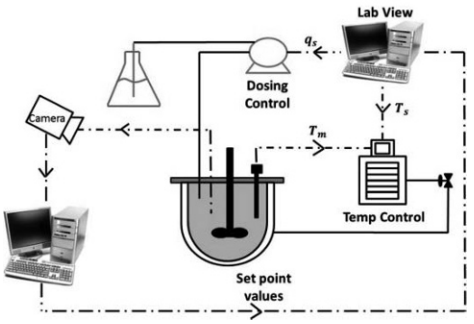

Figure 2: Schematic representation of the experimental system

The region in the (q,T) plane where the matrix of the process gain at asymptotic condition is singular is called catastrophe locus, and it is represented with a black dashed line in Figure 1. As illustrative examples to consider different behaviors of the dynamical system, two asymptotic conditions are chosen as targets, which are: (μ, σ)=(132 μm, 59.16 μm) and (μ, σ)=(142.5 μm, 61.24 μm). According to the operational map these points are feasible and the second one is on the catastrophe locus of the system as shown by gray circles in Figure 1. These two set-points will be considered during the implementation and testing alternative control strategies.

3. Experimental set-up and CSD characterization

Crystallization of sodium chloride in water using ethanol as antisolvent is considered as a case study. Reagent grade sodium chloride (99.5%), 190 proof ethanol and only purified water are used. The initial solution consists of 34 g of NaCl in 100 g of deionized water. All the experiments are carried out in 1 l bench scale crystallizer which is submerged into a temperature control bath. Temperature is measured using an RTD probe that is wired up to a slave temperature control system capable of heating and cooling. Ethanol is added to the solution using a calibrated peristaltic pump. Mixing is provided by a magnetic stirrer at the speed of 400 RPM. Along the experiment, particles are circulated throw a pump into a cell where they are lighted up by an illumination system. Images are taken continuously using a USB microscope camera which fits into the side tube on the side of the microscope with one of the supplied adapters and connects to a computer. Using image-based texture analysis crystal size distribution is determined and the results are compared with the desired set points that have already been defined in the computers by master controller. A schematic representation of the experimental apparatus is shown in Figure 2.

The controller strategies proposed in this work use the mean crystal size and variance of the CSD estimated by a sensor recently developed by Zhang et al., (2014). The novel approach is based on image processing of the crystals, and it is able to extract the required information on textural properties irrespective of whether it is applied to single particles or overlapped as clusters. In this method, which is based on combining

thresholding and wavelet-fractal-energy algorithm, images are considered as a 2D array of pixels with various intensities. Otsu's global thresholding method and an optimum threshold value for the intensity can be exerted to identify the intensity of crystal edges and remove the background. In this way, location of crystal clusters that have different intensities from the background can be detected and the information regarding intensities of those points will be restored into a vector. Discrete wavelet transformation (DWT) is then applied to the signal obtained by processing the image. DWT should extract textural characteristics of crystals by decomposing the signal into several details, which are crystals' edges in our case and an approximation, called the intensity variance caused by illumination. The new information in terms of variance of wavelet coefficients are further processed in order to obtain the fractal dimension (FD). This last property has been selected as texture feature since it has been demonstrated that dynamics of crystal growth follows fractal process. An artificial neural network is then designed using the texture information (FD, energy signatures for details level from 2 to 5) in conjunction with the available online process conditions (flow rate, temperature and time) as inputs for the estimation of the crystal properties (mean size and standard deviation) as output in the whole operating range.

4. On-line control of the Crystal size distribution

Different control strategies have been applied to the crystallization system in order to achieve a desired asymptotic CSD using antisolvent flow rate and temperature to reach the target CSD. For the present system, the target CSD could be assumed lognormal(Grosso et al, 2010), and it is characterized by selecting a proper mean and standard deviation, thus the objective of the controller is to reach the selected mean and standard deviations by manipulating the antisolvent flow rate and temperature. Target selections have been conducted exploiting the model of the process presented in Section 2 and its operative map (Figure 1).

The first strategy applied is a conventional feedback, where two loops are considered to control mean and standard deviation of the CSD by respectively manipulating antisolvent flow rate and temperature. As an alternative to the PIs structure, an open loop (feed-forward) control was also implemented. This approach is introduced because eliminating feedback action should avoid the problems related to ill-conditioning of the gain array matrix (Kumar et al., 2005) and time-varying characteristics of the system (Bovin, 1998). The latter aspects imply that using a linear feedback control ignores the fact that controller parameters should be adapted, as process moves along the given path. The input trajectory for the feed-forward action has been obtained minimizing the area between targets values and outputs calculated by the stochastic model (Cogoni et al., 2014). The feed-forward (FF) approach has the potential to provide minimum residual area and minimize the consumption of antisolvent but will not be able to compensate if any disturbance hits the process or in case of model-plant mismatch, since no feedback action is deployed. Consequently, a two-stage controller (FF/FB) has been also implemented, where a FF strategy is combined with a feedback controller (FB). In particular, the FF action is used to bring the system close to the asymptotic condition at around 5% of the desired set-point, and then the PI controller is activated to remove the offset for the crystals' mean size. As it will be observed, by relinquishing strict control on standard deviation it is possible to have a more efficient control on particles' mean size avoiding problems related to ill-conditioning if they should arise.

5. Results and discussion

The performance of the three different control strategies were be analyzed considering two different cases, which differ from the position of the mean and standard deviation set-points in the (q ,T) plane. Case 1 considers the targets far from the catastrophe locus (point 1 in Figure 2), whereas Case 2 set the target values belonging to the catastrophic locus (point 2 in Figure 2). Due to space restrictions only results for FB and FF/FB configurations for Case 2 are presented. This choice aims to assess the control configurations in a more demanding situation with respect to the previous one, because of the singularity of the input-output relationships.

The results obtained when using the PI controllers are shown in Figure 3 where the inputs and outputs behavior are shown along with the distribution at the end of the batch and the salt concentration. In this case the PI controllers are able to track the system to the desired set-points, thanks to the presence of a higher concentration within the first three hours of the run. In order to adjust the mean crystal size, the antisolvent flow rate is increased after 2 hours and a half to its maximum value by the controller, because it is favored the creation of new nuclei lowering the mean of CSD. However, it is interesting to analyze the shape of the final distribution (bottom of Figure 3) as given by the images taken at the end of the batch. As we can see the final distribution is bimodal showing the effects of secondary nucleation (small crystal are created at the end of the run). This can also be observed by analyzing the images at the end of the run, where small particles are observed jointly with the large particles already created. Consequently, even if the PI controller appears to achieve the control targets in terms of mean and standard deviation, it is not able to bring the system to the target CSD (unimodal lognormal distribution with a specified mean and variance). The poor performance of the conventional PI when operating close to the ill-conditioned region confirms what evidenced in the previous studies (Cogoni et al., 2014). The next experiment reported here has been conducted in order to test the system when either disturbances and/or modeling errors are present and a FF action cannot assure offset-free performance. To accomplish this task, an error in the model estimation of antisolvent flow rate was introduced, and it is set equal to 1.8 ml/min instead of 2.1 ml/min. We should notice that this situation may also represent a calibration error in the feed pump. As presented previously the FF control action is coupled with a PI controller (FB) which is switched on towards the end of the batch to perform final adjustments for the mean size (5% of the final mean size). The performance of the two-step controller are rather good and very close to the results obtained with the FF strategy, both in terms of the two moments and considering the shape of the distribution at the end of the batch, as shown in Figure 3. This clearly shows the importance of a FF/FB combination for realistic situations due to presence of unexpected disturbances.

6. Conclusions

In this contribution an online strategy to directly control crystal size distribution in joint cooling antisolvent crystallization processes was proposed. Alternative control strategies were implemented and tested to achieve a desired CSD. They include multi-loop PIs approach, a feedforward strategy (FF) based on off-line calculated profiles and a two stages control strategy using a combination of feedforward and feedback algorithm (FF/FB). Results demonstrate in some cases poor performance of the PIs control strategy, due to ill-conditioning of the process. On the other hand excellent behavior on the CSD control is achieved when the FF controller was applied. The two

stage (FF/FB) strategy exhibits a perfect control over the mean size and it was able to achieve the asymptotic conditions faster as well as eliminating the natural effect of both model and process disturbances.

Abstract

A multivariable fuzzy logic controller with Lyapunov adaptive control scheme has been developed for a pH neutralisation process. In this study, the nominal neutralisation process condition exhibit nonlinear dynamics and multi-delayed-effects input variables. The proposed controller uses a Takagi-Sugeno fuzzy inference system and it has been optimised by genetic algorithm which minimizing the closed loop error in feedback control system. The optimised structure is used to predict three-difference control action simultaneously. The Lyapunov function is integrated in the fuzzy inference calculation at output membership function. The proposed controller has been tested and compared in several cases such as for set-point tracking, model plant mismatch and unknown disturbance. The adaptive fuzzy controller demonstrate better performance over the conventional PID controller in all the tested cases.

Keywords: Non-linear control; Fuzzy Controller; Adaptive control.

1. Introduction

The pH neutralisation is a typical process in chemical wastewater treatment plant. The effluent from the treatment plant must be neutralised before it can be safety discharged to the environment. Problem that occurs in pH neutralisation control are due to the process characteristics involved in such a process as strong nonlinear respond among acid, neutral, and base regions, wide-ranging time delay of the titration, and the complexity of inlet composition. The characteristic might vary from case to case and thus, the conventional controller can only work at a single desired point and could fail to compensate when the controlled region is changed. There are many solutions in the literature that has been reported, but an ideal solution still depend on the cases involve and it has not been totally solved due to vigour and complexity of the control and process. Thus, the need of an advanced control system is necessary for this situation.

The adaptive technique with a fuzzy logic system has been investigated in this case study is controlling the pH neutralisation for set point tracking and load disturbance. Previously, Salehi (2009) had used fuzzy as an estimator to the adaptive model based control framework , Min (2006) work on adaptive algorithm of universal learning network, and Menzl et al. (1996) had developed self-adapting mechanism inside fuzzy logic controller at neutralisation point. All of these work focus on utilising the fuzzy system for neutralisation control at nominal conditions with satisfactory performance. Related literatures are given in Goodwin (1982), Gustafsson (1984), Henson (1994), Narayanan (1997), Sung (1998), and Boling (2007). However, fuzzy controller incorporated with adaptive mechanism is not easy to build and furthermore an effective control performance

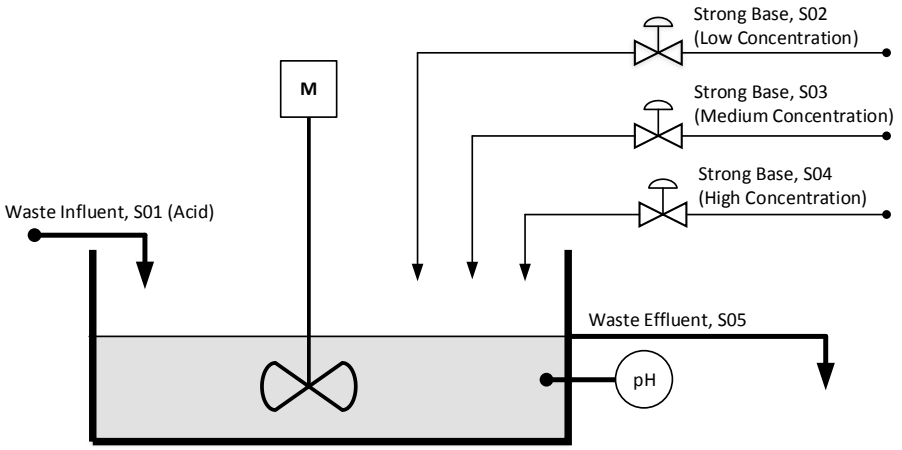

Figure 1: Scheme of pH neutralisation process

for multiple pH regions is very hard to generalize. Therefore, the need of robust controller performance in this field arise significantly.

The objective of this study is to investigate the multivariable controller for the control of nonlinear pH neutralisation process in continuous stirred tank reactor by using the Lyapunov based adaptive Fuzzy Logic approach. The process using the strong acid equivalent model (Zanil et al., 2014). The control system has been set to regulate the pH reactor at neutral point (pH = 7.0) by manipulating several acid flow rates.

2. pH Neutralisation

The potential of hydrogen, pH is mathematically defined the negative logarithm of concentration of ion hydrogen. In pH neutralisation modelling, the nonlinearity characteristic are from the logarithm term in the equation. The model (Eq.1) which follows the law of conservation of mass and chemical equilibrium (Gustafsson et al., 1995). The process is assumed isothermal with constant fluid density and no solid formation occurring during experiment. The schematic diagram (Figure 1) illustrate the multi titration streams with single influent and effluent stream.

The model used in the study is as follows:

$$V\frac{dx}{dt} = F_a C_{a0} - (F_a + \sum_{i=1}^{3} u_{b,i})x - \sum_{i=1}^{3} u_i(t-\theta_i)C_{b0,i} \quad (1)$$

Where x is the remaining acid concentration in the reactor, C_e , C_{p0} and $C_{b0,i}$ is the concentration of the component in the effluent stream, influent stream, and titrating stream, respectively. The input time-delay is used to approximate the dynamics of the pH sensor and non-ideal mixing condition (Sung et al., 1998). In an aqueous solution, the electro neutrality and water-equilibrium theories are used to express the electrolyte disassociations (Eq.2) at an isothermal temperature of 27 ^{o}C, and water equilibrium constant of K_w at 1×10^{-14}.

$$x = [H^+] - \frac{K_w}{[H^+]} \tag{2}$$

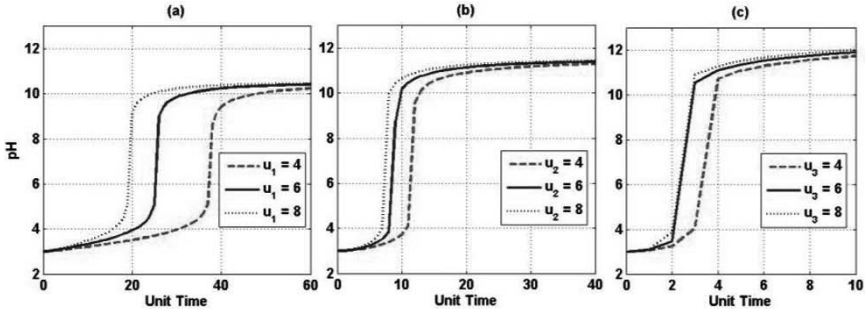

Figure 2: Open loop studies for variation of titration flow rate: (a) Low, (b) Medium, (c) High.

Thus, the hydrogen ion, $[H^+]$ as in Eq.3 can be used to simulate the dynamic profile of hydrogen concentration and pH value of the stirred tank reactor.

$$V\frac{d}{dt}\left([H^+] - \frac{K_w}{[H^+]}\right) = F_a C_{a0} - (F_a + \sum_{i=1}^{3} u_{b,i})\left([H^+] - \frac{K_w}{[H^+]}\right) - \sum_{i=1}^{3} u_i(t-\theta_i)C_{b0,i} \tag{3}$$

The pH value is calculated by taking the logarithm of hydrogen concentration. The simulated result for several titration flow rates has been demonstrate in Figure 2 and it is observed that the variation time response over the titration flow rates has significant effect. The pH value inside the reactor shows several dynamic responses over time. The nominal condition that shows in Table 1 has been used for the simulation study.

3. Control Mechanism

Fuzzy logic consist a set of fuzzy inference that works on approximate reasoning that give a consequence action as the outcome. The structure has been set to receive three inputs and three outputs. The fuzzy logic inference mechanism were computed from the product of input membership function (e, ce and AV) and the fulfilment of fuzzy rules (R_i). i.e.;

$R_i : IF\ e\ is\ A_i\ AND\ ce\ is\ A_i\ AND\ AV\ is\ A_i THEN\ u_1$is $U_{1,i}\ AND\ u_2 is\ U_{2,i}\ AND\ u_3\ is\ U_{3,i}$

Every output membership function can be written as

$$U_{j,i}(k) = A_{1,i}\ e + A_{2,i}\ ce + A_{3,i}\ AV + A_{4,i}\ ; j = 1,2,3\ and\ i = 1,2..N \tag{4}$$

The output parameter, $A_{j,i}$ has been optimised by genetic algorithm depending on the close loop error analysis; Integral Square Error (ISE). The controller output can be formulated as the summation of average weighted inference value for the active rule, R_i.

$$u_i = \frac{\sum_i^n w_i(e,ce,AV)U_{j,i}}{\sum_i^n w_i(e,ce,AV)} \tag{5}$$

$$w_i(e,ce,AV) = min[\mu_i(e), \mu_i(ce), \mu_i(AV)] \tag{6}$$

Table 1: Parameters and value for nominal

Parameter	**Value**	**Unit**
Reactor Volume, V_r	100	Litre
Influent flow rate, F_b	2.5	Litre/Min

Inlet Influent Concentration, C_{b0}	3E-3	Mole/Litre
Inlet Base Concentration (Low) , $C_{a0,1}$	3E-4	Mole/Litre
Inlet Base Concentration (Medium) , $C_{a0,2}$	3E-3	Mole/Litre
Inlet Base Concentration (High) $C_{a0,3}$	3E-2	Mole/Litre

Where w_i is degree of input membership function as Eq. 6 and $\mu_i(e), \mu_i(ce)$, and $\mu_i(AV)$ are the input membership function (triangular types) of error, change of error, and acidic region respectively.

3.1. Adaptive Mechanism

The used of adaptive mechanism is to improve the fuzzy controller performance during the model-mismatch operation in the plant. Let the model identifier approximate the nominal plant response and thus the model error, $\varepsilon = y_m - y$ which detect the existing of model-mismatch condition. So, the adjustable parameter, γ is introduced to minimise Eq. 7 in the negative gradient;

$$\frac{d\theta_i}{dt} = -\gamma_i \left(\frac{1}{2}\varepsilon^2\right) \tag{7}$$

The adaptation law is formulated as in Eq. 8

$$U_i = \frac{d\theta_i}{dt} u_i = -\gamma_i \left(\frac{1}{2}\varepsilon^2\right) u_i \tag{8}$$

3.2. Control System

The study use a conventional closed loop control strategy as in Figure 3 and the neutralisation models as stated in Section 2 has been used for the plant block. Measured disturbance is the signal from influent flow rate (base) and the manipulated variable signal at different concentrations. The fuzzy controller send three-output signals to every individual control valve before the change of titration effect takes place.

In the study, unmeasured disturbance and limited-band white noise has been introduced. A servo and regulator case study has been performed throughout the simulation. Several analysis for servo cases has been carried out; acid/base region at the neutral point and within neutral region. Beside, regulator case analysis has been conducted for ± 5% variation in the measured disturbance flow rate. Plant mismatch of ± 10% from nominal volume reactor has been carried out to test the control performance robustness.

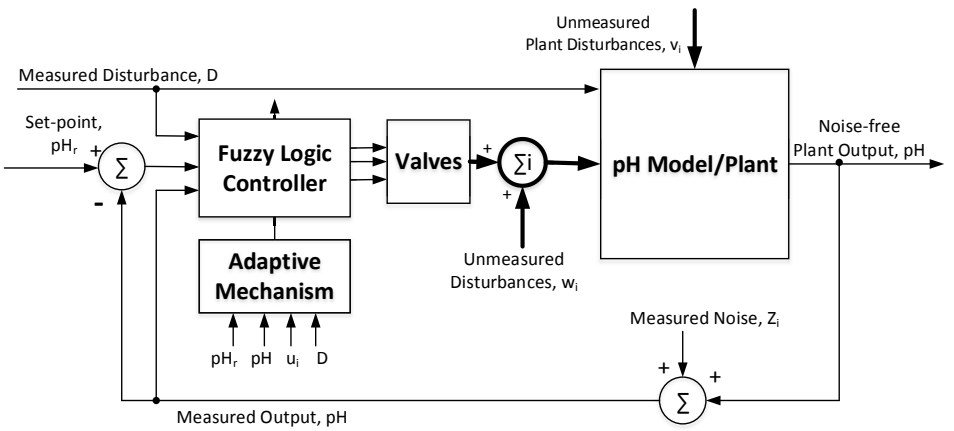

Figure 3: Adaptive Multiple Output Fuzzy Control Scheme for pH Neutralisation

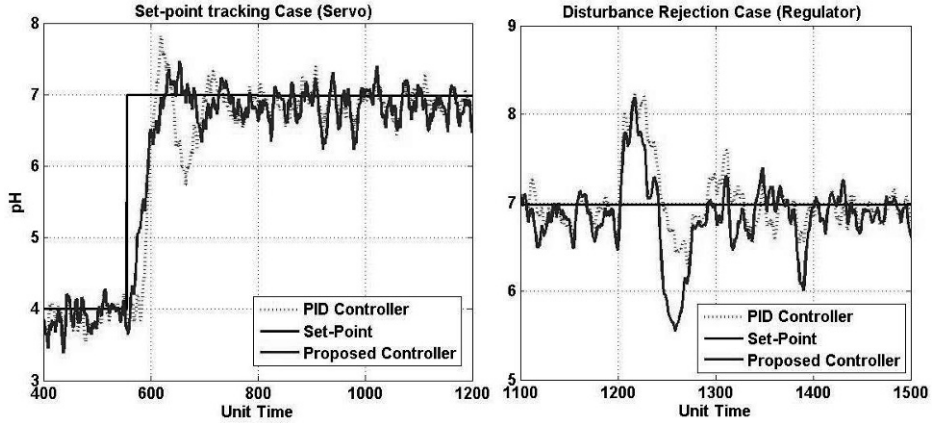

Figure 4: Comparison of control performance for set-point and disturbance rejection cases.

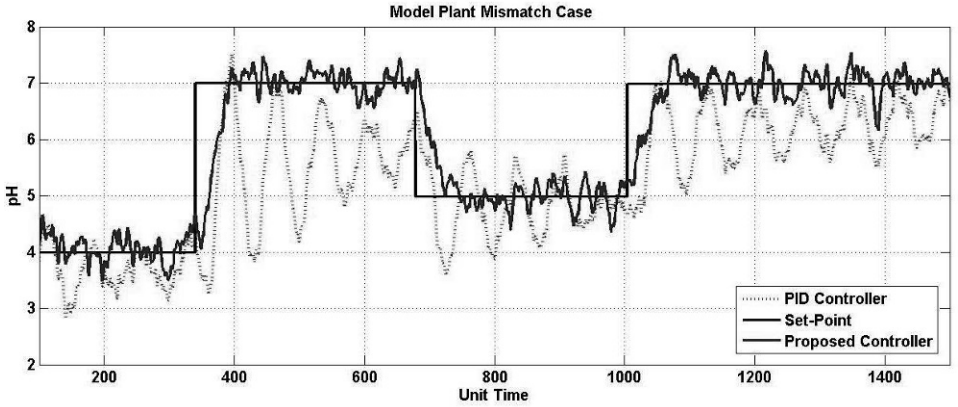

Figure 5: Comparison of control performance for plant mismatch case.

4. Result and Discussion

Simulation result for set point tracking, load rejection of proposed adaptive controller responses are shown in Figures 4 and 5 respectively. Considering the adaptive fuzzy logic controller, its set point and load changes show smoother response over the entire nonlinear region. Furthermore, there is no oscillation or overshoot in proposed control responses. PID controller has showed slightly overshoot and the settling time is more compared to propose controller. This is due to the sluggish control action at the neutralisation region.

The controller performance based on Integral Square Error (ISE), Integral Absolute Error (IAE), and Integral Total Absolute Error (ITAE) as shown in Table 2.

Table 2. Error analysis of control performance according to the case.

Case	Controller Type	ISE	IAE	ITAE
Disturbance Rejection	PID	224,92	367.21	2.57E5
	Proposed Controller	203.95	322.60	2.19E5
Set-point tracking	PID	681.93	582.83	3.64E5
	Proposed Controller	576.07	533.23	3.15E5
Plant mismatch	PID	1.94E3	1.29E3	9.16E5
	Proposed Controller	597.16	624.46	3.90E5

The result shows that the proposed controller gives best performance, which indicate less error analysis compared to conventional controller for all cases. The conventional controller unable to adapt with the plant mismatch case and therefore the error analysis give large value compare to the proposed controller.

5. Conclusions

A multivariable adaptive fuzzy logic controller has been proposed for the nonlinear pH neutralisation control system. It is the integration of empirical optimisation fuzzy logic controller with Lyapunov adaptive law. The results has shown superior performance for the proposed controller compared to conventional controller in all studied cases. The proposed controller has a promising potential for other nonlinear control applications.

Abstract

Monitoring of pre-heat trains in oil refineries is a crucial activity to assess the gradual decay in performance of heat transfer equipment due to fouling. It is also important to assist in operational decisions with respect to fouling mitigation options and cleaning strategies. In this paper, a novel graphical representation of time varying operational data is proposed to monitor crude oil fouling. This dynamic thermo-hydraulic plot, named the TH-λ plot, simultaneously captures both thermal and hydraulic performance and presents it in a way easily interpreted by field engineers. Its features and applications are demonstrated here for typical situations using data generated using an advanced dynamic simulation model for shell-and-tube heat exchanger undergoing fouling. The results show that consideration of thermal and hydraulic effects, together with process dynamics, is essential to adequately monitor performance, detect changes in fouling behaviour and properly interpret available data. They also show this is achievable using only measurements of inlet and outlet streams to heat exchangers.

Keywords: crude oil, fouling, monitoring, energy efficiency, operational performance.

1. Introduction

The performance of pre-heat trains, extensive energy recovery networks at the front end of oil refineries, is gradually degraded by fouling of heat exchangers, leading to severe energy losses, increased costs and operational problems. Typical refinery monitoring techniques assess the thermal performance of heat exchangers by calculating and following over time fouling resistances or heat duties using temperature and flow measurements. However, the thermal performance only tells part of the story and hydraulic performance (i.e. pressure drop increase due to gradual build-up of fouling inside the tubes) is also important and sometimes dominating over the thermal one.

Few publications in the literature address the interaction between hydraulic and thermal effects of fouling. Yeap *et al.* (2004) presented the performance of individual heat exchangers by plotting the thermal effects of fouling, represented by either the fouling Biot Number or the exchanger effectiveness, against the ratio between fouled and clean pressure drop. Lumped models involving simplifying assumptions were used to simulate the effects of fouling for a number of heat exchangers under ideal conditions. This representation was used by Ishiyama *et al.* (2008) to infer the impact of the thermal-conductivity of the deposit, which ultimately determines which effect, hydraulic or thermal, is dominant. Yeap *et al.* (2004) also proposed a "Modified

Temperature Field Plot" to include thermal and hydraulic effects into network analysis by plotting inlet and outlet temperatures and pressure drops at the beginning and end of an operation period. These methods provide some insights, however present several practical disadvantages: the use of thermal performance indicators which are rather difficult to interpret, limited capabilities to include process dynamics, and unclear application with actual plant data.

To overcome the disadvantages listed above and to broaden the scope of application, a new graphical representation for monitoring the performance of a single exchanger is presented in this paper. Here, the approach is illustrated and its results are compared with those obtained from traditional monitoring methodologies (based on fouling resistance calculations, e.g. R_f-based method). For simplicity the time-varying performance is simulated using a state-of-the-art thermo-hydraulic model, the shell-and-tube exchanger model in the Hexxcell Studio^{TM} software from Hexxcell Ltd., based on the work by Coletti and Macchietto (2011). The model is dynamic, distributed, and evaluates fluids and deposit physical properties, fouling rates and deposit growth as a function of local conditions, as well as fluid velocities and pressure drops. The resulting model can capture the combined thermal-hydraulic behaviour experienced in industrial systems undergoing distinct types and rates of fouling, as shown in the reference paper.

A recent modification (Diaz-Bejarano *et al.*, 2014a) implemented in Hexxcell Studio^{TM} allows simulating multi-component deposits, partial and total cleaning actions, and the effect of composition in fouling behaviour. In the general formulation, the rate of change in deposit thickness ($\dot{\delta}_n$) is given by the sum of net deposition rates (during operation) or by the cleaning rate (during cleaning). In refinery preheat trains, organic matter deposition is the main fouling mechanism. In that case, during operation, the local (time and axially varying) $\dot{\delta}_n$ for each pass is assumed to follow a modified version of the threshold model by Panchal *et al.* (1997):

$$\dot{\delta}_n = \frac{d\delta_n}{dt} = \lambda_0 \alpha Re_n^{-0.66} Pr_n^{-0.33} \exp\left(\frac{-E_f}{R_g T_{f,n}}\right) - \lambda_0 \gamma \tau_n \quad (1)$$

where δ_n is the deposit thickness, n is the pass number, τ_n is the shear stress at the layer surface, $T_{f,n}$ is the film temperature, R_g is the ideal gas constant, λ_0 is the conductivity of the fresh deposit or gel, and α, γ, and E_f are fouling parameters. Following previous works, the fresh foulant is assumed to be formed by organic gel, with a thermal-conductivity of 0.2 W/m K. The organic deposit gradually undergoes ageing at high temperatures (depending on temperature history), eventually transforming it into coke, with a conductivity of 1 W/m K. All examples in this paper are for a single shell exchanger with the geometry (number of tubes (N_t), tube outer diameter (d_o), number of passes (N_p), tube length (L_t), shell diameter (D_s)), fluid properties (*API,* Mean average boiling point (*MeABP*) and viscosity at 38°C ($v_{38°C}$)) reported in (Coletti and Macchietto, 2011) (Table 1). Crude oil is in the tube-side. In this paper, constant inlet conditions are used to illustrate the novel graphical representation.

Table 1. Exchanger geometry, fluids properties, inlet conditions and fouling/ageing parameters

Geometry		*Inlet conditions*			*Fouling/ageing*		
Parameter	Value	Parameter	Shell	Tube	Parameter	Set A	Set B
N_t	900	T_{in}[°C]	330	204	α [m^2 K/J]	0.00165	0.00114

2. TH-λ: A Dynamic Thermo-Hydraulic Monitoring Plot

To monitor effectively a refinery heat exchanger, it is desirable to have as much information as possible on a simple plot: its thermal and hydraulic performance, time evolution of performance to easily visualize its trends, approach to operating limits, and ideally some indication of the underlying causes of fouling. This plot should help refinery operators to assess at a glance the performance of units, identify critical ones and take remedial actions if necessary. Here we propose a novel graphical representation, the dynamic thermo-hydraulic TH-λ plot, meeting these requirements. The performance of a heat exchanger is represented using the following indicators:

1) Thermal: Ratio of fouled to clean heat duty ($Q(t)/Q_c$).
2) Hydraulic: Ratio of fouled to clean tube-side pressure drop ($\Delta P(t)/\Delta P_c$).
3) Temporal: Daily data (monthly points emphasized and labelled with month number). More frequent data, actual dates as label, etc. could be used.

An example of this plot is shown in Figure 1(a), where a performance line, named "TH Line" (continuous line) is shown for 12 months of operation, starting from a clean state. Here, the variation in performance of the unit as a result of fouling (Case A) is simulated using the fouling (α, γ, and E_f) and ageing parameters (A_a and E_a) corresponding to Set A in Table 1 (Coletti and Macchietto, 2011). In practice, the TH Line would be based on plant measurements of inlet and outlet temperatures, flow rates, and tube-side pressure drop. Each point along the line simultaneously reflects the thermal and hydraulic performance w.r.t clean conditions. The time trend reflects how fast the relative change is happening. A displacement in the X axis (hydraulic) implies addition or removal of fouling material (increase or decrease in deposit thickness). A displacement in the Y axis (thermal) indicates a change in the heat exchanged, which may be due to: i) addition or removal of deposit; ii) change in the conductivity of the foulant (e.g. due to ageing); iii) change in the type of foulant, also with consequent change in conductivity (hence the λ in the TH-λ name).

The TH-λ plot becomes even more useful when monitored data and trends are complemented with additional reference lines of practical interest:

a) Thermal and hydraulic limit lines, TH and TL (dashed lines in Figure 1(a)).

Useful limits refer to minimum performance and may be operational constraints (e.g. maximum allowable pressure drop) or design targets (e.g. minimum heat duty). In Figure 1(a), the hydraulic limit (HL), indicated by the vertical line, was set at 4 times the value of the clean pressure drops whilst the thermal limit (TL), indicated by the horizontal line, was set so that the minimum heat duty is 30% of the clean one.

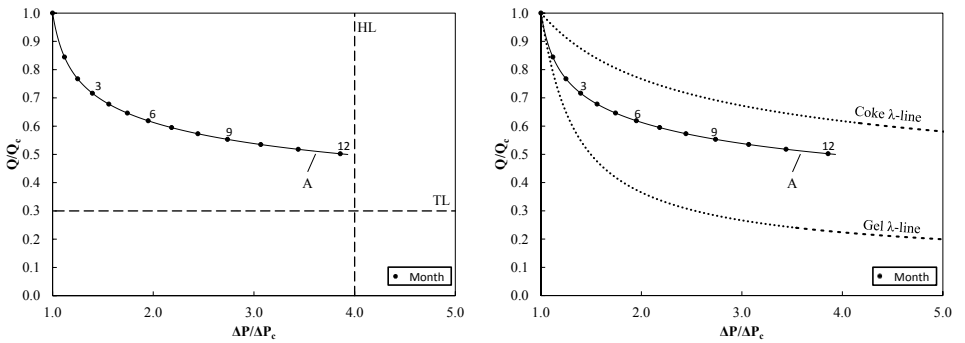

Figure 1. TH-λ Plot (Case A) with added operating limit lines (a) and organic limit λ-Lines (b).

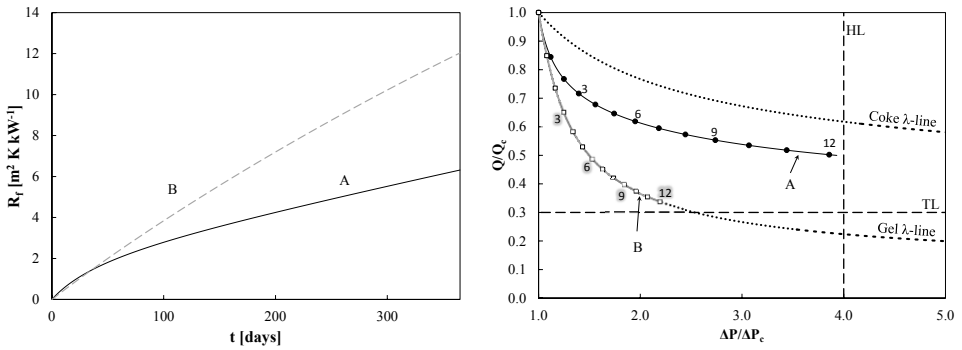
a) Reference conductivity lines, named "λ-Lines" (dotted lines in Figure 1(b)).
Hydraulic and thermal performances are not independent but linked by the thickness and thermal-conductivity of the deposit as it grows (or is removed). As a result, if a suitable thermo-hydraulic model of the exchanger is available, it may be possible to calculate and plot its limiting behaviour. For example, assuming constant inlet conditions, it is possible to calculate two reference lines for fixed deposit conductivities. For organic fouling, for instance, the lines for gel (fresh deposit) and completely coked deposits can be calculated and represented as shown in Figure 1(b). These lines delimit the area of expected performance of the exchanger with organic crude oil fouling. Useful insights on the evolution of the deposit due to ageing can be gained by comparing the TH Line with the reference λ-Lines. For instance, in Figure 1(b), the TH Line gradually moves away from the gel reference line to approach the coke line, indicating significant deposit ageing at month 12. It should be noted that the use of λ-lines as here described is limited to cases where the contribution of shell-side fouling to the overall thermal performance is negligible. This is the most common case in refinery heat exchangers (Coletti and Macchietto, 2011).

3. Applications of the TH-λ Plot – Case studies

3.1. Organic fouling: identification of underlying phenomena

The behaviour of a heat exchanger undergoing fouling depends on the relative values of deposition and ageing rates. Traditional monitoring techniques (e.g. R_f-based method) are inherently unable to discriminate between these phenomena. For instance, consider the two curves A and B in Figure 2(a) (simulated using fouling/ageing parameters Set A - Coletti and Macchietto (2011) and Set B - Yeap *et al.* (2004) in Table 1). Case B seems to clearly indicate substantially greater fouling rate and deposition. On the other hand, using the TH-λ plot for the same 12 months data (Figure 2(b)) some different and more informative conclusions can be extracted straight away: i) the net deposition rate is actually greater in Case A than Case B, as evidenced by a faster increase in ΔP; ii) In Case B, the TH Line follows the lower limit for organic fouling, and therefore the deposit does not age; iii) In Case A, a strong deposit ageing effect is evidenced, which significantly attenuates the thermal losses of fouling; iv) In Case A the hydraulic limit HL will be reached before TL, while the opposite is true in Case B.
The R_f-based monitoring in this case is misleading as it does not evidence ageing effects, whilst the proposed TH-λ representation helps to correctly identify the underlying phenomena and the selection of appropriate operational decisions.



(a) (b)

Figure 2. (a) Fouling resistances over time for Cases A and B; (b) TH-λ Plot for Cases A and B.

3.2. Detection of deviations in fouling behaviour

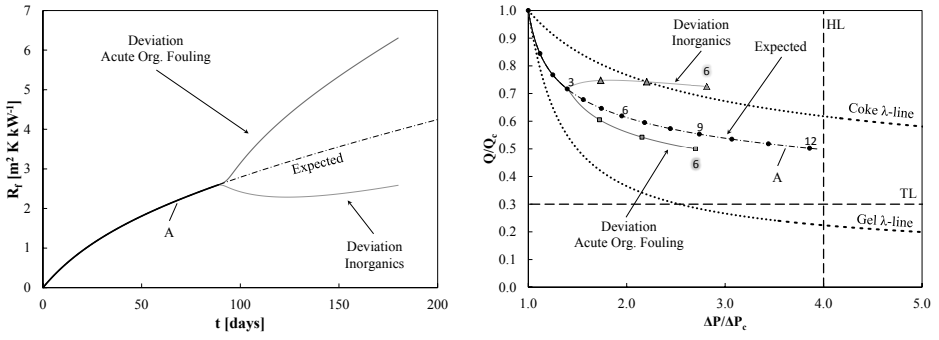
Most current practices not only ignore the hydraulic performance, but also have limited ability to detect changes in fouling behaviour. Here, the heat exchanger is initially assumed to foul as in Case A in the previous examples. After three months of operation an event leading to a change in fouling behaviour is assumed to occur. Two cases are considered:

a) Deviation due to acute organic fouling

The first case is a change in oil blend or type of oil being processed (e.g. to high fouling propensity oils such as slag or heavy oil) leading to acute organic fouling. The composition of the fresh deposit remains unchanged (only gel), but the fouling rate becomes twice as fast. The R_f-based method (Figure 3(a)) shows a sudden increase in the fouling resistance after the event. A change in behaviour is detected, but no information is provided about the hydraulic impact, which may be relevant due to the fast build-up of material. The TH-λ plot (Figure 3(b)) evidences the change as a large increase in pressure drop. This, together with a deviation towards lower values of thermal efficiency, indicates that the additional foulant has low conductivity and is most likely organic in nature. The increase in the relative contribution of fouling rate with respect to ageing explains the offset in thermal efficiency compared to the expected trend. Therefore, although the R_f-based method shows a deviation, the TH-λ plot provides much more complete and useful information as to its causes and effects.

b) Deviation due to inorganic fouling

In this second case, an inorganic material is assumed to start depositing after 3 months in addition to the usual organic fouling. This might be due to failure of upstream equipment (e.g. desalter), upstream corrosion, or change in the composition of the oil to sour or high metal content oils. Inorganic salts generally have greater conductivity than organic deposits, leading to enhanced thermal properties of the fouling deposit. This effect has been recently shown in a case study based on refinery data for a unit undergoing inorganic and organic fouling due to desalter malfunctioning (Diaz-Bejarano et al. (2014b). Here, iron oxide (Fe_2O_3), which has 3 times the conductivity of coke, is considered to deposit. The deposition rate of Fe_2O_3 is assumed to follow the same fouling law as organic fouling (Eq. (1)), leading after the onset of this event to a doubling of total deposition rate and a fresh deposit containing 50% of organic gel and 50% of Fe_2O_3. In this case, the R_f-based method completely fails to show the change in underlying behaviour (Figure 3(a)). In fact, it indicates that fouling becomes less severe than expected, which is incorrect and could potentially lead to erroneous interpretation and mitigation or cleaning decisions.



(a) (b)

Figure 3. Performance of the exchanger undergoing fouling (Case A) for a change in behavior after 3 months: (a) Fouling resistances over time; (b) TH-λ Plot.

In the TH-λ plot (Figure 3(b)), a change in behaviour is evidenced, as in case a), by a higher and much faster increase in pressure drop compared to the expected trend. In this case b), however, a deviation of the TH Line towards greater thermal efficiency also indicates that the new foulant is highly conductive and, probably, of inorganic nature. The fact that the TH Line crosses the reference coke λ-line confirms the latter inference.

4. Conclusions

A new dynamic thermo-hydraulic plot (TH-λ) for monitoring of heat exchangers has been presented. Its features and practical uses have been demonstrated using data produced by a sophisticated novel thermo-hydraulic simulation of shell-and-tube heat exchangers undergoing fouling and cleaning, considering constant inlet conditions of temperature and mass flow rates. It has been shown that this monitoring approach is useful to: a) simultaneously evaluate and trend the interacting thermal and hydraulic performance over time; b) highlight underlying mechanism contributing to overall performance, such as fouling rate and ageing; c) detect deviations from expected performance due to change in fouling behaviour; d) help in the identification of potential fouling causes. The results show that simultaneous consideration of thermal and hydraulic effects, together with process dynamics, is essential to adequately detect changes in fouling behaviour. They also show that this can be achieved merely using measurements of inlet and outlet streams to heat exchangers. The use of the monitoring approach described with actual (time-varying) plant data and its application to heat exchanger networks will be reported in future works.

Acknowledgments

This research was partially performed under the UNIHEAT project for which EDB and SM wish to acknowledge the Skolkovo Foundation and BP for financial support. The support of Hexxcell Ltd, through provision of the Hexxcell Studio™ software and modelling framework, is also acknowledged.

Dosage of Filter Aids in the Case of Pure Surface Filtration – An Optimal Control Approach

Michael Kuhn and Heiko Briesen

Chair for Process Systems Engineering, TU München, Freising, Germany
briesen@wzw.tum.de

Abstract

Filter-aid filtration is widely used to remove impurities which tend to clog the filter medium. In many processes, filter aid is continuously dosed to the suspension to be purified. In these cases, a suitable filter-aid concentration is important to assure good separation with a minimal energy consumption. We here present the first optimal control approach to filter-aid filtration. The optimal dosage trajectories in case of constant and variable impurity concentrations in the suspension are derived for the case of pure surface filtration. These findings are compared to other dosage strategies and the benefits are shown. Consequences of the presented results for process control and further modeling and optimization approaches are highlighted.

Keywords: filtration, filter aid, optimal control, surface filtration

1. Introduction

Filter-aid filtration is widely used to remove impurities which tend to clog the filter medium, e.g. gelatinous particles. Hereby, the septum is covered with a small layer of filter aid, known as the precoat, before the separation takes place. Subsequently, filter aid, known as the body feed, is constantly added to the suspension during the actual separation (Sutherland and Hidi, 1966). This strategy assures increased filtration times and low energy expenditure due to high filter-cake permeabilities. Because of its flexibility concerning the separation task, filter-aid filtration is applied in a whole range of fields, such as in biotechnology and the chemical industry, in water treatment and the production of foodstuff and beverages.

Various researchers emphasized the role of the right amount of body feed for successful filtration (Carman, 1938, 1939; Sutherland and Hidi, 1966; Babbitt and Baumann, 1954; Haba and Koch, 1978; Heertjes and Zuideveld, 1978). Some of these works also present a model that relates cake resistance to the ratio of impurity and filter-aid concentration. They assume that separation only takes place by pure cake filtration, i.e. directly at the surface of the cake (Sutherland and Hidi, 1966; Haba and Koch, 1978; Heertjes and Zuideveld, 1978). Other results also showed that in some cases deep-bed filtration contributes to the overall separation (Heertjes and Zuideveld, 1978; Husemann et al., 2003).

Despite the available research and despite the fact that in various applications the amount of impurities to be separated varies over the course of one process cycle, a constant body-feed concentration is common industrial practice. It is suggested here, that this strategy can be improved by a rigorous application of optimal control theory. Dynamic optimization has scarcely been used in the field of filtration. Some works showed its potential to optimize the operation and cleaning strategies in membrane filtration (Blankert et al., 2006, 2007; Zondervan and Roffel, 2008). However, to the best of our knowledge, optimal control theory has never been applied to filter-aid

filtration. We here show its use to derive the dynamically optimal body-feed concentrations for different process scenarios under the assumption of pure surface filtration employing and modifying classical models from the filtration literature.

2. Derivation

2.1. Mathematical Problem Formulation

If the filter-aid concentration in the suspension c is much smaller than its concentration in the filter cake $\rho_{fa,c}$, the velocity of cake growth can be written as

$$u_s = \frac{c}{\rho_{fa,c}} \cdot q\,, \tag{1}$$

compare e.g. Hackl et al. (1993, p. 11). q is the suspension's superficial velocity which is assumed to be constant in the following, i.e. we here consider filtration at a constant flow rate. It is commonly assumed that the impurities captured at the surface do not contribute significantly to cake growth or, if they do, this usually means that too little filter aid is added to the suspension (Sutherland and Hidi, 1966; Hebmüller, 2003). Therefore, the velocity of cake growth u_s is modeled as only being depended on filter-aid concentration c. Cake resistance is given as

$$R = \int_0^{t_e} (u_s(t) \cdot \rho_{fa,c} \cdot r(t))\,dt = \int_0^{t_e} (c \cdot q \cdot r(t))\,dt\,, \tag{2}$$

where t_e is the total time of filtration which is determined by the volume per area to be filtered and the suspension's superficial velocity. r is the specific cake resistance and can be modeled as

$$r = r_0 \cdot e^{k \cdot \frac{w}{c}}\,, \tag{3}$$

with w being the impurity concentration in the suspension, r_0 the specific resistance of the pure filter-aid cake, and k a model constant characterizing the specific combination of filter aid and impurities at hand. This relation was first found by Sutherland and Hidi (1966) and validated by Haba and Koch (1978); it was later on derived again by Heertjes and Zuideveld (1978) and further used e.g. in Hackl et al. (1993). It should be mentioned that r is formulated here as a purely local property of the filter cake. Therefore, R is its integral value over time because r is explicitly allowed to change over the cake height and therefore over time as well. This is a generalization compared to the studies mentioned above which can be reduced to those solutions for the particular case of a constant w and c. In this study, the resistances of the filter medium and the precoat layer are not taken into account because their effect on the overall resistance is relatively small and they contribute nothing to the optimal control problem that is addressed here. The filter cake height is computed in the following way:

$$h(t) = \int_0^{t_e} u_s\,dt = \int_0^{t_e} \frac{c}{\rho_{fa,c}} \cdot q\,dt\,. \tag{4}$$

2.2. Dynamic Optimization

The following question is addressed in this paper: What is the optimal filter-aid dosage trajectory in the case of pure surface filtration in order to minimize cake resistance, i.e. energy expenditure? This optimal control problem is framed in the following way: The filter-aid concentration c is the control variable, the system state is represented by the filter cake height $h(t)$, and the total filter-cake resistance R is used as the performance index. Due to the form of R, this problem can be classified as being of the Lagrangian type with a fixed final time t_e and a free final state $h(t_e)$. The corresponding Hamiltonian reads as follows:

$$H = c \cdot q \cdot r_0 \cdot e^{k \cdot \frac{w}{c}} + \lambda \cdot \frac{c}{\rho_{fa,c}} \cdot q\,. \tag{5}$$

λ is the costate vector which – in this case – contains only one element. The three necessary condition for an extremal solution are the state equation

$$\frac{dh}{dt} = \frac{\partial H}{\partial \lambda}, \tag{6}$$

the control condition

$$\frac{\partial H}{\partial c} = 0, \tag{7}$$

and the adjungate ordinary differential equation

$$\frac{d\lambda}{dt} = -\frac{\partial H}{\partial h}. \tag{8}$$

The optimal control theory used so far can be found e.g. in Bryson Jr. and Ho (1975) and Lewis et al. (2012). It can be easily checked that the first of the conditions above is naturally fulfilled here. The second condition leads to the costate

$$\lambda = \left[\frac{k \cdot w}{c} - 1\right] \cdot \rho_{fa,c} \cdot r_0 \cdot e^{k \cdot \frac{w}{c}}. \tag{9}$$

An evaluation of the third condition shows that

$$\frac{\partial H}{\partial h} = 0 \tag{10}$$

because H does not explicitly depend on h. Combining the equations above gives

$$\frac{d\lambda}{dt} = \frac{\dot{w} \cdot c - w \cdot \dot{c}}{c^2} \cdot \frac{k \cdot w}{c} \cdot \rho_{fa,c} \cdot r_0 \cdot e^{k \cdot \frac{w}{c}} = 0. \tag{11}$$

That the extrema found by these conditions are indeed the best and not the worst scenarios is shown below by a comparison to other constructed trajectories. In the meantime, the found solutions are already referred to as optima.

3. Results

3.1. Constant Impurity Concentration

In case of a constant impurity concentration w, i.e. $\dot{w} = 0$, Equation (11) only holds if $\dot{c} = 0$, i.e. if the body-feed concentration is kept constant, excluding the irrelevant case of a completely clean suspension ($w = 0$). The question remains which filter-aid concentration to choose. Therefore, a thin filter cake slice grown within the time increment Δt at the beginning of filtration is considered. Its total resistance is

$$R = c \cdot q \cdot r_0 \cdot e^{k \cdot \frac{w}{c}} \cdot \Delta t. \tag{12}$$

The optimal filter-aid concentration c is found by

$$\frac{\partial R}{\partial c} \stackrel{!}{=} 0 \tag{13}$$

which gives

$$c = k \cdot w. \tag{14}$$

At first glance, it may be surprising that there is an optimal body-feed concentration at all because Equation (3) appears to suggest that with respect to cake resistance it is desirable to add as much filter aid as possible. But there are two mechanisms at work at the same time: On the one hand, a higher body-feed concentration leads to a lower cake resistance (Equation 3), on the other hand, an increased body-feed concentration leads to a more pronounced cake growth (Equation 4). The found optimum is the trade-off between these two effects.

3.2. Variable Impurity Concentration

In case of a time-variable impurity concentration w, it must hold that

$$\frac{\dot{c}}{c} = \frac{\dot{w}}{w}, \tag{15}$$

as can be seen from Equation (11). Integration leads to

$$c = e^{ln(w)+a} = a^* \cdot w, \tag{16}$$

where a and a^* are constants resulting from integration and rearrangement, respectively. The optimal start concentration can be determined by the same consideration as presented in Equations (12) to (14) because during the time increment Δt w and c can considered to be constant even in the case of variable concentrations. It follows by comparison of coefficients that a^* must be equal to k in the optimal case. This proves that the global optimum derived by Heertjes and Zuideveld (1978) also leads to the optimal trajectory in case of a variable impurity concentration if their condition is fulfilled at each point in time.

Two examples shall illustrate the benefits of a time-variable dosage of filter aid compared to a constant one. In the first case the impurity concentration varies linearly between $w = 0.025$ kg/m^3 and $w = 0.075$ kg/m^3 within the filtration time of 8 h; in the second case it covers the same range quadratically with time. The resulting impurity and optimal filter-aid concentrations are shown in Figure 1.

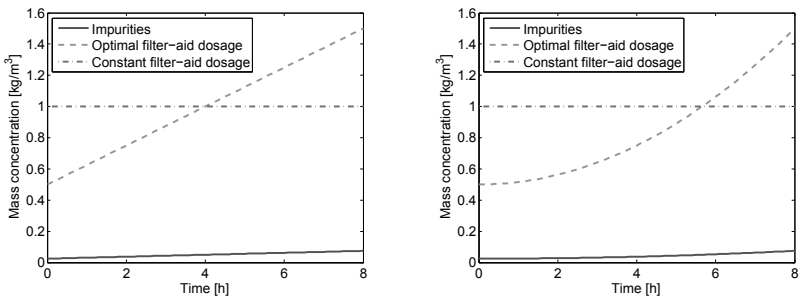

Figure 1: Profile of linearly (left) and quadratically (right) increasing impurity concentration and corresponding optimal filter-aid concentrations.

The required energy per filter area e follows from

$$e = \int_0^{t_e} q \cdot \Delta p \, dt. \tag{17}$$

If Δp is substituted by Darcy's law, one gets

$$e = q^2 \cdot \eta \cdot \int_0^{t_e} R \, dt, \tag{18}$$

with η being the fluid's viscosity. The energy expenditure is computed for both scenarios over the same process time of 8 h with a fluid viscosity $\eta = 1.5$ mPas and a superficial velocity q of $1.4 \cdot 10^{-4}$ m/s. r_0 was set to $2 \cdot 10^{10}$ m/kg and K to 20. These values were taken from Heertjes and Zuideveld (1978). If those results are compared to a constant filter-aid dosage with c at the

arithmetical mean value between its optimal values at $t = 0$ and $t = t_e$ (marked in Figure 1 with the orange dash-dotted line), 4.4 % less energy is consumed in case of the linear impurity profile and 8.9 % in case of the quadratic one. The corresponding energy profiles are shown in Figure 2. However, it is unlikely that the dosage is indeed conducted with the mean value between start and end, because w is only known in the beginning and therefore the dosage is adjusted to fit that value and kept constant there. Therefore, even higher energy savings seem possible in industrial practice.

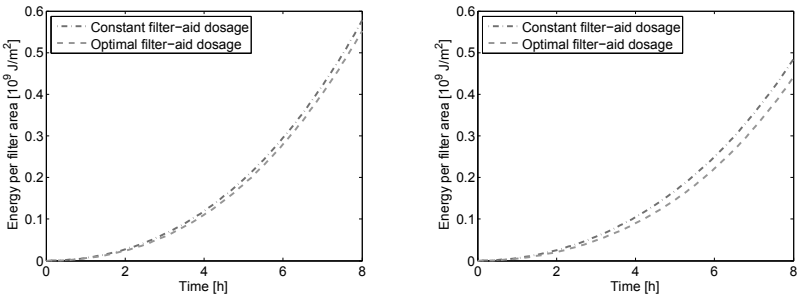

Figure 2: Development of energy expenditure over time in case of linearly (left) and quadratically (right) increasing impurity concentration.

From the presented results also follows that the conditions for extremality evaluated above yield indeed an optimal behavior here because the constant dosage scenarios lead to worse results than the variable ones. Had we incidentally found the worst case, all other scenarios would naturally perform better.

It should be also mentioned that the identified condition only guarantees optimality with respect to filter cake resistance which is not necessarily the economic optimum in every case. To take e.g. the used amount of filter aid into account, an overall cost model would be needed, which is not the aim of this paper. However, it does follow that the concentration of filter aid at each time should not exceed the here determined optimal value because then both filter-aid consumption and pressure drop would be unnecessarily large (compare Section 3.1). Further, the optimality condition also allows to react to discontinuous changes in impurity concentration, as long as they can be detected sufficiently early. A hint on how to implement this practically will be given in the following conclusion.

4. Conclusion

Using dynamic optimization, it was shown that under the assumption of pure surface filtration a constant dosage of filter aid is optimal as long as the impurity concentration is constant. So far this confirms established industrial practice. However, in many processes the impurity concentration varies with time. Therefore, in a second step the corresponding optimal control problem was solved. It was derived that an overall condition from the literature for optimal body-feed concentration in case of constant impurity and filter-aid concentrations also leads to the optimal dosage trajectory if fulfilled at each point in time. This is a far-reaching generalization with benefits e.g. for process control. On-line measurements of impurity mass concentration in the suspension, e.g. by a calibrated turbidity sensor, can be used to determine the optimal body-feed concentration at each time. The insights gained in this study suggest that an optimal control approach may be also beneficial in applications of filter-aid filtration where deep-bed filtration contributes significantly

to the overall separation. The very effect of deep-bed filtration is that earlier filter-cake layers are exposed to ever more impurities over the course of the process. This leads to the hypothesis that in this case, even if the impurity concentration stays constant, more filter-aid should be dosed in the beginning and this dosage should be constantly decreased over time in order to assure a higher capacity for impurities in the earlier filer-aid layers. This more challenging optimal control problem cannot be solved analytically, as done in this paper, but will require sophisticated numerical techniques; it will be addressed in future work.

Abstract

An existing batch precipitation reactor in the mining industry was modelled from first principles using MATLAB S-function language and wrapped into Simulink custom blocks. The model was validated with open loop simulations to evaluate the response to step changes in the model inputs. Two PID controllers with different parameters were implemented on the model at different operating points and their temperature control performance was evaluated based on their ability track a temperature of the industrial reactor as a set-point. The performance of the controllers was measured and compared using an integral time-domain performance measure. A commercial advanced process controller (APC) was implemented on the model, a communication interface between the model in Simulink and the commercial controller was developed with Industrial Data Xchange (IDX); an OPC client and server.

Keywords: Batch Reactors, PID, APC, Aspen DMC plus, OPC

1. Introduction

Batch reactors are integral to the refining process of platinum group metals and their effective control is essential to ensure safe and efficient process in minerals industry (Singh et al. 2010). In these reactors various process phases are encountered in a single process batch; they are heating, cooling and reaction phase. These reactions occur as either an exothermic or endothermic reaction and the control of the batch reactors is essentially treated as a temperature control problem (Friedrich and Perne, 1996). A change from one batch to another batch could necessitate a change in control actions and this makes the control more difficult as different models are applicable for different batch process recipes operating at different operating conditions (Singh et al. 2010).

In many industrial applications, the temperature control of the reactor is carried out with PID controllers in a cascade structure, however rapid and precise temperature control is hard to achieve with these controllers (Stampar et al. 2013).

In terms of a PID controller, the two actuators on the steam and cooling inlet valve to the jacket can be considered as one manipulated variable and a split-range algorithm can be implemented as part of the controlled system (Balaton et al. 2012). Using one controller as long as the system state is close to the corresponding operating point and switching to another when the operating point is sufficiently close to the next operating point gives a better controller performance (Rugh and Shamma, 2000). The use of advanced process control (APC) systems has the potential to improve the control of batch reactors employed in the refining of PGMs (platinum group metals) (Singh et al. 2010). Most of the literature covers process control of continuous reactors in petrochemical industries, reactors with individual heating and cooling jackets. A few literatures cover the application of advanced process control on batch reactors in the minerals industry (Singh et al. 2010). Our aim is to build a platform on which the

performance of the various controllers can be compared and an algorithm to switch between the various controllers for particular process conditions.

2. Process Model Description

The first phase in the reactor involves heating, inflow of steam to achieve a desired temperature set-point. The reaction phase starts at the desired temperature where reagents are added, this result to an exothermic reaction which requires cooling, and then the cooling phase starts with inflow of cooling water (Singh et al. 2010). The temperature control performance mainly depends on the heating-cooling system associated with the reactor. The different configurations of heating-cooling systems cited in literature can be classified into two types: multifluid and monofluid systems (Louleh et al.1999). The commercial reactor modeled in this study has a multifluid system where steam is used as heating medium and water used as a cooling medium as shown in the figure 1 below. The transfer of heat energy to and from the jacket and the reactor is achieved with the transfer fluid through the wall of the reactor. Two exothermic chemical reactions were modelled in the reactor;
Dissolution of Ruthenium

$$Ru_s + 3Cl_{2(g)} \rightarrow RuCl_{3(l)} \quad (1)$$

Evaporation of Ruthenium Chloride

$$2H_2O_{(l)} + 2RuCl_{3(l)} + 2NaClO_{3(l)} \rightarrow 4HCl_{(l)} + 2RuO_{4(g)} + Cl_{2(g)} + 2NaCl_{(l)} \quad (2)$$

The model was developed in an explicit formulation using MATLAB s-function which could be used directly in custom blocks in SIMULINK in pursuit of getting the reactor model to interact effectively with external platform i.e. commercial controllers

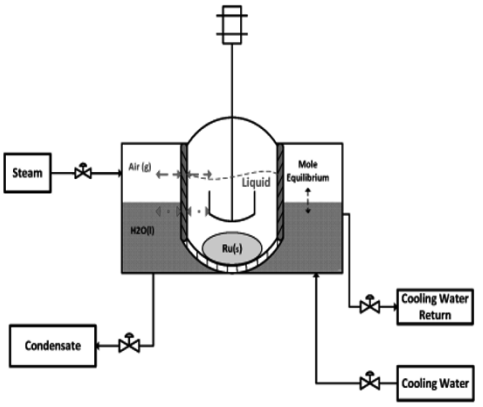

Figure 1: Reactor Model Description

3. PID Control

The process operating conditions are different from phase to phase and also from batch to batch. As such, a requirement on the controller is that it regulates the plant at each operating point or regime. The reactor temperature control is dependent on the control of the steam valve and the cooling water valve of a reactor with a single jacket.
For this design requirement to be correctly modeled using a PID Controller, a split-range algorithm was implemented. The split-range algorithm is preferred in the control of cascaded reactor, to operate two actuators which control the inflow of utilities at the different times during the different phases of a single batch (Balaton et al. 2012).
The two actuators on the steam and cooling water inflow valve to the jacket were considered as one manipulated variable (MV) and the temperature of the reactor as the controlled variable (CV). The PID controllers perform better on operating points they were tuned on. The performance of PIDs degrades with change in process regimes and operating points (Singh et al. 2010). Two PID controllers with different controller

parameters and set points were implemented on the SIMULINK model at different model operating points.

4. Control Objective and Performance Measure

The controller design objective was its set-point tracking ability; its performance can be measured with several integral time-domain performance measures. They are Integral of the Square of the Error (ISE), the Integral of the Absolute value of the Error (IAE), and the Integral of the time-weighted Absolute Error (ITAE).

$$E = \int_0^\infty f(t)\delta t \tag{3}$$

Where f (t) is a function of $\epsilon(t) = y_{sp}(t) - y(t)$

These were all implemented in the performance block of the Simulink model; however the Integral of the Square of the Error (ISE) was used to evaluate the performance of the controllers.

5. Advanced Process Control.

A commercial MPC controller called DMCplus; which is a multivariable controller from AspenTech was developed to control the temperature of the reactor model in Simulink. The DMCplus controller implemented in this work has two manipulated variables (steam and cooling water valves to the same reactor jacket), no feed forward variables and one controlled variable (reactor temperature). As both manipulated variables use the same jacket, they cannot be used at the same time. The controller executes periodically in cycles, the following steps were followed in developing the controller;

- Configuration of MVs and CV tags using Aspen DMC plus Build
- Calculate the open loop prediction for the controlled variable based on step change in manipulated variables which is the model development
- Steady State Simulation using Aspen DMC plus Model
- Determine the path by which the manipulated variables move from their current positions to the end positions i.e. the move plan of the controller.
- Prediction and Tuning of Controller using ASPEN APC web Interface

5.1 Model Interaction with external platforms.

The communication between the Simulink model and the commercial controller shown in figure 2 is very important and this was achieved using MATLAB OPC toolbox and Industrial Data Xchange (IDX); an OPC client and server. The IDX makes the outputs and inputs of the Simulink model available to the ASPEN DMC plus as data tags through the Aspen Cim-IO.The Aspen Cim-IO is an interface solution for AspenTech systems.

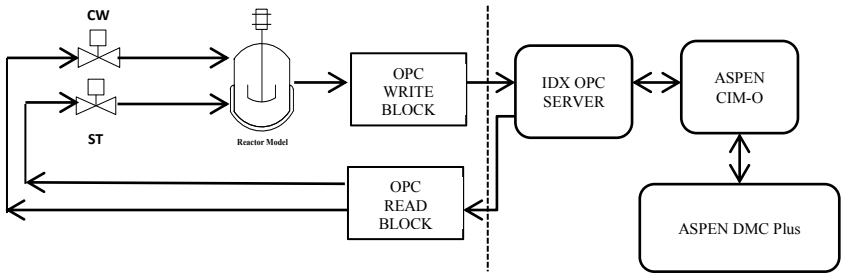

Figure 2 : Simulink model interaction with commercial controller

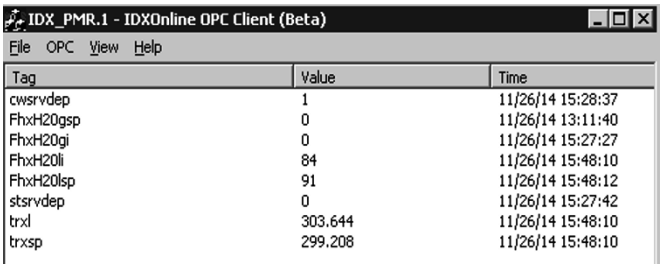

Figure 3 shows the IDX OPC client interface with the MVs and CVs data communication between the Simulink model and commercial controller.

Figure 3: IDX OPC Client

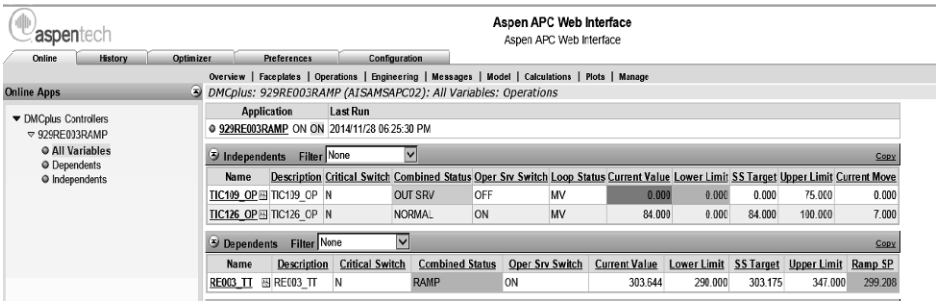

Figure 4: ASPEN APC Web Interface

Figure 4 shows the independent and dependent variables of the controller configuration developed using Aspen DMC plus Build, and monitored on the APC Web Interface. A controller model was built using the Aspen DMC plus Model, the open loop prediction of the model is shown in figure 5. This shows a test controller with cooling phase; increase in cooling water and decrease in steam.

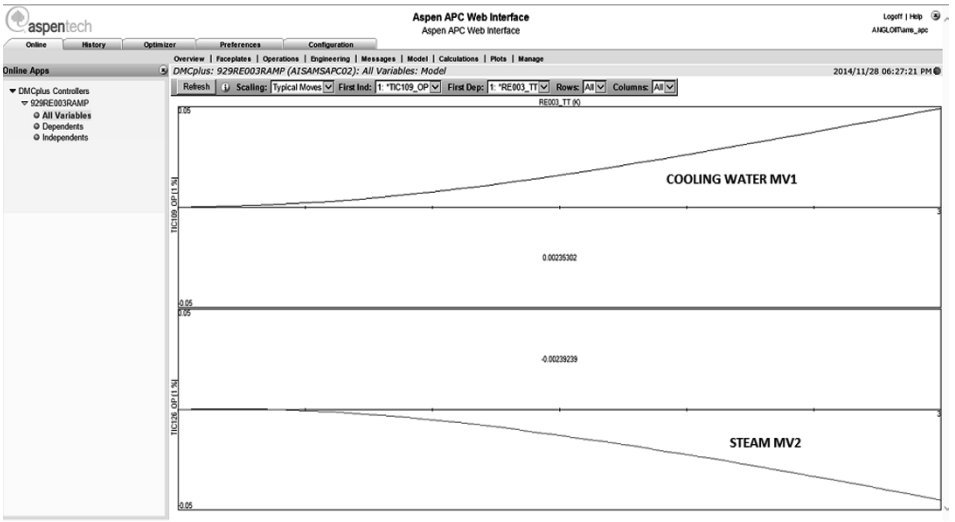

Figure 5: Open Loop Simulation.

Figure 6 shows a closed loop test simulation of the model, the response of the CV to predicted moves of the MVs; this validates the communication between the variables.

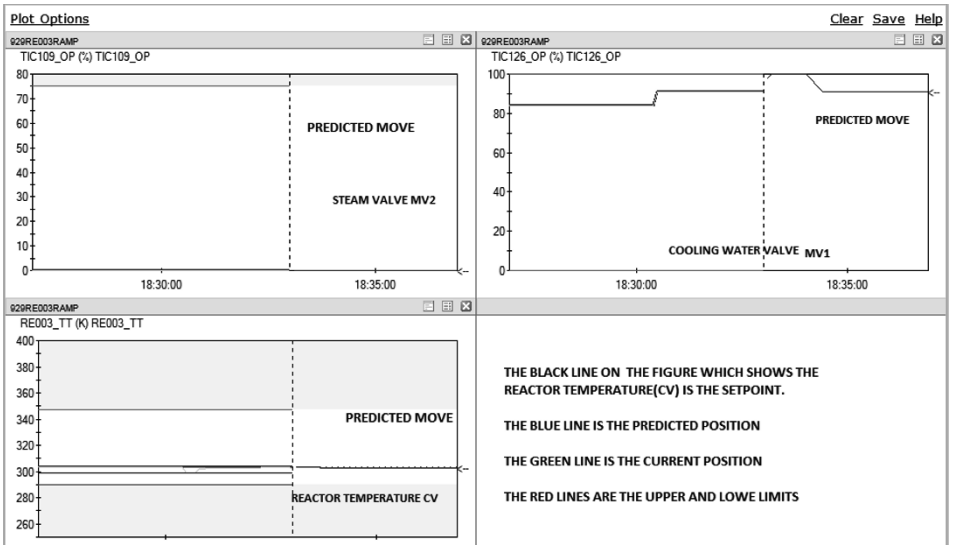

Figure 6: Closed Loop Simulation Response

6. Results and Discussion

The Simulink model was linearized to obtain linear time-invariant state-space models at two different steady state operating points, open loop simulations were ran on two the models and closed loop models were developed using Simulink PID compensator design tool.

The open loop response of the reactor temperature to a step change in the inflow of utilities; steam inflow for heating and cooling water inflow for cooling was done. This validates the response of the model to a unit step change in input at set utility temperatures which are cooling water at 278K and steam at 400.15K.

The closed loop performance results of the PID controllers show the model reactor tracking the set point temperature which is the plant temperature data.

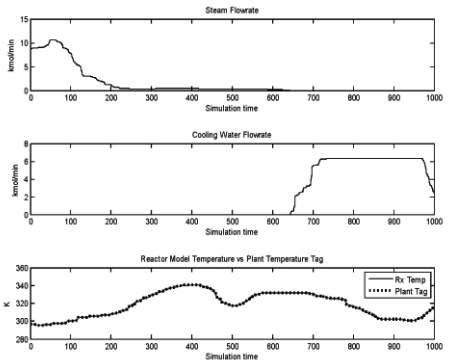

Figure 10: Simulation results of PID 1 on model 1

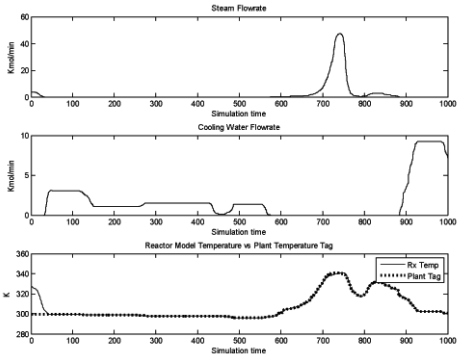

Figure 11: Simulation with PID 2 on model 1

Figure 10 and Figure 11 shows closed loop simulation using using temperature from plant data as PID set point. In Figure 10, PID controller 1 tuned on model 1 shows a very good set-point tracking performance with a lower integral square error of 5.995.

In Figure 11, PID controller 2 tuned on model 1 shows a bad set-point tracking performance with a higher integral square error of 132.62.

Table 1 shows different operating point of the linearized state-space models and Table 2 shows the performance of different controllers implemented on different models using temperature from plant data as reference temperature. The PID 1 performed better on model 1 and PID 2 performed better on model 2

Table 1: Model operating points

Operating Points	Model 1	Model 2
Reactor Temperature (K)	303.1040	292.1161
Jacket Temperature (K)	304.1142	299.0432

Table 2: Controller Performance Values

Controller	Model	Integral Square of Error (ISE)
PID 1	1	**5.995**
PID 1	2	87.61
PID 2	1	132.62
PID 2	2	7.993

7. Further Work

The Advanced Process Controller (APC) implemented on the reactor model will be tuned to its best performance and the performance will be compared to that of the PID controllers and a combination of controllers will be implemented on the model in order to assess if the hybrid controller will out-perform a single controller.

8. Conclusions

PID controllers perform better on model operating points there were tuned on with a lower integral square error (ISE) and their performance degrades with change in process operating points and batches (Noguchi and Kobari, 2005). To overcome these limitations, a commercial APC (Aspen DMC Plus) which has been successfully connected to the Simulink model will be tuned and completely implemented to validate (Singh et al. 2010)'s work on the actual commercial reactors which proves that the APC controller out-performs PID controller. The platform needed to compare ability of the PID and the APC control system with the reactor model is now developed.

Abstract

Multivariate analysis allows process understanding to be gained from the vast and complex datasets recorded from fermentation processes, however the application of such techniques to this field can be limited by the data pre-processing requirements and data handling. In this work many iterations of multivariate modelling were carried out using different data pre-processing and scaling methods in order to extract the trends from the industrial data set, obtained from a production process operating in Novozymes A/S. This data set poses challenges for data analysis, combining both online and offline variables, different data sampling intervals, and noise in the measurements, as well as different batch lengths. By applying unfold principal component regression (UPCR) and unfold partial least squares (UPLS) regression algorithms, the product concentration could be predicted for 30 production batches, with an average prediction error of 7.6%. A methodology is proposed for applying multivariate analysis to industrial scale batch process data.

Keywords: Multivariate Data Analysis, Bioprocess, Process Optimisation

1. Introduction

There is a vast amount of batch process data generated in industry, which can be investigated with the aim of identifying desirable process operating conditions, and therefore areas of focus for optimising the process operation. Although multivariate methods are highly established for analysis of large data sets, their application to batch processes is less common due to the additional challenges associated with data dimensionality, as well as high measurement noise. Data mining of such a complex data set requires additional pre-processing stages, however the importance of these steps prior to modelling is often underappreciated (Gurden et al. 2001).

Nomikos and Macgregor (1994, 1995) pioneered the application of multivariate statistical methods to batch processes. With a lack of mechanistic models which can define the non-linear process dynamics and unsteady-state operation, and a lack of sensors which measure key process variables, empirical modelling shows promise for characterizing batch operations (Nomikos and MacGregor 1995).

Fermentation processes are highly sensitive to operational changes, however the underlying mechanisms are often poorly understood. Multivariate methods are therefore suitable tools for gaining process insight (Formenti et al. 2014). Such biological processes are also sensitive to system variations between batches and are often hard to implement in a reproducible manner. In addition, there is evidence to suggest that not only the main fermentation conditions, but also the seed fermentation conditions are vital in order to dictate the resulting yield of the process (Ignova et al. 1999). An additional benefit of multivariate methods is that offline data can be incorporated into the model which helps to account for differences observed between batches (Kourti et al. 1995).

In this work, a 30 batch dataset from a filamentous fungus production process operating at Novozymes A/S is analysed by multivariate analysis with the aim of predicting the final product concentration, which is measured offline at the end of each batch. By investigating the contribution of each variable to the model prediction (Kourti et al. 1995), differences between batches can be diagnosed. This diagnosis procedure can be used to understand the process, and therefore guide future process optimisation efforts.

2. Methodology for applying multivariate analysis to batch data

The multivariate methods require a two dimensional dataset, however batch production processes have dimensions of time, batch number and variable. It is also a requirement for UPCR and UPLS that the data matrix for each batch should have the same dimensionality, however this is not the case due to different data logging and data compression for each variable, as well as different batch durations. These issues must be addressed as part of the data pre-processing. There are then considerations for data scaling, so that all variables have the same weighting in the resulting model. Finally the method of model validation should be discussed in order to validate the conclusions drawn from the regression model. Each of these challenges will now be approached with a discussion of the options available. Figure 1 provides the general methodology for applying the methods discussed.

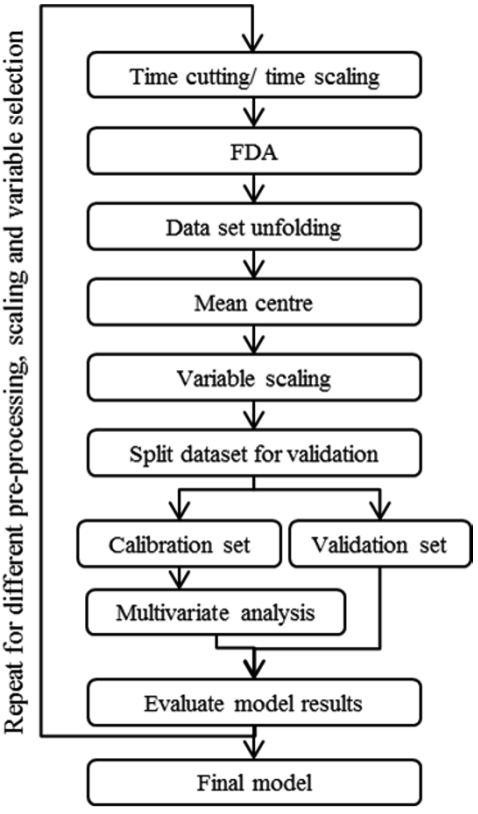

Figure 1: Proposed methodology for multivariate analysis of batch process data.

2.1. Time Scaling Methods

Since batch operations have different durations, the time must be scaled in order to compare multiple batches. The most simple method is to cut the data to the length of the shortest batch, however this is only applicable if the batches show only small variations in duration, otherwise key

data may be lost. There is also the option to cut the data from the beginning, so that the data which is removed is only lag phase data which contains limited relevant dynamics, however the implications of the lag phase can then not be captured, and this may also have an impact on the process.

Alternatively there is the option to linearly scale the time, so that the index of a time unit is scaled such that all batches have the same dimensionality, but with different absolute times. This maintains all data, however it affects the relevance of certain time dependent variables, such as rates or cumulative variables, since the scaling removes this time dependence. Time scaling is highly compatible with functional data analysis (FDA) pre-processing, by fitting the same number of functions across the different batch lengths, which is the method applied in figure 2, and discussed in the next section.

More advanced methods include dynamic time warping which is an example of time series alignment (Keogh and Ratanamahatana 2002). This is a non-linear time scaling, whereby the time series is warped in order to align events in the series, which can be defined by a numerical property of the data, for example a maxima in a variable. This allows batch profiles to be compared relative to key events. As an example, aligning DO limitation profiles in the initial stages, which represents the initial exponential growth phase ending. This method is suitable to aligning events on batch data which can show between batch variations in timing (Kassidas et al. 1998). This method was not applied in this work.

2.2. Data set pre-treatment

It is common that the data logging algorithms result in very different data dimensionality for each variable. In order to avoid large-dimensional datasets, one approach is to log values only after a specified magnitude of change and in addition after a set amount of time. This causes each variable to have a different number of samples, and at different batch times. In order to apply uPCR and uPLS algorithms, data pre-processing stages must create a data matrix for each variable, and each batch with an even time distribution. In addition, variables can be measured with varying degrees of precision, meaning measurements capture different levels of noise. In the literature

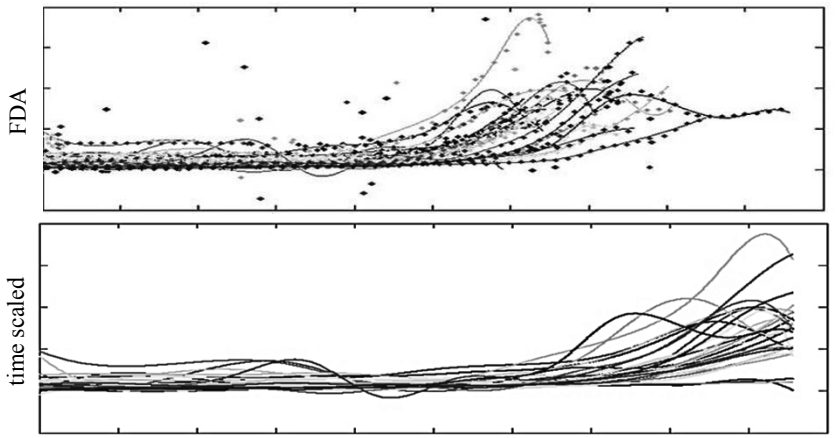

Figure 2: Variable pretreatment, showing the results for FDA (top) plotted with the raw data, and the results of time scaling using functional data analysis (bottom). No axis for confidentiality.

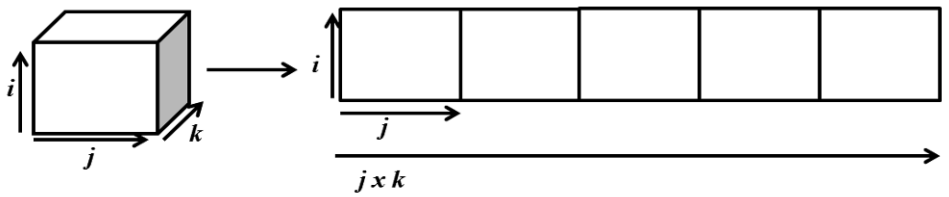

Figure 3: Batchwise unfolding, for i batches, j time, and k variables.

there are different methods used to approach this issue ranging from manual outlier removal (Albert and Kinley 2001), moving average filters, and data interpolation (Le et al. 2012), showing that there is no consensus on the optimal approach.

In this work, the application of functional data analysis (FDA) prior to multivariate methods (Baert et al. 2012) has proven highly valuable in order to greatly reduce the dimensionality of the dataset whilst also filtering noise from the measurements and dealing with outliers in the data in a single processing step. FDA involves fitting of a function across intervals of the data. This method is highly suited, as it allows flexibility in the function output so that the same method can be applied in series to multiple variables. Since this work focusses on non-periodic data, only the spline basis system is considered. Optimal fitting parameters were determined by means of the leave-one-out procedure discussed in James and Silverman (2005).

2.3. Data unfolding

The uPCR and uPLS algorithms apply to a two dimensional data set, therefore dataset unfolding is required (Nomikos and MacGregor 1995). Given a three dimensional matrix with i batches, j time index, and k variables, as shown in Figure 3, unfolding refers to taking slabs from the dataset to create multiple two dimensional matrices of [i x j]. These are aligned to give a two dimensional matrix [i x jk]. This method is most applicable to regression methods for end of batch quality variables, as is discussed in this work.

2.4. Variable Scaling Methods

Column scaling is applied to each time index, so that each time point has equal variance. This is commonly used, however there is the risk that noise is amplified in variables where the overall trend in the data is important but there is high background noise present (Gurden et al. 2001). For example for a cumulative flow profile, implementing column scaling may amplify noise at the start of the batch, where the variance in the values is lower, and lose important information on the final cumulative flow profile as the variance is scaled equally at each time index.

In single-slab scaling all time points for a single variable are scaled for equal cumulative variance. This means that the trajectory shape is maintained more than in column scaling. Figure 4 shows the effect of the variable scaling method on the data profiles.

Model validation methods

In order to assess the resulting model, it is important that suitable model validation is in place, where there is a balance between the fit of the model to the validation dataset, compared to the number of components in the multivariate model. A simple but

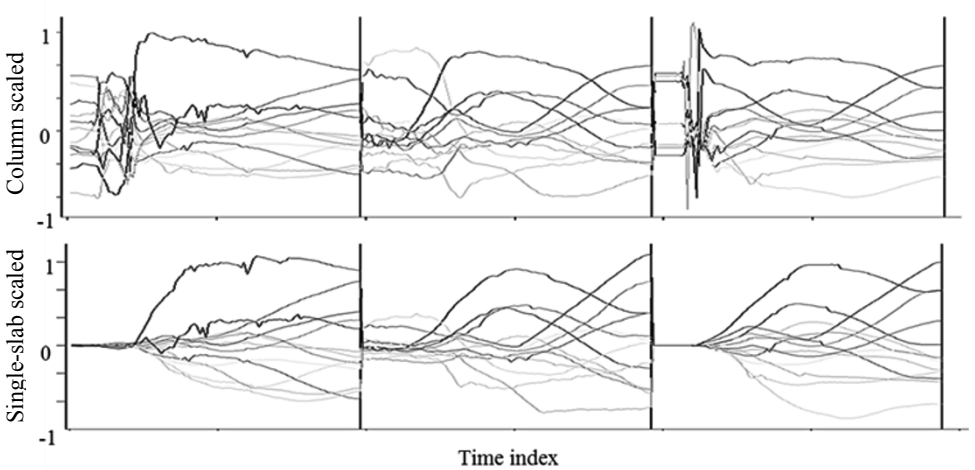

Figure 4: Column scaling (top) and single-slab scaling (bottom) applied to three variables unfolded batchwise. Column scaling affects the cumulative profile, and amplifies noise in the initial time indexes. Variable names and time indexes are excluded for confidentiality reasons.

computationally expensive validation method is leave-one-out, whereby every batch is used as a validation batch. Alternatively the full data set can be split into calibration and validation sets, however the results can then be dependent on the division of the dataset. Leave-one-out validation is suitable for regression applications, since it is then possible to see the effect of individual batches on the model prediction at each calibration stage. This means that if individual batches are outlying, this is seen in the results.

3. Multivariate analysis results from Novozymes A/S industrial dataset

The 30 batch dataset has been analysed by utilising PCR and PLS algorithms implemented in Matlab at Eawag. The discussed data pre-processing stages have been applied, in order to assess the effect on the resulting regression. Many iterations of the modelling were completed, following the methodology in Figure 1, and the effect of the different scaling methods is apparent, as shown by an example in figure 5.

For the final model, time cutting to the shortest batch length was always found to be most effective. Then FDA was applied, with fitting using a roughness penalty (James and Silverman 2005). After dataset unfolding, mean centring was applied followed by

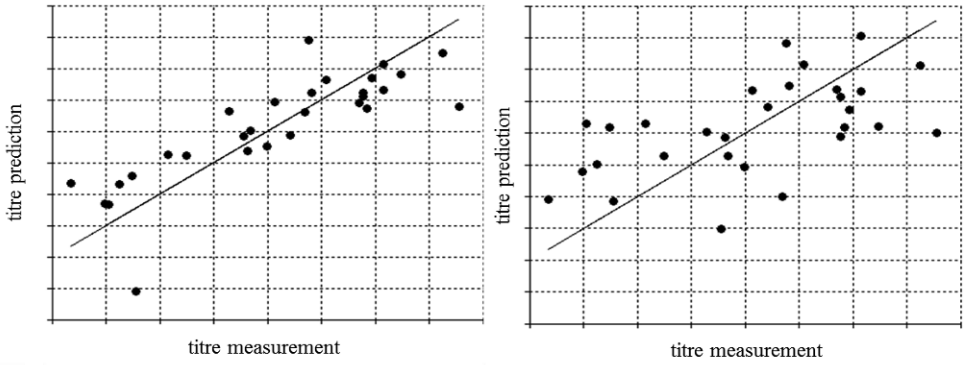

Figure 5: UPCR titre regression models for 30 batch production scale data set at Novozymes A/S. Single slab scaling (left), Column scaling (right). Axis values removed for confidentiality.

single-slab scaling. This resulted in the regression shown to the left in Figure 5.

Based on analysis of the regression coefficients, variables were removed if they had low influence on the resulting model. The accuracy of the model was greatly improved by removal of some variables, which shows that certain variables, although showing high variability, did not show variance relevant to the product concentration prediction, and this therefore affects the model results. The final model included only five online variables, making the model interpretation more straight forward for process optimisation. By analysis of the regression coefficients, it is possible to identify the trend in the data responsible for a higher product concentration prediction. This can lead to identification of potential process optimisation leads.

4. Conclusions

This work discusses how pre-processing is an important and integral stage in multivariate analysis of batch process data, and the choice of methods has an effect on the resulting model, which in this case has been proven by analysis of an industrial fermentation data set from Novozymes A/S. This study was initiated following the observation of practical challenges met during application of conventional statistical process control techniques to an industrial data set. Figure 5 shows that with successful pre-processing it is possible to predict the titre from an industrial fermentation process with an average prediction error of 7.6%. The methodology proposed aims to provide a framework for approaching the multivariate analysis of batch process data.

Abstract

Control of multivariate population balance systems is a challenging task in process engineering, which is in particular due to difficulties in observing the state of the dispersed phase. In this article, we present a setup based on video microscopy and Kalman filtering to observe the evolution of a crystal population in batch crystallization processes. We demonstrate the applicability of our methods on the cyclic batch crystallization of potassium dihydrogen phosphate. It is shown that the cyclic process strategy can lead to crystal shapes which would not have been attainable via pure growth processes.

Keywords: crystallization, crystal shape, crystal shape observation, growth-dissolution cycles, Kalman filter

1. Introduction

The final crystal size and shape distribution is a product property that is decisively influencing the final solid state properties of crystalline materials. For example, elongated or platelet like crystal shapes are known to cause difficulties during filtration and drying, and hence these downstream processes may become the bottleneck of the entire crystallization process. However, due to the high surface-to-volume ratio, such crystals might be desirable in specific application areas like catalysis. Hence, crystal shape control offers the possibility to directly adjust the final product properties. However, for this purpose reliable measurement techniques are required to observe the crystal shape distribution over time. For this purpose, video microscopy has received much attention during the last decade, as it offers an immediate impression on the state of the crystalline phase. Recently, Borchert et al. (2014) presented an algorithm to estimate crystal shapes from the recorded videos, which is used in this work to construct an observer for the crystal shape evolution. This observer is then used to monitor the state of the dispersed phase during a cyclic growth-dissolution process of potassium dihydrogen phosphate. Such a process concept was found to be suitable to attain a wider region of crystal shapes, compared to pure growth processes, as demonstrated on the single crystal level by Lovette et al. (2012). In the present contribution this strategy is applied to an entire batch crystallization process, i.e. a system containing a crystal population distributed w.r.t. size and shape.

This article is organized as follows. The experimental setup which has been used is presented in the next section. In Section 3, the experimental results are presented and discussed, and a technique to filter the measured mean crystal shape evolution is presented. Finally, Section 4 concludes this work.

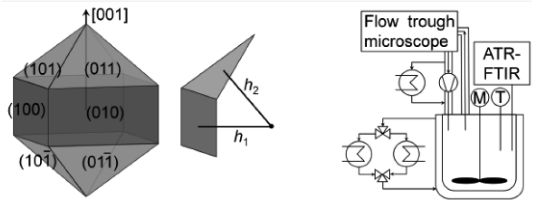

Figure 1: Left: Idealized geometry of a KDP crystal consisting of prismatic {100} faces (dark gray, index 1) and pyramidal {101} faces (light gray, index 2). The crystal shape is represented by the orthogonal face distances h_1 and h_2 of the {100} and {101} faces to the crystal center; right: schematic of the experimental setup.

2. Experimental

Potassium dihydrogen phosphate (KDP) is chosen as a model substance in this work. KDP crystallizes in the tetragonal space group I-42d with a = 7.460 Å and c = 6.982 Å and exhibits prismatic {100} and pyramidal {101} faces on the outer crystal surface, see Figure 1, left. The geometrically possible crystal shapes of KDP range from elongated crystals with a high prominence of {100} faces to compact crystals as depicted in Figure 1 and in an extreme case to octahedral crystals exhibiting only {101} faces on the crystal surface. The solubility of KDP in water is rather high, and can be described with the empirical correlation:

$$w_{\mathrm{eq}} = 4.6479 \cdot 10^{-5} T^2 - 0.022596T + 2.8535 \tag{1}$$

where w_{eq} is the mass of KDP which is in equilibrium dissolved in 1 kg water. The supersaturation is then defined as the ratio of the actual concentration w to the equilibrium concentration w_{eq}:

$$\sigma = \frac{w}{w_{\mathrm{eq}}} - 1 \tag{2}$$

Recently, Eisenschmidt et al. (2015) have presented the face specific growth and dissolution rates of the {100} and {101} faces of KDP, respectively. It was found, that growth at low and intermediate supersaturations is strongly influenced by impurities present in the solution and hence, growth under these conditions is affected by batch to batch variations. Therefore, the authors conclude that KDP crystals should preferably be grown at high supersaturations, which is in accordance to the conclusions of Zaitseva et al. (1999). Due to these constraints on the applicable supersaturation range, the region of possible crystal shapes which are attainable by pure growth is rather confined; see the gray shaded region in Figure 2d. To overcome these limitations, growth-dissolution cycles are performed in this study, by using an experimental setup as depicted in Figure 1. To realize the temperature switches that are required for this cyclic operating policy with minimal time effort, two thermostats are employed, which have been connected to the crystallization vessel via two tree-way valves. KDP is purchased from Carl Roth GmbH Analytica (purity 98%, pH = 4.12 at T_{eq} = 35 °C) and used without further purification. The suspension is stirred with an overhead pitch bladed impeller (d = 4.5 cm) at a speed of 400 rpm to achieve a homogeneous solution. The temperature is measured using a standard PT100 thermo couple and an ATR-FTIR is used to monitor the solute concentration. To monitor the state of the crystalline phase, a flow through microscope (QicPic, Sympatec) has been used, which is fed by an external sampling

loop. Videos of the crystal suspension with a length of 10 seconds are collected at a rate of 20 frames/s with a resolution of 1024 x 1024 pixels. The field of view has a size of 5000 µm by 5000 µm. The videos are processed after the experiment using the algorithms presented by Borchert et al. (2014), to obtain the evolution of the crystals size and shape distribution over time.

According to Bajcinca (2010, 2013), the time optimal operating policy for a cyclic growth-dissolution process is composed of growth and dissolutions phases at constant levels of super- and undersaturations. The corresponding optimization problem is solved for the constraints $0.10 \leq \sigma_G \leq 0.14$, to ensure reproducible growth conditions and to avoid massive nucleation, and $-0.025 \leq \sigma_D \leq 0$ to guarantee dissolution conditions which are well controllable. An initial temperature of $T = 35°C$ is chosen and a mass of 602.0 g KDP is dissolved in 1.8 kg water, corresponding to a supersaturation level of $\sigma = 0.1$. After complete dissolution of the raw material, the temperature is lowered to 35°C and 0.8 g KDP crystals of a sieve fraction between 212 µm – 300 µm has been added to the solution as seed crystals. Afterwards, a temperature control program, calculated in a feedforward manner, is started to achieve growth and dissolution phases at constant super- / undersaturation levels, see Eisenschmidt et al. (2015) for details. The durations of the individual growth and dissolution phases are chosen such that a supersaturation switch is completed when the mean seed crystals reach a maximal or minimal crystal volume. These times are determined in preliminary experiments which are, for the sake of brevity, not shown here. Therefore, the concentration signal is expected to oscillate between a maximal and minimal value as well, which allows for process control based on concentration measurements as well, see Bajcinca et al. (2010).

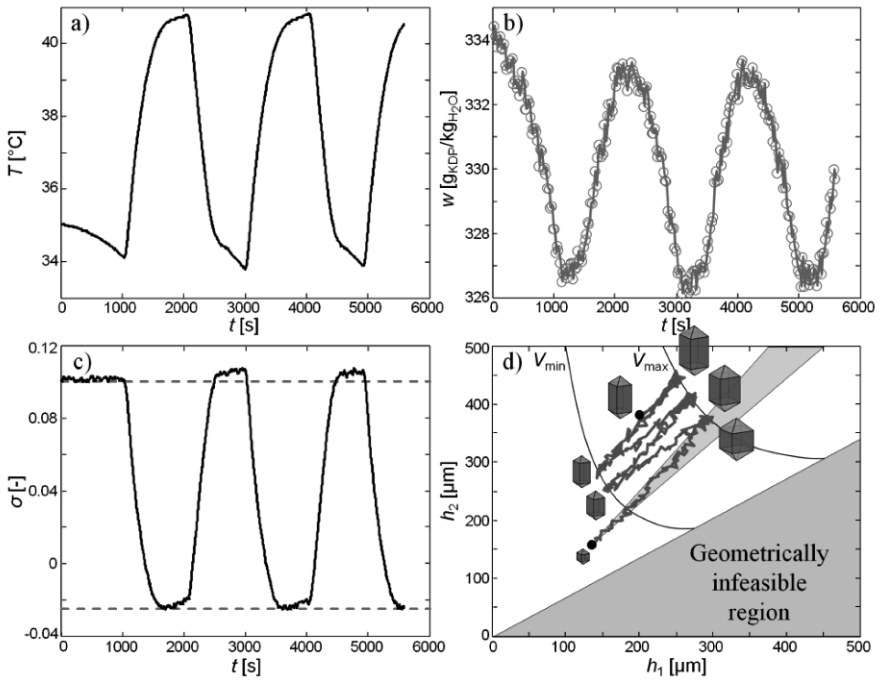

Figure 2: Experimental realization of growth-dissolution cycles. a) applied temperature profile; b) measured concentration profile; c) resulting supersaturation profile (solid lines) together with the set point supersaturation levels (dashed lines); d) observed mean crystal shape trajectory with example crystal shapes.

3. Results and Discussion

Figure 2 depicts the experimental results that were obtained by the procedure described in the previous section. As can be seen, the supersaturation can be controlled reasonably well with the applied temperature profile. Also the concentration profile is oscillating between a minimal and maximal value and hence a control setup based on concentration measurements as proposed by Bajcinca et al. (2010) is indeed feasible. In Figure 2d the measured mean crystal shape evolution of the seed crystal population is depicted. As can be seen, the region which is attainable by growth, indicated as gray cone originating at the starting point, can be left with this approach, which results in the successive mean crystal shape evolution towards elongated crystals.

However, the observed mean crystal shape evolution is significantly affected by the occurring measurement noise, which makes potential feedback control difficult. Therefore, a Kalman filter was applied to the measured mean crystal shapes. To apply this filter, the error covariance matrix $\mathbf{R}_k$ for the measured mean crystal shapes was determined to be:

$$\mathbf{R}_k = \frac{1000}{N_{\mathrm{cryst,k}}} \begin{bmatrix} 1.09 & 0.18 \\ 0.18 & 0.18 \end{bmatrix} \tag{3}$$

where $N_{\mathrm{cryst,k}}$ denotes the number of observer seed crystals. The necessary a priory state estimates can be obtained by integrating the kinetic data presented by Eisenschmidt et al. (2015) and hence an a priory estimate error covariance matrix $\mathbf{Q}_k$ can be defined:

$$\mathbf{Q}_k = 0.01 \begin{bmatrix} \left(\int_{t_{k-1}}^{t_k} G_1(\tau)\, d\tau\right)^2 & 0 \\ 0 & \left(\int_{t_{k-1}}^{t_k} G_2(\tau)\, d\tau\right)^2 \end{bmatrix} \tag{4}$$

where an average error of the kinetic data of 10 percent was assumed. The filtered measurements are shown in Figure 3. As can be seen, the measurement noise can be significantly reduced. However, some systematic deviations in the order of 15 µm between filtered observation and measurements are occurring during the dissolution phases; see the magnification on the right side of Figure 3. These deviations can be attributed to larger errors in the dissolution kinetics. To reduce this bias, we extended the space of the estimated states by two variables δ_1 and δ_2. In this framework, the estimated mean crystal shapes can be calculated by

$$\overline{\mathbf{h}} = \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} \cdot \begin{bmatrix} \tilde{h}_1 & \tilde{h}_2 & \delta_1 & \delta_2 \end{bmatrix}^T \tag{5}$$

With these two additional states, also the a priory estimate error covariance matrix $\mathbf{Q}_k$ has to be adjusted. In this particular case, the matrix

$$\mathbf{Q}_k = 2.5 \cdot 10^{-5} \begin{bmatrix} \left(\int_{t_{k-1}}^{t_k} G_1(\tau)\, d\tau\right)^2 & 0 & 0 & 0 \\ 0 & \left(\int_{t_{k-1}}^{t_k} G_2(\tau)\, d\tau\right)^2 & 0 & 0 \\ 0 & 0 & 100\,(\Delta t_k)^2 & 0 \\ 0 & 0 & 0 & 100\,(\Delta t_k)^2 \end{bmatrix} \tag{6}$$

was found to result in a reasonably good filter performance, see Figure 4. As can be seen from this equation, the assumed error for the model predictions is significantly decreased while the model error for the additional states δ_i is rather high. Therefore, deviations between model predictions and observations are essentially attributed to the states δ_i, which results in a significant decrease of the deviation between measurement and filtered observations; see Figure 4 left and middle. Besides the improvement of the filter performance, the estimated states δ_i provide additional information about the quality of the kinetics applied for the a priori state estimates. On the right side of Figure 4, the temporal evolutions of the states δ_i are depicted. As can be seen, these evolutions are approximately constant during each growth phase, compare to Figure 2c, whereas they are decreasing during the dissolution phases.

This information can be used in turn to re-estimate the crystallization kinetics. This has been done by adjusting the pre-exponential factors of the growth and dissolution kinetics respectively. The new parameters are determined on the basis of the first growth and dissolution phase using a nonlinear regression approach. The resulting kinetics are afterwards used to re-calculate the observed mean crystal shape evolution. As can be seen in Figure 5, there are significant deviations between observations and model predictions. This is particularly due to the uncertainties in the dissolution kinetics. However, if the adjusted kinetics are applied, model predictions and observations match almost perfectly, and hence the new kinetic data can be used for further process control.

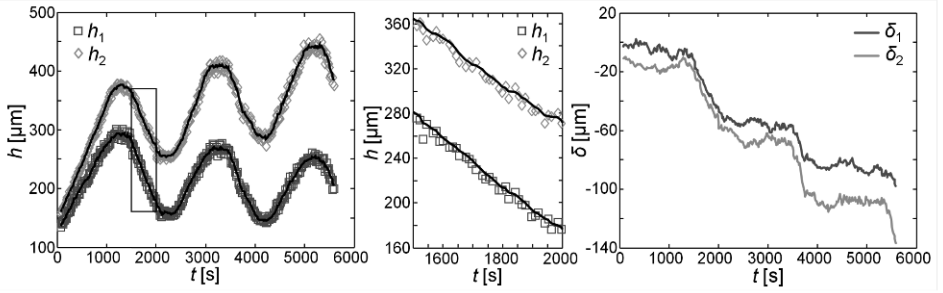

Figure 4: Left, middle: Measured evolution of the face distances of the {100}-faces (squares) and {101}-faces (diamonds) and the results of filtering the states by applying eq. (5) (solid lines); right: evolution of the additional states δ_i over time.

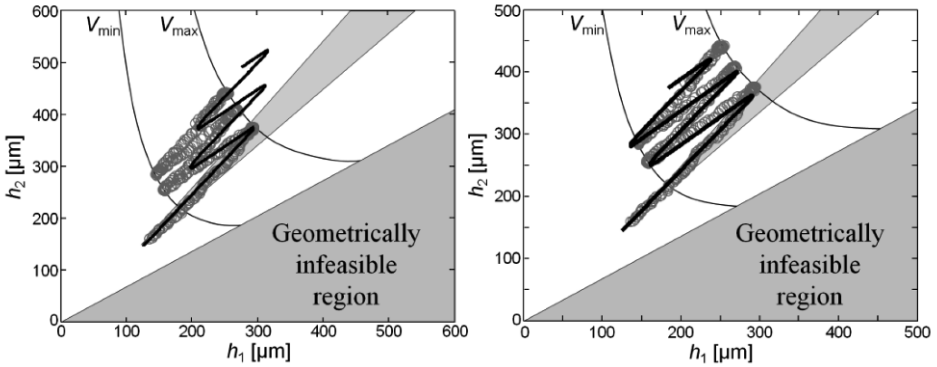

Figure 5: Filtered crystal shape evolution during growth dissolution cycles (circles) together with the model predicted evolution (solid line) with the initial kinetics (left) and adjusted kinetics (right).

4. Conclusions

In this article, the observation of a multivariate population balance system is exemplified on the cyclic crystallization of potassium dihydrogen phosphate. The observations that were obtained by video microscopy are passed to a Kalman filter which serves to reduce the measurement noise significantly. The filtered observations are shown to be robust against process noise and can therefore be used for the re-estimation of the governing process kinetics. The application to growth-dissolution cycles of KDP confirms the usefulness of the observer in generating a feedback which can be used for process control. Furthermore, the investigated cyclic crystallization process provides a promising novel process concept for crystal shape engineering without using any additives.

Abstract

Impurities often have influence on crystallization and properties of the crystal product such as nucleation and growth kinetics, polymorphism or particle size and shape distribution. In most cases, these effects are undesired and thus purification of the product is necessary. This paper represents a novel purity control method based on competitive adsorption. Additive which competes with the undesired impurity for the available active sites on the crystal surface leads to changed adsorption equilibria and finally results lowered impurity concentration. This method is tested numerically by using the developed population balance model. The study shows that competitive purity control (CPC) which uses model based optimization can be an effective alternative for lowering undesired impurity concentration in the crystal product without additional purification steps in the production line.

Keywords: Cooling crystallization, competitive adsorption, population balance model, purity control.

1. Introduction

Crystallization is an industrially often applied separation and purification unit operation. The properties of the obtained product such as particle size and shape distribution, stability are important especially in pharmaceutical industry. Effect of impurity on the crystal properties is widely investigated and numerous studies focuses on the impact of impurities on the crystal growth and thus changes in the crystal size and shape distribution. For instance Fu et al., (1999) experimentally investigated the effect of anionic impurities on the growth habit of an inorganic crystal, while Prasad et al., (2001) compared and studied experimentally the Paracetamol crystallization in the presence of impurity and in pure media. Since the crystal size and morphology has impact on the possible application in the production line, considerable number of researches looks into impurity effect on the physical and chemical properties of the pharmaceutical products. Variankaval et al., (2008) focused not only for the impurities, but listed some often occurred challenges in production of active pharmaceutical ingredients (API) e.g., polymorphism, impurity/additive or solvent effect.
Different types of models were also developed in order to describe the impact of impurity on crystal properties. The mathematical model developed by Cabrera and Verilyea (1958) was the earliest which considered impurity adsorption. Rosenberg and Riveros (1974) take into account the relation between impurity and heat of mixing terms. The most widespread impurity adsorption model is based on Langmuir's

adsorption isotherms and ait is originally developed and investigated by Kubota and Mullin (1995). Langmuir type adsorption model was discussed substantially in Ruthven's work (1984). The Kubota-Mullin model was further extended and combined with population balance model in numerous researches such as numerical study by Borsos et al., (2014) who developed a shape control method by using multiple crystal growth modifiers (CGMs).
Additional aspects of product behaviour are required to be considered in pharmaceutical production such as bioavailability, toxicity, and stability which can also be influenced by impurities, thus limited impurity concentration of product is required (Goole et al., 2010). Different methods are used in order to achieve the desired concentration level in the API product. Recrystallization is widely used as an effective purification technique of crystallization (e.g. Nara, 1997; Morito et al., 2013). However this technique does strongly influence the productivity. Further techniques are also available as additional step in the production line: Membrane filtration (e.g., Peeva et al., 2014) and also chromatographic methods (Amanullah and Mazzotti, 2006; Szekely et al., 2011) are also often used as purification unit operation.
The aim of this work is to present a new purity control method which does not require additional unit operation and does not have significant impact on the productivity. Adsorption based competitive purity control (CPC) is proposed and investigated. A morphological population balance model including nucleation, growth, and competitive impurity adsorption kinetics is developed to describe the process when multiple impurities can competitively adsorb on the crystal surface. The numerical study presented in the paper shows that the method may be a useful technique when appropriate control additive is available.

2. Competitive purity control

Competitive purity control is a method which helps lowering the concentration of undesired impurity in crystal products. Figure 1 shows a schematic representation of competitive adsorption mechanism with a harmful impurity which has a suitable active group (orange part of impurities on Fig 1) for connecting to the active sites (orange rectangles on the moving front) on the growing surface layer of crystal, while a harmless additive with same adsorption behaviour also has same/similar group. In this case competitive adsorption occurs between the undesired impurity (Impurity_1) and the control additive (Impurity_2) on the same type of active sites.

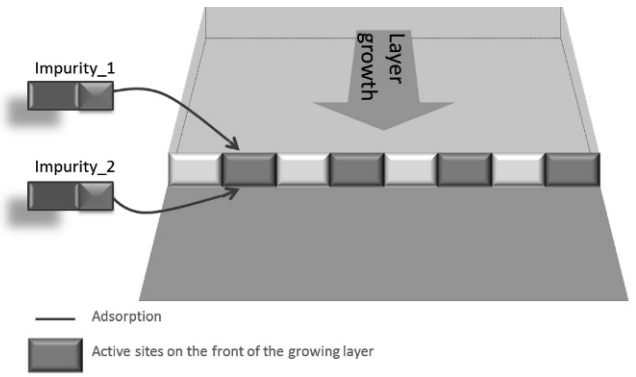

Figure 1 Schematic image of the competitive adsorption mechanism of two crystal growth modifiers.

Hence, competitive adsorption leads to changed equilibria of Langmuir isotherms in accordance of the impurity/additive concentrations in the system. These changes of the equilibria result in lowered level of the harmful impurity concentration in the solid crystal product.

Mathematical models including impurity adsorption have been developed previously in order to investigate the impurity effect on the crystal properties. In the present work, morphological population balance based competitive multi-impurity adsorption model is developed. The effect of growth modifiers on the distribution function leads to an extended population balance model formulation (Fevotte and Fevotte, 2010). The new distribution function includes the time of crystals spending in impure media. The modified distribution function takes the form

$$n(t,\boldsymbol{x}) = \int_0^t \phi(t,\boldsymbol{x},\eta)d\eta \tag{1}$$

where $\phi(t,\boldsymbol{x},\eta)$ defines the new distribution function and $\boldsymbol{x}$ is vector of characteristic crystal sizes.Then the morphological population balance equation is determined as the follow

$$\frac{\partial}{\partial t}\phi(t,\boldsymbol{x},\eta) + \nabla_x\left[\boldsymbol{G}\phi(t,\boldsymbol{x},\eta)\right] + \frac{\partial}{\partial \eta}\phi(t,\boldsymbol{x},\eta) = B_p\delta(\boldsymbol{x}-\boldsymbol{x}_0)\delta(\eta-0) \tag{2}$$

The initial and boundary conditions of the PBE are

$$\phi(0,\boldsymbol{x},0) = \phi(\boldsymbol{x}); \boldsymbol{G}\phi(t,\boldsymbol{x},\eta) = 0, \boldsymbol{x} \in \partial\Omega_x, \ \eta = 0 \tag{3}$$

The $\partial\Omega_x$ is the boundary of the size space.

Primary nucleation is considered and determined in the right side of the PBE. Nucleation rate can be written as the function of the actual and saturation concentrations, c and c_{sat}:

$$B_p = k_p \exp\left[-k_e \ln^{-2}\left(c_{sat}^{-1}c\right)\right] \tag{4}$$

The k_p and k_e are coefficient and kinetic constant of primary nucleation, respectively.

The growth kinetics according to the competitive adsorption mechanism can be written as (Borsos et al., 2014)

$$G_i = k_{gi}\sigma^{g_i}\left\{1 - \sum_j\left(\frac{\beta_i K_{i,j}c_{CGM,j}}{T\sigma\left[1+\sum_j K_{i,j}c_{CGM,j}\right]}\left[1-\exp\left(-\frac{\eta}{\tau_{i,j}}\right)\right]\right)\right\} \tag{5}$$

where G_i is the growth rate of the i^{th} characteristic crystal face, $\sigma = (c - c_{sat})/c_{sat}$, g_i and k_{gi} are the growth exponent and kinetic coefficient. The $\beta_i = \gamma_i a_i/(kL_i)$ which are the edge free energy on the i^{th} crystal face per unit length, the area per growth

unit appearing on the i^{th} surface, Boltzmann constant and average distance between the active sites, respectively. The Langmuir constant, $K_{i,j}$, of the j^{th} CGM on i^{th} characteristic face of the crystal. The adsorption time constant, τ, is the function of adsorption and desorption rates as well as impurity concentration as it is defined by Kubota and Mullin (1995).

The method of moment was used to solve the PBE as it provides effective solution. In the case of morphological population balance the PBE is transformed into a closed set of ordinary differential equation system of cross-moments. The general form of the moment equation system is written as the follows

$$\frac{d\mu_{0,0}}{dt} = B_p \text{ and } \frac{d\mu_{m,r}}{dt} = mG_1\mu_{m-1,r} + rG_2\mu_{m,r-1} \tag{6}$$

It is well known that the first moment is related to the particle number, while the third cross-moment is proportional to the particle volume.

The mass balance is also important in order to describe the crystal purity. The following equation represents the mass balance of solute

$$\frac{dc}{dt} = -\rho_c k_v \frac{d\mu_{1,2}}{dt} \tag{7}$$

The ρ_c is the density of the crystal, k_v is the shape factor. The mass balance of the impurities can be written as the follows

$$\frac{dc_{CGM_j}}{dt} = \frac{\chi_{c,j}}{1-\sum_j \chi_{c,j}} \frac{M_{CGM_j}}{M_c} \frac{dc}{dt} \tag{8}$$

where M_{CGM_j} and M_c are the molecular weights of the impurities/CGMs and solute. The $\chi_{c,j}$ determines the mole fraction of the j^{th} CGM in the crystal phase (Maeda et al., 2006; Borsos et al., 2014). The closed set of differential equations with the mass balance is suitable to describe competitive adsorption of multiple impurities during crystallization.

3. Simulation and results

The presented morphological population balance model was implemented in Matlab environment in order to investigate and control the crystal purity by using multiple impurities or additives in the system.

The sensitivity of crystal purity was studied at the end of the crystallization by applying various mixtures of the impurity/additive. Figure 2a shows how the concentration of adsorbed impurity in the product depends on the initial concentration of the impurity and control additives in the system. The surface shows that increased amount of control additive results in reduced impurity concentration in the solid phase. Figure 2b describes the dependence of the total impurity in the crystal product on impurity and the control additive concentration. It can be seen that a small amount of control additive leads to lowered level of total impurity concentration while further addition of it increases the amount of adsorbed impurity.

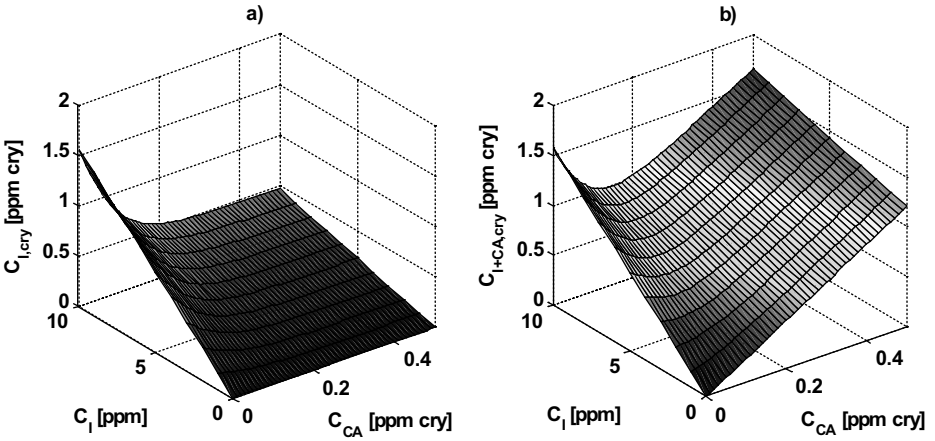

Figure 2 Study on the effect of initial impurity and control additive concentration on the adsorbed amount of a) impurity and b) sum of impurity and control additive in crystal product

A case study of the application of CPC is presented in Fig 3. The objective function of the optimization is defined as the minimization of the weighted multiplication of impurity and total impurity concentration, which are important quality indicators in pharmaceutical crystallization. Fig 3a shows the results of a simulated scenario of 20 batches with batch to batch variation of impurity concentration when the initial concentration of the impurity varies. The squares represent the impurity concentration level in the system without treatment, while the stars indicate the case of applied CPC according to the model based optimization on the basis of the objective function. Figure 3b shows the model based calculation of the optimal amount of control additives used.

4. Conclusions

A new purification method so called competitive purity control is presented in this paper. This method is based on competitive multi-impurity adsorption theorem which was combined with the developed morphological population balance model including primary nucleation, growth of the two characteristic sizes and competitive multi-adsorption kinetics.

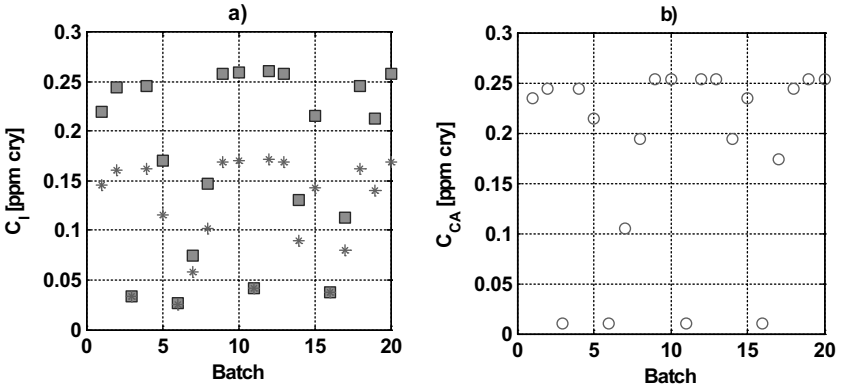

Figure 3 a) Batch to batch variation of impurity concentration in the crystal product; b) optimal amount of control additives in each batches

The CPC method was numerically studied in order to examine the effectiveness on the crystal product purity. The simulation based case study shows that the impurity concentration could be lowered to around 60% of the non-treated system by using CPC method with the chosen kinetic, process parameters and objective function. While alternative purification methods can be more effective, all of those have unfavorable properties such as reduced productivity or cost and time consuming additional unit operations. Furthermore, combinations of the presented and existing purification methods may be considerable solution in order merge the benefits of the techniques.

Stabilizing control for reactor/separator processes with gas and liquid recycles

Hiroya Seki

Chemical Resources Laboratory, Tokyo Institute of Technology, 4259-R1-19, Nagatsuta, Midori-ku, Yokohama 226-8503, Japan

Abstract

A reactor/separator process with gas and liquid recycles is one of the most common process configurations in chemical plants. A control system design problem for such processes is discussed using the two representative plant-wide control benchmark problems, VAM (vinyl acetate monomer) production and HDA (hydrodealkylation of toluene) plants. The most commonly used control configuration for such systems is to introduce the gas feed as a pressure controller handle, while the fresh liquid feed is provided as a make-up to the liquid feed inventory. Installation of a liquid hold-up tank, to which the liquid recycle and fresh feed streams are introduced, is most helpful for eliminating the positive feedback effect due to the material recycle and making control system design easy. This paper seeks the possibility of eliminating such buffer tanks from the viewpoint of process safety (the concept of inherently safer processes), and configures a stable control system despite the positive feedback effect. The liquid feed stream to the reactor is put on flow control by manipulating the fresh feed stream. Locally, configuring a simple mixing control may seem sufficient, but it is shown that the stability depends on the reaction kinetics and the gas component inventory control: the elimination of the buffer tank results in an open-loop unstable process for both benchmark problems, but an appropriate control scheme, ex. PI control, can easily realize a stable closed-loop system

Keywords: process control, plant-wide control.

1. Introduction

Material recycles are common in chemical processes. When a reactor is so designed that the per-pass conversion is well below 100%, separators are introduced to recover and recycle the unconsumed reactants. Often, a reactor per-pass conversion is designed at a moderate value due to increased side reactions and increased reactor construction costs for a higher conversion.

The simplest configuration of the reactor-separator-recycle (RSR) process, which comprises a CSTR and distillation column with one material recycle as shown in Fig. 1, has been extensively studied as one of the representative examples of plant-wide control problems (Luyben,1994; Larsson et al., 2003), since the existence of even a single material recycle complicates the overall behaviour of the combined units.

This paper deals with multiple recycle processes, which include liquid and gas recycles. By using the two representative benchmark problems as examples, namely the VAM (vinyl acetate monomer)

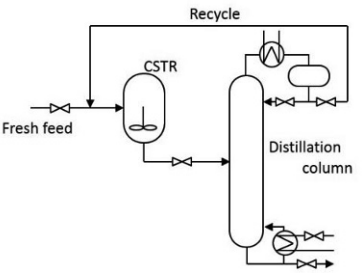

Figure 1 Example of reactor-separator-recycle (RSR) process, consisting of a CSTR and distillation column.

production process (Luyben et al., 1998) and the HDA (hydrodealkylation of toluene) plant (Douglas, 1988; Luyben, 2002), plant-wide control system design is discussed.

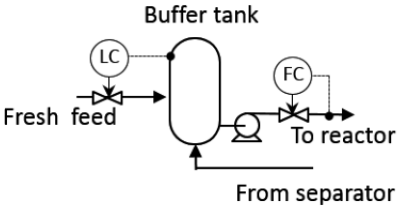

Figure 3 Use of a feed buffer tank to introduce fresh feed (Bildea et al., 2003)

The most commonly used control configuration for gas and liquid recycle systems is to introduce the gas feed as a pressure controller handle, while the fresh liquid feed is provided as a make-up to the liquid feed inventory. Installation of a liquid feed buffer tank may be the most straightforward way of realizing an operable process (Bildea et al., 2003), but an alternative process configuration which does not use the extra buffer tank is considered in this paper. The liquid feed stream to the reactor is put on flow control by manipulating the fresh feed stream: the liquid feed to the reactor is the sum of the fluctuating recycle stream and the fresh feed stream. Locally, configuring simple mixing control may seem sufficient for such systems, but it is shown that the stability depends on the reaction kinetics and the gas component inventory control. Simulation results using dynamic simulators are shown.

2. Control configuration for liquid feed introduction in recycle processes

2.1. Luyben's rule

Luyben (1994) introduced so-called "Luyben's rule" for configuring control system for plants with recycles. Luyben's rule states that at least one stream on the recycle path should be put on flow control: in the RSR system of Fig.1, the reactor effluent and the distillate (recycle stream) should not be used as the level control handles at the same time. Otherwise, "snow ball effect" arises: the recycle flow rate may increase significantly when the fresh feed is provided over the reaction capacity. He pointed out that the reactor effluent should be put on flow control and the fresh feed has to be used to regulate the CSTR level. He also showed that the control configuration violating Luyben's rule introduces very slow dynamics, which can be understood from the block diagram shown in Fig.2 (Luyben, 2012).

Later, Bildea et al. (2003) pointed out the reactor inlet stream is the most appropriate place where the flow control should be applied. To realize this, they suggested a process configuration as shown in Fig. 3 which incorporates a buffer tank: the fresh feed is provided as the level controller handle. If the buffer tank is inserted, positive feedback due to the material recycle is eliminated, and control system design becomes considerably easy. Without a feed buffer tank, it would not be always obvious where to configure level control for introducing the fresh feed.

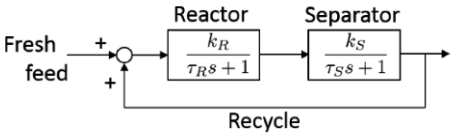

Figure 2 Block diagram of a recycle process configuring positive feedback

However, from the viewpoint of process safety (the concept of inherently safer processes), the extra inventory would not be preferable (Bollinger, 1996). The fresh feed can be introduced into the

reflux drum of a separator to be used as the manipulated variable of the reflux drum level control, but such a configuration limits the control system design for the distillation column.

2.2. Proposed configuration

Figure 4 shows the process and control configuration we employ in this study. Simply, the feed buffer tank is eliminated and the total feed flow to the reactor, which is the sum of the fresh feed flow and the recycle flow, is put on flow control by manipulating the fresh feed flow. The advantage of this configuration is that there is no extra feed buffer tank, and the recycle flow can be used for control system design of the separator. The drawback is that we have to take the positive feedback effect into consideration when we design control system.

Let the fresh feed flow, the total feed flow to the reactor, and the recycle flow be F, F_{tot}, and F_{rec}, respectively. The transfer function from the reactor feed F to the recycle flow F_{rec} is denoted as $G(s)$. Then the transfer function from F to F_{rec}, for which the flow controller is to be designed, can be expressed as

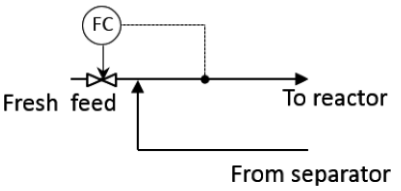

Figure 4 Proposed process and controller configuration. Elimination of the feed buffer tank and introduction of the total liquid feed control by the fresh feed

$$\frac{F_{tot}}{F} = \frac{1}{1-G(s)}. \quad (1)$$

The flow control shown in Fig. 4 has to be designed for the process whose transfer function is described above. We have to be aware of the effect of the positive feedback on the dynamics of the process to be controlled. As shown in the next section, the open-loop dynamics may become unstable.

3. Examples

3.1. VAM plant

3.1.1. Process description

Figure 5 shows a process flow of the vinyl acetate monomer production plant. This process was proposed as a benchmark problem for plant-wide control study (Luyben et al., 1998; Chen et al., 2003). It is a typical reactor/separator process with gas and liquid recycles. Acetic acid is provided as liquid feed, and ethylene and oxygen are provided as gaseous feed.

In the plug flow reactor, the following gas-phase reactions are assumed to occur:

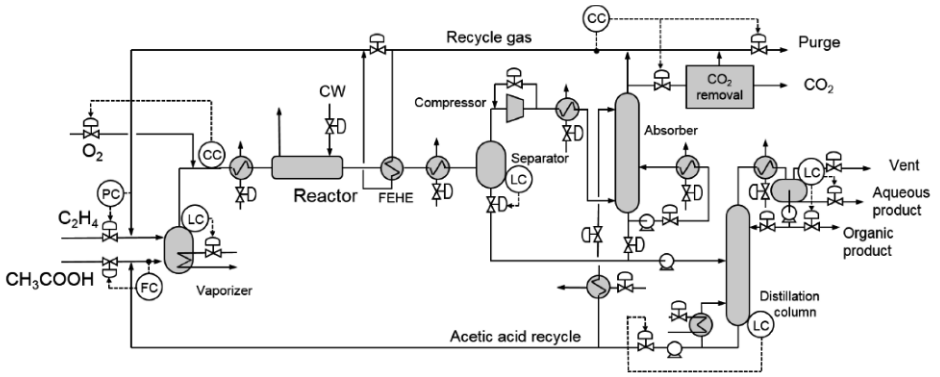

Figure 5 Process flow of the VAM plant with basic inventory control loops

Main reaction

$$C_2H_4 + CH_3COOH + \frac{1}{2}O_2 \xrightarrow{r_1} CH_2 = CHOCOCH_3 + H_2O$$

Side reaction

$$C_2H_4 + 3O_2 \xrightarrow{r_2} 2CO_2 + 2H_2O$$

The rate of the main reaction [mol/min/g-catalyst] is expressed as

$$r_1 = 3.16 \times 10^{-4} \exp\left(\frac{-3670}{T}\right) \cdot p_E \cdot \frac{p_A}{1 + 0.986 p_A} \cdot \frac{p_O(1 + 0.247 p_W)}{1 + 0.0846 p_O(1 + 0.247 p_W)}, \qquad (2)$$

where T [K] is a reactor temperature, p_E, p_A, p_O, and p_W are the partial pressure [kPa] of ethylene, acetic acid, oxygen, and water, respectively. The throughput manipulator is the reactor outlet temperature, which is controlled by the cooling water flow.

3.1.2. Simulation

Figure 6 shows a simulation result. The simulation was performed on the commercial dynamic simulator Visual Modeler (Seki et al., 2010; Yumoto et al., 2010). During t=2 – 15 h, the flow controller for the total liquid feed was turned off and the fresh feed was held constant. The recycle acetic acid continued to decrease: this implies the open-loop is unstable. After the controller was turned on (t=15 h), the recycle flow rate was stabilized.

The instability of the transfer function from the acetic acid fresh feed to the liquid recycle, $1/(1-G(s))$, can be explained as follows. When the total acetic acid feed is increased, the partial pressure of acetic acid p_A should increase. This would lead to increased reaction rate according to (2), but the total pressure is controlled at the reactor inlet, decreasing the partial pressure of ethylene p_E. Consequently,

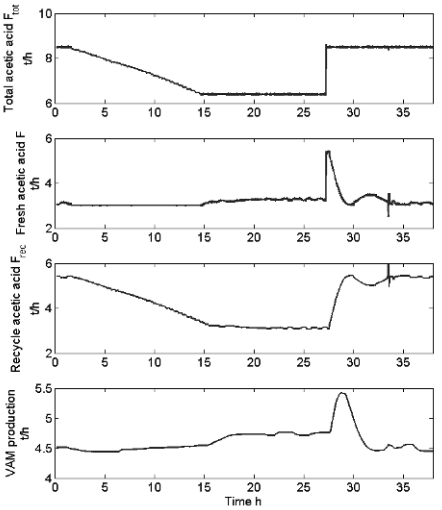

Figure 6 Simulation result for the VAM plant

the reaction rate decreases. This results in $G(0)>1$(increasing the acetic acid feed to the reactor leads to increased amount of acetic acid recycle), which destabilizes the transfer function $1/(1-G(s))$. If the gas-phase pressure is controlled at the separator where it is free from the acetic acid partial pressure, such instability does not occur.

Although the process is open-loop unstable, it is not a difficult task to configure a stable closed-loop. Simply, integral control was sufficient.

3.2. HDA plant

3.2.1. Process description

The HDA process, shown in Fig. 7, is for producing benzene through hydrodealkylation of toluene (Douglas, 1988). It consists of an adiabatic plug flow reactor and separators with gas and liquid recycle streams. Fresh toluene and hydrogen are introduced to the process and they are mixed with the recycled liquid and gas streams. The reactant mixture is pre-heated by the feed-effluent heat exchanger (FEHE) and then heated up to the reaction temperature by the furnace before being fed to the PFR. The following two reactions are considered:

Main reaction:

$$C_6H_5CH_3 + H_2 \longrightarrow C_6H_6 + CH_4$$

Side reaction:

$$2C_6H_6 \longleftrightarrow C_{12}H_{10} + H_2$$

The model of the HDA process used in this study is a modified version of the model by Luyben (2002) and it has been implemented on the commercial dynamic simulator UniSim. The throughput manipulator in this control configuration is the total toluene flow rate; the reactor inlet temperature is controlled by manipulating the fuel to the furnace so that the per pass toluene conversion becomes 85% by looking at the liquid composition of the stabilizer bottom outlet stream.

3.2.2. Simulation

Figure 8 shows a simulation result. During t=2~12 h, the total toluene flow controller was put into manual. As shown in the figure, the open-loop dynamics was found to be unstable with the growing oscillation in the recycle toluene, although the steady state gain $G(0)$ was smaller than 1 in this process. After t=12 h, the controller was turned on

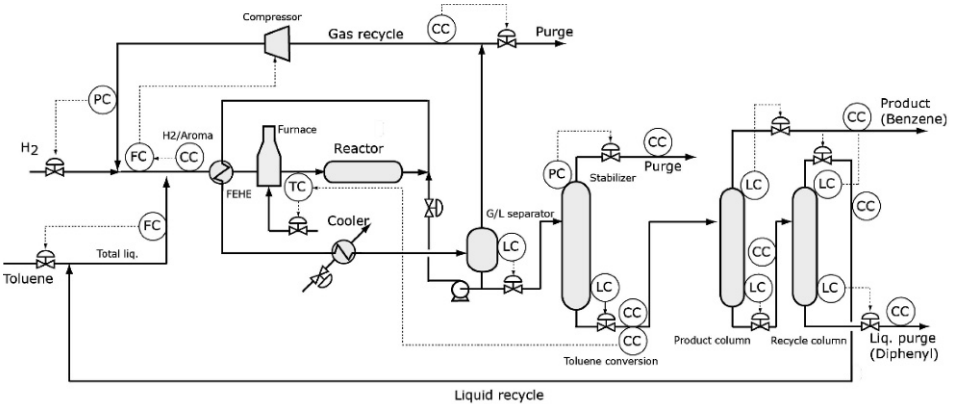

Figure 7 Process flow of the HDA plant with basic inventory control loops

and the closed loop was stabilized. PI control with the control parameter K_p=1 (kmol/h/kmol/h) and T_i=1 min was used.

At t=22 h and 32 h, step changes in the total toluene flow rate were made. As shown in the bottom plot, the production rate was successfully controlled.

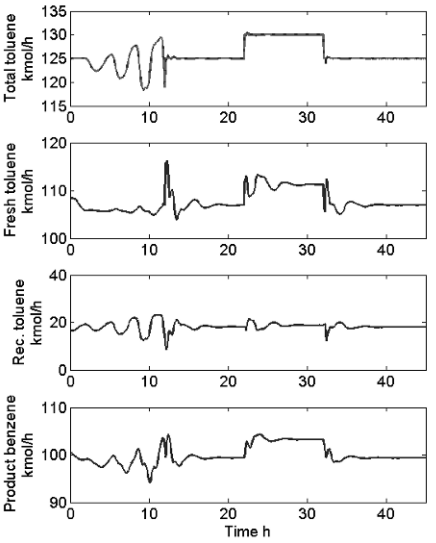

Figure 8 Simulation result for the HDA plant

4. Conclusion

By using the two representative benchmark plants with gas and liquid recycles, a control system design problem concerning liquid feed introduction was discussed. Fresh feed was introduced as the manipulated variable of the controller which regulates the total liquid feed to the reactor. No feed buffer tank was used. In both cases, the open-loop processes were found unstable, but PI or I-control was capable of stabilizing the closed-loop.

Abstract

This paper presents a novel data-based controller design for nonlinear systems based on the VRFT design framework and block-oriented modeling. Identification of a complete dynamic model of the nonlinear system is not required, whereas only the static nonlinearity has to be estimated. Moreover, the nonlinearity estimation and the controller design are performed simultaneously without the needs of iterative procedures or nonlinear optimization. Simulation studies of a distillation column and a pH neutralization process confirms the effectiveness of the proposed design method.

Keywords: Nonlinear process control; Hammerstein system; Wiener system; VRFT.

1. Introduction

Most dynamical systems exhibit nonlinear characteristics so that they can be better represented by nonlinear models. One of the most frequently studied classes of nonlinear models is the block-oriented nonlinear model. Two typical block-oriented model structures are the Hammerstein and Wiener models. In the Hammerstein structure, the linear dynamic element is preceded by the static nonlinearity. The order of connection is reversed in the Wiener structure. Traditional model-based control design approaches require identification of an empirical model for the system. The identification process, however, usually relies on some prior assumptions such as model structure and order, which are often unavailable or subject to uncertainties. Hence, the complexity and modeling errors associated with such models increase the difficulty of the control design task, and lead to considerable degradation of control performance.

Data-based control design methods are very useful in many practical control applications, where obtaining a suitable model is a very difficult task. The virtual reference feedback tuning (VRFT) method (Campi et al., 2002) can be used to design the controller by directly utilizing plant I/O data without resorting to plant models. Most existing results on the VRFT design are however restricted to linear systems. Campi and Savaresi (2006) explored the extension of VRFT to nonlinear systems, which requires iterative procedure. Adaptive VRFT design (Yang et al., 2012) was proposed for adaptive PID controller parameter tuning. Unlike the linear VRFT, these extended versions of VRFT are no longer one-shot method so that a significant advantage of VRFT is lost. In this study, we propose a novel controller design method for nonlinear systems based on the one-shot (noniterative) VRFT design framework and the Hammerstein/Wiener modeling for the system. Combining the parameterization of the nonlinearity with VRFT framework enables putting the system in linear regressor form,

so that least-squares techniques can be used to determine parameters of the nonlinearity and the controller simultaneously, without identifying the linear dynamic subsystem.

2. Controller design based on Hammerstein modeling

The control scheme for Hammerstein system is shown in Figure 1 where f, G, f^{-1}, and C denote the static nonlinear element, linear dynamics, inverse of nonlinearity, and controller, respectively. This linearizing control scheme results in an equivalent linear control system shown in Figure 2(a). The static nonlinear function is parameterized as

$$v_k = f(u_k) = \sum_{i=1}^{s} a_i B_i(u_k) \tag{1}$$

where B_i are (known) basis functions, and a_i are unknown coefficients. A linear controller with integral action is given by

$$C(z) = \frac{c_0 + c_1 z^{-1} + \cdots + c_r z^{-r}}{1 - z^{-1}} \tag{2}$$

Because the gain of a Hammerstein system can be arbitrarily distributed in nonlinear and linear blocks, it is assumed, without loss of generality, that $c_0 = 1$. The problem of controller design is to determine the controller parameters c_i (i = 1,2,…,r) and the unknown coefficients a_i (i = 1,2,…,s), from an N-point data set $\{u_k, y_k\}_{k=1\sim N}$ of observed input-output measurements.

We apply the VRFT method to the equivalent linear control system (Figure 2(a)), so that a model-reference problem, as depicted in Figure 2(b), is to be solved. The reference model $T(z)$ describes the desired behavior of the closed-loop system, which is specified as the following second-order dynamics:

$$T(z) = \frac{(\alpha + \beta z^{-1}) z^{-d-1}}{1 - 2Az^{-1} + A^2 z^{-2}}; \quad \alpha = 1 - A + A\ln A; \quad \beta = A^2 - A - A\ln A \tag{3}$$

where d is related to the time delay of the system and A is a user-specified tuning parameter related to the speed of response. The design goal is to determine the controller parameters c_i and the unknown coefficients a_i, such that the control system in Figure 1 behaves as similarly as possible to the reference model $T(z)$. Based on the virtual reference signal $\tilde{r}(z) = T^{-1}(z)\, y(z)$, the virtual controller output is calculated as

$$\begin{aligned} \tilde{v}(z) &= C(z)\left[\tilde{r}(z) - y(z)\right] \\ &= \left(\frac{1 + c_1 z^{-1} + \cdots + c_r z^{-r}}{1 - z^{-1}}\right)\left[\frac{1 - 2Az^{-1} + A^2 z^{-2} - (\alpha + \beta z^{-1}) z^{-d-1}}{(\alpha + \beta z^{-1}) z^{-d-1}}\right] y(z) \end{aligned} \tag{4}$$

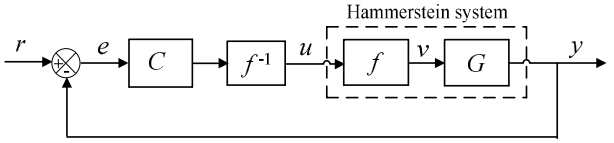

Figure 1. Linearizing control scheme for Hammerstein system.

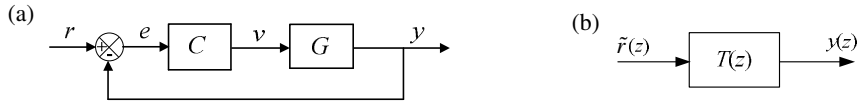

Figure 2. (a) Equivalent linear control system for Hammerstein system and (b) its reference model.

Equation (4) can be rewritten as

$$Q(z)y(z)=\left(\alpha+\beta z^{-1}\right)\tilde{v}(z)-\left(c_1z^{-1}+c_2z^{-2}+\cdots+c_rz^{-r}\right)Q(z)y(z) \tag{5}$$

where

$$Q(z)=z^{d+1}-\left(2A-1\right)z^{d}+\left(1-A\right)^2\sum\nolimits_{\ell=1}^{d-1}z^{\ell}+\beta \tag{6}$$

When the linear block is fed by v_k, it generates y_k. Therefore, a controller that shapes the closed-loop behavior to the reference model generates v_k when the error signal is given by $\tilde{r}_k-y_k$. The task of controller design then becomes minimizing the difference between v_k (Eq.(1)) and $\tilde{v}_k$ (Eq.(4)), or equivalently, minimizing the difference between $\varphi_{k,0}$ and $\boldsymbol{\psi}_k\boldsymbol{\theta}$, where

$$\begin{aligned}
&\varphi_{k,j}=y_{k+d+1-j}-\left(2A-1\right)y_{k+d-j}+\left(1-A\right)^2\sum\nolimits_{\ell=1}^{d-1}y_{k+\ell-j}+\beta y_{k-j};\quad j=0,1,\cdots,r\\
&\boldsymbol{\psi}_k=\begin{bmatrix}-\varphi_{k,1} & -\varphi_{k,2} & \cdots & -\varphi_{k,r} & \eta_{k,1} & \eta_{k,2} & \cdots & \eta_{k,s}\end{bmatrix}\\
&\eta_{k,i}=\alpha B_i\left(u_k\right)+\beta B_i\left(u_{k-1}\right);\quad i=1,2,\cdots,s\\
&\boldsymbol{\theta}=\begin{bmatrix}c_1 & c_2 & \cdots & c_r & a_1 & a_2 & \cdots & a_s\end{bmatrix}^T
\end{aligned} \tag{7}$$

Therefore, the parameter $\boldsymbol{\theta}$ is computed by solving the following minimization problem:

$$\min_{\boldsymbol{\theta}}J\left(\boldsymbol{\theta}\right)=\min_{\boldsymbol{\theta}}\sum_{k=1}^{N-d-1}\left[\varphi_{k,0}-\boldsymbol{\psi}_k\boldsymbol{\theta}\right]^2=\min_{\boldsymbol{\theta}}\left\|\boldsymbol{\varphi}-\boldsymbol{\Psi}\boldsymbol{\theta}\right\|_2^2 \tag{8}$$

where

$$\boldsymbol{\varphi}=\begin{bmatrix}\varphi_{1,0} & \varphi_{2,0} & \cdots & \varphi_{N-d-1,0}\end{bmatrix}^T;\quad \boldsymbol{\Psi}=\begin{bmatrix}\boldsymbol{\psi}_1^{\,T} & \boldsymbol{\psi}_2^{\,T} & \cdots & \boldsymbol{\psi}_{N-d-1}^{\,T}\end{bmatrix}^T \tag{9}$$

The solution can be calculated using the least-squares technique given by

$$\hat{\boldsymbol{\theta}}=\left(\boldsymbol{\Psi}^T\boldsymbol{\Psi}\right)^{-1}\boldsymbol{\Psi}^T\boldsymbol{\varphi} \tag{10}$$

The controller parameters c_i and estimates of the coefficients a_i can be obtained by partitioning the estimate $\hat{\boldsymbol{\theta}}$, according to the definition of $\boldsymbol{\theta}$ in Eq.(7).

3. Controller design based on Wiener modeling

The control scheme for Wiener system is as shown in Figure 3, which results in an equivalent linear control system shown in Figure 4(a). It is assumed that the inverse function of the static nonlinearity is parameterized as

$$v_k=f^{-1}\left(y_k\right)=\sum\nolimits_{i=1}^{s}a_iB_i\left(y_k\right) \tag{11}$$

The problem of controller design is to determine the controller parameters c_i ($i=0,1,\ldots,r$) and the unknown coefficients a_i ($i=1,2,\ldots,s$) from an N-point I/O data set $\{u_k, y_k\}_{k=1\sim N}$. The VRFT method is applied to the equivalent linear control system shown in Figure 4(a), so that a model-reference problem, as depicted in Figure 4(b), is to be solved. The design goal is to determine the controller parameters and the unknown coefficients a_i, such that the control system in Figure 3 behaves as similarly as possible to the prespecified reference model $T(z)$. Based on the virtual reference signal $\tilde{r}_v(z)=T^{-1}(z)v(z)$, the virtual controller output is calculated as

$$\begin{aligned}
\tilde{u}(z)&=C(z)\left[\tilde{r}_v(z)-v(z)\right]\\
&=\left(\frac{c_0+c_1z^{-1}+\cdots+c_rz^{-r}}{1-z^{-1}}\right)\left[\frac{1-2Az^{-1}+A^2z^{-2}-\left(\alpha+\beta z^{-1}\right)z^{-d-1}}{\left(\alpha+\beta z^{-1}\right)z^{-d-1}}\right]v(z)
\end{aligned} \tag{12}$$

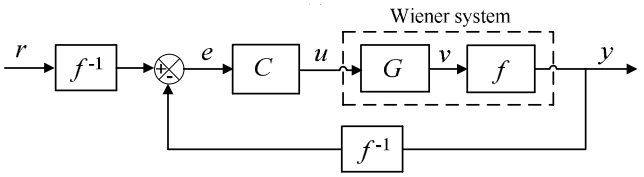

Figure 3. Linearizing control scheme for Wiener system.

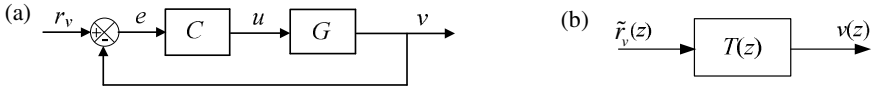

Figure 4. (a) Equivalent linear control system for Wiener system and (b) its reference model.

When the linear block is fed by u_k, it generates v_k. Therefore, a controller that shapes the closed-loop behavior to the reference model generates u_k when the error signal is given by $\tilde{r}_{v,k} - v_k$. The task of controller design becomes minimizing the difference between u_k and $\tilde{u}_k$. Equation (12) can be rewritten as

$$\left(\alpha + \beta z^{-1}\right)\tilde{u}(z) = \left(c_0 + c_1 z^{-1} + c_2 z^{-2} + \cdots + c_r z^{-r}\right)Q(z)v(z) \tag{13}$$

Substituting Eq.(11) into Eq.(12) and rearranging yields $\tilde{\phi}_k = \boldsymbol{\psi}_k \boldsymbol{\theta}$, where

$$\begin{aligned}
&\tilde{\varphi}_k = \alpha\tilde{u}_k + \beta\tilde{u}_{k-1} \\
&\boldsymbol{\psi}_k = \begin{bmatrix} \psi_{k,1} & \psi_{k,2} & \cdots & \psi_{k,s} \end{bmatrix}; \quad \psi_{k,i} = \begin{bmatrix} \psi_{k,i,0} & \psi_{k,i,1} & \cdots & \psi_{k,i,r} \end{bmatrix} \\
&\psi_{k,i,j} = B_i\left(y_{k+d+1-j}\right) - (2A-1)B_i\left(y_{k+d-j}\right) + (1-A)^2 \sum_{\ell=1}^{d-1} B_i\left(y_{k+\ell-j}\right) + \beta B_i\left(y_{k-j}\right) \\
&\boldsymbol{\theta} = \begin{bmatrix} \vartheta_1 & \vartheta_2 & \cdots & \vartheta_s \end{bmatrix}^T; \quad \vartheta_i = \begin{bmatrix} c_0 a_i & c_1 a_i & \cdots & c_r a_i \end{bmatrix}
\end{aligned} \tag{14}$$

By defining $\varphi_k = \alpha u_k + \beta u_{k-1}$, minimizing the difference between u_k and $\tilde{u}_k$ is equivalent to minimizing the difference between φ_k and $\tilde{\varphi}_k$. Thus, the parameter $\boldsymbol{\theta}$ is computed by solving the following minimization problem:

$$\min_{\boldsymbol{\theta}} J(\boldsymbol{\theta}) = \min_{\boldsymbol{\theta}} \sum_{k=1}^{N-d-1} \left[\varphi_k - \boldsymbol{\psi}_k \boldsymbol{\theta}\right]^2 = \min_{\boldsymbol{\theta}} \left\|\boldsymbol{\varphi} - \boldsymbol{\Psi}\boldsymbol{\theta}\right\|_2^2 \tag{15}$$

where

$$\boldsymbol{\varphi} = \begin{bmatrix} \varphi_1 & \varphi_2 & \cdots & \varphi_{N-d-1} \end{bmatrix}^T; \quad \boldsymbol{\Psi} = \begin{bmatrix} \boldsymbol{\psi}_1^T & \boldsymbol{\psi}_2^T & \cdots & \boldsymbol{\psi}_{N-d-1}^T \end{bmatrix}^T \tag{16}$$

The solution can be calculated using the least-squares technique given by Eq.(10). The problem is how to obtain the controller parameters c_i and estimates of the unknown coefficients a_i from the estimate $\hat{\boldsymbol{\theta}}$. Define

$$\boldsymbol{\Theta} = \begin{bmatrix} \vartheta_1^T & \vartheta_2^T & \cdots & \vartheta_s^T \end{bmatrix} = \mathbf{c} \cdot \mathbf{a}^T \tag{17}$$

where $\mathbf{c} = \begin{bmatrix} c_0 & c_1 & \cdots & c_r \end{bmatrix}^T$ and $\mathbf{a} = \begin{bmatrix} a_1 & a_2 & \cdots & a_s \end{bmatrix}^T$. An estimate $\hat{\boldsymbol{\Theta}}$ of the matrix $\boldsymbol{\Theta}$ can be obtained from the estimate $\hat{\boldsymbol{\theta}}$. Let the economy-size SVD of $\hat{\boldsymbol{\Theta}}$ be given by

$$\hat{\boldsymbol{\Theta}} = \mathbf{U}\boldsymbol{\Sigma}\mathbf{V}^T = \begin{bmatrix} U_1 & U_2 & \cdots & U_{r+1} \end{bmatrix} \cdot \mathrm{diag}\begin{bmatrix} \sigma_1 & \sigma_2 & \cdots & \sigma_{r+1} \end{bmatrix} \cdot \begin{bmatrix} V_1 & V_2 & \cdots & V_{r+1} \end{bmatrix}^T \tag{18}$$

Then, the closest, in the 2-norm sense, estimates of the parameter vectors $\mathbf{c}$ and $\mathbf{a}$ can be computed as (Gómez and Baeyens, 2004)

$$\hat{\mathbf{c}} = U_1; \quad \hat{\mathbf{a}} = \sigma_1 V_1 \tag{19}$$

4. Simulation examples

4.1. Example 1: Distillation column

The proposed controller design method for Hammerstein systems was applied to a binary distillation column (Horton et al., 1991). The distillate composition x_D is controlled by manipulating the reflux ratio R. A time delay of 2 min is assumed for the composition measurement. At the steady-state of $R = 3$ and $x_D = 0.935$, a uniform random signal was introduced to the reflux ratio R and the resulting x_D was simulated with a sampling time of 2 min, as shown in Figure 5. To simulate a more realistic condition, measurement noise with NSR = 15% was added to the output data. A set of 600 data points were used for implementing the proposed controller design, with parameters in the reference model chosen as $A = 0.67$ and $d = 3$. The static nonlinearity was represented by the third-order B-splines. Using a third-order controller ($r = 3$), the estimated nonlinearity is plotted in Figure 6. For the purpose of comparison, a linear control system was also designed based on the (linear) VRFT method using the same process data and reference model. Figure 7 shows the response of the proposed nonlinear control system and the linear control system to successive set-point changes. The response of proposed nonlinear control system is close to the reference trajectory and better than that of the linear control system for the set-point changes, indicating that the proposed controller effectively compensates the process nonlinearity. The robustness of the proposed control was evaluated through varying the process parameters. The result (not shown due to page limitation) is still satisfactory.

4.2. Example 2: pH neutralization process

The proposed controller design method for Wiener systems was applied to a pH process (Palancar et al., 1998). The pH of the effluent solution is controlled by manipulating the base flow rate q_b. A set of 3000 data points were generated around the steady-state of q_b = 14.2 mL/s and pH = 9.407, as shown in Figure 8. The estimated inverse of nonlinearity is plotted in Figure 9. Figure 10 shows the closed-loop performance of the proposed nonlinear control system and the linear control system to successive set-point changes.

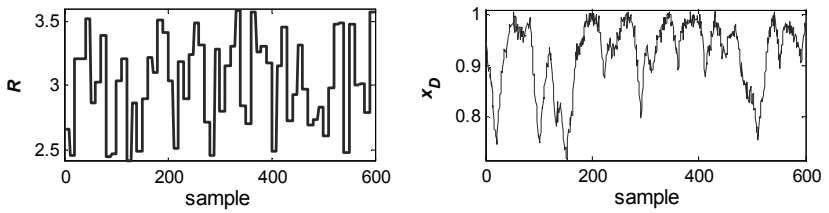

Figure 5. Input-output data used for controller design (Example 1).

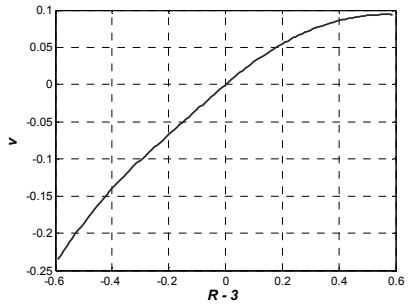

Figure 6. Estimated nonlinearity (Example 1).

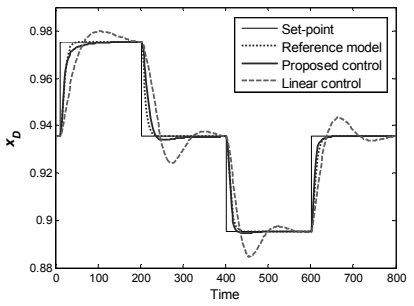

Figure 7. Closed-loop response (Example 1).

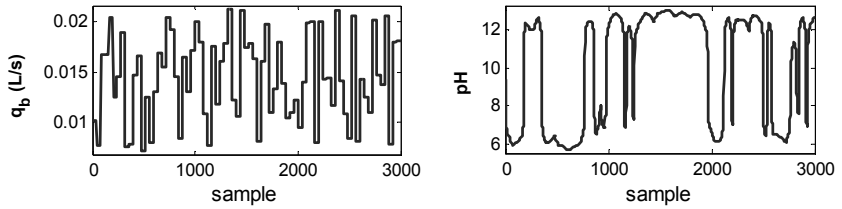

Figure 8. Input-output data used for controller design (Example 2).

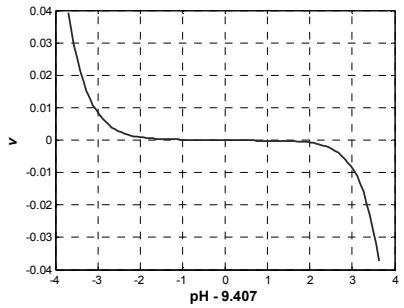

Figure 9. Inverse of nonlinearity (Example 2).

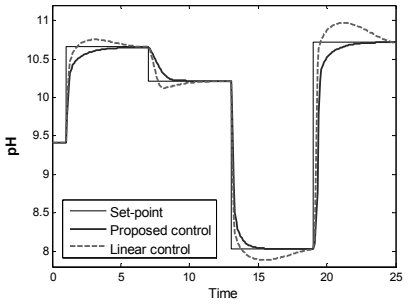

Figure 10. Closed-loop response (Example 2).

The nonlinear control system shows favorable and almost the same control performance for the set-point changes, which verifies the effectiveness of the proposed method.

5. Conclusions

We proposed extended VRFT methods for nonlinear controller design based on the Hammerstein/Wiener modeling for nonlinear systems. The controller parameters and system nonlinearity are simultaneously obtained based directly on a set of plant data. This is in sharp contrast to the model-based design methods that require first identifying an approximate process model, which is often difficult and subject to modeling errors. The proposed algorithms combine the basis function representation of the nonlinearity with the VRFT framework to enable putting the system in linear regressor form, which avoids implementation problems due to computational limitations. The superiority of the proposed nonlinear control design over linear control has been illustrated using two benchmark processes (i.e., a distillation column and a pH neutralization process).

Abstract

Nonlinearity plays a significant role in the closed loop performance of a controller/process as it can render controller tuning ineffective. Nonlinearities can initiate oscillations in process variables that may cause plantwide oscillations, which in turn results in loss of plant profitability and rapid wear and tear of plant machinery. Thus, quantification of nonlinearity is important for designing appropriate controllers, troubleshooting process faults and ensuring smooth operation of a process plant. In this paper, two data-based nonlinearity measures namely, bicoherence and surrogate-data based measures are compared using physical models of a few common processes to identify which method works better for which process.

Keywords: nonlinearity, bicoherence, surrogate, modeling

1. Introduction

Study of Nonlinear systems have been of foremost interest to researchers because most physical systems in reality are nonlinear. Nonlinear systems are defined by those, which do not follow the principle of superposition. Nonlinearities in process variables can be caused by stiction in control valves, which, in turn, sets up oscillations that propagate throughout the whole plant. So, quantification of nonlinearity takes precedence over implementing linear or nonlinear control methods. Two broad approaches exist for measuring nonlinearity of a a process: Model based measures and Time-series or Data-based based measures. The preference of the Data-based approaches over the Model-based resides on the fact that Model-based approaches, like Best Linear Approximation and Curvature-Based methods, require a process model which is often unavailable or difficult to obtain (Choudhury et al. (2008)). Therefore, in recent times, data based methods are gaining popularity because they require time series data of the process which are readily available from the DCS or data historian. The data-based approaches include bicoherence based approach, surrogate data-based approach, Lyapunov exponents and Correlation Dimension.

Most notable data based methods include Bicoherence-Based Measures, proposed by Emara-Shabaik et al. (1996) and Choudhury et al. (2004), Surrogate Data-based Measures by Kantz and Schreiber (1997) and Theiler et al. (1992) and Harmonic Analysis by Paulonis and Cox (2003), Ruel and Gerry (1998), and Thornhill and Hägglund (1997). Correlation dimension and maximal Lyapunov exponent have been examined for the diagnosis of nonlinearity in chemical processes by Zang and Howell (2005a,b).

In this paper, an overview of nonlinearity is given in section 1. Two data based methods are briefly reviewed in section 2. Two common processes, which include a 'Continuous Stirred Tank Reactor'(CSTR) and a 'Spherical Tank' are described in section 3. The nonlinearities of the aforementioned systems are quantified using data-based measures of nonlinearity in section 4. The paper ends with a conclusion.

2. Nonlinearity Measures

2.1. Bicoherence-based Method

The bispectrum is the simplest of the various frequency domain HOS (Higher Order Statistics) measures. It is the frequency domain counterpart of the third-order moments. The bispectrum is normalized in the following way to give a measure called bicoherence whose magnitude is bounded between 0 and 1:

$$bic(f_1,f_2)^2 \triangleq \frac{|E\left[X(f_1)X(f_2)X^*(f_1+f_2)\right]|^2}{E\left[|X(f_1)X(f_2)|^2\right]E\left[|X(f_1+f_2)|^2\right]} \tag{1}$$

where $X(f)$ is the Fourier transform of the data series $x(t)$. Significance of bicoherence magnitude at each individual bifrequency is given by

$$P\{bic(f_1,f_2)^2 > \frac{c_\alpha^{\chi^2}}{2K}\} = \alpha \tag{2}$$

where K is the number of data segments used in bicoherence estimation and $c_\alpha^{\chi^2}$ is the critical value calculated from the central χ^2 distribution table for a significance level of α with two degrees of freedom. Those bicoherence values which satisfy the above condition are called $bic^2_{significant}$. Then Choudhury et al. (2008) quantified the total nonlinearity present in the time series as the following index:

$$TNLI \triangleq \sum bic^2_{significant} \tag{3}$$

2.2. Surrogate-data based Method

The purpose of surrogate data methods is to create synthetic data sets called surrogate time series, having the same power spectrum, but with the phase coupling removed by randomization. A key property of the test time series is then compared to that of its surrogates, and nonlinearity is diagnosed if the property is significantly different in the test time series (Theiler et al. (1992); Kantz and Schreiber (1997)). For a time-series, the surrogate data is calculated by:

$$\text{z}=FFT(\text{test time series}) \quad ,$$

where, FFT=Forward Discrete Fourier Transform; then,

$$z_{surr} = \begin{array}{ll} z[i] & i=1 \\ z[i]\,e^{j\phi_{i-1}} & i=2,.....,N/2 \\ z[i] & i=N/2+1 \\ z[i]\,e^{-j\phi_{N-i+1}} & i=(N/2+2),.....N \end{array} \tag{4}$$

N = number of samples in the time-series. The quantity $\phi_k, k=1,...,(N/2-1)$, is a random phase in the range 0-2π.
Then, surrogate data = IFFT(z_{surr}) , where IFFT=Inverse Discrete Fourier Transform.

An embedded matrix is created of both test and surrogate data. Squared Prediction errors of both test data, Γ_{test} and of surrogate data, Γ_{surr} are calculated as described in Choudhury et al. (2008). Surrogate Nonlinearity Index, N_{surr} is then calculated from :

$$N_{surr} = \frac{\bar{\Gamma_{surr}} - \Gamma_{test}}{3\sigma_{\Gamma_{surr}}} \tag{5}$$

where $\bar{\Gamma}_{surr}$ and $\sigma_{\Gamma_{surr}}$ are mean and variances of M sets of Γ_{surr} , respectively.

3. Processes for Simulation Study

3.1. Continuous Stirred Tank Reactor (CSTR)

The first model is that of a CSTR. The model equations are given by Pottman and Seborg (1992), in which a single exothermic reaction is taking place $A \rightarrow B$. The dynamic behavior of the system is represented by a set of differential equations, portraying the rate of change of concentration of reactants and temperature of the reactor respectively. The equations of the system are given by:

$$\frac{dc_A}{dt} = \frac{q}{V}(c_{Af} - c_A) - k_0 c_A e^{\frac{-E}{RT}} \tag{6}$$

$$\begin{aligned}\frac{dT}{dt} = {} & \frac{q}{V}(T_f - T) - \frac{(-\Delta H)k_0 c_A}{\rho C_p} e^{\frac{-E}{RT}} \\ & + \frac{\rho_c C_{pc}}{\rho C_p V} q_c \left[1 - e\left(\frac{-hA}{q_c \rho_c C_{pc}}\right)\right](T_c - T)\end{aligned} \tag{7}$$

where C_{Ao}=feed concentration, T_{fi}=inlet temperature of the feed, T_c=inlet temperature of coolant, q= feed flow rate, V=reactor's volume, UA=overall heat transfer co-efficient$*$Area, $\rho\&\rho_c$=density of the reactant and coolant respectively, Cp=Specific Heat of the product, k_o=reaction rate constant, ΔH=Heat of reaction. The values of the respective parameters are taken from Luyben (1995).

3.2. Spherical Tank

The second model is that of a spherical tank. The model equation is as follows:

$$\pi R^2 \left[1 - \frac{(R-h)^2}{R^2}\right] \frac{dh}{dt} = F_i(t-d) - F_0(t) \tag{8}$$

Where $F_o(t)$ is the outlet flow rate at time t, h the height of the water level from the bottom of the tank, R the radius of the spherical tank and d corresponds to the delay in the input flow rate. The outlet flow rate, F_o, can be expressed as $F_o(t) = \sqrt{2g(h-h_o)}$, where g is the gravitational constant and h_o the height of the outlet pipe from the base of the vessel. For the open-loop simulation of the system, we use $R = 0.5$ m, $h_o = 0.01$ m. The details of the parameters of the aforementioned model equation can be found in Agrawal and Lakshminarayanan (2003). The control of water level in the tank is accomplished by manipulating the inlet volumetric flow rate, F_i.

4. Simulation Results

Linear systems are said to exhibit *sinusoidal fidelity*, i.e. a sinusoidal input will produce a sinusoidal output of the same frequency; nonlinear systems, however, produce additional frequencies as well. Thus, to incorporate oscillations, a sinusoidal wave of varying frequencies and amplitudes are added to the systems. The measures of nonlinearity are then applied to output data.

4.1. Nonlinearity Study of a CSTR

The inlet reactant concentration, C_{Ai}, was excited using sinusoidal signals of varying frequencies and amplitudes. The data from output concentration was collected and tested for nonlinearity of the system.

Figure 1 shows that for small changes in amplitude, i.e., small changes in reactant concentration, the values of TNLI are close to zero (the lower left portion of the plot). This is expected, because for small excitations, the nonlinear processes can be assumed to be 'locally linear'. Thus TNLI is close to zero. As the amplitude increases, the nonlinearity goes up and so does the TNLI. The nonlinearity has increased monotonically with changes in frequencies and amplitudes. Thus, Total Nonlinearity Index increases with increasing frequency and amplitude.

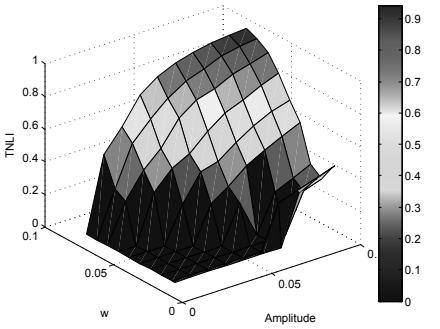

Figure 1: Total Nonlinearity Index (TNLI) Pattern for CSTR

Figure 2 shows the variation in N_{surr}, when Surrogate data-based measure is applied to the same data-set. As seen from the figure, N_{surr} is not monotonically increasing with amplitudes and frequencies, rather, it generates an irregular pattern. The plot shows that the nonlinearity is mostly increasing with increasing frequency. At the same time, the nonlinearity index, N_{surr} does not show good sensitivity with increasing amplitudes. This may be due to the almost sinusoidal nature of the output data because it is known that Surrogate data-based measure, does not work good for purely sinusoidal or strong cyclic signals.

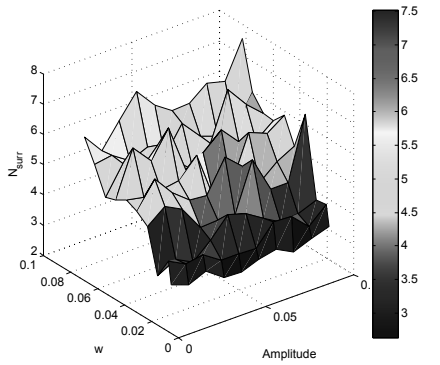

Figure 2: Surrogate Nonlinearity Index Pattern for CSTR

While the the plot of Total Nonlinearity Index appeared to vary between 0 and 1, the plot of N_{surr} showed higher sensitivity to nonlinearity for small excitation signals.

4.2. Nonlinearity Study of a Spherical Tank

In this simulation, the input sinusoidal signal is applied to the inlet flow, F_i, of a spherical tank to introduce sinusoidal disturbance in the water-level of the tank. The data of water-level was collected and nonlinearity measures were calculated from this data. The experiment is operated at a steady-state height of 0.35 m of water in the tank so that the water in the tank neither dries out nor overflows.

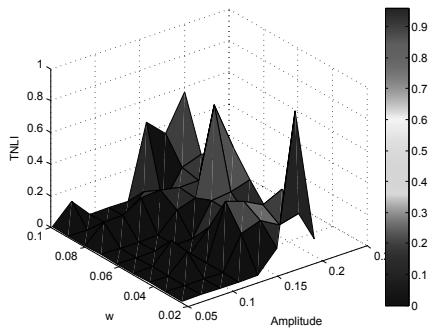

Figure 3: Total Nonlinearity Index (TNLI) Pattern for Spherical Tank

Figure 3 shows that for small magnitudes of input signals, the spherical tank system can also be assumed locally linear as portrayed by the flat regions on the left portion of the plot. As the amplitude of excitation signal increases beyond a certain value, nonlinearity suddenly jumps as visualized from the several peaks at the right portion of the plot. The reason for this can be attributed to the fact that nonlinearity increases at a point where the total surge volume of the tank drops below a certain level. With the decrease in liquid volume, the tank loses its ability to attenuate disturbances, and thus it contributes to an increase in TNLI. Another fact is that the curvature of the spherical tank increases as we move away from the center along the top or bottom direction of the tank. Thus the height of the same volume of water will behave in a more nonlinear fashion when operating closer to the top or bottom portion of the tank than it would while operating near the centre. Another finding is that the nonlinearity of this particular system is not very sensitive to changes in frequency. Therefore, it can be concluded that nonlinearity of the process depends on the size of the excitation signal.

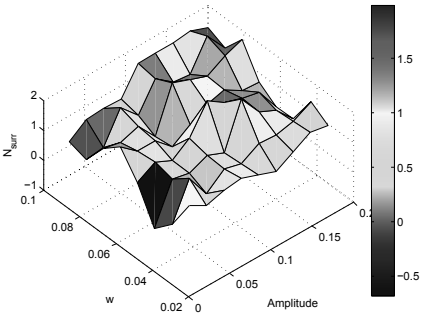

Figure 4: Surrogate Nonlinearity Index Pattern for Spherical Tank

The Surrogate data-based measure is applied to the same data-set. Figure 4 shows that nonlinearity is increasing with both frequency and amplitude. However, the rise in N_{surr} is neither uniform nor monotonic. The dependency of N_{surr} on amplitude can be attributed to the fact as discussed previously.

5. Applicability and Practical Issues

5.1. Applicability

i The comparison of nonlinearity measures will eventually allow the users to find the suitability of each measure for quantifying and finding the degree of nonlinearity for different kinds of processes.

ii The degree of nonlinearity will help to decide whether a linear controller is adequate or a nonlinear controller is required.

iii Multiple nonlinearity measures can be used to increase the reliability of data-based methods for diagnosis of root cause in plant wide oscillations.

5.2. Practical Issues

i For simulation study, sinusoidal excitation was used. In industry, sinusoidal excitations might not be allowed. Since it is widely perceived that often oscillations are existent in industrial processes, the pertaining oscillatory data could itself be used for analyzing purposes. It is to be noted that data-based nonlinearity measures, discussed in this study, are not dependent on sinusoidal excitations only; they can be applied to any time series.

ii It was noted that in case of CSTR, Bicoherence-based measure required approximately 1 minute of computational time while Surrogate data-based measure required around 6.5 hours for execution.

6. Conclusion

The study compares Bicoherence-based measure and Surrogate data-based measure for quantifying nonlinearity. A CSTR and a spherical tank were used for simulation study.

- Bicoherence-based measure appeared to be more sensitive towards changes in amplitude of excitation signals.
- Execution of Bicoherence-based algorithm was much faster than that of surrogate-based algorithm. This makes the bicoherence-based algorithm suitable for application on large data-sets.
- Surrogate data-based measure required a shorter data length in comparison to Bicoherence-based measure for a consistent and reliable estimate of nonlinearity.

Abstract

This paper describes a procedure to find the best economically controlled variables for the activated sludge process in a wastewater treatment plant despite the load disturbances. A further controllability analysis of those variables including a nonlinear model predictive controller (NMPC) has been performed. The self-optimizing methodology has been applied, considering the most important measurements of the process. A first pre-screening of those measurements has been done based on the nonlinear model of the process and typical disturbances, in order to avoid non feasible operation. The NMPC performance has been compared with a distributed NMPC-PI structure.

Keywords: self-optimizing control; model predictive control; wastewater treatment plant

1. Introduction

The efficiency of most wastewater treatment plants (WWTP) is an important issue that must be improved. In order to fulfil the effluent legal requirements for all weather conditions, which generate large variations of the influent, the operating costs are usually higher than the actually needed. Therefore, the optimization of the WWTP operation can provide a significant cost reduction. In the existing literature, most works only consider the problem from a heuristic viewpoint or stating a particular optimization problem. Only Araujo et al. (2013) provides a comprehensive approach, performing a sensitivity analysis of optimal operation. In Francisco et al. (2011) the process is optimized offline but including also plant design.

In order to minimize the economic loss when disturbances occur, one approach is the re-optimization of the plant by applying Real Time Optimization techniques which can be very demanding computationally, or perform some set point optimization off-line. In this work, a different approach is considered, called self-optimizing control (SOC) (Skogestad, 2000), which consists of determining some primary controlled variables (CVs), also called self-optimized variables, and their corresponding set points, that when kept constant, the economic loss is small with respect to costs if the operation is re-optimized. Although there are many successful works of SOC (see e.g. Umar et al., 2012) the dynamic validation of the results is usually performed by means of decentralized PI controllers (Araujo and Skogestad, 2008).

The first objective of this work is to find the self-optimized variables in a WWTP as a combination of measurements, and the second objective is to evaluate the dynamic behavior of those variables by implementing two control structures: a centralized nonlinear multivariable model predictive controller (NMPC) and a distributed control structure with an NMPC and local PI controllers. The methodology explained has been applied to the activated sludge process using the Benchmark Simulation Model No. 1 (BSM1) (Alex et al., 2008).

2. Local methods for self-optimizing control

The controlled variables selection, particularly for SOC, is a fundamental issue within the plant-wide design. The first step of the methodology is the determination of the optimal operation, assuming here that the economics of the plant are primarily determined by steady state behavior. The following problem is solved, considering nominal disturbances:

$$\min_{\mathbf{u}_0} J_0\left(\mathbf{x},\mathbf{u}_0,\mathbf{d}\right) \tag{1}$$

subject to:

$$\mathbf{g}_1\left(\mathbf{x},\mathbf{u}_0,\mathbf{d}\right)=0\,;\ \mathbf{g}_2\left(\mathbf{x},\mathbf{u}_0,\mathbf{d}\right)\le 0$$

where $\mathbf{x}$ is the state vector, $\mathbf{u}_0$ is the manipulated variables vector (degrees of freedom), $\mathbf{d}$ is the disturbances vector, $\mathbf{g}_1$ is a vector function representing the process model equations and $\mathbf{g}_2$ the process constraints. The active constraints found when solving problem (1) must be controlled tightly for optimal operation (active constraints control), and in this work it is assumed that the set of active constraints does not change for all typical disturbances.

Then, the identification of as many economic controlled variables as the number of remaining degrees of freedom is performed, by using the SOC methodology explained below. The selection is based on the Taylor expansion of the loss function around the equilibrium nominal point $\mathbf{u}_{opt}(\mathbf{d})$:

$$L\left(\mathbf{u},\mathbf{d}\right)=J_c\left(\mathbf{u},\mathbf{d}\right)-J_{opt}\left(\mathbf{u}_{opt}(\mathbf{d}),\mathbf{d}\right)=\frac{1}{2}\left[\mathbf{u}-\mathbf{u}_{opt}(\mathbf{d})\right]^T\mathbf{J}_{uu}\left[\mathbf{u}-\mathbf{u}_{opt}(\mathbf{d})\right] \tag{2}$$

where J_c is the cost value when the set point is kept constant, and J_{opt} is the optimum cost re-optimizing for the corresponding $\mathbf{d}$, $\mathbf{u}_{opt}$ is the optimum value for $\mathbf{u}$ and $\mathbf{J}_{uu}$ is the Hessian of the cost function.

In order to achieve near-optimal operation without the need to re-optimize the process when disturbances occur, the loss must be minimized. Although CV can be selected as a subset of the available measurements, lower loss is achieved by selecting CV as linear combinations of measurements. For that reason, a combination matrix $\mathbf{H}$ with real coefficients is defined as $\mathbf{c}=\mathbf{H}\cdot\mathbf{y}$, where $\mathbf{c}$ is the vector of controlled variables and $\mathbf{y}$ is the vector of available independent measurements, that can include manipulated variables (e.g. flow rate measurements) or measured disturbances. The matrix $\mathbf{H}$ can be found through minimization of the following expression (Halvorsen et al., 2003; Alstad et al., 2009):

$$\min_{\mathbf{H}} \left\| \mathbf{J}_{uu}^{1/2} \left(\mathbf{H}\mathbf{G}^{y} \right)^{-1} \mathbf{H}\mathbf{Y} \right\|_{F} \tag{3}$$

where $\mathbf{Y} = \begin{bmatrix} \mathbf{F}\mathbf{W}_d & \mathbf{W}_e \end{bmatrix}$; $\mathbf{F} = \mathbf{G}_d^{y} - \mathbf{G}^{y}\mathbf{J}_{uu}^{-1}\mathbf{J}_{ud}$; $\mathbf{y} = \mathbf{G}^{y}\mathbf{u} + \mathbf{G}_d^{y}\mathbf{d}$, $\mathbf{W}_d$ and $\mathbf{W}_e$ are scaling matrices for disturbances and implementation errors, $\mathbf{G}^{y}$ and $\mathbf{G}_d^{y}$ are the process transfer matrices (linearized model) , and $\mathbf{J}_{uu}$, $\mathbf{J}_{ud}$ are the hessians.

For problem (3), explicit solutions have been developed, where **Q** is any nonsingular matrix of n_c x n_c (n_c = No. of controlled variables) (Yelchuru and Skogestad, 2011)

$$\mathbf{H}^{T} = \left(\mathbf{Y}\mathbf{Y}^{T} \right)^{-1} \mathbf{G}^{y}\mathbf{Q} \tag{4}$$

3. Methodology applied to the BSM1

3.1. Description of the process

The benchmark simulation model nº 1 (BSM1) (Alex et al., 2008) has been used as a standard activated sludge process model in a WWTP for performance assessment of control strategies and optimization. It consists of five biological reactors connected in series and one secondary settler. The reactors are modeled according to mass balances described in the Activated Sludge Model nº 1 (ASM1), developed by the IWAQ (International Association on Water Quality). An internal recycle (Q_a) from the last tank to the first one is used to supply the denitrification step with nitrate. In order to maintain the microbiological population, sludge from the settler is recirculated into the reactors by means of an external recycle (Q_r), and sludge excess is purged from the bottom of the settler (Q_w). Note that in this benchmark no pH control is considered. More details are given in Alex et al. (2008).

3.2. Operational objectives and constraints

The operational objectives of the WWTP include operational costs and other process and regulations constraints. The cost defined in Alex et al. (2008) has been considered:

$$J = k_E \left(AE + PE + ME \right) + k_D SP \tag{5}$$

where *PE* is the pumping energy, *AE* is the aeration energy, *ME* is the mixing energy, *SP* is the sludge production, and k_E, k_D are the weights representing prices. The constraints needed for process operability are listed in table 1, where COD_e is the chemical oxygen demand, $BOD_{5,e}$ is the 5 day biological oxygen demand, TSS_e is the total suspended solids concentration, and TN_e is the total nitrogen concentration, all measured in the effluent.

For the BSM1 there are eight manipulated variables that correspond to eight degrees of freedom (**u**): Q_a, Q_r, Q_w, $K_La^{(1\text{-}5)}$. The disturbances selected are some of the most important inputs to the plant: $Q^{(in)}$, $COD^{(in)}$, $TSS^{(in)}$. $TN^{(in)}$ is not considered in the methodology in order to simplify the results, but it is inclusion is straightforward. The weather profile events specified in the BSM1 derive the following disturbance vectors: $\mathbf{d}_0$ corresponds to the nominal load conditions, $\mathbf{d}_1$ are the average load values during the rainy weather, $\mathbf{d}_2$ are the average values only for a rain event (extracted from the rain BSM1 disturbances), $\mathbf{d}_3$ are the average during the whole period for storms, $\mathbf{d}_{42}$ are the average values during a storm, $\mathbf{d}_5$ are the average values for one year with average temperature.

Table 1: Process constraints

Effluent constraints and constraints on manipulated variables		
$COD_e \leq 100$ (gCOD/m^3)	$TSS_e \leq 30$ (gSS/m^3)	$Q_w \leq 1844.6$ (m^3/d)
$BOD_{5,e} \leq 10$ (gBOD/m^3)	$S_{NH\,e} \leq 4$ (gN/m^3)	$Q_a \leq 92230$ (m^3/d)
$TN_e \leq 18$ (gN/m^3)	$0 \leq KLa_{1-5} \leq 360$ (1/d)	$Q_r \leq 36892$ (m^3/d)

The nominal optimal operating point has been obtained solving problem (1) for the WWTP, considering cost function (5) and constraints of table 1. This optimization has also been performed for different disturbances, always showing the same three active constraints Q_a (m^3/d)=0, S_{NH_e} (g/m^3)=4, TSS_e (g/m^3)=30. Two of them are output active constraints, so they will be linked to two degrees of freedom, remaining 5 available degrees of freedom.

For the selection of the five self-optimized variables, the Eq. (4) with matrix **Q** selected as the identity has been considered to obtain the corresponding matrix **H**. The initial set of measurements selected has been taken out of Alex et al. (2008), adding also the inputs and disturbances as measurements. In this work, a previous selection of measurements has been performed, very useful to avoid infeasibilities for the CV variables selected later (Larsson et al., 2001). The economic losses have been calculated with Eq. (2) for different weather conditions using the nonlinear model of the process, considering individual measurements. The primary CV candidate variables that make the process infeasible for some load disturbances have been removed, which are in this case S_{NH} for all reactors. Then, based on this study, several sets of measurements have been considered, giving different combination matrices **H**. In order to select the most suitable, as SOC procedure is local, nonlinear losses have been obtained for each set (Table 2) and only $\mathbf{H_3}$ gives feasible solutions for all disturbances.

Set 1 ($\mathbf{H}_1$): $S_O^{(1)}, S_{NO}^{(1)}, S_O^{(5)}, S_{NO}^{(5)}, Q^{(in)}, COD^{(in)}, TSS^{(in)}, K_L a^{(5)}, Q_r$

Set 2 ($\mathbf{H}_2$): $S_O^{(1)}, ..., S_O^{(5)}, S_{NO}^{(1)}, ..., S_{NO}^{(5)}, Q^{(in)}, COD^{(in)}, TSS^{(in)}, MLSS, K_L a^{(5)}, Q_r$

Set 3 ($\mathbf{H}_3$): $S_O^{(1)}, ..., S_O^{(5)}, S_{NO}^{(1)}, ..., S_{NO}^{(5)}, Q^{(in)}, COD^{(in)}, TSS^{(in)}, K_L a^{(5)}, Q_r$

Table 2: Nonlinear losses for different combination matrices and disturbances

	$\mathbf{d}_1$	$\mathbf{d}_2$	$\mathbf{d}_3$	$\mathbf{d}_{42}$	$\mathbf{d}_{43}$	$\mathbf{d}_5$
$\mathbf{H}_1$	Infeas	Infeas	Infeas	Infeas	Infeas	Infeas
$\mathbf{H}_2$	0.223	Infeas	0.127	Infeas	Infeas	1.229
$\mathbf{H}_3$	0.038	0.627	0.069	1.182	0.821	0.300

4. Process controllability analysis

In this section, the dynamic behavior of the selected CV as combination of measurements defined by $\mathbf{H}_3$ is evaluated. This study is important in order to validate the possible implementation of a controller which keeps the selected CV at optimal set points in spite of influent disturbances. The first control structure considered is a

centralized multivariable nonlinear constrained MPC for controlling the active constraints and the self-optimized variables, with the full BSM1 as internal prediction model, and the following objective function:

$$V(k)=\sum_{i=H_w}^{H_p}\left\|\mathbf{y}(k+i\mid k)-\mathbf{r}(k+i\mid k)\right\|_{\mathbf{Q}}^2+\sum_{i=0}^{H_c-1}\left\|\Delta\mathbf{u}(k+i\mid k)\right\|_{\mathbf{R}}^2+\left\|\mathbf{y}(k+H_p\mid k)-\mathbf{r}(k+H_p\mid k)\right\|_{\mathbf{P}}^2$$

where **y** are the controlled outputs, **u** the manipulated variables and **r** the reference, k denotes the current sampling point, $\mathbf{y}(k+i\mid k)$ is the predicted output at time $k+i$, depending of measurements up to time k, $\Delta\mathbf{u}$ are the changes in the manipulated variables, H_c is the control horizon, H_w and H_p are the initial and final prediction horizons respectively, **R** and **Q** are positive definite constant matrices, and **P** is the terminal weight. A second control structure with two PI controllers for the active constraints and the NMPC to control the self-optimized variables has been considered. This control structure has the advantage that if the MPC fails, the PI controllers still keep set points for the active constraints. For selecting a good pairing for the PIs, the RGA matrix has been studied; TSS_e is controlled with Q_w and $S_{NH,e}$ is controlled with $K_La^{(5)}$.

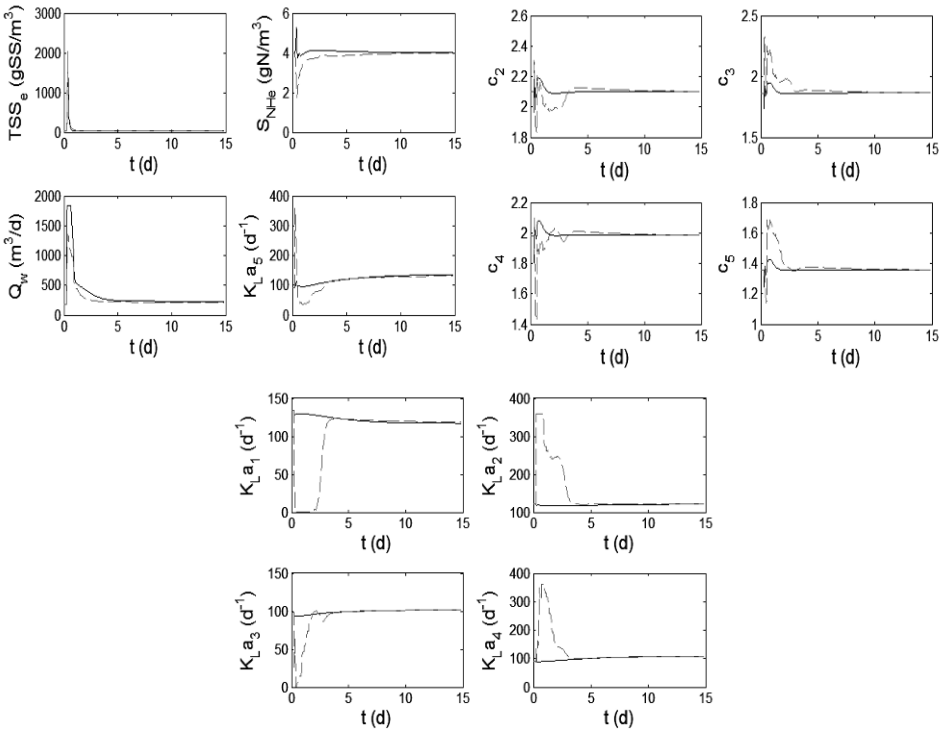

Figure 1: Control performance comparison of NMPC-PI control structure (solid line) and centralized NMPC (dashed line) for rain event disturbance ($\mathbf{d}_2$) at t=0. Active constraints control (top left), self-optimized variables (top right) and manipulated variables (bottom).

In Fig. 1 the dynamic responses are presented, comparing the performance of the control structures when a $\mathbf{d}_2$ step disturbance is applied. They show a good set point tracking both for active constraints and selfoptimized variables, with reasonable control actions. The selfoptimized variable c_1 is not presented because its significance in costs

is negligible. The tuning of the NMPC has been performed by trial and error procedure, choosing $\mathbf{Q}$ = diag(0.1 1 0.001 2 2 2 2) and $\mathbf{R}$ = diag(0.1 0.014 0.014 0.014 0.014 0.014 0.005) for the centralized NMPC; and $\mathbf{Q}$ = diag(0.001 2 2 2 2), $\mathbf{R}$ = diag(0.05 0.01 0.01 0.01 0.01) for the distributed NMPC-PI control. The horizons for both control structures are $H_w = 1$, $H_p = 20$ and $H_c = 1$ .The tuning parameters for the PI control No.1 are K_p= -54.8,T_i= -27.4 and K_p= -12,T_i= -0.2 for No. 2, the first one selected by SIMC guidelines (Skogestad, 2003). For simplicity in the comparative dynamic analysis, the manipulated variables have not been considered in the linear combinations determined by $\mathbf{H}_3$.

5. Conclusions

In this work, the SOC methodology has been applied to find the optimum controlled variables as a combination of measurements in a WWTP. A previous prescreening of measurements to avoid unfeasibilites for large load disturbances has been performed. The dynamic controllability of these variables has also been studied, by implementing two control structures. The results show that both control structures give good set point tracking, despite of a long transient due to the slow process dynamics, particularly for the most severe disturbances. The distributed MPC-PI control shows better transient, particularly for large disturbances, because of the separate treatment of the different time scales of the process and the easier tuning compared to the centralized NMPC.

Abstract

Polymerization processes usually contain some uncertain parameters such as those in kinetic rate constants and heat transfer coefficients. An inefficient handling of these uncertain parameters may lead to unexpected thermal runaway of the reaction. In this paper, off-line tube-based robust model predictive control (MPC) is developed. The trajectories of uncertain systems are restricted to lie in a sequence of tubes so robust stability and constraint satisfaction are guaranteed in the presence of both uncertain parameters and disturbances. All of the optimization problems are solved off-line so the proposed algorithm is applicable to fast dynamic polymerization processes. The proposed algorithm is applied to an illustrative example of continuous stirred tank reactor where highly exothermic polymerization reactions occur. The results show that robust stability and constraint satisfaction are guaranteed.

Keywords: Tube-based robust model predictive control; polymerization processes; uncertain parameters; disturbances

1. Introduction

Chemical processes are usually involved with complex chemical reactions. These reactions usually contain some uncertain parameters and disturbances. In order to efficiently control uncertain chemical processes, a multivariable control algorithm that can handle both uncertain parameters and disturbances needs to be developed (Lee, 2011).

Polymerization process is one of the chemical processes that usually contain some uncertain parameters such as those in reaction rate constants and heat transfer coefficients (Gao et al., 2013). Moreover, the polymerization process usually contains some disturbances such as measurement noises. Since most of the polymerization processes are highly exothermic, inefficient handling of these uncertain parameters and disturbances may lead to unexpected thermal runaway of the system (Shamiri et al., 2013). For this reason, it is necessary to develop an efficient multivariable control algorithm for uncertain polymerization process that is able to ensure both robust stability and constraint satisfaction in the presence of uncertain parameters and

disturbances. Additionally, it should be able to handle fast dynamics of exothermic polymerization reactions.

In this paper, an off-line tube-based robust MPC algorithm is developed. Both robust stability and constraint satisfaction are guaranteed in the presence of uncertain parameters and disturbances. Moreover, all of the optimization problems are solved off-line so the developed MPC algorithm is applicable to fast dynamic processes. This paper is organized as follows. The problem description is presented in Section 2. The off-line tube-based robust MPC algorithm is developed in Section 3. An illustrative example is presented in Section 4. The conclusions are drawn in Section 5.

Nomenclature: Given two subsets X and Y of $\mathbb{R}^n$, Minkowski set addition is defined as $X \oplus Y := \{x+y \mid x \in X, y \in Y\}$ and Minkowski set difference is defined as $X \ominus Y := \{x \mid x \oplus Y \subseteq X\}$.

2. Problem Description

Consider the following discrete-time system subject to uncertain parameters and disturbances

$$x^+ = A^\lambda x + B^\lambda u + w \tag{1}$$

where $x \in \mathbb{R}^n$ is the vector of states, $u \in \mathbb{R}^m$ is the vector of control inputs, $w \in \mathbb{R}^n$ is the vector of bounded disturbances and $x^+ \in \mathbb{R}^n$ is the vector of successor states. The system is subject to the constraints $x \in \mathbb{X}$, $u \in \mathbb{U}$ and $w \in \mathbb{W}$ where $\mathbb{X} \subset \mathbb{R}^n$, $\mathbb{U} \subset \mathbb{R}^m$ and $\mathbb{W} \subset \mathbb{R}^n$ are compact, convex and each set contains the origin as an interior point. The matrices A^λ and B^λ satisfy

$$[A^\lambda \; B^\lambda] \in \text{Conv}\{[A_1 \; B_1], \ldots [A_L \; B_L]\} \tag{2}$$

where Conv denotes the convex hull, $[A_j \; B_j]$ are vertices of the convex hull and L is the number of vertices of the convex hull. Any $[A^\lambda \; B^\lambda]$ can be written as

$$[A^\lambda \; B^\lambda] = \sum_{j=1}^{L} \lambda_j [A_j \; B_j] \tag{3}$$

where $\lambda = [\lambda_1, \lambda_2, \ldots \lambda_L]$ is the vector of uncertain parameters satisfying $\sum_{j=1}^{L} \lambda_j = 1$. The objective is to robustly stabilize the system (1) while satisfying all of the state and input constraints. The presence of additive bounded disturbances means it is only possible to drive the states to the neighborhood of the origin.

3. Off-Line Tube-Based Robust MPC Algorithm

In this section, an off-line tube-based robust MPC algorithm is developed. The trajectories of uncertain systems subject to disturbances are restricted to lie in a sequence of tubes so robust stability and constraint satisfaction are guaranteed. Additionally, all of the optimization problems are solved off-line so the developed

algorithm is applicable to fast dynamic processes. Let the nominal system (the system with no uncertain parameters and disturbances) be defined by

$$\bar{x}^{+} = A\bar{x} + B\bar{u} \tag{4}$$

where $A = \frac{1}{L}\sum_{j=1}^{L} A_j$, $B = \frac{1}{L}\sum_{j=1}^{L} B_j$, $\bar{x} \in \mathbb{R}^n$ is the vector of nominal states and $\bar{u} \in \mathbb{R}^m$ is the vector of nominal control inputs. The predicted nominal states and nominal control inputs when the initial state is $\bar{x}_0$ are denoted by $\bar{\mathbf{x}} := \{\bar{x}_0, \bar{x}_1, \ldots, \bar{x}_N\}$ and $\bar{\mathbf{u}} := \{\bar{u}_0, \bar{u}_1, \ldots, \bar{u}_{N-1}\}$, respectively where N is the prediction horizon. Consider the following difference equation between (1) and (4)

$$x^{+} - \bar{x}^{+} = A(x - \bar{x}) + B(u - \bar{u}) + d \tag{5}$$

where the artificial disturbance d is defined as $d := (A^{\lambda} - A)x + (B^{\lambda} - B)u + w$. Since $x \in \mathbb{X}$, $u \in \mathbb{U}$ and $w \in \mathbb{W}$, it is seen that $d \in \mathbb{D}$ where $\mathbb{D} := (A^{\lambda} - A)\mathbb{X} \oplus (B^{\lambda} - B)\mathbb{U} \oplus \mathbb{W}$. In order to counteract the effect of disturbance, the control law $u = K(x - \bar{x}) + \bar{u}$ is employed where K is the disturbance rejection gain. The system (5) can be rewritten as

$$x^{+} - \bar{x}^{+} = (A + BK)(x - \bar{x}) + d. \tag{6}$$

If the disturbance rejection gain K is chosen such that $(A^{\lambda} + B^{\lambda}K)^T P (A^{\lambda} + B^{\lambda}K) - P < 0$, $\forall [A^{\lambda} \; B^{\lambda}] \in \mathrm{Conv}\{[A_1 \; B_1], \ldots, [A_L \; B_L]\}$ where P is a Lyapunov matrix, then we can bound $x^{+} - \bar{x}^{+}$ by a robust positively invariant set Z satisfying $(A + BK)Z \oplus \mathbb{D} \subseteq Z$, $\forall (x - \bar{x}) \in Z$ and $\forall d \in \mathbb{D}$. It is desirable that Z be as small as possible. The minimal Z can be calculated as

$$Z = \bigoplus_{i=0}^{\infty} (A + BK)^i \mathbb{D} = \mathbb{D} \oplus (A + BK)\mathbb{D} \oplus (A + BK)^2 \mathbb{D} \oplus (A + BK)^3 \mathbb{D} \oplus \ldots\ldots \tag{7}$$

The method to approximate the minimal Z in (7) can be found in Raković et al. (2005). In order to ensure the satisfaction of the original state and input constraints $x \in \mathbb{X}$ and $u \in \mathbb{U}$, the tighter constraint sets for the nominal system (4) are employed $\bar{x}_i \in \mathbb{X} \ominus Z$, $\bar{u}_i \in \mathbb{U} \ominus KZ$ for $i \in \{0, \ldots, N-1\}$. In order to ensure robust stability, an additional terminal constraint is employed $\bar{x}_N \in \bar{X}_f \subset \mathbb{X} \ominus Z$ where $\bar{X}_f$ is the terminal constraint set satisfying the usual assumptions (Mayne et al., 2005). Since we can bound $x^{+} - \bar{x}^{+}$ by a robust positively invariant set Z, we can control the nominal system $\bar{x}^{+} = A\bar{x} + B\bar{u}$ in such a way that the uncertain system with disturbance $x^{+} = A^{\lambda}x + B^{\lambda}u + w$ is robustly stabilized while all of the original state and control

constraints are satisfied. At each sampling time, the state x is measured and the following optimization problem is solved on-line

$$\min_{\bar{x}_0,\bar{\mathbf{u}}} \sum_{i=0}^{N-1} \frac{1}{2}(\bar{x}_i^T Q \bar{x}_i + \bar{u}_i^T R \bar{u}_i) + \frac{1}{2}\bar{x}_N^T P_f \bar{x}_N \tag{8}$$

$$\text{s.t. } x \in \bar{x}_0 \oplus Z \tag{9}$$

$$\bar{x}_{i+1} = A\bar{x}_i + B\bar{u}_i,\ i \in \{0,\ldots,N-1\} \tag{10}$$

$$\bar{x}_i \in \mathbb{X} \ominus Z,\ \bar{u}_i \in \mathbb{U} \ominus KZ,\ i \in \{0,\ldots,N-1\} \tag{11}$$

$$\bar{x}_N \in \bar{X}_f \tag{12}$$

where Q, R and P_f are positive definite weighting matrices. Then, the control law $u = K(x - \bar{x}) + \bar{u}$, $\bar{x} = \bar{x}_0$, $\bar{u} = \bar{u}_0$ is implemented to the process.

On-line tube-based robust MPC is computationally demanding because the on-line optimization problem (8) must be solved at each sampling time. The recent advances in multi-parametric optimization (Kvasnica et al., 2004) make it possible to reduce such high on-line computational time. In order to reduce on-line computational burdens, off-line tube-based robust MPC can be formulated as follows

Algorithm 3.1

Off-line: Solve the optimization problem (8) off-line using the Multi-Parametric Toolbox (Kvasnica et al., 2004) to find the explicit nominal control inputs $\bar{u}$ corresponding to the regions of $\bar{x}$.

On-line: At first sampling time ($t = 0$), measure the state x and find $\bar{u}$ corresponding to the region of x (at the first sampling time $x = \bar{x}$). Apply the control law $u = \bar{u}$ to the process and calculate $\bar{x}^+$ from $\bar{x}^+ = A\bar{x} + B\bar{u}$.

At each sampling time ($t > 0$), find $\bar{u}$ corresponding to the region of $\bar{x}$ which is calculated from the previous step. Measure the state x and apply the control law $u = K(x - \bar{x}) + \bar{u}$ to the process. Then, calculate $\bar{x}^+$ from $\bar{x}^+ = A\bar{x} + B\bar{u}$.

4. An Illustrative Example

This section illustrates the implementation of the developed off-line tube-based robust MPC algorithm. The polymerization reaction is assumed to take place in a continuous stirred tank reactor where a cooling coil is used to remove heat from the exothermic reaction. The reaction rate constant (k_o) and the heat of reaction (ΔH_{rxn}) are

considered to be two uncertain parameters. The behaviour of the reactant concentration ($\overline{C}_A$) and the reactor temperature ($\overline{T}$) can be described as

$$\begin{bmatrix} \overline{C}_A(k+1) \\ \overline{T}(k+1) \end{bmatrix} = \begin{bmatrix} 0.85-0.0986\alpha(k) & -0.0014\alpha(k) \\ 0.9864\alpha(k)\beta(k) & 0.0487+0.01403\alpha(k)\beta(k) \end{bmatrix} \begin{bmatrix} \overline{C}_A(k) \\ \overline{T}(k) \end{bmatrix} + \begin{bmatrix} 0.15 & 0 \\ 0 & -0.912 \end{bmatrix} \begin{bmatrix} \overline{C}_{A,F}(k) \\ \overline{F_C}(k) \end{bmatrix} + \begin{bmatrix} 1 \\ 1 \end{bmatrix} 0.01\sin k \tag{13}$$

Where $\overline{C}_{A,F}(k)$ is the feed concentration of reactant and $\overline{F_C}(k)$ is the coolant flow rate. The uncertain parameters $1 \le \alpha(k) = k_o / 10^9 \le 10$ and $1 \le \beta(k) = -\Delta H_{rxn} / 10^7 \le 10$ are randomly time-varying within the predefined range. The state constraint is $\overline{T}(k) \le 7$ K. The input constraints are $\left|\overline{C}_{A,F}(k)\right| \le 0.1$ kmol/m^3 and $\left|\overline{F_C}(k)\right| \le 1$ m^3/min. Figure 1 shows the regions of state computed off-line by Algorithm 3.1.

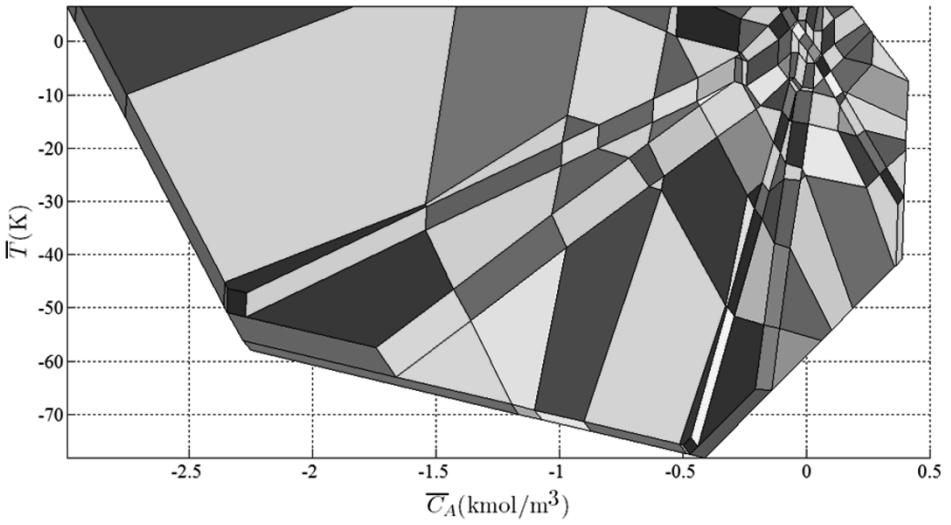

Figure 1 The regions of state computed off-line

Figure 2 shows the state trajectories. The infeasible region of the state constraint is shown in yellow. A sequence of tubes (Z) are shown in green. The trajectory of the uncertain system with disturbances (13) is shown in red line. The trajectory of the nominal system (the system with no uncertain parameters and disturbances) is shown in black line. Starting from the initial point of $(0.2,\ 5)$, the trajectory of uncertain system with disturbances is restricted to lie in a sequence of tubes so robust stability and constraint satisfaction are guaranteed.

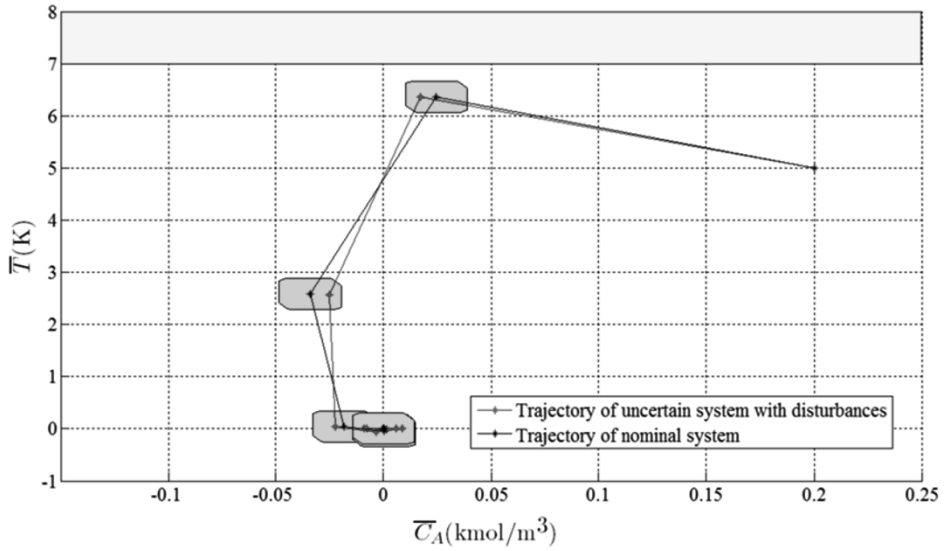

Figure 2 The state trajectories

5. Conclusions

In this paper, off-line tube-based robust MPC is developed. Robust stability and constraint satisfaction are guaranteed in the presence of both uncertain parameters and disturbances. The developed algorithm is applied to an illustrative example of uncertain continuous stirred tank reactor where highly exothermic polymerization reactions occur. The results show that the state trajectory is restricted to lie in a sequence of tubes.

Abstract

Bayesian state estimation for constrained nonlinear systems involves two main issues: (i) appropriate representation of the underlying non-Gaussian densities, and (ii) use of appropriate techniques to bound the estimates so that they satisfy the give constraints. In this work we present a new constrained state estimation approach, named as Optimization based Constrained Unscented Gaussian Sum Filter. The proposed approach uses Unscented Gaussian Sum Filter to represent the non-Gaussian densities and an optimization approach to incorporate the state constraints. Benefits of the proposed approach are illustrated by applying it to a benchmark case study.

Keywords: Unscented transformation, Unscented Gaussian sum filter, Sum of Gaussians

1. Introduction

Recursive Bayesian estimation for nonlinear dynamical systems uses process and measurement models along with available process measurements to obtain conditional density of states. These process models are often derived from first principles, that is material and energy balances, and are typically nonlinear. Further, the process states inherently satisfy thermodynamic properties/constraints, for e.g. mole fraction of individual species/components in a multi component mixture are positive and their sum is unity. Hence, a practical nonlinear constrained state estimation approach should have the following two features: (i) an ability to approximate non-Gaussian densities arising out of nonlinear transformation or non-Gaussian noise, and (ii) an ability to incorporate constraints on the state estimates.

Several nonlinear state estimation approaches such as Extended Kalman Filter (EKF) (Anderson and Moore, 1979), Unscented Kalman Filter (UKF) (Julier and Uhlmann, 2004), Ensemble Kalman Filter (EnKF) (Gillijns et al., 2006), Gaussian Sum Filters (Sorenson and Alspach, 1971) and Particle Filters (Arulampalam et al., 2002) have been reported in literature that account for the nonlinear transformations and/or the non-Gaussian nature of the densities. While EKF involves linearization of the nonlinear process and measurement models, other approaches utilize deterministically or randomly chosen samples thereby avoiding the explicit linearization. Among these sampling based approaches, UKF is based on unscented transformation (UT) that requires only $(2n+1)$ deterministically chosen sigma points, with n being the number of states. This use of limited number of samples opens up possibilities of applying UKF for solving practical (industrial) state estimation problems (Kolas et al., 2009; Vachhani et al., 2006). However, similar to Kalman Filter (Kalman, 1960), UKF also assumes that the underlying probability densities are Gaussian, an assumption commonly violated for nonlinear systems and/or non-Gaussian noise.

In literature, a few modifications of UKF have been proposed that avoid the Gaussianity assumption. In particular, Gaussian-sum UKF (GS-UKF) (Šimandl and Duník, 2006) is based on the

result that a sum of Gaussians can approximate any density to an arbitrary degree of accuracy (Sorenson and Alspach, 1971). GS-UKF uses $N(2n+1)$ sigma points to obtain a sum of Gaussians based representation of non-Gaussian prior, where N refers to the number of Gaussians used and is a user defined parameter. Recently Unscented Gaussian Sum Filter (UGSF) (Kottakki et al., 2014) has been proposed that enables a sum of Gaussians representation of the non-Gaussian prior using only $2n+1$ sigma points. In particular, the computational effort in UGSF is similar to that in UKF and it can thus be potentially applied to practical systems (Kottakki et al., 2014). The sum of Gaussians prior in UGSF is subsequently updated using Bayes' rule. The updated Gaussian sum posterior in UGSF is reapproximated as a single Gaussian at the next time instant using the first two moments of the updated Gaussian sum density. This reapproximation avoids degeneracy of the individual Gaussians in the sum of Gaussians representation. Implementation on several case studies demonstrated superior performance of UGSF when compared to UKF. While UGSF addresses the issue of non-Gaussianity of the prior density, it does not incorporate constraints on the state estimates making them potentially infeasible and thus unusable.

In this work, we propose an extension of the UGSF approach so that it can effectively incorporate state constraints in the estimation procedure. This is achieved by modifying the sigma point generation step to incorporate constraints as well as using explicit constrained optimization formulation to obtain the posterior density. The resulting approach is labeled as Optimization Based Constrained Unscented Gaussian Sum Filter (OCUGSF). In particular, the proposed OCUGSF solves $2n+1$ optimization problems to obtain a constrained posterior estimate.

Organization of this paper is as follows: Problem statement with a brief summary of elements used in the proposed method is presented in Section 2 and Section 3, respectively. Benefits of the proposed OCUGSF are demonstrated by comparing its performance with other state estimation techniques on a benchmark three state isothermal batch reactor case study in Section 4. The paper is concluded in Section 5.

2. Problem Statement

Consider a sampled data system consisting of nonlinear process dynamics, a linear measurement function and interval constraints on the states as,

$$x(t_k) = x(t_{k-1}) + \int_{t_{k-1}}^{t_k} f(x(t),u(t))dt + w_k, \quad w_k \sim \mathcal{N}(0,Q) \tag{1}$$

$$y_k = Hx(t_k) + v_k, \; v_k \sim \mathcal{N}(0,R) \tag{2}$$

$$d_k \leq x_k \leq e_k \tag{3}$$

where, $x(t) \in \mathbb{R}^n$, $u(t) \in \mathbb{R}^p$, represent the state and input vectors at time t while $y_k \in \mathbb{R}^m$, $w_k \in \mathbb{R}^n$, $v_k \in \mathbb{R}^m$ represent observation, state noise and measurement noise, respectively at time t_k. Function $f : \mathbb{R}^n \times \mathbb{R}^p \to \mathbb{R}^n$ represents the nonlinear state dynamics and $H \in \mathbb{R}^{mxn}$ represents the linear observation model. Measurements y_k are assumed to be available at regularly spaced sampling instants t_k, at $k = 0,1,2,3,\ldots$ with $T_s = t_k - t_{k-1}$ being the sampling interval. For ease of notation, we define $x_k \triangleq x(t_k)$. Eq.(3) specifies the interval constraints on each component of state vector x. The problem is to find a point estimate for x_k, whose dynamics are described in Eq.(1), using available measurements $Y_k = y_1,\ldots,y_k$, in Eq.(2) subject to the interval constraints given in Eq.(3). We limit our attention to the linear measurement model Eq.(2) for ease of presentation. For nonlinear measurement models, the UGSF approach can be extended (Kottakki et al., 2014) using ideas presented in the current work. Now we briefly review the proposed OCUGSF for the given system (Eqs.(1), (2)) and the state constraints (Eq.(3)).

3. Optimization Based Constrained Unscented Gaussian Sum Filter (OCUGSF)

The proposed OCUGSF approach uses a three step framework to obtain constrained state estimate for the problem (Eqs.(1) to (3)). These steps are: (i) use of Interval Constrained Unscented Transformation (ICUT) approach (Vachhani et al., 2006) to generate the constrained sigma points from the given posterior density, (ii) propagation of sigma points through the process model, and (iii) a constrained optimization based update step. These are discussed next.

3.1. Interval Constrained Unscented Transformation (ICUT) Based Sigma Point Generation:

Given that the random variable x_{k-1} has a Gaussian distribution with mean $\hat{x}_{k-1|k-1}$ and covariance $P_{k-1|k-1}$ at time t_{k-1}, the Interval Constrained Unscented Transformation approach deterministically selects $2n+1$ constrained sigma points and corresponding weights as (Vachhani et al., 2006),

$$\chi^{(i),c}_{k-1|k-1} = \begin{cases} \hat{x}_{k-1|k-1}, & w^{(i),c} = b_{k-1}, \quad i = 0 \\ \hat{x}_{k-1|k-1} + \theta_{i,k-1}[\sqrt{P_{k-1|k-1}}]i, & w^{(i),c} = a_{k-1} + \theta_{i,k-1}b_{k-1}, \quad i = 1,\ldots,n \\ \hat{x}_{k-1|k-1} - \theta_{i,k-1}[\sqrt{P_{k-1|k-1}}]i{-}n, & w^{(i),c} = a_{k-1} + \theta_{i,k-1}b_{k-1}, \ i = n+1,\ldots,2n \end{cases} \tag{4}$$

$$a_{k-1} = \frac{(2\kappa - 1)}{2(n+\kappa)\big[\sum_{i=1}^{2n}\theta_{i,k-1} - (2n+1)\sqrt{n+\kappa}\big]}, \ \ b_{k-1} = \frac{1}{2(n+\kappa)} - a_{k-1}\sqrt{n+\kappa} \tag{5}$$

$$\theta_{i,k-1} = \min_{1\le j\le n}(\Theta_{j,i}), \ \ i = 1,2,\ldots,2n \tag{6}$$

where, for $j = 1,2,\ldots,n;\ i = 1,2,\ldots,2n$

$$\Theta_{j,i} \triangleq \begin{cases} \sqrt{n+\kappa} & \text{if } \ S_{j,i} = 0 \\ \min\left(\sqrt{n+\kappa}, \frac{e_{j,k-1} - \hat{x}_{j,k-1|k-1}}{S_{(j,i)}}\right) & \text{if } \ S_{j,i} > 0 \\ \min\left(\sqrt{n+\kappa}, \frac{d_{j,k-1} - \hat{x}_{j,k-1|k-1}}{S_{(j,i)}}\right) & \text{if } \ S_{j,i} < 0 \end{cases} \tag{7}$$

$$\text{with } \ S \triangleq \begin{bmatrix} \sqrt{P_{k-1|k-1}} & -\sqrt{P_{k-1|k-1}} \end{bmatrix} \tag{8}$$

In Eq.(4), $\chi^{(i),c}_{k-1|k-1}, w^{(i),c}$ represent the i^{th} constrained sigma point and its corresponding weight, respectively. It can be noted that these sigma points have been projected away from the mean using a factor $\theta_{i,k-1}$. Since this factor has been chosen according to the state constraints (Eqs.(6) to (8)), the sigma points will be feasible with respect to the interval constraints Eq.(3). Further, if the constraints are not active ($d_k = -\infty$ and $e_k = +\infty$), the expressions (Eqs.(4) to (8)) result in unconstrained sigma points obtained using UT as have been reported in the literature (Julier and Uhlmann, 2004; Vachhani et al., 2006).

3.2. Prediction Step:

The constrained sigma points obtained in Eq.(4) are then transformed through the process model (Eq.(1)) to obtain the predicted sigma points as follows:

$$\chi^{(i),c}_{k|k-1} = \chi^{(i),c}_{k-1|k-1} + \int_{t_{k-1}}^{t_k} f(x(t),u(t))dt, \ \ i = 0,\ldots,2n \tag{9}$$

Without loss of generality, it is assumed that since the sigma points generated by Eq.(4) satisfy the interval constraints, the predicted sigma points $\chi^{(i),c}_{k|k-1}$ (Eq.(9)) will also satisfy these constraints. The proposed OCUGSF uses the UGSF design choices (Kottakki et al., 2014) to obtain non-Gaussian prior as a sum of Gaussians. These design choices are: (i) Number of Gaussians in prior

is the same as the number of sigma points i.e $2n+1$, (ii) $\chi^{(i),c}_{k|k-1}$ is the mean of i^{th} Gaussian in the sum of Gaussians prior, (iii) the covariance of each i^{th} Gaussian, $i=0,\ldots,2n$ is identical and equal to the process noise covariance Q and (iv) weight $w^{(i),c}$ of the i^{th} sigma point is the weight of i^{th} Gaussian, $i=0,\ldots,2n$ in the sum of Gaussians. These design choices result in a constrained non-Gaussian prior:

$$p_{x_k|Y_{k-1}}(\xi_k|Y_{k-1}) = \sum_{i=0}^{2n} w^{(i),c} \frac{1}{(2\pi)^{n/2}|Q|^{1/2}} \exp\left\{\frac{-1}{2}[\xi_k - \chi^{(i),c}_{k|k-1}]^T Q^{-1}[\xi_k - \chi^{(i),c}_{k|k-1}]\right\} \tag{10}$$

Now we illustrate a procedure to obtain a constrained posterior corresponding to the prior (Eq.(10)), measurement model (Eq.(2)) and the state constraints (Eq.(3)).

3.3. Main Contribution: Constrained Update Using Optimization

For the linear measurement model with Gaussian uncertainties (Eq.(2)), the likelihood density is given as,

$$p_{y_k|x_k,Y_{k-1}}(\zeta_k|\xi_k,Y_{k-1}) = \frac{1}{(2\pi)^{m/2}|R|^{1/2}} \exp\left\{\frac{-1}{2}[\zeta_k - H\xi_k]^T R^{-1}[\zeta_k - H\xi_k]\right\} \tag{11}$$

where $\zeta_k \in R^m$ is the random variable corresponding to the measurement y_k. Since the above likelihood density is an unconstrained Gaussian, direct application of Bayes' rule with the non-Gaussian prior (Eq.(10)) and likelihood densities (Eq.(11)), can yield an unconstrained sum of Gaussians posterior density (Vachhani et al., 2006). To avoid this situation, we propose to update the means of the individual Gaussians in the sum of Gaussians prior by using a constrained optimization formulation. This formulation replaces the conventional Bayes' rule based update step as presented by Kottakki et al. (2014). Thus the constrained updated mean $(\chi^{(i),c}_{k|k})$ and updated covariances (Ξ) of i^{th} individual Gaussians are given by,

$$\chi^{(i),c}_{k|k} = \underset{\chi_k : d_k \le \chi_k \le e_k}{arg\ min} \left[(y_k - H\chi_k)^T R^{-1}(y_k - H\chi_k) + (\chi_k - \chi^{(i),c}_{k|k-1})^T Q^{-1}(\chi_k - \chi^{(i),c}_{k|k-1})\right] \tag{12}$$

$$\Xi = Q - QH^T[HQH^T + R]^{-1}HQ \tag{13}$$

while the updated weights $\delta^{(i)}_k$ are given by,

$$\tilde{w}^{(i),c}_k = w^{(i),c} \exp\left\{-\frac{1}{2}(y_k - H\chi^{(i,c)}_{k|k-1})^T[HQH^T + R]^{-1}(y_k - H\chi^{(i,c)}_{k|k-1})\right\},\ i=0,\ldots,2n \tag{14}$$

$$\delta^{(i),c}_k = \tilde{w}^{(i),c}_k \Big/ \sum_{j=0}^{2n} \tilde{w}^{(j),c}_k,\quad i=0,\ldots,2n \tag{15}$$

Conventional Gaussian sum filters often encounter degeneracy in weights in subsequent iterations (Sorenson and Alspach, 1971). The proposed OCUGSF overcomes this problem by approximating the sum of Gaussians posterior density as a single Gaussian for subsequent step of sigma point generation at the next time instant (Kottakki et al., 2014). The mean and covariance of this single Gaussian are chosen to be the mean and covariance of the sum of Gaussians posterior density which are given as:

$$\hat{x}^c_{k|k} = \sum_{i=0}^{2n}\left[\delta^{(i),c}_k \chi^{(i),c}_{k|k}\right],\ P^c_{k|k} = \sum_{i=0}^{2n} \delta^{(i),c}_k \left[\Xi + [\chi^{(i),c}_{k|k} - \hat{x}^c_{k|k}][\chi^{(i),c}_{k|k} - \hat{x}^c_{k|k}]^T\right] \tag{16}$$

To summarize, Eqs.(4) to (16) illustrate the steps involved in the proposed OCUGSF approach for obtaining the constrained posterior moments at k^{th} time instant for the given posterior moments at $(k-1)^{th}$ time instant.

It can be shown that if the state constraints are not active, then the proposed OCUGSF approach reduces to UGSF approach. Further, if the non Gaussian prior density (Eq.(10)) is approximated by a single Gaussian instead of sum of Gaussians, then for the unconstrained and the constrained scenarios, OCUGSF reduces to the UKF (Julier and Uhlmann, 2004) and the Unscented Recursive Nonlinear Dynamic Data Reconciliation (URNDDR) (Vachhani et al., 2006; Narasimhan and Rengaswamy, 2009) approaches, respectively.

4. Results and Discussions

A three state isothermal batch process is chosen to validate the performance of proposed OCUGSF. The process involves gas-phase reversible reactions under isothermal conditions, $A \rightleftharpoons B+C,\ 2B \rightleftharpoons C$. The dynamical process and measurement models are (Kolas et al., 2009):

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \end{bmatrix} = \begin{bmatrix} -k_{c_1}x_1 + k_{c_2}x_2x_3 \\ k_{c_1}x_1 - k_{c_2}x_2x_3 - 2k_{c_3}x_2^2 + 2k_{c_4}x_3 \\ k_{c_1}x_1 - k_{c_2}x_2x_3 + k_{c_3}x_2^2 - k_{c_4}x_3 \end{bmatrix} \tag{17}$$

$$y_k = \begin{bmatrix} 32.84 & 32.84 & 32.84 \end{bmatrix} \begin{bmatrix} x_1 & x_2 & x_3 \end{bmatrix}^T \tag{18}$$

Eqs.(17) and (18) represent the nonlinear process model and linear measurement model, respectively. In Eq.(17), x_1, x_2 and x_3 represent the concentrations of the species A, B and C, respectively, and k_{c_i} $(i = 1,\ldots,4)$ represents the rate constant for i^{th} reaction. True states were generated for 100 different noise realizations consisting of 720 sampling time instants, i.e. for 180 seconds. The parameters used for true state generation and for state estimation are reported in Table 1.

Table 1: Process and simulation parameters for isothermal batch reactor (Kolas et al., 2009)

$x_0 = \begin{bmatrix} 0.5 & 0.05 & 0 \end{bmatrix}$	$k_c = \begin{bmatrix} 0.5 & 0.05 & 0.2 & 0.01 \end{bmatrix}$	$P_0 = 4I_{3\times3}$
$\Delta t = 0.25 seconds$	$Q = diag(0.001^2 \ \ 0.001^2 \ \ 0.001^2)$	$\hat{x}^2_{0\|0} = \begin{bmatrix} 0.6 & 0.1 & 0.05 \end{bmatrix}^T$
$\hat{x}^1_{0\|0} = x_0$	$d_k = \begin{bmatrix} 0.0129 & 0.0743 & 0.0243 \end{bmatrix}^T$	$e_k = \begin{bmatrix} 0.4758 & 0.3575 & 0.6601 \end{bmatrix}^T$

The performance of estimation algorithms, namely, OCUGSF, URNDDR, UGSF, and UKF are investigated for two different scenarios of initial posterior densities, i.e Case I: $\hat{x}_{0|0} = \hat{x}^1_{0|0}$ and $P_{0|0} = P_0$, and Case II: $\hat{x}_{0|0} = \hat{x}^2_{0|0}$ and $P_{0|0} = P_0$. Average of sum of the square roots of the estimation errors (ASSREE) was chosen to compare the performance of estimation algorithms and is defined as: $\text{ASSREE} = \frac{1}{100}\sum_{l=1}^{100}\left[\sqrt{\frac{1}{720}\sum_{k=1}^{720}[\hat{x}^{(l)}_{k|k} - x^{(l)}_k]^T[\hat{x}^{(l)}_{k|k} - x^{(l)}_k]}\right]$. Here $x^{(l)}_k$ and $\hat{x}^{(l)}_{k|k}$ represent the true and the estimated states for the l^{th} simulation run, respectively. The ASSREE values for four estimation algorithms along with their computational times are reported in Table 2 for both Cases I and II. The average number of constraint violations is also reported under the heading #violations in this Table. From the ASSREE values reported in Table 2, it can be observed that the proposed OCUGSF results in superior state estimates compared to the other three algorithms with higher, but acceptable computational cost. It can also be noted that OCUGSF estimates have satisfied the state constraints for all the time instants across the simulation runs. Even though the URNDDR approach has reported no constraint violation, the Gaussian approximation of non-Gaussian prior (Narasimhan and Rengaswamy, 2009) has resulted in inferior performance compared to OCUGSF. For UGSF, while the prior approximation is non-Gaussian, it has violated the state constraints at several time instances as it is an unconstrained estimator. Gaussian approximation of non-Gaussian prior and unconstrained state estimation has resulted in inferior performance of UKF. State x_2 tracking for one particular simulation run has been shown in Fig. 1 and illustrates the superior performance of OCUGSF over UKF, UGSF and URNDDR approaches.

Table 2: Performance comparison for three state isothermal batch reactor

	Case-I ($\hat{x}_{0\|0} = x_0$)			Case-II ($\hat{x}_{0\|0} = \hat{x}^2_{0\|0}$)		
Algorithm	ASSREE	#violations	CPU Seconds	ASSREE	#violations	CPU Seconds
UKF	159.39	705	0.0271	155.29	705	0.0320
UGSF	5.9164	645	0.0273	6.0094	643	0.0322
URNDDR	3.5503	0	0.1131	3.4396	0	0.1781
OCUGSF	2.1247	0	0.1400	2.7890	0	0.2172

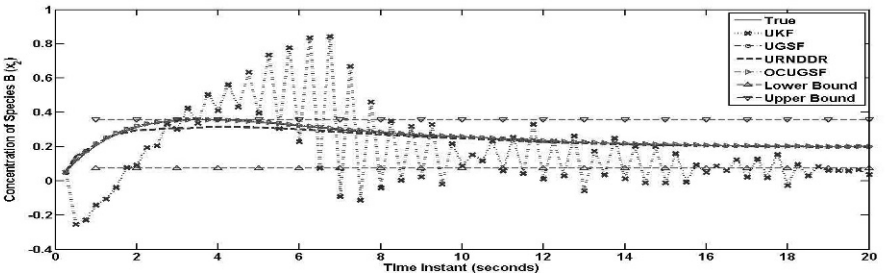

Figure 1: Tracking of state x_2 by UKF, UGSF, URNDDR and OCUGSF for Case-I ($\hat{x}_{0|0} = x_0$)

5. Conclusions

In this work, a new approach, labeled OCUGSF is proposed for constrained state estimation of nonlinear dynamical systems. The approach uses the attractive features of UGSF, in better representation of non-Gaussian densities using a sum of Gaussians, and explicitly incorporates the state constraints. Comparison with UKF, UGSF and URNDDR on a literature case study demonstrated the superior performance of the proposed OCUGSF approach.

Abstract

Control structure selection plays an important role in achieving an effective control system. Through the application of open-loop and closed-loop steady-state multiplicities, the primary goal of this paper is to obtain the best control structure from candidates selected based on heuristic reasoning for a demonstration Two-Stage-Riser Fluidized Catalytic Pyrolysis (TSRFCP) process which can maximize propylene yield without any significant losses in gasoline/diesel yields. Steady state multiplicity analysis can not only elucidate the relationships between potential manipulated variables and controlled variables over a large operational horizon but can also identify the perfect control action for tackling uncertainties in each control structure. It is illustrated that output temperatures from the two risers and the regenerator controlled by two regenerated catalyst flow rates and the cooling water flow rate, respectively, which have the best controllability characteristics and most superior dynamic behavior, are the most suitable control structure for further control system design of the studied process.

Keywords: Control structures, multiplicity, control actions, TSRFCP process.

1. Introduction

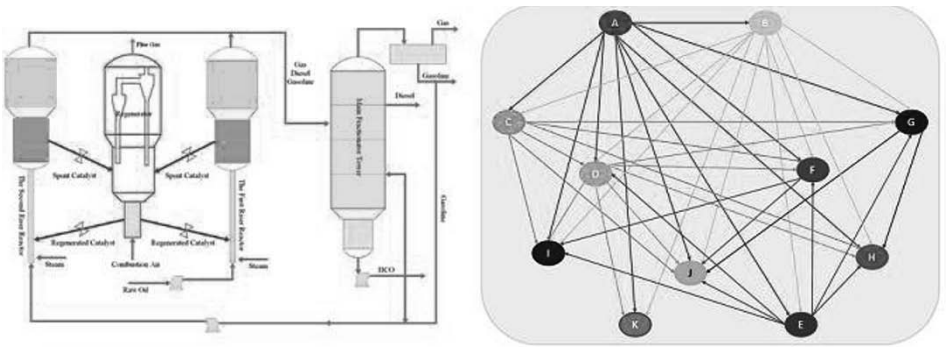

Figure 1. Schematic of the TSRFCP process and the relevant 11-lump kinetic network. (A: Heavy oil; B: Diesel; C: Alkenes; D: Aromatics; E: Paraffins; F: Butane+Propane; G: Butene; H: Propylene; I: Ethylene; J: Ethane+Methane+Hydrogen; K: Coke)

Two-Stage-Riser Fluidized Catalytic Pyrolysis (TSRFCP) for maximizing propylene yield, which applies a subsidiary riser operated under appropriate condition to reprocess crude gasoline from the main riser fed with fresh feedstock, is recognized as an efficient route to handle the expanded propylene supply/demand gap and to moderate the increased propylene price (Li *et al*., 2007). Due to strong interactions between the

exothermic reactions of catalyst regeneration in the regenerator and endothermic pyrolysis reactions in the two risers, the TSRFCP process exhibits complex nonlinear behavior which may lead to difficulties in operation. Furthermore, product quality requirements along with environmental/safety considerations drive the TSRFCP process to operate close to its operational boundaries such as minimization of dry gas yield, or maximization of propylene yield. Clearly, to increase industrial adaption, high-efficient control mechanisms for the TSRFCP process are greatly needed. Selection of the proper primary control structure, to some extent, is far more important than the detailed algorithm used in the design of the actual controllers. Based on the detailed nonlinear model of the TSRFCP process (Liu, 2008; Wang *et al*., 2014) and according to the selected control structures based on heuristic reasoning, this paper focuses on the evaluation of the selected candidates for the TSRFCP process through analyzing the steady-state multiplicity.

2. Control structure candidates

As illustrated by Figure 1, the complex pyrolysis reactions take place in two risers sharing the same regenerator. Fresh feedstock (raw oil) dispersed with steam is fed to the first-stage-riser and subjected to a certain degree of endothermic pyrolysis reactions. The recycling oil (crude gasoline and HCO) from downstream separation units dispersed with steam is introduced into the second-stage-riser under more severe pyrolysis conditions to maximize the selectivity towards light olefins and to increase the octane number of the naphtha. Changes in products from the first-stage-riser can alter the composition and properties of the feedstock for the second-stage-riser and thus affect the final product quality. For the TSRFCP process, spent catalysts with low activity and selectivity, which are separated from the gas products at the end of each riser to suppress further thermal and catalytic pyrolysis, are regenerated in the regenerator. The regenerated catalyst flows through two standpipes from the regenerator to the bottom of each riser. In the studied TSRFCP process, the regenerator is mainly comprised of two distinct regions, i.e. the dense region and the dilute region. In general, the regenerator is designed with a high-efficiency combustor and an external catalyst cooler. The combustor, where the gas and the solid flows are fast-fluidized with excess air, ensures that the coke content of regenerated catalyst is maintained at a very low level. The cooler, on the other hand, is used to remove the excess heat in the regenerator above the requirement for heat balance. Thus, the cooler helps to control regenerator temperature within a desired range especially when the feedstock contains a high percentage of carbon.

With regard to the integrated model of the TSRFCP process, the 11-lump kinetic model and the energy/mass balance equations, which were validated by experimental data sets, are two main components. Because of the short residence time of oil vapour in the two risers (1.1s~1.5s), the two risers are modelled as pseudo-steady state plug flow reactors. The regenerator system is modelled as two continuous stirred-tank reactors (CSTRs) in series. In other words, the high-efficiency combustor and the dense region of the fluidized bed reactor are modelled as CSTRs, and these parts are connected by internal circulated catalyst flows. In total, the integrated model has 34 differential equations. The detailed models can be found in (Liu, 2008; Wang *et al*., 2014).

The selection of control structure traditionally contains manipulated variable (input) selection, measurement (output) selection, and control configuration (input-output partitioning and pairing) selection (Skogestad, 2004). Compared with the control

structure selection, the control structure evaluation, which is the main purpose of this paper, is less complex. In this paper, candidates for the manipulated/controlled variables are decided based on heuristic reasoning. From existing contributions to the control structure selection of conventional fluidized catalytic cracking units and the knowledge of open-loop bifurcation analysis, a total of six control structure candidates are generated. For the riser system, outlet temperatures, $T_{\mathrm{ris},1|z=1}$ and $T_{\mathrm{ris},2|z=1}$, which have the most significant influences on the product distributions along the two riser reactors, are the controlled variables. These two variables can be controlled by the corresponding regenerated catalyst flowrates, $G_{\mathrm{reg},1}$ and $G_{\mathrm{reg},2}$. Moreover, $T_{\mathrm{ris},1|z=1}$ can also be controlled by the inlet temperature of the crude oil, $T_{\mathrm{oil,in}}$. For the regenerator system, oxygen composition of the flue gas, y_{O2} and outlet temperature, T_{rg2} are two potential controlled variables. Combustion air flowrate, F_{g}, combustion air inlet temperature, $T_{\mathrm{air,in}}$, and cooling water flowrate, F_{c} are three candidates for the manipulated variables. In order to facilitate the subsequent investigations, these six control structure candidates are denoted as follows.

- Control structure 1 (CS1): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, T_{rg2}; $G_{\mathrm{reg},1}$, $G_{\mathrm{reg},2}$, F_{c}]
- Control structure 2 (CS2): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, T_{rg2}; $G_{\mathrm{reg},1}$, $G_{\mathrm{reg},2}$, F_{g}]
- Control structure 3 (CS3): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, T_{rg2}; $G_{\mathrm{reg},1}$, $G_{\mathrm{reg},2}$, $T_{\mathrm{air,in}}$]
- Control structure 4 (CS4): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, y_{O2}; $G_{\mathrm{reg},1}$, $G_{\mathrm{reg},2}$, F_{g}]
- Control structure 5 (CS5): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, y_{O2}; $G_{\mathrm{reg},1}$, $G_{\mathrm{reg},2}$, F_{c}]
- Control structure 6 (CS6): [$T_{\mathrm{ris},1|z=1}$, $T_{\mathrm{ris},2|z=1}$, T_{rg2}; $T_{\mathrm{oil,in}}$, $G_{\mathrm{reg},2}$, F_{c}]

It is apparent that each control structure has three control loops. All these six control structures have two common controlled variables $T_{\mathrm{ris},1|z=1}$ and $T_{\mathrm{ris},2|z=1}$. The remaining issues are to compare the perfect control actions based on closed-loop steady-state multiplicity analysis to rank these candidates.

3. Closed-loop steady-state multiplicity analysis

The TSRFCP process is described as Differential Algebraic Equations (DAEs) which actually can be reformulated as Eqs (1) and (2) through substituting algebraic equations into differential ones.

$$\dot{\boldsymbol{x}} = \boldsymbol{f}(\boldsymbol{x},\boldsymbol{u}) = \boldsymbol{f}(\boldsymbol{x}) + \sum_{j=1}^{m} \boldsymbol{g}_j(\boldsymbol{x})\boldsymbol{u}_j \tag{1}$$

$$\boldsymbol{y} = \boldsymbol{h}(\boldsymbol{x}) \tag{2}$$

Where $\boldsymbol{x} = [x_1, x_2, ..., x_n]^T \in R^n$ are state variables, $\boldsymbol{u} = [u_1, u_2, ..., u_m]^T \in R^m$ are input variables ($n > m$), $\boldsymbol{y} = [y_1, y_2, ..., y_m]^T \in R^m$ are outputs. $\boldsymbol{f}(\boldsymbol{x})$ and $\boldsymbol{g}(\boldsymbol{x})$ are smooth vector functions, $h_i(x), i = 1, 2...m$ is a smooth scalar function. Closed-loop steady-state multiplicity can provide the control actions each control structure should take for dealing with disturbances and set point changes. In order to do so, Eq (1) can be reformulated as Eqs (3) and (4).

$$\dot{\boldsymbol{X}} = \boldsymbol{f}(\boldsymbol{X}, \boldsymbol{X}_1, \boldsymbol{u}_1, \boldsymbol{u}_2) \tag{3}$$

$$\boldsymbol{X}_1 = \boldsymbol{X}_{1,\mathrm{set}} \tag{4}$$

Where $\mathbf{X} \in R^{n-n_1}$ is a $n - n_1$ dimensional vector of the state variables; $\mathbf{X}_1 \in R^{n_1}$ is a n_1 dimensional vector of the state variables which are assumed as constant through

adjusting the relevant input variables. $u_1 \in R^{m_1}$ is a m_1 dimensional vector of primary manipulated variables; $u_2 \in R^{m-m_1}$ is a $m-m_1$ dimensional vector of the remained manipulated variables. The closed-loop steady-state multiplicity can be achieved through solving Eqs (3) and (4). Relationships between the primary manipulated variables and the remained ones can be simultaneously established. In this paper, $T_{\mathrm{ris},1|z=1}$ and $T_{\mathrm{ris},2|z=1}$ will be kept constant by adjusting the corresponding manipulated variables at the operating point to analyse the closed-loop steady-state multiplicity under different scenarios.

4. Evaluation of the control structure candidates

Table 1. Operating conditions at point A.

Variables	$T_{\mathrm{ris},1\|z=1}$	$T_{\mathrm{ris},2\|z=1}$	T_{rg2}	y_{O2}	$G_{\mathrm{reg},1}$	$G_{\mathrm{reg},2}$	F_{c}	F_{g}	$T_{\mathrm{air,in}}$
Units	K	K	K	%	kg/s	kg/s	kg/s	kmol/h	K
Values	786	798	954	0.8	41	24	450	850	428

In this section, all analysis and simulations are based on point A (Table 1) which is a representative operating point of the industrial demonstration TSRFCP plant.

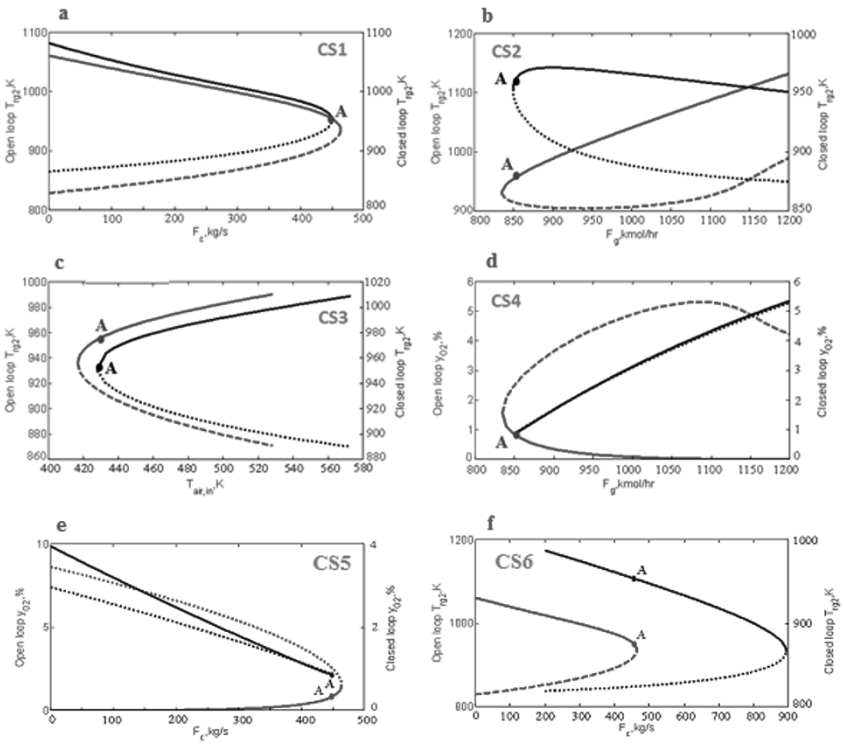

Figure 2. Comparisons of open-loop/closed-loop multiplicity for each control structure.

The implementation of a control system may alter the open-loop topologies representing relationships between the manipulated and controlled variables. Fig. 2 compares the open-loop and closed-loop steady-state multiplicity associated with point A under each

control structure. With regard to CS1, CS3 and CS6, closed-loop steady-state topologies are similar to the open-loop ones and no input multiplicity exists. Illustrated by Fig. 2d, CS4 demonstrates very interesting properties. Point A does not have a reachable counterpoint in the region of interest in the open-loop. However, closed-loop input multiplicity appears, and moreover the distance between the designed operating point and its counterpoint can be ignored. In such situations, even very minor disturbances may suddenly cause the system to become unstable. Hence, employing CS4 for designing a control system at point A is undesirable. As shown in Fig. 2e which is similar with Fig. 2d, CS5 is also undesirable. Illustrated by Fig. 2b, the open-loop/closed-loop steady-state multiplicity, when CS2 is introduced, may promote the TSRFCP process to operate initially at point A and then switch to its counterpoint with higher F_g. Apparently, comparisons on open-loop and closed-loop multiplicity suggest that CS1, CS3, and CS6 are better than CS2, CS4, and CS5. In order to support such conclusion, control actions that each control structure should take for overcoming various disturbances are also investigated.

Table 2. Control actions required for each control structure under various disturbances.

Variables	$k_{0,c}$ (+30%)						$F_{oi,in}$ (+1t/h)					
	CS1	CS2	CS3	CS4	CS5	CS6	CS1	CS2	CS3	CS4	CS5	CS6
$\Delta G_{reg,1}$(%)	0	0	0	-11	-12	0	6.6	6.6	6.6	-5.9	-18.5	0
$\Delta G_{reg,2}$(%)	0	0	0	-13	-14	0	0	0	0	-14.2	-27.9	0
ΔF_c(%)	6.5	0	0	0	-1	7	-8.2	0	0	0	-19	9
ΔF_g(%)	0	42	0	0.2	0	0	0	50.8	0	3.6	0	0
$\Delta T_{air,in}$(%)	0	0	-5.8	0	0	0	0	0	7.2	0	0	0
$\Delta T_{oil,in}$(%)	0	0	0	0	0	0	0	0	0	0	0	8
T_{rg2}	0	0	0	19.4	20	0	0	0	0	21	48	0
y_{O2}	-0.2	4.3	-0.2	0	0	-0.2	-0.3	4.8	-0.3	0	0	-0.2

Table 2 lists the control actions at point A for all six control structures. Increasing $k_{0,c}$ accelerates the combustion in the regenerator and in turn reduces y_{O2}. In order to maintain y_{O2}, action on F_g of CS4 or F_c of CS5 simultaneously increases T_{rg2} which subsequently requires $G_{reg,1}$ and $G_{reg,2}$ to take negative actions to control $T_{ris,1|z=1}$ and $T_{ris,2|z=1}$. Hence, the lowered catalyst-to-oil ratios may negatively affect the product yields from the two risers. In other words, three loops of CS4 or CS5 are heavily coupled with each other. When CS1, CS3, and CS6 are introduced to address the disturbance on $k_{0,c}$, the effects of control actions taken by F_c or $T_{air,in}$ on the other two loops can be ignored. Among these three control structures, CS3 takes the minimum action. Similarly, three control loops of CS4 or CS5 are also heavily coupled to reject the disturbance on $F_{oi,in}$. At the same time, the actions of both CS4 and CS5 cause upsets in T_{rg2}. For dealing with the disturbances on both $k_{0,c}$ and $F_{oi,in}$, effects of CS1, CS3, and CS6 on y_{O2} can be neglected. However, actions of CS2 result in significant influence on y_{O2}. The aforementioned closed-loop multiplicity of CS2 predicted that the saturation of F_g may occur. As can be seen from Table 2, the magnitudes of CS2 for tackling disturbances on $k_{0,c}$ and $F_{oi,in}$ reach 42% and 50.8%, respectively. Obviously, these large actions are undesirable for actual control system implementation. In summary, CS1, CS3, and CS6 are top three candidates.

PID controllers are implemented based on CS1, CS3, and CS6 for tackling an +30% perturbation on $k_{0,c}$, and the behavior of classic PID controllers tuned by critical proportioning method is given in Fig.3. Each of the following simulations takes around 1.5 min. On the other hand, the transient behavior of CS2 is also demonstrated. Shown in Fig.3, CS3 has the longest settling time. CS1 and CS6 have similar settling times and

maximum deviations. Interestingly, CS2 takes the minimum settling time at the cost of almost saturated action. Accounting for the results from closed-loop steady-state multiplicity and the dynamic simulation, CS1 and CS6 are the top two control candidates.

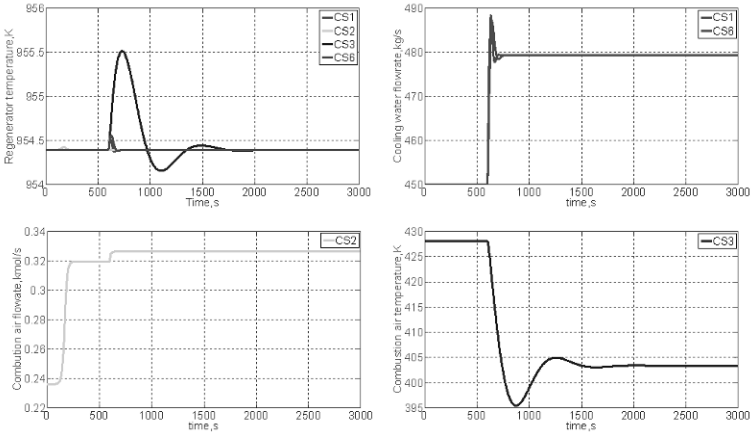

Figure 3. Closed-loop dynamic simulations of disturbance rejections at point A.

5. Conclusions

The performance of a control system for the TSRFCP process in the face of uncertainties and disturbances with minimum performance loss is heavily dependent on the control structure used. Control structure candidates of the demonstration TSRFCP process have been evaluated through applying closed-loop steady-state multiplicity analysis and dynamic simulation validation. Several key conclusions from the control structure selection for the TSRFCP process include: Closed-loop steady-state topologies of the TSRFCP process under CS4 and CS5 are totally different from their open-loop counterparts. For CS1, CS3, and CS6, closed-loop and open-loop steady-state topologies of the TSRFCP process are similar to each other; CS2 is not a suitable control structure due to the uneconomical control actions for F_g. CS3 shows the longest transient time for disturbance rejections when compared to CS1 and CS6. As the studied TSRFCP process is still in its demonstration stage, we believe that the control structure selection and the subsequent control system design will accelerate the scale-up of the demonstration TSRFCP plant to industrial applications.

Abstract

With the advent of computer control and Distributed Control System (DCS), it has become easy for process industries to store a huge amount of data everyday. These data are rich sources of information. Often it requires selecting a window of data from a large data set for calculating or estimating various performance metrics of the control loops or the process itself. For example, if data is collected at a sampling rate of 4s, there will be 21,600 samples for each variable each day. Calculation of a performance measure or metric requires only a few hundred or a couple of thousand data points. The question is which part of the data should be used. This study attempts to find suitable data segmentation methods appropriate for the various purposes of data analysis. This study utilizes various simple statistical measures such as autocovariance function, signal to noise ratio, and skewness for selecting appropriate segment of the data. The performance of the segmentation methods has been evaluated using simulation examples and real industrial data sets. The selection of appropriate window of data largely increases the reliability of the data driven analyses.

Keywords: Autocovariance, Data segmentation, Nonlinearity analysis, Oscillation detection, Signal to noise ratio.

1. Introduction

Choudhury et al. (2008) presented theories to calculate various performance metrics for example process nonlinearity and oscillation for monitoring the performance of a process using routine operating data. In data driven analysis of process, selection of an appropriate data segment is important since computation of performance metric on non-representative data may give erroneous results. For system identification and forecasting, Shardt (2012) proposed entropy based approach for data segmentation. In entropy based approach, the difference in entropy between the input and output signals for routine operating data is used to separate the data into its constituent models. Fu and Mui (1981) reviewed various image segmentation techniques for partitioning of an image into a set of regions that cover it. Various region extraction techniques are applied to find meaningful regions of an image. Similarly, data segmentation techniques are applied to segment a time series for finding appropriate data window to estimate performance metrics of control loops. In this study, suitable data segmentation methods are developed for oscillation detection and nonlinearity analysis using routine operating data. In this paper, section 3 describes a data segmentation method for oscillation detection and section 4 describes a data segmentation method for nonlinearity quantification. Both sections also give application results and the paper ends with a conclusion section.

2. Motivation

The main motivation of this study is to find suitable methods to select a data window (a part of a time series) from a large time series to calculate various performance metrics of the control loops. Figure 1 shows time series data of 16 industrial variables. These data corresponds to 6 hours operation of a fertilizer plant and they are collected at a sampling rate of 4s. As shown in Figure 1, data windows separated by vertical lines, are different from each other, though they correspond to same tag. To calculate performance metrics from such industrial time trends, two common problems are encountered by engineers. First, which data window is to be used and second, what would be the length of each data window. Selection of data window depends on data analysis purposes. For example, less noisy data window is preferred for oscillation detection, but in case of a filter design noisy data window is required. In this study, suitable data segmentation methods are developed for segmenting data into different windows and then choosing the appropriate window of data for analysis. Two common purposes of data analysis are covered in this paper, namely, oscillation detection and nonlinearity quantification.

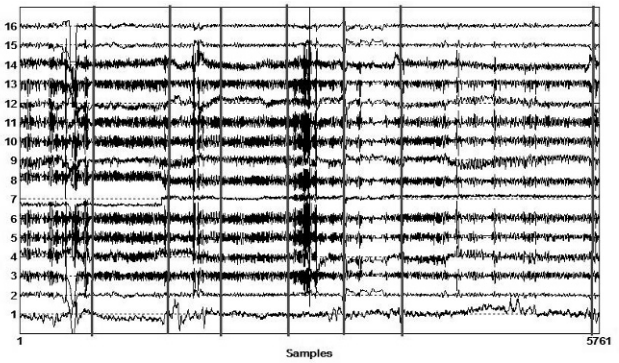

Figure 1: Industrial time trends

3. Data Segmentation for Oscillation Detection

Detection and diagnosis of oscillation is a regular issue in process industries. Oscillatory behavior in a chemical process causes inferior quality products, higher rejection rates, and larger consumption of energy; all of which impact the profitability of the plant. This section presents a method for selection of a window of data from a large data set for detection of oscillation based on regularity of zero crossing of filtered autocovariance function. The first step is to find the data window length.

3.1. Determination of Data Window Length

Data segmentation method allows us to break a time trend into smaller windows of data. Thornhill and Hägglund (1997) proposed zero crossing of autocovariance function (ACF) method for oscillation detection. In their method, intervals between regular zero crossings of autocovarience function are used to determine Oscillation period, T_p and Oscillation regularity, r. But they did not discuss about the minimum required length of a time trend to detect oscillation. Number of data in the selected time trend must be large enough for accurate determination of oscillation period. In this study, minimum required length of a time trend is calculated. Thornhill et al. (2003) proposed the following: *"The 10 intervals between the first eleven zero crossings are used for calculation of $\overline{T_p}$ and σ_{T_p}. The interval from lag zero up to the first zero crossing is excluded from the calculation because it corresponds to only one half of a completed deviation."* Box et al. (1994) stated that for reliable estimation of autocovarience at a lag, r_K, total number of data points must be equal to or greater than four times of the lag value. Ten intervals between the first eleven zero crossings equal

Table 1: Oscillation analysis for different size of data

Data length	Mean oscillation period, T_p	Deviation from actual period	Std of T_p
$\frac{L_m}{2}$ (1 to 1045)	103.78	3.78	4.29
L_m (1 to 2090)	99.56	0.44	0.88
$2L_m$ (1 to 4180)	99.78	0.22	0.67
All data (1 to 20000)	100.22	0.22	1.2

to five times of period and interval from lag zero up to the first zero crossing is equal to the one fourth of the period.

Therefore, the minimum required length of a time trend,

$$L_m = (5+\frac{1}{4})T_{pi} \times 4$$

$$L_m = 21 \times T_{pi} \quad (1)$$

Here, T_{pi} is the initial assumed value of oscillation period. Power spectrum of the time series is used to estimate the value of T_{pi}. The inverse of frequency corresponding to the highest power in the power spectrum gives the value of T_{pi}. In order to minimize the effects of disturbances and sampling errors, a data length more than the minimum length, L_m, should be used. From the experience of analyzing industrial data sets, it is observed a data length twice the minimum length is adequate. Thus, data can be segmented into windows of length $2L_m$.

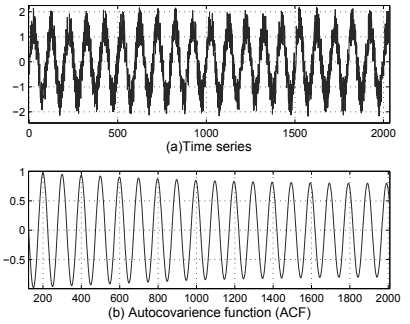

Figure 2: (a) Oscillatory time series (b) ACF of time series

3.1.1. Simulation Study

To observe the effect of length of a time trend on ACF based oscillation detection method, a time series shown in Figure 2, was generated as following:

$$X(t) = \sin(2\pi f_1 t + \phi_1) + d(k) \quad (2)$$

where $f_1 = 0.01\ Hz$, $\phi_1 = 0$, t varying from 1 s to 20000 s and white noise, d(k) with variance 0.2. The value of SNR for this analytical time series was 5. The frequency of the constructed time series was 0.01 Hz. Therefore, the actual oscillation period is 100 s. From Table 1, it is observed that for a selected data length equal to $2L_m$, the deviation of the estimated oscillation period from the actual oscillation period is 0.22 s and the estimated standard deviation of T_p is 0.67. This is the lowest among the four cases presented in Table 1. Therefore, the proposed method of choosing data length provides a better result in estimating oscillation period using ACF method.

3.2. Selection of Data window

After determining minimum required window length, L_m, a time series is divided into data windows each of length $2L_m$. Finally, a data window with high SNR value is selected for oscillation detection. High SNR values indicate less noisy data as variance of the noise is smaller compared to the variance of the signal. Signal to noise ratio (SNR) of a window is estimated indirectly. A

Table 2: Oscillation analysis of an industrial time series using data segmentation methods

Tag no.	Method name	Mean T_p	Std of T_p	r	Power (%)
1	Data segmentation (window length= $\frac{L_m}{2}$)	194.25	19.26	3.36	35
	Data segmentation (window length= L_m)	171.33	29.05	1.97	31
	Data segmentation (window length= $2L_m$)	171.33	18.06	3.16	24
	All data (1 to 16200)	168.00	17.83	3.14	23

simplified Wiener filter is used to separate noise from data windows. After that, all data windows of a particular time trend are filtered and the percentage of power retained in the filtered spectrum by different windows at the specified frequency range are compared. Finally, the window that retains the maximum percentage of power in the filtered spectrum is chosen. The retained power in the filtered spectrum increases with the increase of SNR value. Summary of the proposed data segmentation method for oscillation detection using ACF method is shown in Figure 3.

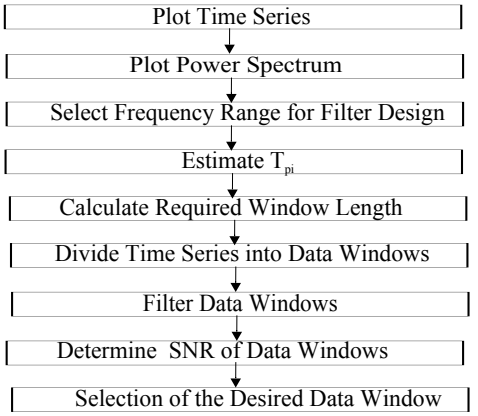

Figure 3: Algorithm for Data Segmentation

3.3. Application to Industrial Data

Figure 4 shows an industrial oscillatory time series data obtained from Karnaphuli Fertilizer Company Limited (KAFCO) located in Chittagong, Bangladesh. This time series data is labeled as Tag 1. Data were collected at a sampling rate of 4s; 16,200 samples were collected corresponding to 18 hours of operation. Table 2 represents the results of oscillation analysis in industrial time series using all data points (conventional method) and data segmentation methods (using a selected data window). By comparing the values of Mean T_p, standard deviation of T_p and oscillation regularity, r calculated from data segmentation methods considering window length $\frac{L_m}{2}$, L_m and $2L_m$, with the results obtained from conventional method (using all data points), it has been concluded that the proposed data segmentation method considering window length equal to $2L_m$, provides representative results for oscillation detection.

4. Data Segmentation for Bicoherence based Measure of Nonlinearity

A linear controller does not perform well for highly nonlinear processes, so the measurement of the degree of nonlinearity of a process is essential to take a decision about the necessity of a nonlinear controller. This section presents a method of data window selection for bicoherence based nonlinearity quantification.

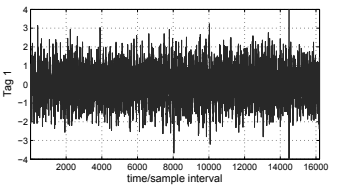

Figure 4: An industrial time trend

4.1. Determination of Data Window Length

Bicoherence method proposed by Choudhury et al. (2008) is a data based approach, which requires only

output time series of a process variable to estimate nonlinearity. For nonlinearity detection and quantification Choudhury et al. (2008) proposed three indices: Non-Gaussianity Index (NGI), Nonlinearity Index (NLI) and Total Nonlinearity Index (TNLI). $NLI > 0$ indicates the presence of nonlinearity; for linear process $NLI \leq 0$. TNLI quantifies the total nonlinearity present in a time series. For bicoherence estimation, a time series of finite length is divided into K segments. Size of data in each segment and length of discrete Fourier transform (DFT length) are two key parameters for bispectral analysis. Hinich (1982) suggested that if no frequency domain filtering is used, number of segments should be equal to or greater than DFT size (M) i.e. $K \geq M$. However, this may not be achievable in real life applications. For determining number of segments, Jamšek et al. (2003) stated the following: *" For a real signal, with a finite number of points, the compromise between bispectral resolution and statistical stability may be expected at K around 30"*. So, the window length should be,

$$L = 30 \times M \tag{3}$$

where, M is DFT length. Since M equal to 128 or 256 is usually used, it demands for a long data window length.

4.2. Selection of Data window

After determining the required length, L, a time series is divided into data windows of length L. After windowing a times series, an appropriate window can be selected based on SNR since higher SNR provides better bispectral estimation (Fackrell, 1996). However, there is no suitable method to determine SNR of an industrial times series having distributed power spectrum over wide frequency range. It is well known that there is a relationship between skewness and nonlinearity. So, skewness is proposed as a criterion for window selection. If the variation of skewness in different windows of a time trend is large, then selecting the window having the highest absolute skewness represents the highest nonlinear portion of the data.

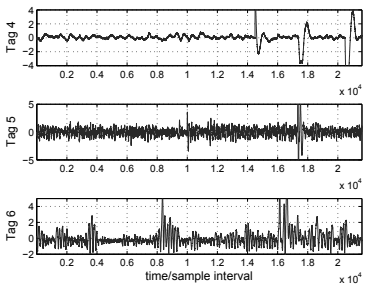

Figure 5: Normalised nonlinear industrial time trends

4.3. Application to Industrial Data Sets

Figure 5 shows three normalised industrial time trends. These data are labeled as tag 4, tag 5 and tag 6. Each time series is divided into three windows, each of length L equal to 7680 corresponding to M = 256. Bispectral analysis for nonlinearity detection is performed on overall time trend as well as data-windows. Results of nonlinearity analysis are presented in Table 3 for both conventional method and proposed data segmentation method. In conventional method (using all data points of a time trend), presence of nonlinearity is detected in all tags. As shown in Table 3, nonlinearity differs from window to window. In tag 4, no nonlinearity is found in window 1 ($NGI = 0$) but found in window 2 ($NGI = 0.47, NLI = 0.84$) and window 3 ($NGI = 0.4, NLI = 0.73$). This may be due to change in the operating points. In tag 5, nonlinearity is present in all data windows, but window 3 ($TNLI = 16.33$) is the most nonlinear. Due to large variation of skewness in windows of tag 4 and 5, maximum nonlinearities are observed in windows having the highest skewness. Variation of skewness is small in different windows of tag 6, so nonlinearity is almost the same in all windows. Therefore, it can be concluded that bicoherence based nonlinearity quantification is sensitive to data skewness and the data window having the highest skewness corresponds to the most nonlinear part of the data.

Table 3: Nonlinearity analysis of industrial time trends

Tag	Window	Skewness	NGI	NLI	TNLI	Max_bicoherence
Tag 4	All Data	-3.08	0.31	0.75	48.05	0.81
	1	0.11	0	0.05	0	0.05

	2	1.9	0.1	0.22	1.25	0.22
	3	2.33	0.08	0.14	1.21	0.14

5. Conclusion

In this paper, data segmentation methods are developed for increasing the reliability of oscillation detection and nonlinearity analysis.

- A method for choosing minimum data window length for oscillation detection has been developed.
- Once data is divided into several windows, the window having the highest SNR value provides the representative results for oscillation detection.
- For nonlinearity analysis based on bicoherence method, a method for finding the data window length has been developed.
- The data window having the highest skewness corresponds to the most nonlinear region of the data.

Work is in progress to improve these data segmentation methods further.

Abstract

Solid oxide fuel cell (SOFC) is an electrochemical device operating at a high temperature, converting the chemical energy of a fuel directly to electrical energy. Moreover, it can directly convert hydrocarbon fuels to a hydrogen-rich gas via internal reforming inside the fuel cell stack itself. However, the endothermic cooling effect resulting from the reforming reaction at the anode side causes the temperature gradient and thermal stress within the fuel cell stack. This requires an efficient control design for assuring a stability of the system. In this study, a robust linear model predictive control (MPC) based on uncertain polytopic approach is synthesized for controlling the SOFC. Different designs of the robust MPC using linear time-varying (LTV) and linear parameter varying (LPV) models are studied. The state feedback control laws are derived by minimizing an upper bound on the worst-case performance cost and are implemented to the cell voltage and temperature controls of the direct internal reforming SOFC. The simulation results show that under model uncertainties, the proposed robust MPC can control the SOFC when disturbances in the fuel feed and air temperature are introduced and guarantee the stability of the SOFC. The performance of the MPC using different linear models is compared and discussed.

Keywords: robust model predictive control, solid oxide fuel cell, linear time-varying model, linear parameter varying model.

1. Introduction

Model predictive control (MPC) is a multivariable control algorithm that has been widely used in many industries. In general, a MPC problem is solved on-line at each sampling time to compute optimal control inputs based on predicted future outputs. MPC can be designed to guarantee its stability, independence of the controlled plant. However, as a model-based control strategy, it is difficult for the MPC to handle with an uncertain plant model.

In order to improve the MPC robustness property, a number of studies have been focused on the development of a robust MPC algorithm. Kothare at el. (1996) synthesized the robust MPC using linear matrix inequalities (LMIs). The state feedback control law was proposed to minimize a worst-case value of the objective function. The LMIs optimization was implemented to solve input and output constraints and described the uncertain plant. Bumroongsri and Kheawhom (2012) developed a polyhedral off-line robust MPC algorithm for the polytopic uncertain discrete-time system. The nonlinear process model was approximated by a linear time varying (LTV) system with

the polytopic uncertain. They showed that the robust stability of the proposed MPC was guaranteed. Recently, the controller synthesis based on a linear parameter varying (LPV) system has been received considerable attention. Casavola et al. (2012) proposed the MPC for feedback regulation problems. The LPV model was used to explain a nonlinear plant in the MPC algorithm. The performance of the developed MPC based on LPV and LTV models was compared.

A solid oxide fuel cell is regarded as the power generation device with high efficiency. Due to its high operating temperature, SOFC can directly convert hydrocarbon fuels into hydrogen fuel inside a cell stack by a steam reforming process. However, the reforming reaction at the anode side causes the complicated dynamic behavior, and the temperature gradient and thermal stress within the fuel cell stack. As a result, an efficient control is necessary for this process to avoid thermal cracking and ensure system stability. Kouramas et al. (2011) focused on the design of MPC controller to control the cell voltage and cell temperature. The result showed that the controller can manage the SOFC voltage and temperature to its desired value. Because the SOFC model involves many uncertain parameters, the control design should take care this model uncertainty.

The aim of this study is to develop the robust constrained MPC with a state feedback control law for the direct internal reforming SOFC. Uncertain polytopic discrete-time linear time varying (LTV) and linear parameter varying (LPV) models are employed to explain the SOFC behavior and to design the MPC control. Performance of the MPC based on the two different linear models are investigated and compared.

2. Model Description and MPC Formulation

The discrete-time linear time varying (LTV) and linear parameter varying (LPV) systems with multi-model paradigm polytopic uncertainty are considered and expressed in Table 1.

It is noted that $x(k)$ is the state of the plant, $u(k)$ is the control input and $y(k)$ is the plant output. The scheduling parameter $p(k)$ is measurable on-line at each sampling time k. Furthermore, we define the set Ω which is the polytope for polytopic systems. Co represents the convex hull, and A_j and B_j are the vertices in the convex hull. [A(k)B(k)] and [$A(p(k))B(p(k))$] are the linear combination of the vertices and λ is the uncertain parameter vector.

Table 1. Discrete-time model for LTV and LPV systems

Linear time varying system	Linear parameter varying system
$x(k+1) = A(k)x(k) + B(k)u(k)$	$x(k+1) = A(p(k))x(k) + B(p(k))u(k)$
$y(k) = Cx(k)$	$y(k) = Cx(k)$
$[A(k) \quad B(k)] \in \Omega$	$[A(p(k)) \quad B(p(k))] \in \Omega$
$\Omega = \mathrm{Co}\{[A_1 \quad B_1],[A_2 \quad B_2],...,[A_L \quad B_L]\}$	$\Omega = \mathrm{Co}\{[A_1 \quad B_1],[A_2 \quad B_2],...,[A_L \quad B_L]\}$
$[A(k) \quad B(k)] = \sum_{j=1}^{L} \lambda_j [A_j \quad B_j]$	$[A(p(k)) \quad B(p(k))] = \sum_{j=1}^{L} p_j(k)[A_j \quad B_j]$
$\sum_{j=1}^{L} \lambda_j = 1, \quad 0 \le \lambda_j \le 1$	$\sum_{j=1}^{L} p_j(k) = 1, \quad 0 \le p_j(k) \le 1$

At each sampling time k, the robust performance objective is a min-max problem (minimization of worst-case performance cost) in term of the quadratic objective as given in Eq. (1) and (2) for the LTV and LPV systems, respectively.

$$\min_{u(k+i|k),i=0,1,\ldots,m} \max_{[A(k+i)\ B(k+i)]\in\Omega,i\geq 0} J_\infty(k) \tag{1}$$

$$\min_{u(k+i|k),i=0,1,\ldots,m} \max_{[A(p(k+i))\ B(p(k+i))]\in\Omega,i\geq 0} J_\infty(k) \tag{2}$$

$$J_\infty(k)=\sum_{i=0}^{\infty}\left[x(k+i|k)^T Q_1 x(k+i|k)+u(k+i|k)^T Ru(k+i|k)\right] \tag{3}$$

where $Q_1(>0)$ and $R(>0)$ are the symmetric weighting matrices

A state-feedback control law is defined to synthesis the robust MPC algorithm.

$$\begin{aligned} &u(k)=Kx(k), \quad i\geq 0 && \text{For LTV system} \\ &u(k)=K(p(k))x(k), \quad K(p(k))=\sum_{j=1}^{L} p_j(k)K_j && \text{For LPV system} \end{aligned} \tag{4}$$

3. Off-Line Robust MPC Scheme

The optimization problem at each sample time step is formulated as the convex optimization problem involving linear matrix inequalities constraints (Kothare et al., 1996).The Lyapunov function is presented to guarantee the stability for the MPC algorithm. Table 2 shows the proposed MPC algorithm for LTV and LPV systems. For LTV system, the state feedback gains K_i in the control law are defined as $K_i=Y_iQ_i^{-1}$ (Kothare et al., 1996) while the state feedback gains are defined as $K_i=Y_iG_i^{-1}$ for the LPV system(Wada et al., 2006) to stabilize the closed-loop system.The matrix variables Q_i, G_i, and Y_i are achieved from the result of the linear objective minimization problem with the upper bound γ on the worst-case MPC. The symbol * represents the corresponding transpose of the lower block part of symmetric matrices.

Table 2. MPC algorithm for LTV and LPV systems

4. Control of SOFC

4.1. SOFC model

Figure 1 illustrates the direct internal reforming solid oxide fuel cell (DIR-SOFC). Methane as fuel is directly fed at the anode side and air as oxidant is introduced at the cathode side to produce electricity by the electrochemical reactions. The mathematical model including three major elements: electrochemical model and mass and energy balances,is used in the SOFC as shown in Table 3.For the electrochemical model, the operating cell voltage or the actual voltage (V_{FC}) decreases from its open-circuit voltage due to ohmic losses (η_{Ohm}), concentration overpotentials (η_{conc}), and activation overpotentials (η_{act}).The mass and energy balances represented in a lumped-parameter model are implemented to analysis, design, and control the SOFC. In the fuel channel, the chemical species i consist of CH_4, H_2O, CO, H_2, and CO_2, whereas the chemical species i in the air channel are O_2 and N_2.The chemical reactions taking place in the SOFC are shown in Table 4.

Table 3. SOFC model (Chatrattanawet et al., 2014)

Electrochemical models		
Cell voltage	$V_{FC} = E_{OCV} - \left(\eta_{\text{Ohm}} + \eta_{\text{conc}} + \eta_{\text{act}}\right)$	(5)
Open-circuit voltage	$E_{OCV} = E_0 - \frac{RT_{FC}}{2F}\ln\left(\frac{p_{\text{H}_2\text{O}}}{p_{\text{H}_2} p_{\text{O}_2}^{0.5}}\right)$	(6)
Ohmic losses	$\eta_{\text{Ohm}} = jR_{\text{Ohm}}$	(7)
Concentration overpotentials	$\eta_{\text{conc}} = \frac{RT_{FC}}{2F}\ln\left(\frac{p_{\text{H}_2\text{O,TPB}} p_{\text{H}_2}}{p_{\text{H}_2\text{O}} p_{\text{H}_2,\text{TPB}}}\right) + \frac{RT_{FC}}{4F}\ln\left(\frac{p_{\text{O}_2}}{p_{\text{O}_2,\text{TPB}}}\right)$	(8)
Cathode activation overpotentials	$j = j_{0,\text{cathode}}\left[\exp\left(\frac{\alpha nF}{RT_{FC}}\eta_{\text{act,cathode}}\right) - \exp\left(-\frac{(1-\alpha)nF}{RT_{FC}}\eta_{\text{act,cathode}}\right)\right]$	(9)
Anode activation overpotentials	$j = j_{0,\text{anode}}\left[\frac{p_{\text{H}_2,\text{TPB}}}{p_{\text{H}_2}}\exp\left(\frac{\alpha nF}{RT_{FC}}\eta_{\text{act,anode}}\right) - \frac{p_{\text{H}_2\text{O,TPB}}}{p_{\text{H}_2\text{O}}}\exp\left(-\frac{(1-\alpha)nF}{RT_{FC}}\eta_{\text{act,anode}}\right)\right]$	(10)
Mass balances		
Fuel channel	$\frac{dn_{i,f}}{dt} = \dot{n}_{i,f}^{in} - \dot{n}_{i,f} + \sum_{\text{k}\in\{\text{(i)},\text{(ii)},\text{(iii)}\}} \upsilon_{i,\text{k}} R_{\text{k}} A$	(11)
Air channel	$\frac{dn_{i,a}}{dt} = \dot{n}_{i,a}^{in} - \dot{n}_{i,a} + \upsilon_{i,\text{(iii)}} R_{\text{(iii)}} A$	(12)
Energy balances		
	$\frac{dT_{FC}}{dt} = \frac{1}{\rho_{SOFC} Cp_{SOFC} V_{SOFC}}\left(\dot{Q}_{f,in} - \dot{Q}_{f,out} + \dot{Q}_{a,in} - \dot{Q}_{a,out} + \sum_{\text{k}\in\{\text{(i)},\text{(ii)},\text{(iii)}\}}\left(-\Delta H\right)_{\text{k}} R_{\text{k}} A - jAV_{FC}\right)$	(13)

Table 4. Reactions considered in a SOFC

Reaction name	No.	Reaction equation	ΔH (kJ/mol)
steam reforming	(i)	$CH_4 + H_2O \leftrightarrow 3H_2 + CO$	206.10
water-gas shift	(ii)	$CO + H_2O \leftrightarrow H_2 + CO_2$	-41.15
Electrochemical reaction	(iii)	$H_2 + 1/2O_2 \rightarrow H_2O$	-241.83

Table 5. Operating conditions used in this study

Parameters	Value	Parameters	Value
Cell temperature (K)	1058	Power density (W/cm^2)	0.32
Cell voltage (V)	0.72	Inlet temperature (K)	1023
Current density (A/cm^2)	0.45	Steam to carbon ratio	2

The mathematical model is used to perform steady state analysis for the SOFC in order to select the operating point. The operating conditions for designing the SOFC controller are summarized in Table 5.

4.2. Control implementation

The implementation of the off-line robust MPC for LTV and LPV systems is performed by using Matlab. The lumped-parameter model represented by nonlinear ODEs is linearized and then discretized using Euler first-order approximation into discrete-time model with a sampling period of 5 second. The objective is to control the cell temperature to its desired value by manipulating the inlet temperature of air with $Q_1=I$ *and* $R=0.1I$.

Figure 2 shows the closed-loop responses for the robust MPC based on the LTV and LPV systems. The MPC controller for LTV and LPV systems can maintain the cell temperature (T_{FC}) to its setpoint by manipulating the control input ($T_{air,in}$). Moreover, it is observed that the cell voltage (V_{FC}) also moves to its desired value. By comparing the MPC design based on the LTV and LPV systems, it seems that the MPC with the LPV system can achieve a better control performance because the scheduling parameter is taken into the controller synthesis.

5. Conclusions

In this work, the robust constrained MPC algorithm based on uncertain polytopic discrete-time LTV and LPV systems is synthesized for controlling the direct internal reforming SOFC. The state feedback control law minimizing an upper bound on the worst-case objective function is implemented. The lumped-parameter model is used to explain the SOFC dynamic behavior and employed to design the MPC controller. The performance of the MPC controller using the proposed different models is compared. The simulation results show that under model uncertainties, the proposed robust MPC can control the cell voltage and temperature to its setpoint. The proposed control can guarantee the stability of the SOFC. The results also show the control performance of the robust MPC algorithm based on LPV system is better than LTV system.

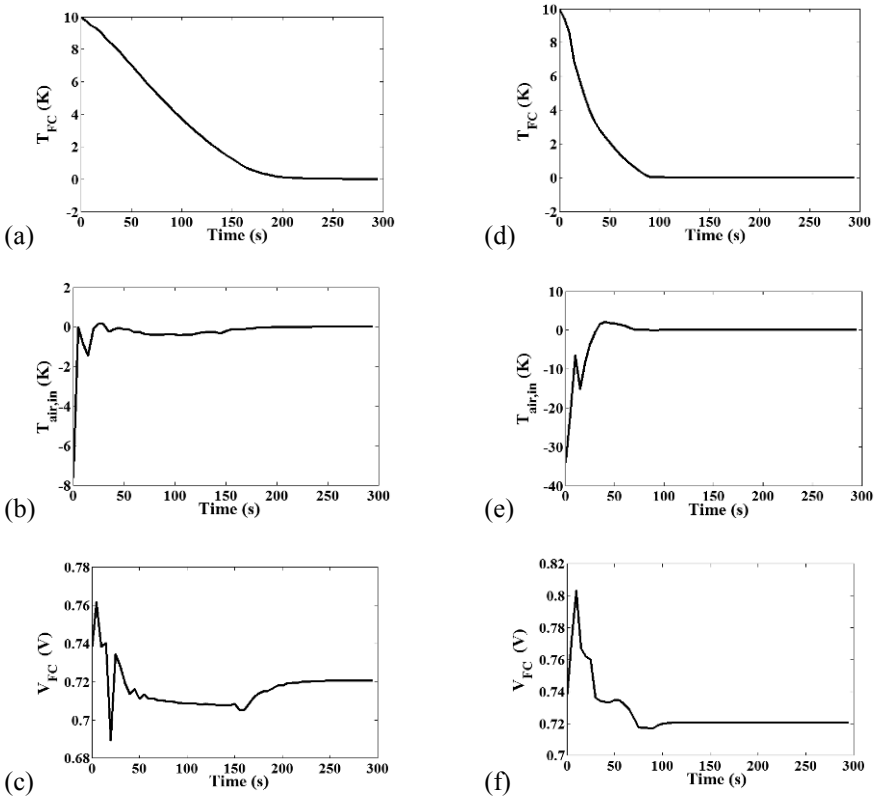

Figure 2. The closed-loop responses of the MPC based on the LTV system ((a)-(c)) and the LPV system ((d)-(f)).

Abstract

Plantwide predictive monitoring is a useful tool for observation of certain compounds of interest (e.g. pollutants) depending on fluctuations in the feed stream and operating conditions of plant sections. A general framework for the dynamic modeling of packed bed reactors (PBRs) in sulfur tail gas treatment is broached and implemented for related processes and a wide range of operating conditions. The model was validated using experimental data from both a miniplant for industrial off gas treatment and an industrial plant for sulfur recovery. After its validation, the model has been coupled with the existing multiscale models for thermal furnace already adopted to simulate Claus processes to get the plantwide prediction of plant emissions. The proposed approach allows to carry out a priori the estimation of environmental impact according to the current feedstock and operating conditions as well as to exploit in advance the hidden potential of the plant in mitigating/removing them before achieving the stack.

Keywords: dynamic modeling; plantwide process monitoring; sulfur emissions.

1. Introduction

In recent years, environmental regulations are becoming more and more stringent and therefore are forcing engineers and technicians to find novel solutions for emission reduction. Beside carbon dioxide, sulfur emissions (mostly in the form of sulfur dioxide) have become a key target for several countries (Guangxiang, 2014). Promising solutions to this are predictive technologies that enable the real-time monitoring of certain components, thus the accurate estimation of final concentrations just by assigning inlet conditions of a plant. Hence, they give in advance the possibility to act on the degrees of freedom of the plant to avoid any threshold overcoming. In addition, it can be realized in real-time what in the operational range is to fulfill the environmental limitations. Dynamic models for entire plants have been developed previously in the fields of CO_2 capture (Bui et al., 2014), gasification (Pérez-Fortes et al., 2009) or cracking units (Berreni and Wang, 2011). Recently, the same methodology has been successfully adopted for the minimization of SO_x emissions of a sulfuric acid plant (Kiss et al., 2010), but many issues are still unresolved to extend it to other chemical and oil & gas areas. In tail gas units, for instance, such as Claus processes, there is the need to characterize complex kinetics to get a reliable prediction of the dynamic behavior of the plants. Nevertheless, a plantwide predictive monitoring is most welcome

especially in these tail gas processes due to their typical strong fluctuations in the feedstock and lack in instrumentation and redundancy. Moreover, sulfur reduction is of great importance in many industrial branches and it is often realized by processes with a thermal section and/or a catalytic section, consisting of heterogeneous catalysis in fixed bed reactors. While thermal models are already discussed elsewhere(Manenti et al., 2013), there is still the need to define computer-aided tools for the catalytic section to bridge the gap between the literature on sulfur removal and the practical expected benefits. On this basis, the paper mainly focuses on the formulation, implementation and validation of a new general dynamic model of packed bed reactors (PBRs). The model is structured to get high generality and modularity and can therefore easily be adapted only by providing geometrical data of the reactor, chemical properties of the species and kinetic data. As a benchmark for tail gas treatment units, the model was employed to simulate a sulfur recovery unit (Selim et al., 2013). Furthermore, the model was validated with experimental data from a miniplant operation for deep desulfurization of industrial off gas.

2. Dynamic modeling of the packed bed reactor (PBR)

The pseudo-homogeneous catalytic (PHoCa) reactor simulation suite (available at http://super.chem.polimi.it) is a first principles model involving spatio-temporal evolution (partial differential-algebraic equation system). Modeling has required the following assumptions, which could progressively be removed in future activities: (1) the fluid phase behaves as perfect gas; (2) thermodynamic properties such as pressure and volume are considered constant with temperature; specific heat and enthalpy of reaction are dependent on temperature and were acquired from the *NIST Chemistry Webbook*; (3) gas transport properties such as axial dispersion, thermal conductivity, viscosity, global heat transfer coefficient are considered constant with temperature and composition; (4) no diffusive limitations inside catalyst (i.e. efficiency factor is one); (5) reactor temperature can be controlled with a phase changing fluid on the lateral area of the reactor, so there is no variation in the coolant temperature profile over the lengths; and (6) gas-catalytic phase gradients are neglected, i.e. a homogenous approach is used. The PBR model includes the mass balances for the *i*-th component and energy balance:

$$\frac{\partial \rho_i^{(G)}}{\partial t} = -\frac{1}{\varepsilon A_{cs}} \frac{\partial}{\partial z}\left(\rho_i^{(G)} Q\right) + D_i^{eff} \frac{\partial^2 \rho_i^{(G)}}{\partial z^2} + \frac{1-\varepsilon}{\varepsilon} PM_i \sum_{j=1}^{N_R} \nu_{ij} R_j^{(r)} \tag{1}$$

$$\frac{\partial T}{\partial t} = \frac{1}{\varepsilon \sum_{i=1}^{N_C} \rho_i^{(G)} Cv_i + (1-\varepsilon)\rho_c Cp_c} \left[\begin{array}{l} -\frac{Q}{A_{cs}} \sum_{i=1}^{N_C} \rho_i^{(G)} Cp_i \frac{\partial T}{\partial z} - (1-\varepsilon) \sum_{j=1}^{N_R} \Delta H_{R_j} R_j^{(r)} + k^{eff} \frac{\partial^2 T}{\partial z^2} + \\ + \frac{U}{A_{cs}} \frac{dA_{exc}}{dz}\left(T_c - T\right) - \frac{P}{A_{cs}} \sum_{i=1}^{N_C} \frac{1}{\rho_i^{(P)}} \frac{\partial}{\partial z}\left(\rho_i^{(G)} Q\right) + \\ + P\left(1-\varepsilon\right) \sum_{i=1}^{N_C} \frac{PM_i}{\rho_i^{(P)}} \sum_{j=1}^{N_R} \nu_{ij} R_j^{(r)} \end{array} \right] \tag{2}$$

Energy balance (2) includes the correction of pressure for internal energy, which provides with a wide application range, from low pressure (e.g., Claus converter) to high pressure PBR (e.g., methanol and ammonia synthesis). For reaction kinetics a general Langmuir-Hinshelwood approach is chosen that can be easily adapted to a more simplified Arrhenius approach:

$$R_j^{(r)} = \frac{k_j^0 e^{Ea_j/RT} \prod_{i=1}^{N_C} P_i^{\gamma_{ji}}}{\left(1 + \sum_{i=1}^{N_C} k_{ji}^{eq,0} e^{Ea_{ji}^{eq}/RT} P_i\right)^{\psi_j}} \tag{3}$$

In addition, the pressure loss over the fixed bed is described by the Ergun equation (Ergun 1952):

$$\frac{\partial P}{\partial z} = -\frac{1-\varepsilon}{\varepsilon^3} \frac{G}{DP_c \sum_{i=1}^{N_C} \rho_i^{(G)}} \left[1.75G + 150(1-\varepsilon)\left(\frac{\mu_{mix}^{(G)}}{DP_c}\right)\right] \tag{4}$$

According to the assumptions above, variations of volumetric flow is as follows:

$$Q = Q_{IN}\left(\frac{T}{T_{IN}}\right)\left(\frac{P_{IN}}{P}\right)\left(\frac{PM_{mix}^{IN}}{PM_{mix}}\right) \tag{5}$$

The model is solved by spatial discretization with finite-difference method based on backward derivative approximation so a set of DAE systems are received. Parallel Gear multi-value methods (Buzzi-Ferraris and Manenti, 2012a, b) are adopted.

3. Model validation

Model validation was carried out on different systems to assess the generality and reliability of the model. Hereinafter, the agreement of model predictions and experimental data is given for the deep desulfurization process of industrial off gas obtained using the mobile miniplant technology available at TU Berlin. This process aims at converting sulfur content of COS and CS_2 into H_2S by heterogeneous catalysis. The desired hydrolysis reactions are:

$$COS + H_2O \leftrightarrow H_2S + CO_2 \quad \text{and} \quad CS_2 + 2H_2O \leftrightarrow 2H_2S + CO_2 \tag{6}$$

The inlet molar fraction was: H_2, 0.61; CH_4, 0.21; CO, 0.06; N_2, 0.07; olefins, 0.02; CO_2, 0.012; and organosulfur compounds, 0.0002.

3.1. Experimental Setup

Experiments were conducted with a mobile and modular test plant that was constructed for testing catalysts under real conditions with industrial gas (Günther et al., 2012). The main part of the plant is a fixed bed reactor with a diameter of 100 mm and a maximum number of 5 catalytic beds, each of which is 100 mm long (Figure 1). The ratio of bed diameter to particle diameter is >8 for most industrial catalysts, which leads to the assumption of negligible radial concentration gradients (Chu and Ng, 1989) as in PHoCa suite. The temperature was measured at the reactor inlet and after each catalyst bed by resistance thermometers PT 100 inside the gas stream, as well as on the outer wall by thermocouples. Values were recorded every second by ABB Freelance control system. Therefore, heat generation and losses over the wall can be determined. For chemical analysis, gas samples were drawn in front of and after the reactor. Relevant components (organosulfur compounds and H_2S) were quantified by gas chromatography at stationary points. The inlet reactor temperature and the Gas Hourly Space Velocity (GHSV) were varied in the experiments and determine the conversion of COS and CS_2.

3.2. PBR simulations and data fitting

The model described above was adapted to the miniplant process by assigning geometric data, inlet conditions and reaction kinetics. The kinetic parameters of the main reactions (6) were estimated by adaption to the experimental data (both temperature and concentration) using a stationary method developed by Schöneberger (2010). The results of the simulations are shown in Figures 2 and 3 for the temperature profiles and concentration of organosulfur compounds, respectively. Due to the heat losses over the wall, a drop of temperature can be seen over the length of the reactor. Upon feeding the process gas to the reactor at t = 0 s, the temperature starts to rise until a stationary profile is reached after approx. 10,000 s. As can be seen in Figure 2, the measured temperatures can be well predicted with the simulations. In addition, the concentrations of the two key components COS and CS_2 were simulated and the result is shown in Figure 3. The simulations show good agreement with the measured outlet concentrations of both components for the relevant operating range.

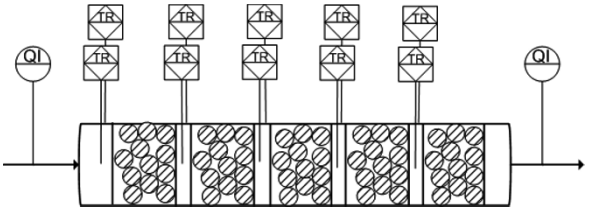

Figure 1. Schematic drawing of miniplant test reactor with temperature and quality measurement.

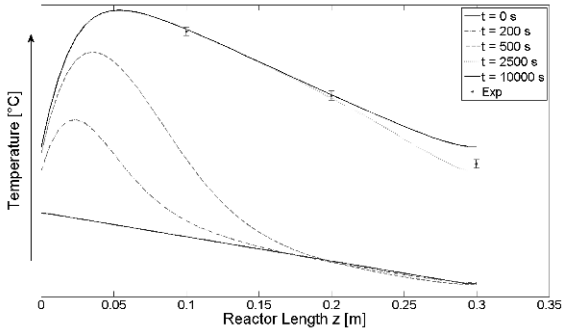

Figure 2. Qualitative gas temperature over the length of the reactor and for different times until a stationary point is reached after 10,000s. Experimental data points are indicated at z = 0.1, 0.2, 0.3.

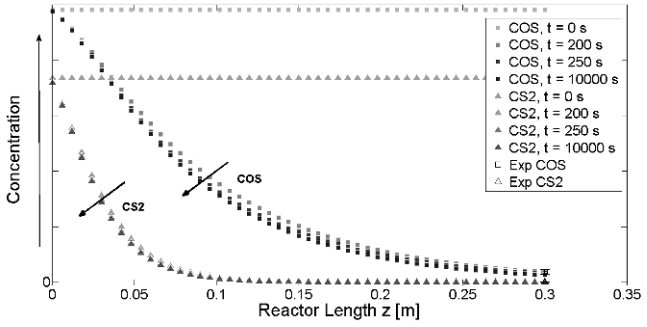

Figure 3. Qualitative concentration of the components COS and CS_2 over reactor length and variation over time. The stationary outlet concentrations of both components were measured and are indicated at z = 0.3.

4. Plantwide predictive monitoring of sulfur emissions of Claus plants

After validation, the dynamic model was applied to model the catalytic units of a Claus process. Claus processes consist of a thermal reactor furnace, where the acid gas (mainly H_2S) is fed together with combustion air, a waste heat boiler to recover heat and generate medium pressure steam, a series of sulfur condenser and a series of catalytic reactors (packed bed reactors for sulfur removal and organosulfur hydrolysis). The most relevant emission for these processes is SO_2; therefore, the reactions of interest is the Claus reaction to produce elemental sulfur:

$$2H_2S + SO_2 \leftrightarrow \frac{1}{2}S_6 + 2H_2O \tag{7}$$

S_6 only is considered in this study as it is the principal allotrope at the reactor operating conditions (sulfur equilibria). The chemical kinetics for reaction (7) were taken from the literature (Tong et al., 1997) and employed to the model. Using the outlet stream of the previously developed model of the thermal furnace and waste heat boiler (Manenti et al., 2013) as an inlet for the newly developed model of PBRs, the entire Claus plant can be simulated. A sensitivity analysis considering the inlet airflow to the thermal furnace was conducted and extreme conditions for the main polluting component SO_2 are displayed in the same graph (Figure 4). The trends show that under optimum conditions, the concentrations of SO_2 is relatively low. However, a change in operating conditions, (here an increase of inlet air mass flow by 25%) shows a major impact on the outlet concentration of SO_2 and therefore a critical condition for emission production is reached.

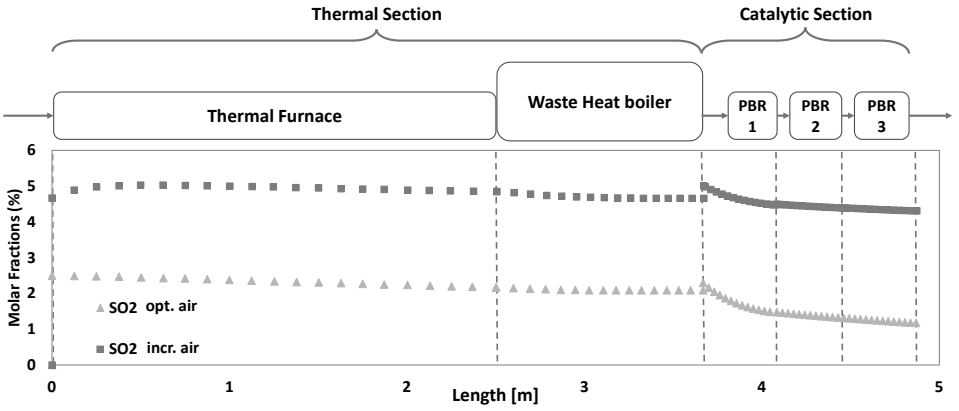

Figure 4. Simulation of relevant sulfur component SO_2 for entire Claus plant including thermal section and catalytic section for two operating conditions concerning airflow.

5. Conclusions

In this work, a first principle fixed bed reactor model based on a partial differential equation system for simulation and monitoring of sulfur recovery units was presented. The predictive monitoring of sulfur emissions was experimentally validated using process data from a miniplant which was coupled to an industrial production line and operated over a wide range. The PBR model was then applied to the catalytic train of a Claus plant which therefore enables plantwide monitoring of relevant species such as

SO_2. Therefore, it is possible to predict in advance which operating conditions lead to a violation of emission limit values.
In contrast to the work of Tong et al. (1997), who developed a stationary and heterogeneous model for the catalytic Claus units in particular with high degree of detail, our model can be used as a first approach for sulfur tail gas treatment units when the level of information on the process is little as this is mostly the case in industrial processes.

Acknowledgments

Alexander von Humboldt Foundation is gratefully acknowledged by the authors for funding professorship and hosting institution. We also thank the student Riccardo Ratti for his contribution on the simulations.

Robust Control of Industrial Propylene-Propane Fractionation Process

Cristian Patrascioiu, Nicolae Paraschiv, Anh Cao Minh, Marian Popescu

[a]*Petroleum-Gas University of Ploiesti, Bd. Bucuresti 39, Ploiesti 100680, Romania*

Abstract

The paper presents some results in the field of the industrial propylene-propane separation process control. The process inputs and outputs, the quality specifications for the separated products and the possible pairs of control agents, based on the relative gain array, are analyzed. The analysis emphasized the fact that the control structure based on L and B control agents is the most suitable. Starting from this result two robust control structures for the quality of the separated products are developed. The first structure refers to the feedback control of the distillate quality, and the second structure is associated with feedforward control of top and bottom products quality. Each structure was tested using dynamic simulation for the same step input of the feed flowrate disturbance. Test results confirmed the superiority of feedforward control.

Keywords: fractionation process, dynamic simulation, robust control, feedback control, feedforward control, quality specification

1. Introduction

A binary distillation process may be described by the following groups of variables: outputs (compositions of distillate and bottom product), disturbances (feed flowrate and composition), control agents (reflux flowrate, bottom product flowrate). In systemic approach this is a 2x2 multivariable process. For this process the distillate composition is a hard target and the bottom product composition is a soft target. A hard target refers to a fixed value of the specification (propylene concentration in distillate x_D), and a soft target indicates a range of variation for the specification (propylene concentration in bottom product x_B) (Patrascioiu et al., 2010). This feature directs the automation of the process to a robust control which may ensure the distillate specification at minimum cost. This objective can be achieved by feedback or feedforward control structures.

2. Analysis of quality control structures

Robust control (viewed as secure, powerful control) of the quality of the separated products in the propylene-propane separation column requires an adequate selection of the control agents used for separated products quality control. A powerful tool for the analysis of theoretical structures for separated products quality control is the Relative Gain Array (RGA). The elements of RGA, denoted by Λ, were calculated using the relations developed by Shinskey (1996) and also based on a steady-state simulation of the process using Unisim® Design simulation environment (Honeywell, 2009). Table 1 presents the calculated values of the relative gains for a series of control structures: *L-V*, *L-B*, *D-V*, *D-B/L*, *D-V/B*, *S-B/L*, *S-V/B*. The significance of the symbols used in table 1 is: *L* – reflux flowrate; *B* – bottom product flowrate; *D* – distillate flowrate; *V* – boilup flowrate; *S* – separation factor.

Table 1. Values of the relative gains for different control structures

Structure name	RGA value	Structure name	RGA value	Structure name	RGA value	Structure name	RGA value
Λ_{DV}	0.841	Λ_{LV_B}	0.828	Λ_{LD}	0.165	$\Lambda_{SL/B}$	0.942
$\Lambda_{DL/B}$	1.019	Λ_{SD}	0.241	Λ_{LB}	1.010	$\Lambda_{SV/B}$	1.015
$\Lambda_{DV/B}$	1.042	Λ_{SV}	2.435	Λ_{LV}	20.831	Λ_{DS}	0.758
$\Lambda_{LL/B}$	0.910						

The criteria used for selecting the best control structure were: value of the relative gains as close to 1 as possible and use of the lowest flowrate (*B* or *D*) as control agent (Mihalache et al., 2008). The analysis of the mentioned structures showed that the *L-B* structure is the most adequate for industrial implementation of a robust control system for separated products quality. Figure 1 shows the control structure of top and bottom compositions using *L* and *B* flowrates as control agents.

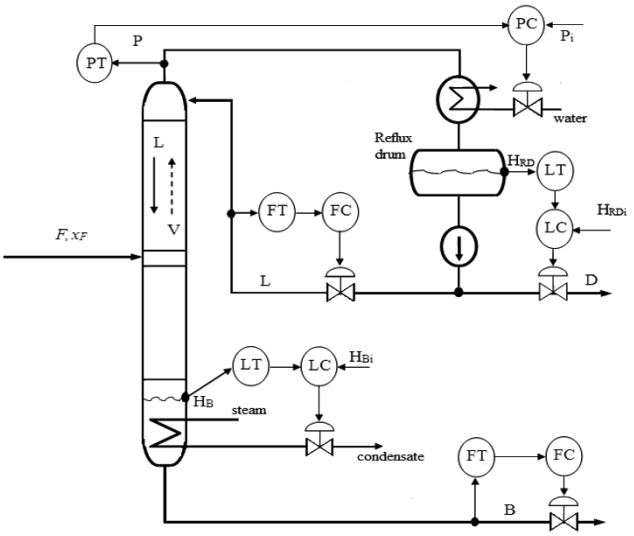

Figure 1 L-B control structure

3. Dynamic simulation of proposed control structures

Performance testing of the proposed control structures for the propylene-propane separation column was done by dynamic simulation using Unisim® Design simulation environment (Honeywell, 2010). In order to achieve this the following steps were completed: steady-state configuration of the separation process, implementation of the *L-B* structure, tuning of the (pressure, level and flowrate) controllers associated with *L-B* structure, implementation of the quality control system and tuning of the related controllers, implementation of the feedforward control structure.

3.1. Steady-state configuration of the separation process using UniSim® Design

The simulator for the propylene-propane separation column was configured using the standard Distillation Column module, taking into account the design and operating parameters presented in table 2.

Table 2 Main design and operating parameters of the column

Parameter	Measurement unit	Value
Number of theoretical trays	-	80
Feed tray	-	30
Feed flowrate	kmole/h	612.4
Feed pressure	bar	20.68
Condenser pressure	bar	19.31
Reboiler pressure	bar	20.68
Reflux flowrate	kmole/h	5500
Bottom product flowrate	kmole/h	150

3.2. Implementation of the L - B control structure

Figure 2 shows a diagram of the simulator obtained by implementing the control structure from figure 1. The control systems in figure 2 have the following meanings: FIC-100 – feed flowrate controller, PIC-100 – top pressure controller, LIC-100 – reflux drum level controller, LIC-101 – reboiler level controller, FIC-101 – bottom product flowrate controller. Some implementation details are presented in (Patrascioiu et al., 2014). As regards the solving of the dynamic models compatibility problems, the Dynamic Assistant function included in Unisim® Design was used.

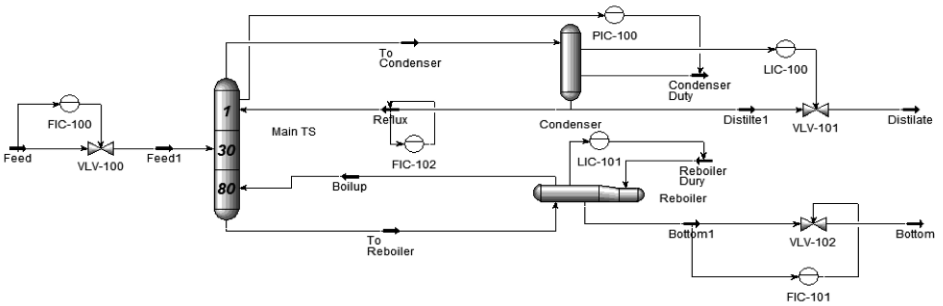

Figure 2 Dynamic simulation diagram of the *L-B* control structure

Table 3. Control system configuration parameters

	Parameter	FIC-100	FIC-101	FIC-102	PIC-100	LIC-100	LIC-101
Controller	Action	Reverse	Reverse	Reverse	Direct	Direct	Direct
	PV min	0 m^3/h	0 m^3/h	0 m^3/h	0 kPa	0 %	0 %
	PV max	80 m^3/h	26 m^3/h	894 m^3/h	3800 kPa	100 %	100 %
	Kc	0.25	0.20	0.25	2	0.05	0.5
	Ti [min]	0.20	0.25	2	0.1	25	0.75
Control valve	Cv	41.10	32.63	-	-	93.80	-
	DeltaP	500 kPa	50 kPa	-	-	50 kPa	-

3.3. Controller tuning of the L-B control structure

The dynamic simulator cannot be used without tuning the controllers associated ~~to~~ with the distillation column and the feed flowrate. Table 3 contains the values of the tuning parameters and other elements related to the control loops configuration (Action, PVmin, PVmax, Cv, DeltaP).

The configured *L-B* structure was tested through simulation to step variation of feed flowrate from 50.62 m^3/h to 55 m^3/h. As shown in figure 3, which displays the simulation results, there are different dynamics on channels F-x_D and F-x_B. This behavior is caused by different speeds of L and V flows through the column and by hydraulic delays introduced by the plates below the feed tray.

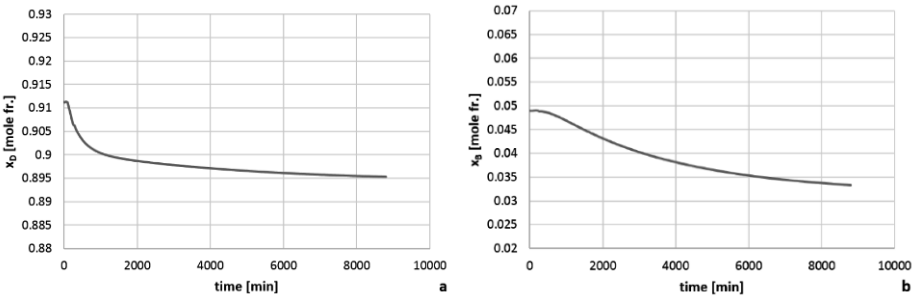

Figure 3 Dynamic response of the propylene concentration in: a) distillate; b) bottom product

Analysis of the time evolutions in figure 3 showed that the dynamic on channel F-x_D can be approximated with a first order element, whereas on channel F-x_B the approximation can be described with a second order element. These results will be starting points for the development of the robust control structure.

3.4. Feedback robust control design

The propylene-propane distillation column is characterized by strong interactions on channels disturbances – propylene concentration and control agents – propylene concentration. These interactions would require the use of a multivariable controller for quality control, solution which is not considered robust because of the fact that the decoupling algorithms are dependent on operating parameters.

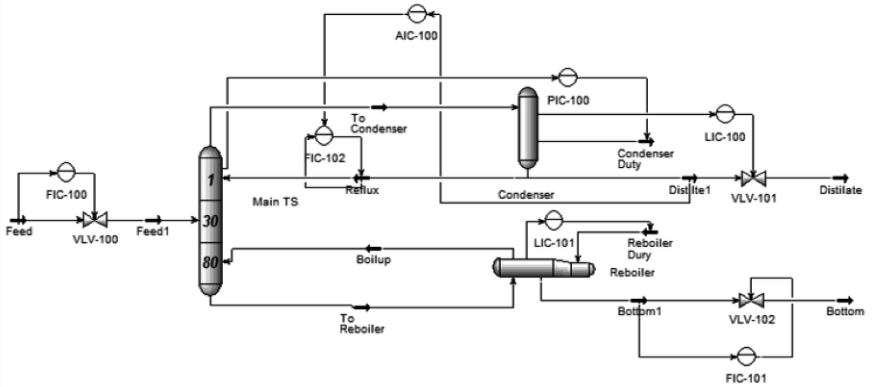

Figure 4 Dynamic simulation diagram of the feedback robust control structure

The design of the feedback robust control structure is based on the fact that only the propylene concentration in distillate requires a fixed value (hard target). The propylene concentration in the bottom product may take values within a range (soft target). In these conditions, the distillate quality control is sufficient. This objective is materialized in a feedback control system for the propylene concentration in distillate with reflux flowrate as manipulated variable. In order to dynamically simulate this system the simulator was reconfigured obtaining the structure in figure 4. For the concentration controller, AIC-100, the following parameters were set: Action = Reverse, PV min = 0, PV max = 1, Kc = 1.2, Ti = 25 min.

The developed control structure was simulated for the same variation of the feed flowrate as in the first case, from 50.62 m^3/h to 55 m^3/h. The time evolutions of the propylene concentration in distillate and bottom product are illustrated in figure 5. It can be observed that this control structure ensures the control of x_D (propylene concentration in distillate), whereas the propylene concentration in the bottom product is allowed to evolve relatively free. The decrease of x_B is explained by the fact that the bottom product flowrate was controlled when the feed flowrate was increased.

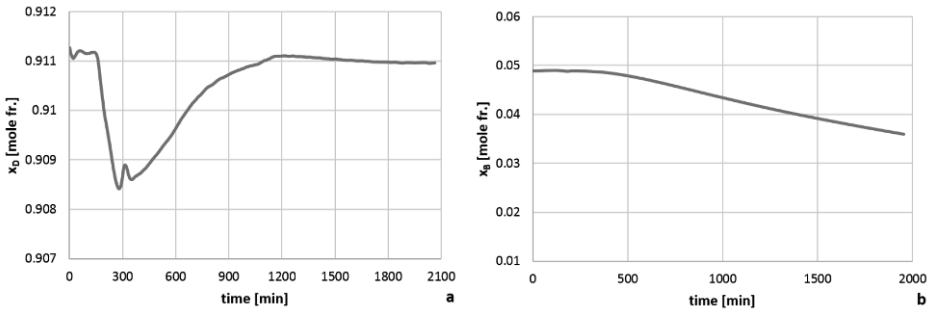

Figure 5 Dynamic response of the propylene concentration in: a) distillate; b) bottom product

3.5. Feedforward control structure

The developed feedforward robust control system is also based on *L-B* structure. The feedforward controller generates set-points for the reflux flowrate and the bottom product flowrate control system. These signals are calculated in real time by processing the two disturbances (feed flowrate - F and concentration of propylene in feed - x_F).

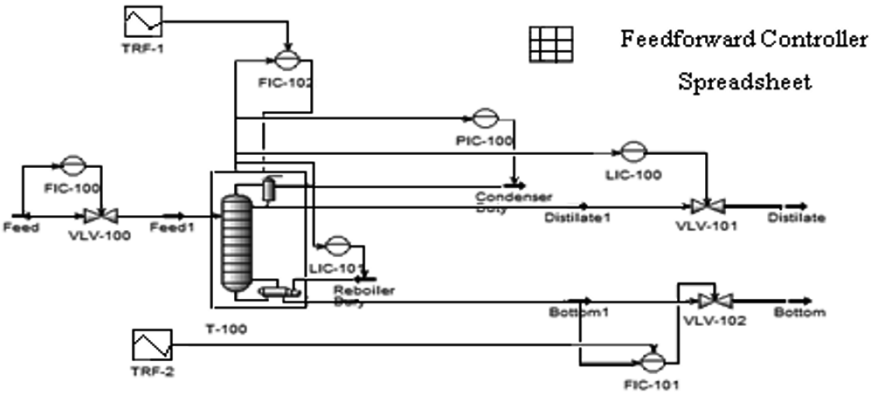

Figure 6 Dynamic simulation diagram of feedforward control structure

The feedforward controller implements the model based on Fenske-Underwood relations and Gilliland correlation (Marinoiu et al., 1986). The steady-state values of the controller outputs were calculated in the simulator using Feedforward Controller Spreadsheet module. Regarding the dynamic components, they have associated first order elements with gain=1 and the time constants T_L = 150 min. and T_B = 175 min., implemented with TRF module.
The feedforward control structure presented in figure 6 was tested for a change of the feed flowrate from 50.62 m^3/h to 55 m^3/h. Analysis of the time evolutions of concentrations x_D and x_B in figure 7 indicated the absence of transient regimes which were present in the case of feedback robust control system.

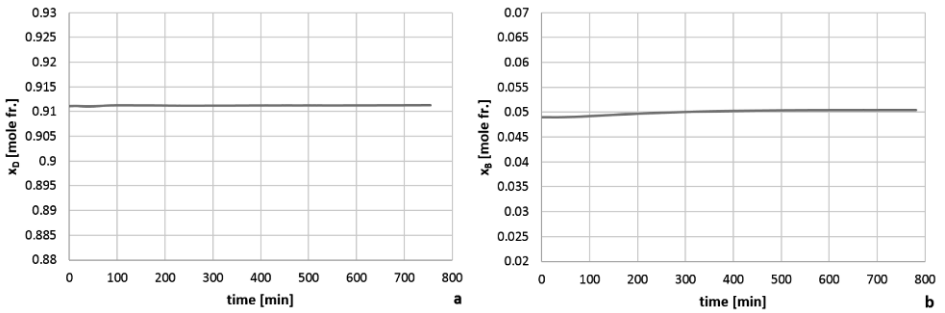

Figure 7 Dynamic response of the propylene concentration in: a) distillate; b) bottom product

4. Conclusions

The paper presents two robust control structures for the quality of products separated in a propylene-propane separation column. Based on relative gain array, the best control structure was selected, respectively *L-B* structure. For this structure, a feedback control system and a feedforward control system for separated products quality control were developed. The dynamic tests performed using Unisim® Design configured for the two robust structures emphasized the superiority of the feedforward control system.

Improved Optimization-based Design of PID Controllers Using Exact Gradients

Chriss Grimholt and Sigurd Skogestad*

Department of Chemical Engineering; NTNU; Trondheim, Norway
**e-mail: skoge@ntnu.no*

Abstract

Finding good controller settings that satisfy complex design criteria is not trivial, even for the simple three parameter *proportional-integral-derivative* (PID) controller. One strategy is to formulate the design problem into an optimization problem. However, when using gradient based optimization with finite differences to estimate the gradients, the algorithm often fails to converge to the optimal solution. This is thought to be a result of inaccuracies in the estimation of the gradients. In this paper we show exact gradients for a typical performance (IAE) versus robustness (M_S, M_T) design problem. We demonstrate increased accuracy in the optimization when using exact gradients compared with forward finite differences.

Keywords: PID control, controller design, optimization, exact gradients, IAE, M_S.

1. Introduction

The simple three parameter *proportional-integral-derivative* (PID) controller is the most adopted controller in the process industry. However, finding good parameter values by trial and error is not only difficult, but also time consuming. In combination with simple models, good parameters are usually found using tuning rules like Ziegler-Nichols or SIMC. When the design complexity increases, in the form of process model complexity or special requirements on controller performance or robustness, it is beneficial to switch to optimization-based design.

Our optimization problem can be formulated as follows,

$$\begin{aligned} \underset{parameters}{\text{minimize:}} \quad & \text{performance cost } (J) \\ \text{subject to:} \quad & \text{required robustness} \end{aligned}$$

where we want the best performance subjected to a required robustness.

The background for this study was to find optimal PID and Smith predictor controller settings for a first-order plus delay process. Here, the performance requirements were to minimize integrated absolute error (IAE) for input and output disturbances, and the robustness criterion was to have a given sensitivity peak (M_S). A similar design formulation has been proposed by Shinskey (1990) where load disturbance was optimized when subjected to sensitivity constraints. By using the link between integral error and integral gain (IE $= 1/k_i$), Åström et al. (1998) formulated the optimization problem for PI control as a set of algebraic equations which could be efficiently solved. In Panagopoulos et al. (2002) the formulation was extended to PID control. However, using IE as the performance criterion can lead to oscillatory response, especially for PID controllers.

Initially, we solved this optimization problem using gradient-free optimization, similar to the work done by Garpinger and Hägglund (2008). Natively, gradient-free approaches, like the simplex

method, does not explicitly handle constraints. To bypass this, the constraints are handled internally by an internal solver. For our application, generating optimal trade-off curves for PID controllers, requiring hundreds of accurate sequential optimizations, the gradient-free method was too slow due to the internal solver and the number of iterations required to converge.

By switching to gradient based methods, using finite-differences to estimate the gradients, we achieved faster convergence. However, the optimization algorithm frequently failed to converge to the solution. Surprisingly, this also occurred even though the initial guess was very close to the local optimum. In our case, it seems that the main problem is not necessarily the non-convexity of the problem and the possibility for local minima, but rather inaccuracies in the estimation of the gradients when using finite-differences. We found that the robustness of the optimization was significantly improved by supplying the exact gradients.

In this paper we show and use exact gradients for IAE of the time response and the peak of the sensitivity functions M_S, and M_T. The main advantage of using accurate gradients is that we improve the convergence properties and make the problem less sensitive to the initial point. The approach has been successfully used to find optimal PID on a first-order with delay processes. But the method can also easily be extended to other processes and controllers.

2. The closed-loop system

In this paper we consider the linear feedback system as shown in Figure 1. Disturbances can enter the system at two different locations, at the plant input (d_u) and the plant output (d_y). The disturbance at the plant output is equivalent to a setpoint change. However, unlike setpoint changes, the output disturbance is not known in advance. Measurement noise (n) enters the system at the measured output (y). This system is represented by four transfer functions nicknamed *the gang of four*,

$$S(s) = \frac{1}{1+G(s)K(s)} \qquad T(s) = 1 - S(s)$$

$$GS(s) = G(s)S(s) \qquad KS(s) = K(s)S(s)$$

where their effect on the control error and plant input is,

$$-e = S(s)\,d_y + GS(s)\,d_u + T(s)\,n \tag{1}$$

$$-u = KS(s)\,d_y + T(s)\,d_u + KS(s)\,n \tag{2}$$

Though we could use any fixed-order controller, we chose in this paper to use the parallel PID controller as an example;

$$K_{\text{PID}}(s;p) = k_p + \frac{k_i}{s} + k_d s = K_c\left(1 + \frac{1}{\tau_I s} + \tau_D s\right); \quad p = \begin{pmatrix} k_p & k_i & k_d \end{pmatrix}^T \tag{3}$$

where $k_p = K_c$, $k_i = K_c/\tau_I$, and $k_d = K_c\,\tau_D$ is the proportional, integral, and derivative gain, respectively. The parallel PID controller can have complex zeros, which we have observed can result in several peaks or plateaux for the magnitude of sensitivity function in the frequency domain $|S(j\omega)|$. This becomes important when adding specifications on the frequency behaviour, which we will show later.

3. Quantifying the optimal controller

3.1. Performance

In this paper we chose one of the most popular ways of quantifying controller performance, the integrated absolute error (IAE);

$$\mathrm{IAE}(p) = \int_0^{t_f} |e(t;p)| \, \mathrm{d}t \tag{4}$$

when subjecting the system to a disturbance. We take both input and output disturbances into account and choose the weighted cost function,

$$J(p) = 0.5 \left(\varphi_{dy} \, \mathrm{IAE}_{dy}(p) + \varphi_{du} \, \mathrm{IAE}_{du}(p) \right); \quad \varphi_{du} = \frac{1}{\mathrm{IAE}^{\circ}_{du}}; \quad \varphi_{dy} = \frac{1}{\mathrm{IAE}^{\circ}_{dy}} \tag{5}$$

where both terms are weighted equally with 0.5 to get a good balance. The φ_{dy} and φ_{du} are scaling factors from IAE-optimal PID controllers for a step load change on the input and output, respectively. To ensure robust reference controllers, they are required to have $M_S = M_T = 1.59$. Note that two different controllers are used to obtain the reference IAE° values, whereas a single controller $K(s;p)$ is used to find $\mathrm{IAE}_{dy}(p)$ and $\mathrm{IAE}_{du}(p)$.

3.2. Robustness

In this paper we have choosen to quantify robustness in terms of M_S and M_T;

$$M_S = \max_{\omega} |S(j\omega)| = \|S(j\omega)\|_{\infty}$$
$$M_T = \max_{\omega} |T(j\omega)| = \|T(j\omega)\|_{\infty}$$

where $\|\cdot\|_{\infty}$ is the H_{∞}-norm. In the Nyquist plot, M_S is the inverse of the closest distance between the critical point $(-1,0)$ and the loop transfer function $L(s) = G(s)\,K(s)$.

The closed-loop system is insensitive to small process variations for frequencies where the sensitivity function $\left|S(j\omega)\right|$ is small (Åström and Hägglund, 2006). On the other hand, small values of the complementary sensitivity function $|T(j\omega)|$ tells us that the closed-loop system is insensitive to larger process variation. The system is most sensitive at the peak of the sensitivity functions (M_S and M_T).

From experience, using only the peaks can lead to cycling between iterations. This is typical for PID control on first order models, where the optimal controller has several peaks of equal magnitude in $S(j\omega)$. The optimizer then discreetly jumps from using one peak to the other between iterations. It is assumed that this results from the peaks having different gradients. To avoid this problem,

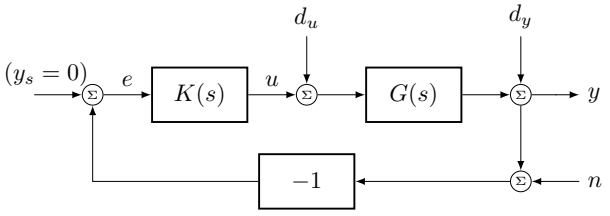

Figure 1: Block diagram of the closed loop system, with controller $K(s)$ and plant $G(s)$.

instead of putting the upper bounds on the peaks, e.g. $M_S \leq M_S^{ub}$, we choose to require

$$\left|S(j\omega)\right| \leq M_S^{ub} \qquad \text{for all } \omega$$

which in addition to handling multiple peaks and plateaux, also improves convergence for infeasible initial controllers. The constrain is approximated by gridding the frequency domain within the interesting region, resulting an inequality constraint for each grid point;

$$\left|S(j\omega)\right| \leq M_S^{ub} \qquad \text{for all } \omega \text{ in } \Omega$$

where Ω is the set of selected frequency points during the gridding of the frequency domain. This results in reduced accuracy and increased computational load. However, the benefit gained towards improved convergence properties makes up for this.

4. Implementation of the optimization problem

The optimization problem can be stated as follows,

$$\begin{aligned}
\underset{p}{\text{minimize}} \quad & J(p) = 0.5\left(\varphi_{dy}\,\text{IAE}_{dy}(p) + \varphi_{du}\,\text{IAE}_{du}(p)\right) \\
\text{subject to} \quad & c_s(p) = |S(j\omega;p)| - M_S^{ub} \leq 0 \quad \text{for all } \omega \text{ in } \Omega \\
& c_t(p) = |T(j\omega;p)| - M_T^{ub} \leq 0 \quad \text{for all } \omega \text{ in } \Omega
\end{aligned}$$

where M_S^{ub} and M_T^{ub} are the upper bounds on $\left|S(j\omega)\right|$ and $\left|T(j\omega)\right|$. If there is a trade-off between performance and robustness, at least one robustness constraint will be active.

5. Gradients

The gradient of a function $\nabla f(p)$ with respects to p is defined as

$$\nabla_p f(p) = \begin{pmatrix} \frac{\partial f}{\partial p_1} & \frac{\partial f}{\partial p_2} & \cdots \frac{\partial f}{\partial p_n} \end{pmatrix}^T \tag{6}$$

where n_p is the number of parameters. In this paper, p_i reference to the parameter i, and the partial derivative $\frac{\partial f}{\partial p_i}$ is called the sensitivity of f. The sensitivities can be approximated by forward finite differences,

$$\frac{\partial f}{\partial p_i} \approx \frac{f(p_i + \Delta p_i) - f(p_i)}{\Delta p_i} \tag{7}$$

requiring $(1+n_p)$ perturbations. For our problem this results in $2(1+n_p)$ step response simulations. The accuracy can be improved by using central differences, which requires $(1+2n_p)$ perturbations.

5.1. Cost function gradient

The gradient of the cost function $\nabla_p J(p)$ is then expressed in terms of the sensitivities,

$$\frac{\partial J(p)}{\partial p_i} = 0.5\left(\varphi_{dy}\,\frac{\partial \text{IAE}_{dy}(p)}{\partial p_i} + \varphi_{du}\,\frac{\partial \text{IAE}_{du}(p)}{\partial p_i}\right) \tag{8}$$

For even relatively simple systems with time delay, these integrals becomes quite complicated, if not impossible, to solve. However, the sensitivities can be found in a fairly straight forward manner by developing them such that the integrals can be numerically evaluated. The sensitivity of IAE can be expressed as,

$$\frac{\partial \text{IAE}(p)}{\partial p_i} = \int_0^{t_f} \text{sign}\left\{e(t;p)\right\}\left(\frac{\partial e(t;p)}{\partial p_i}\right) \mathrm{d}t \tag{9}$$

where $e(t;p) = \mathscr{L}^{-1}\left\{e(s;p)\right\}$ and $\frac{\partial e(t;p)}{\partial p_i} = \mathscr{L}^{-1}\left\{\frac{\partial e(s;p)}{\partial p_i}\right\}$

For the case given in Figure 1 with unit steps load disturbances, the error $e(s;p)$ is $S(s;p)/s$ for the output disturbance dy and $GS(s;p)/s$ for the input disturbance du. The transient $\partial e(t;p)/\partial p$ can then easily found by step response simulations of

$$\frac{\partial S(s)}{\partial p_i} = -GS(s)\, S(s)\, \frac{\partial K(s)}{\partial p_i} \tag{10}$$

$$\frac{\partial GS(s)}{\partial p_i} = -GS(s)\, GS(s)\, \frac{\partial K(s)}{\partial p_i} \tag{11}$$

The gradient of IAE is then calculated by evaluating (9) using numerical integration, and the method is closely related to using direct sensitivities in optimal control problems. This results in $2(1+n_p)$ step response simulations, which is the same as the forward finite differences approximation in (7).

5.2. Constraint gradients

The gradient of the robustness constraints $\nabla c_s(p)$ and $\nabla c_t(p)$ expressed in terms of the parameter sensitivities are,

$$\frac{\partial c_s(j\omega)}{\partial p_i} = \frac{\partial |S(j\omega)|}{\partial p_i} = \frac{1}{\left|S(j\omega)\right|} \mathrm{Re}\left\{S(-j\omega)\, \frac{\partial S(j\omega)}{\partial p}\right\} \qquad \text{for all } \omega \text{ in } \Omega \tag{12}$$

$$\frac{\partial c_t(j\omega)}{\partial p_i} = \frac{\partial |T(j\omega)|}{\partial p_i} = \frac{1}{\left|T(j\omega)\right|} \mathrm{Re}\left\{T(-j\omega)\, \frac{\partial T(j\omega)}{\partial p}\right\} \qquad \text{for all } \omega \text{ in } \Omega \tag{13}$$

If the constrains were instead expressed in terms of the peaks of the transfer functions (e.g. $M_S \leq M_S^{ub}$) the gradients become as follows,

$$\frac{\mathrm{d}}{\mathrm{d}p_i} \|G(j\omega;p)\|_\infty = \frac{\partial}{\partial p_i} |G(j\omega_{peak};p)| \tag{14}$$

where ω_{peak} is the frequency of the peak.

6. Case study

The exact gradients were implemented for the problem;

$$G(s) = \frac{e^{-s}}{s+1};\ \mathrm{IAE}^{\circ}_{dy} = 1.56;\ \mathrm{IAE}^{\circ}_{du} = 1.42;\ M_S^{ub} = M_T^{ub} = 1.3;\ p_0 = \begin{pmatrix} 0.2 \\ 0.02 \\ 0.3 \end{pmatrix} \tag{15}$$

To make the loop function proper, a first order filter with filter time constant $\tau_F = 0.001$ was added to the controller. The error response and parameter sensitivity was found by fixed step integration ($t_f = 25$, $n_{\text{steps}} = 10^4$), with the initial point p_0. The problem was solved using Matlab's fmincon with the active set algorithm. For comparison, forward finite differences was used to approximate the gradients. This problem has two equal M_S peaks at the optimum (Figure 2), and is a typical example of a problem exhibiting cyclic behaviour when using the $M_S \leq M_S^{ub}$ constraint. The optimal error response is shown in Figure 3.

The exact gradients performed better than the finite differences (Table 1). The exact cost function gradients give the best improvement. This signals that the optimum is relatively flat, and that the approximated cost function gradients are not precise enough to find the true local optimum. The same test was performed for different numbers of time steps during the integration. Even with $n_{\text{steps}} = 10^5$, the forward finite differences failed to converge to the local optimum (controller parameter error in the second digit). On the other hand, the exact gradient could still converge to the local optimum with as low as $n_{\text{steps}} = 500$ (control parameters error in the fifth digit). The exact gradient converged for most stable initial guesses, but the forward finite differences failed to

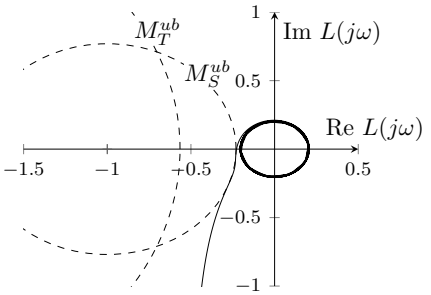

Figure 2: Nyquist plot of $L(j\omega)$ with the optimal controller for the problem given in (15).

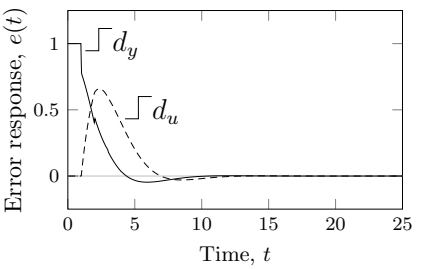

Figure 3: Optimal error response for the problem given in (15).

find the optimum even when started very close to the optimum $p_0 = \begin{pmatrix} 1.001p_1^\star & p_2^\star & p_3^\star \end{pmatrix}^T$. When using central finite differences, the accuracy was increased. However, this requires $2(1+2n_p)$ step simulations.

Table 1: Comparison between optimal solutions with different combinations of gradients.

Gradient type		Cost function	Optimal parameters			number of
Cost-function	Constraints	$J(p^\star)$	k_p	k_i	k_d	iterations
exact	exact	2.0598	0.5227	0.5327	0.2172	13
fin.dif.	exact	2.1400	0.5204	0.4852	0.1812	16
exact	fin.dif.	2.0598	0.5227	0.5327	0.2172	13
fin.dif.	fin.dif.	2.9274	0.3018	0.3644	0.2312	11

7. Conclusion

In this paper we have successfully applied the exact gradients for a typical performance (IAE) versus robustness (M_S, M_T) optimization problem. The exact gradients improved the convergence to the true optimal point when compared to gradients approximated by forward finite difference.

Abstract

The xylitol production has become an important process to investigate given the diverse product applications, especially in the food industry. The biotechnological xylitol production has been assessed mainly through an experimental approach via batch and fed-batch operation. This study presents an analysis for optimal operation of the fed batch process following a systematic methodology. The model based approach includes the collection, validation and calibration of the mathematical model, followed by the proposal of some operation scenarios. The implementation of such methodology allowed to increase 20% the yield of xylitol compared with the obtained previously in some experiments. Moreover, an analysis for the diauxic phenomenon was also performed, allowing to determine an optimal feeding ratio between substrates.

Keywords: xylitol bioproduction, fed-batch operation, optimal feeding policy

1. Introduction

Due to the gradual increase in worldwide energy consumption, research efforts have been directed to biofuels production mainly employing lignocellulosic material. Nevertheless, economic analyses have shown that production of biofuels and high value-added products should be performed simultaneously to enhance profitability; such high value-added products are xylitol, polylactic acid acid, sorbitol, levulinic acid, furfurals, among others (van Ree and Annevelink, 2007).

Xylitol is a natural five-carbon sugar alcohol usually employed as sugar substitute since it prevents dental caries. Recently, its biotechnological production using yeast from genera *Saccharomyces*, *Candida* and *Pichia* has gained interest (Granström et al., 2007). For instance, *Candida mogii* can produce xylitol from xylose by action of the enzyme xylose reductase. A drawback of this bioprocess is that the produced xylitol can be consumed by the microorganism to generate cell mass and maintenance energy. It has been shown that the addition of glucose in the fermentation broth can improve the

xylitol yield, because glucose can partially substitute xylitol as substrate in the growth metabolic pathway. However, it must be considered that high glucose concentration might inhibit xylose transport into the cell and repress induction of relevant enzymes for the xylose assimilation. From the model-based simulation perspective, a mathematical model describing xylitol batch production has been presented by Tochampa et al. (2005), and it has also been extended by Hernandez-Escoto et al. (2014) for a continuous reactor including some control scenarios. In order to improve the xylitol production, Sirisansaneeyakul et al. (2012) performed some experiments introducing a fed-batch operation for xylitol production, where a feeding policy was proposed to increase the yield xylitol/xylose in the reactor. The experiments showed an improvement in the xylitol production during intermittent fed-batch fermentations; however, there was no certainty whether the findings can be considered as optimal results. In order to address this issue, the objective of this work is to propose fed-batch operation scenarios for xylitol production using a model-based framework. The process system provided by Sirisansaneeyakul et al. (2012) was taken as benchmark.

2. Methodology

The methodology employed to reach the proposed objective is illustrated in Figure 1, which considers 4 main steps.

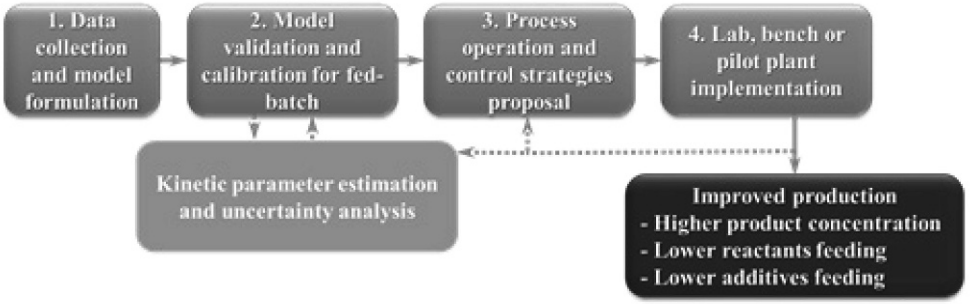

Figure 1. Model-based framework for enhanced and controlled operation of a fed-batch reactor.

The first step is the data collection and model structure formulation, where a kinetic mathematical model is proposed or obtained/extended from the literature. The second step is the model validation employing experimental data; if necessary, a model parameters calibration is performed, and complemented by an uncertainty analysis. Using the model and process insights from step 2, the third step is to propose diverse optimal operation scenarios according to a processing objective, i.e. higher product concentration, enhanced bioreactor productivity and higher biomass growth. The main outcome of the scheme is the final step where experiments are proposed at lab, bench or pilot plant scale, based on the outcomes of step 3. The results of step 4 can be then employed to recalibrate the model or to propose other operational and control scenarios. In general, this methodology could be used for other fed-batch fermentations systems in order to enhance product generation related to certain constraints, such as, product inhibition, substrate inhibition, operational constraints, etc.

3. Results

The implementation of the model-based framework (Figure 1) for optimized operation of a fed-batch reactor was performed for xylitol production employing a biotechnological route.

3.1. Data collection and model formulation

This work considered the mathematical model of xylitol production proposed by Tochampa et al. (2005). Since the mathematical model was originally proposed for a batch operation, the model structure was extended to describe a fed-batch operation.

3.2. Model validation and calibration for fed-batch

The modified mathematical model was then validated using some data previously published by Sirisansaneeyakul et al. (2012), where the authors proposed a fed-batch operation. Figure 2a illustrates the validation performed by comparison of fed-batch model with original kinetics parameters with respect to experimental data. The model trajectories showed mismatch with respect to experimental data, which could be associated with the experimental conditions during fed-batch operation.

Therefore, a calibration of the kinetic parameters was related with low accuracy of the model in the fed-batch operation. The least-squares nonlinear function "lsqrnonlin" of Matlab® was employed to re-estimate the kinetic parameters of the mathematical model using three experimental datasets published by Sirisansaneeyakul et al. (2012). Table 1 shows the parameters modified from the original model.

Table 1. Parameter values obtained after parameter estimation.

Parameter	Value	Parameter	Value
$\mu_{xit}^{\max}$, h^{-1} (maximum specific growth rate on xylitol)	0.189	$q_{xyl}^{\max}$, $g-xylose \cdot g-DWC^{-1} \cdot h^{-1}$ (maximum specific uptake rate of xylose)	0.342
$K_{s,xyl}$, $g-xylose \cdot l^{-1}$ (saturation constant based on xylose)	11.761	$K_{s,xit}$, $g-xylitol \cdot l^{-1}$ (saturation constant based on xylitol)	16.06

The simulation results after parameter calibration are illustrated in Figure 2 (solid line), which showed an improvement and better prediction than original parameters of the model. There is still room for improvements.

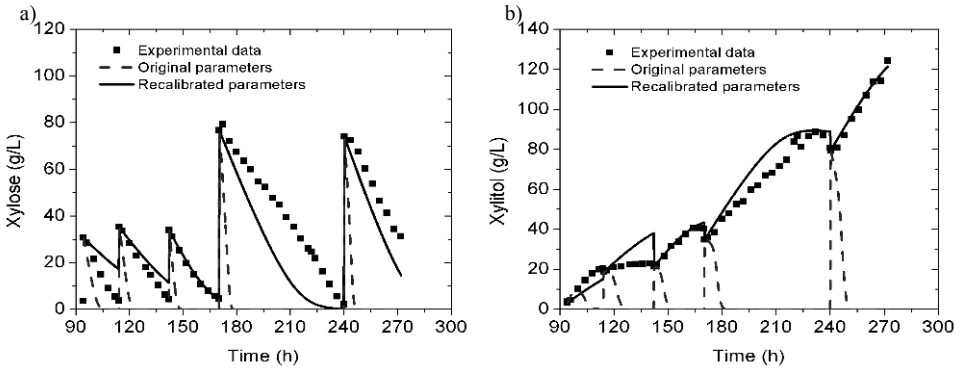

Figure 2. Validation of the recalibrated mathematical model parameters for intermittent operation: a) xylose concentration; b) xylitol concentration.

3.3. Process operation and control strategies proposal

The aim of this part was to investigate operational challenges and potential improvements of the fed-batch fermentation for xylitol production. For this purpose, two case studies were analysed within this contribution: optimal xylose feeding policy and optimal diauxic cultivation. An important characteristic of the implementation is to account for the volume change due to sampling. This is relevant since the final aim is to propose an optimal operation scenario to test at laboratory scale. The constrained optimization problem included the mass balances for the species involved in the reacting system (Eq. 1), the objective function (Eq. 2) and constrains of the problem (Eq. 3).

$$\frac{dX}{dt} = h\left(X, \theta, u\right) \tag{1}$$

$$Max_u\left(F_{obj}\right) = \left(VC_{xylitol} - VC_{xylose}\right)_{final,ts} \tag{2}$$

s.t.

$$g_{operational,l} < g_{operational}\left(X, \theta, u\right) < g_{operational,u} \tag{3}$$

where, X is the set of state variables, u is the model inputs, and θ is the set of model parameters.

The proposed objective function maximizes the amount of xylitol obtained while penalizes the remaining xylose in the fermenter as illustrated in Eq. (2). In this work the influence of weight factors for each contribution in the objective function was not investigated. The optimization problem was subject to operational constraints, which depended on the investigated scenario. The optimization was solved through Matlab® function “fmincon”, based on the interior-point algorithm. During the resolution, the best solution was selected from a series of found local minima.

3.3.1. Optimal xylitol feeding policy

Using selected experimental data from Sirisansaneeyakul et al. (2012) as reference model inputs, the attempt of this study case was to compare the performance of the experimental cultivation and the simulated optimal fed-batch fermentation. The operational constraint imposed in this scenario was that the final reactor volume must not surpass the 70% of the initial value. Each experimental sampling instant was considered as a feeding change instant, where an inlet flow rate was calculated in order to obtain a maximum value of the objective function. The simulation results of the optimal policy for five feeding steps are shown in Figure 3. The biomass concentration remained almost constant since the low growth rate of the microorganism on xylose was compensated with dilution and the simulated bleeding due to sampling. Regarding to xylose concentration, the penalty imposed in the objective function made the feeding policy to dose xylose in order to avoid its accumulation. The final xylitol concentration after almost 180 h reached 48.4 g/L. During the solution of other optimization scenarios for this bioreaction system (not shown here), it was possible to observe that there was a trend in the feeding policy on using a larger amount of substrate at the beginning of the fermentation. The reason was that the system did not exhibit substrate inhibition in the evaluated experimental conditions. Comparing the simulated results with the experimental values used for validation (see Figure 2), lower xylitol production was predicted. The different results are attributed to the model mismatch (especially biomass growth), the different biomass states used during the experiments (pH variations and increasing substrate loads in the intermittent fermentations) and intermittent cultivation

broth dilution with fresh substrate at different concentration. However, the simulation under xylose feeding has shown potential improvement since the xylitol yield from substrate was increased almost 20%. Further work is required in order to find better optimization scenarios.

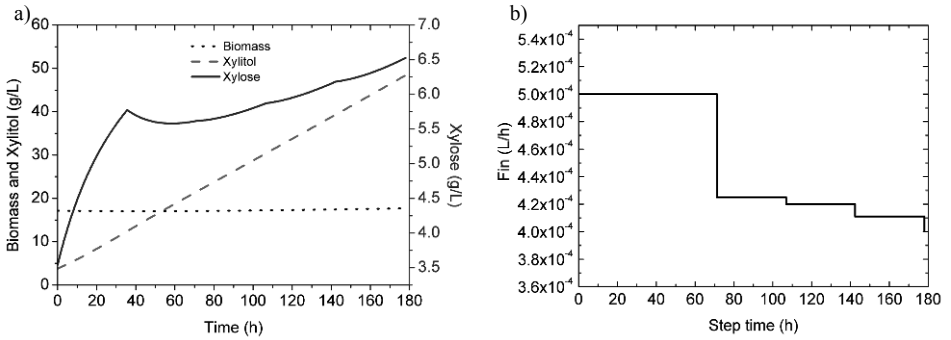

Figure 3. Optimal Fed-batch operation simulation results. The initial conditions are after a batch fermentation to achieve high biomass density. a) Bioreactor concentrations; b) xylose feeding policy at 595 g/L.

3.3.2. Optimal diauxic fermentation

In order to complement the previous efforts using only xylose as substrate, a diauxic growth on xylose and glucose was also investigated; recalling that the addition of glucose in the fermentation broth can improve the xylitol yield, but high concentration can also produce an inhibition on xylitol production (Sánchez et al., 2008; Tochampa et al., 2005). Hence, the objective function was maximized to find the optimal initial concentrations of xylose and glucose as well as the appropriate fermentation time. The problem was subject to maximum concentrations of 100 g/L and fermentation time of 100 h. The optimal solution of diauxic growth and fermentation on xylose are shown in Figure 4. The optimization results indicated that there was an optimal glucose initial concentration and fermentation time in order to exploit the loaded xylose; in this case, the maximum allowed. The optimal glucose addition delayed the xylitol production while favoured the biomass growth. Higher biomass density enhanced the xylose uptake and subsequently the xylitol production. In this case, there is a 40% improvement on xylitol production.

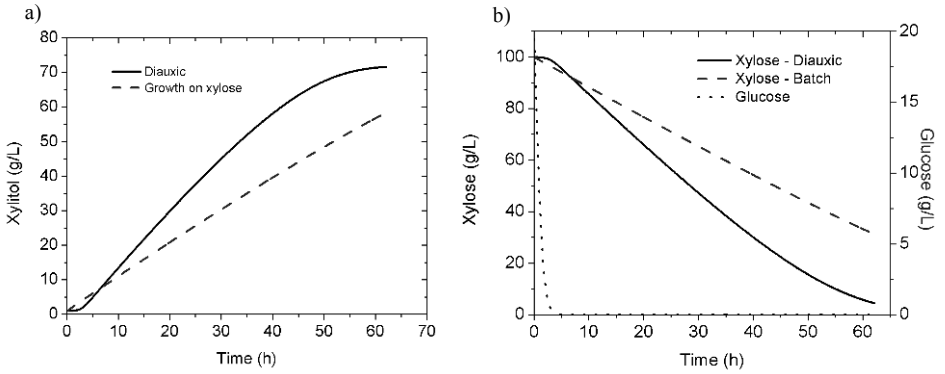

Figure 4. Fed-batch fermentation on xylose compared to fed-batch cultivation on optimal glucose and xylose initial concentrations: a) xylitol; b) xylose and glucose

Despite the main objective of this work that was to generate model-based alternative scenarios to be tested at laboratory, bench or pilot plant scales, an economic analysis was also performed. The economic potential of the processes was evaluated using the current average prices available on-line of product and reactants as bulk chemicals. The results showed that the ratio between the economic potential of the diauxic against batch fermentation was over 2.6. These results are encouraging to validate experimentally the outcomes of the proposed methodology. On the other hand, qualitatively speaking on the basis of results, it is advantageous to use diauxic fermentations since: higher xylitol concentration in the fermentation broth facilitates its downstream separation, and a mixture of substrates makes this process compatible within a biorefinery framework.

4. Conclusion

Due to the challenge of finding optimal operation conditions for bioprocesses from an experimental approach, a model based framework was proposed in this work. The framework was useful to provide system insights that lead to alternative operation scenarios to be tested in the laboratory. Using the xylitol bioproduction as study case, it was shown the potential of using optimal feeding policies in order to enhance productivity and substrate utilization. Comparing the experimental presented by Sirisansaneeyakul et al. (2012) and optimization results obtained in this work, it was possible to observe an improvement in the yield xylitol/xylose by 20%. The analysis of diauxic phenomenon allowed to identify an improvement up to 40% on xylitol production and 260% on the crude economic potential comparing the simulated fed-batch and batch operations. This work showed the potential of a model based approach to bring new perspectives for optimal operation of bioprocesses. Further investigations are required in order to propose and optimal operation scenario to be tested experimentally.

Abstract

If it is desired to control a reactive distillation (RD) system at an unstable operating point, then use of a reliable nonlinear state estimator becomes an essential step in the controller synthesis. This work aims at carrying out a comparative evaluation of the performances of two recently developed nonlinear Bayesian estimators for systems modelled as DAEs, namely extended Kalman filter (EKF) and unscented Kalman filter (UKF) (Mandela et al., 2010). Efficacies of DAE-EKF and DAE-UKF have been evaluated by simulating state estimation problems associated with a benchmark ideal RD column (Olanrewaju and Al-Arfaj, 2006). When compared on the basis of sum squared estimation errors, the DAE-UKF was found to outperform the DAE-EKF. However, contrary to the claims in the state estimation literature regarding the computational efficiency of UKF vis a vis EKF, the average computation time needed for the DAE-EKF computations was found to be significantly less (by factor of 50) than the average computation time needed for the DAE-UKF computations. Moreover, the performance of DAE-EKF was found to improve if the top and the bottom concentration measurements are included in the estimation problem along with temperature measurements on alternate trays. Thus, DAE-EKF was found to be better suited for development of an observer based control scheme.

Keywords: Reactive Distillation, Differential Algebraic Equations (DAEs), EKF, UKF

1. Introduction

Reactive Distillation (RD) systems can exhibit steady state input and output multiplicity behavior due to complex interaction between reaction and phase equilibrium (Purohit et al., 2013a). Occurrence of the output multiplicity behavior leads to an open loop unstable dynamics at some of the multiple steady states. The behavior of the process in the presence of output multiplicities, thus, depends on the process history and the process output can be different for the identical input moves. The difficulties are further compounded by the fact that dynamic models for RD systems often turn out to be a set of coupled stiff differential algebraic equations (DAEs). Thus, if it is desired to control the system at one of the unstable operating points, then use of a reliable nonlinear state estimator becomes an essential step in the controller synthesis (Purohit et al., 2013b).

With regards to the RD columns, relatively little work has been reported on the application of state estimation methods for estimating compositions (Grüner et al., 2003; Olanrewaju and Al-Arfaj, 2006; Venkateshwarlu and Kumar, 2006). These contributions directly apply the state estimation approach developed for the systems modeled as ODEs. However, since the RD systems are typically modelled as DAEs, a different treatment is needed to handle the associated state estimation

problem. The area of nonlinear Bayesian observers for systems modeled as DAEs is relatively unexplored. The extension of the Kalman Filter to nonlinear DAE systems was developed by Becerra et al. (2001) under the assumption that only the differential states are measured. Mandela et al. (2010) have recently extended the work of Becerra et al. (2001) to accommodate measurements obtained from differential as well as algebraic states. In addition, they also developed a version of unscented Kalman filter (UKF) suitable for the DAE systems.

As a step towards observer based controller synthesis for a RD system, this work aims at carrying out a comparative evaluation of the performances of DAE-EKF and DAE-UKF. Efficacies of these estimators have been evaluated by simulating state estimation problems associated with a benchmark ideal RD column (Olanrewaju and Al-Arfaj, 2006), which exhibits input and output multiplicity behavior simultaneously. In contrast to small dimensional examples considered in the available literature on state estimation of DAE systems, the RD model considered in this work is of moderately high dimension i.e. it consists of 90 differential states and 21 algebraic states. The performances of the DAE observers are investigated in the neighborhood of an unstable operating point of the RD system by assuming that only the temperatures on alternate trays are measured.

This paper is organized in five sections. The modeling assumptions are stated in Section 2. Section 3 briefly presents the DAE-UKF algorithm. The simulation results are presented in Section 4 and main conclusions reached through the simulation studies are presented in Section 5.

2. Model for Plant Simulation and State Estimation

The system under consideration can be represented in abstract form by a semi-explicit DAE of the form

$$\frac{d\mathbf{x}}{dt} = \mathbf{f}[\mathbf{x}(t), \mathbf{z}(\mathbf{t}), \mathbf{m}(t), \mathbf{d}(t)] \text{ and } \mathbf{G}[\mathbf{x}(t), \mathbf{z}(t)] = \overline{0} \tag{1}$$

where, $\mathbf{x} \in \mathbb{R}^{n_d}$ represents the differential state variables, $\mathbf{z} \in \mathbb{R}^{n_a}$ represents the algebraic state variables, $\mathbf{m} \in \mathbb{R}^m$ represents the input variables, and $\mathbf{d} \in \mathbb{R}^d$ represent the unmeasured disturbance variables. The state estimation using this model have been carried out under the following simplifying assumptions:

- The measurements, $\mathbf{y}_m(k), \in \mathbb{R}^r$ are obtained at a regular interval, h, and the measurement equation at $k'th$ sampling instant is given by

$$\mathbf{y}_m(k) = \mathbf{C}\begin{bmatrix} \mathbf{x}(k) \\ \mathbf{z}(k) \end{bmatrix} + \mathbf{v}(k) = \mathbf{C}\mathscr{X}(k) + \mathbf{v}(k) \tag{2}$$

  where $\mathscr{X}(k)$ represents augmented state vector. Here, measurement noise, $\mathbf{v}(k)$, is modelled as a zero-mean Gaussian white-noise process with covariance matrix $\mathbf{R}$, i.e. $\mathbf{v}(k) \sim \mathscr{N}(\overline{\mathbf{0}}, \mathbf{R})$

- In discrete time settings, the true value of the inputs (**m**) are related to the known / computed values of the inputs (**u**) as $\mathbf{m}(k) = \mathbf{u}(k) + \mathbf{w}_u(k)$ where $\mathbf{w}_{u,k} \in \mathbb{R}^m$ denotes an unknown disturbance in inputs such that $\mathbf{w}_u(k) \sim \mathscr{N}(\overline{\mathbf{0}}, \mathbf{Q}_u)$.

- The variation of the unmeasured disturbances around a desired steady state $\overline{\mathbf{d}}$ can be adequately approximated using piecewise constant functions of the form $\mathbf{d}(k) = \overline{\mathbf{d}} + \mathbf{w}_d(k)$ over $[t_k, t_k + h]$ where $\mathbf{w}_d(k) \in \mathbb{R}^{d_u}$ such that $\mathbf{w}_d(k) \sim \mathscr{N}(\overline{\mathbf{0}}, \mathbf{Q}_d)$.

Thus, the plant is simulated by solving the set of DAEs (1) using a suitable DAE solver. For the sake of convenience, the following notation is adopted to represent the DAEs in discrete form

$$\mathbf{x}(k+1) = \mathbf{F}[\mathbf{x}(k), \mathbf{z}(k), \mathbf{u}(k), \mathbf{w}(k)] \quad \text{and} \quad \mathbf{G}[\mathbf{x}(k+1), \mathbf{z}(k+1)] = \overline{0} \tag{3}$$

where $\mathbf{w}(k) \in R^{n_w}$ represents augmented state noise vector, $\mathbf{w}(k) = \begin{bmatrix} \mathbf{w}_u^T(k) & \mathbf{w}_d^T(k) \end{bmatrix}^T$, with covariance matrices $\mathbf{Q} = \mathbf{diag}\begin{bmatrix} \mathbf{Q}_u & \mathbf{Q}_d \end{bmatrix}$.

3. State Estimation

The state estimation has been carried out using two recently developed nonlinear Bayesian estimators for systems modelled as DAEs, namely extended Kalman filter (EKF) and unscented Kalman filter (UKF) (Mandela et al., 2010). For the sake of brevity, only the DAE-UKF algorithm is summarized here. The details of DAE-EKF can be found in Mandela et al. (2010).

Given prior estimates $(\widehat{\mathbf{x}}(k-1|k-1), \widehat{\mathbf{z}}(k-1|k-1))$, and covariance matrix $\mathbf{P}(k-1|k-1)$, generate $2(n+n_w)+1$ sigma points for $\xi(k-1) = \begin{bmatrix} \mathbf{x}^T(k-1) & \mathbf{w}^T(k-1) \end{bmatrix}^T$ are constructed as follows:

$$\mathbf{P}_a(k-1|k-1) = \mathbf{diag}\begin{bmatrix} \mathbf{P}(k-1|k-1) & \mathbf{Q} \end{bmatrix} \tag{4}$$

$$\mathbf{S}(k-1|k-1) = \sqrt{\mathbf{P}_a(k-1|k-1)} \tag{5}$$

$$\widehat{\xi}^{(0)}(k-1|k-1) = \widehat{\xi}(k-1|k-1) \text{ with } w_0 = \frac{\kappa}{(n+n_w)+\kappa} \tag{6}$$

$$\widehat{\xi}^{(i)}(k-1|k-1) = \widehat{\xi}(k-1|k-1) + \rho \mathbf{S}^{(i)}(k-1|k-1) \tag{7}$$

$$\widehat{\xi}^{(n+n_w+i)}(k-1|k-1) = \widehat{\xi}(k-1|k-1) - \rho \mathbf{S}^{(i)}(k-1|k-1) \tag{8}$$

$$w_i = w_{(n+n_w)+i} = \frac{1}{2((n+n_w)+\kappa)} \text{ for } i = 1,2,...,(n+n_w) \tag{9}$$

where, $\mathbf{S}^{(i)}$ represents the i^{th} column of matrix square of $\mathbf{S}$, $\rho = \sqrt{((n+n_w)+\kappa)}$, w_i represents the weight associated with i^{th} sigma point and κ denotes a tuning parameter. The associated algebraic state, $\widehat{\mathbf{z}}^{(i)}(k-1|k-1)$, has to be generated by solving for $\mathbf{G}\left(\widehat{\mathbf{x}}^{(i)}(.), \widehat{\mathbf{z}}^{(i)}(.)\right) = \overline{\mathbf{0}}$. The sigma points are then propagated using a DAE solver to obtain predicted differential, $\widehat{\mathbf{x}}^{(i)}(k|k-1)$, and algebraic states, $\widehat{\mathbf{z}}^{(i)}(k|k-1)$. The mean and covariance of the differential states is then estimated as follows:

$$\widehat{\mathbf{x}}(k|k-1) = \sum_{i=0}^{2(n+n_w)} w_i \widehat{\mathbf{x}}^{(i)}(k|k-1) \text{ and } \mathbf{P}(k|k-1) = \sum_{i=0}^{2(n+n_w)} w_i \varepsilon^{(i)}(k|k-1)\left[\varepsilon^{(i)}(k|k-1)\right]^T$$

where $\varepsilon^{(i)}(k|k-1) = \left(\widehat{\mathbf{x}}^{(i)}(k|k-1) - \widehat{\mathbf{x}}(k|k-1)\right)$. The Kalman gain matrix is computed as $\mathbf{L}(k) = \mathbf{P}_{\mathscr{X}y}(k)\mathbf{P}_{yy}(k)^{-1}$ where

$$\mathbf{P}_{yy}(k) = \sum_{0}^{2(n+n_w)} w_i \left[\left(\mathbf{e}^{(i)}(k)\right)\left(\mathbf{e}^{(i)}(k)\right)^T\right] + \mathbf{R}$$

$$\mathbf{P}_{\mathscr{X}y}(k) = \sum_{0}^{2(n+n_w)} w_i \left(\widehat{\mathscr{X}}^{(i)}(k|k-1) - \widehat{\mathscr{X}}(k|k-1)\right)\left(\mathbf{e}^{(i)}(k)\right)^T$$

Here, $\mathbf{e}^{(i)}(k) = \left(\widehat{\mathbf{y}}^{(i)}(k|k-1) - \widehat{\mathbf{y}}(k|k-1)\right)$ and

$$\widehat{\mathscr{X}}(k|k-1) = \sum_{i=0}^{2n} w_i \widehat{\mathscr{X}}^{(i)}(k|k-1) \text{ and } \widehat{\mathbf{y}}(k|k-1) = \sum_{i=0}^{2(n+n_w)} w_i \mathbf{C}\widehat{\mathscr{X}}^{(i)}(k|k-1)$$

The Kalman Gain corresponding to the differential states $\mathbf{L}_x(k)$ is $n \times n$ matrix constructed using the first n rows of $\mathbf{L}(k)$.The mean and covariance of the differential states is then updated as follows

$$\widehat{\mathbf{x}}(k|k) = \widehat{\mathbf{x}}(k|k-1) + \mathbf{L}_x(k)(\mathbf{y}_m(k) - \widehat{\mathbf{y}}(k|k-1)) \tag{10}$$

$$\mathbf{P}(k|k) = \mathbf{P}(k|k-1) - \mathbf{L}_x(k)\mathbf{P}_{yy}(k)\mathbf{L}_x(k)^T \tag{11}$$

The updated algebraic states, $\widehat{\mathbf{z}}(k|k)$, consistent with $\widehat{\mathbf{x}}(k|k)$ are then estimated by solving for $\mathbf{G}(\widehat{\mathbf{x}}(k|k), \widehat{\mathbf{z}}(k|k)) = \overline{\mathbf{0}}$

4. Simulation Studies

The simulation exercise is aimed at comparison of the performances of DAE-EKF and DAE-UKF algorithms proposed by Mandela et al. (2010) using an ideal RD system. An example of the RD column with hypothetical quaternary reaction, $a+b \leftrightarrow c+d$, and ideal VLE (Olanrewaju and Al-Arfaj, 2006) is chosen for simulation. The RD model considered here has 90 differential states and 21 algebraic states. The liquid compositions of all the components on all the stages including reboiler and condenser stages and molar holdup of reboiler and condenser are considered as differential states. Temperatures on all the stages are considered as algebraic states. Details regarding the structural parameters, operating parameters, reaction kinetics and mathematical model of this RD column are available in Olanrewaju and Al-Arfaj (2006) and Purohit et al. (2013b). The RD column considered in the present work exhibits nonlinear input and output multiplicities behavior as shown in Figure 1. The desired operating point is indicated in Figure 1 which is an unstable operating point. There are two other stable steady states, indicated as IC-1 and IC-2 in Figure 1, at the same input value of the vapor boil up rate.

To carry out state estimation of the RD system under consideration, it was assumed that, total 11 temperatures on the alternate stages, starting from the reboiler stage, are measured. Also, the temperature measurements are available at regular interval of 30 sec. Details of covariances of the measurement noise and unmeasured disturbances in the manipulated inputs can be found in Purohit et al. (2013b). The value of κ in UKF is chosen as 1. To compare the performances of EKF and UKF for the DAE RD column considered here, the following two performance indices were used: (a) Sum of square of estimation errors (SSEE) defined as $SSEE_i = \sum_{i=1}^{N} \left(\mathbf{x}_i(k) - \widehat{\mathbf{x}}_i(k|k)\right)^2$ where N represents number of data points in a simulation experiment and (b) average computational time (on Intel CORE^{TM} i3 2120 CPU 3.3 GHz with 4 GB RAM).

The process states are maintained at the middle unstable steady state whereas the state estimator is initialized at the either of the two steady states, that is, IC-1 or IC-2 (Figure 1). Initial condition, IC-1 is close to the unstable steady state, whereas IC-2 is far away from the steady state. Thus, these two initial conditions are representative of a *good initial guess* and a *bad initial guess* scenarios. From control point of view, the mole fraction of heaviest component d in bottoms (x_b) and lightest component c in distillate (x_d) are of prime importance and are selected as main indicators of the observer performance. The comparison of state estimates of x_b and x_d generated by UKF and EKF is presented in Figure 2 for both the initialization of state estimates, IC-1 and IC-2.

Since, IC-1 steady state (Figure 1) is a good estimate of desired operating steady state, both the estimators converge close to desired operating steady state in about the same time. SSEE values (Ref. Table 1) for unmeasured differential states (x_b and x_d) and for unmeasured algebraic states

Table 1: SSEE values for UKF and EKF

Estimator⟶	UKF		EKF

19	8.56	2.06	175.2	74080	111

**In presence of concentration measurements*

(Temperatures) are listed in Table 2. It can be seen that, except for stages 11, 13, 15, 17 and 19, UKF outperforms EKF in terms of SSEE values of algebraic states. When the initialization of estimates was chosen as IC-2, which is far from the desired operating steady state, UKF is able to converge (Ref. Fig. 2) to desired operating steady state accurately despite the large initial mismatch. On the other hand, the performance of EKF degrades resulting in large deviations from the desired operating steady state. As a consequence, SSEE values (Ref. Tables 1 and 2) of the unmeasured differential states (x_b and x_d) and for unmeasured algebraic states (Temperatures) for UKF are significantly smaller than those for EKF. Thus, UKF's performance is found to be robust against initial mismatch considered here. However, UKF is computationally significantly more expensive than EKF. The average computation time for DAE-UKF (*41.57 sec for IC1 and 73.03 sec for IC2*) is about 50 times more than for DAE-EKF (*0.8456 sec for IC1 and 2.2433 sec for IC2*). In UKF formulation, it is necessary to integrate the DAEs $2(n+n_w)+1$ (=185) times at each prediction step, which is computationally expensive step. On the other hand, the EKF, only requires computation of Jacobian matrices using finite differences. It was observed that the Jacobian computation is far less computationally intensive than multiple solutions of DAEs needed in UKF.

To examine whether the estimation performance of EKF can be improved by including additional measurements, it was assumed that the measurements of concentrations x_d and x_b are available in addition to the temperature measurements and hold up measurements (Purohit et al. (2013b)). The performance of the EKF with the initial estimate as IC-2 under the assumption of availability of measurements of concentrations is presented in Figure 2. It can be seen that, the EKF now converges to desired operating steady state when bottom and top products concentrations are assumed to be measured. The SSEE values for estimates of differential states (x_d and x_b) and for algebraic states also significantly decreased when compared with the SSEE values in absence of concentration measurements as listed in Tables 1 and 2.

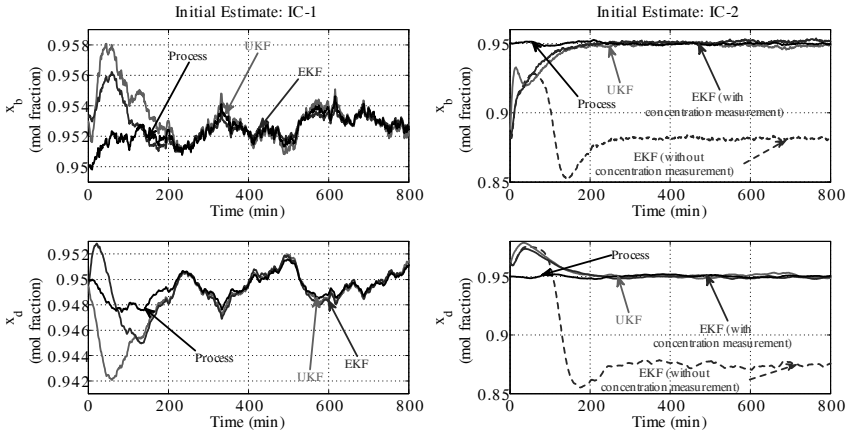

Figure 2: State Estimates of x_b and x_d generated by UKF and EKF

5. Conclusions

In this work, the performance evaluation of two recently developed nonlinear Bayesian estimators for systems modeled as DAEs, namely EKF and UKF have been investigated by simulating state estimation problems associated with a moderately high dimensional RD column. When compared on the basis of sum squared estimation errors (SSEE), the DAE-UKF outperformed the DAE-EKF. Whereas DAE-UKF was able to work even with a large mismatch in the initial state, the DAE-EKF performed satisfactorily only when initial estimation error was relatively small. However, under the identical simulation conditions, the average computation time needed for the DAE-EKF computations is significantly less (by factor of 50) than the average computation time needed for the DAE-UKF computations. Contrary to the claims in the literature regarding the drawbacks of EKF, the calculation of Jacobian for local linearization in the DAE-EKF formulation was found to be significantly faster than the multiple integrations needed in the DAE-UKF formulation for carrying out the prediction step. Moreover, the performance of EKF is found to improve if the top and the bottom concentration measurements are included in the estimation problem. Thus, the DAE-EKF with proper initialization appears to be better suited for development of an observer based control scheme.

Abstract

The application of the continuous-discrete extended Kalman filter (CD-EKF) as a powerful tool for state estimation in biochemical systems is assessed here. Using a fermentation process for ethanol production as a case study, the CD-EKF can effectively estimate the model states even when highly non-linear measurements such as pH are included. Several configurations of the CD-EKF are tested and it is seen that including pH, which is a readily available measurement in virtually every biochemical process, provides information that significantly improves the performance of the filter.

Keywords: state estimation; non-linear filtering; fermentation; lignocellulosic ethanol

1. Introduction

Monitoring of biochemical processes is essential for fault-diagnosis, control and optimisation. However, a number of factors have hindered the development of advanced monitoring techniques, especially in comparison with standard chemical processes. Lack of appropriate sensors and the high non-linearity inherent to biochemical processes are some of the main obstacles among these factors. In this context, the continuous-discrete extended Kalman filter (CD-EKF) is an appropriate tool for state estimation in biochemical processes. The non-linearity of the model can be efficiently tackled by the CD-EKF since the sensitivity of the dynamic model is updated at each sampling time via ODE integration. Commonly this step consumes a non-negligible computation time. However, the sampling time in biochemical processes is usually relatively slow (>>1 min) and computation time is rarely an issue. Another consequence of the slow sampling is that non-linearity between samples may be significant; other EKF formulations using linear approximations for the forecasting step are then unsuitable.

In this contribution we present the application of the CD-EKF to the monitoring of a fermentation process aimed at producing ethanol from C6 and C5 sugars. The focus is specifically on the use of pH as this is a variable that correlates well with the yeast catabolism (CO_2 is co-produced with ethanol, leading to acidification of the medium) and that can be easily measured online. Several configurations of the CD-EKF are presented and it is concluded that using pH measurements is 1) a suitable means to monitor the process if a good prediction model is available; and, 2) a good complement to other measurements if model mismatch is more severe.

2. Process description and modelling

The process studied here corresponds to the production of second generation bioethanol by fermentation by *Saccharomyces cerevisiae* of C6 and C5 monosaccharides (mainly glucose and xylose respectively), obtained from lignocellulosic biomass. One of the specific challenges of this operation is to minimise the effect of the inhibitory compounds that are produced during biomass hydrolysis such as furfural, 5-hydroxymethylfurfural (HMF) and acetate. Besides, in the case of organic acids, there is evidence that only the unionized form of the acid (e.g. acetic acid and not acetate) is responsible for the inhibition (Casey et al. 2010) and pH must be taken into account.

This simulation case study is based on common configurations for fermentation found in the literature. It is carried out in a 100 m^3 reactor and is run in fed-batch mode as follows: 1) first a batch phase with the inoculum (0.2 m^3) during 1 h; 2) a feeding phase for 7 h with a flowrate of $4 \cdot 10^{-3}$ $m^3 s^{-1}$; 3) finally a batch phase during 92 h. The composition of the inflow, which includes a strong base for pH regulation, is assumed to be known. The model of the process is composed of 11 states: reactor holdup (M), cell biomass (X_{bio}), glucose (Glu), xylose (Xyl), ethanol (Eth), furfural (Fur), total acetate (Ac), 5-hydroxymethylfurfural (HMF), furfuryl alcohol (FA), base conjugated cations (K) and total inorganic carbon (TIC), which includes several species in equilibrium (CO_2, H_2CO_3, HCO_3^- and CO_3^{2-}). Of these, only M is routinely measured at a relatively fast sampling time; Glu, Xyl and Eth are often measured but at slow sampling times. As in virtually every other fermentation, pH is measured at a relatively fast sampling time but it does not correspond directly or linearly to any state.
The total mass balance is expressed as:

$$\frac{dM}{dt} = F_{in}\ \rho_{in} \tag{1}$$

where F_{in} is the feed flowrate (m^3/s) and ρ_{in} is the feed density (kg/m^3). As the reactor is modelled as a stirred tank, the partial mass balances are generically expressed as:

$$\frac{d\,C_i}{dt} = \frac{F_{in}}{V}\left(C_{i,in} - C_i\right) + r_i \tag{2}$$

In Eq.(2), V represents the volumetric holdup of the reactor, C_i represents the concentration of component i in the reactor (kg/m^3) and r_i is a lumped term representing the reaction and gas-liquid transfer of compound i. The reactions describe the fermentation of the C6 and C5 sugars by a generic strain of *Saccharomyces cerevisiae*; it has not been attempted to model any particular strain but to build a multi-purpose model that takes into account the phenomena that impact the fermentation of lignocellulosic ethanol. Hence, several references have been used to describe the consumption of glucose and xylose (Krishnan et al. 1999), the effect of pH on metabolism (Nielsen et al. 2003), and the effect of inhibitors (Hanly and Henson, 2014). The stoichiometric matrix and the process rates description are provided in table 1.

The gas-liquid mass transfer, which in this case is only relevant to CO_2 is described as:

$$J_{CO_2} = k_L a \left(P_{CO_2} - H_{CO_2}\, C_{CO_2}\right) \tag{3}$$

where k_La is the volumetric mass transfer coefficient, P_{CO2} is the partial pressure of CO_2 in the headspace, H_{CO2} is the Henry's constant and C_{CO2} is the liquid concentration of CO_2 which can be obtained from the concentration of TIC and the pH in the liquid.

Table 1. Stoichiometric matrix and process rates for the fermentation process. Note that I represents an inhibitory term for the fermentation process. K_{si} represent affinity constants while J_i and K_{Ii} represent inhibition constants.

Comp.→ Process↓	X_{bio}	Glu	Xyl	Eth	Fur	Ac	HMF	FA	TIC
Glu uptake	$Y_{X/Glu}$	-1	0	$Y_{Eth/Glu}$	0	0	0	0	$Y_{CO2/Glu}$
Xyl uptake	$Y_{X/Xyl}$	0	-1	$Y_{Eth/Xyl}$	0	0	0	0	$Y_{CO2/Xyl}$
Fur uptake	~0	0	0	0	-1	0	0	$Y_{FA/Fur}$	0
Ac uptake	~0	0	0	0	0	-1	0	0	$Y_{CO2/Ac}$
HMF uptake	~0	0	0	0	0	$Y_{Ac/HMF}$	-1	0	0

	Equation expressed as substrate consumption
Glu uptake	$\nu_{Max} X_{bio} \frac{Glu}{K_{SGlu} + Glu + \frac{Glu^2}{K_{IGlu}}} \frac{1}{1+\frac{Fur}{J_{Fur}}} \frac{1}{1+\frac{HMF}{J_{HMF}}} \frac{1}{1+\frac{HAc}{J_{HAc}}} I(Xyl, Eth, pH)$
Xyl uptake	$\nu_{Max} X_{bio} \frac{Xyl}{K_{SXyl} + Xyl + \frac{Xyl^2}{K_{IXyl}}} \frac{1}{1+\frac{Fur}{J_{Fur}}} \frac{1}{1+\frac{HMF}{J_{HMF}}} \frac{1}{1+\frac{HAc}{J_{HAc}}} I(Glu, Eth, pH)$
Fur uptake	$\nu_{Max} X_{bio} \frac{Fur}{K_{SFur} + Fur}$
Ac uptake	$\nu_{Max} X_{bio} \frac{Ac}{K_{SAc} + Ac}$
HMF uptake	$\nu_{Max} X_{bio} \frac{Fur}{K_{SFur} + Fur}$

Finally, pH is calculated as the solution, at every time step, of the algebraic equation accounting for the charge balance.

$$C_{H^+} + K^+ - \frac{K_w}{C_{H^+}} - \frac{K_{Ac} C_{Ac}}{C_{H^+} + K_{Ac}} - \frac{K_{1,C} C_{TIC} C_{H^+}^2 + K^2_{1,C} C_{TIC}\ C_{H^+}}{\left(C_{H^+} + K_{1,C}\right)\left(C_{H^+}^2 + K_{1,C} C_{H^+} + K_{1,C} K_{2,C}\right)} = 0 \qquad (4)$$

where K_w is the ionic product of water, K_{Ac} is the acid constant of acetic acid, $K_{1,C}$ is the pseudo-acid constant between carbon dioxide and the bicarbonate anion and $K_{2,C}$ is the acid constant between the bicarbonate and carbonate anions. Lactic acid bacteria (LAB) in simulation scenario 2 were modelled according to Pinelli et al (1997).

3. State estimation and filter configuration

The system described by Eq. (1-4) can be written in a general non-linear state-space form using the reactor volume as system boundary.

$$\frac{dx}{dt} = f\left(x(t), u(t), d(t)\right) \qquad (5a)$$

where the states (x), inputs (u) and disturbances (d) represent:

$$x = [M \; C_i]^t \qquad u = [F_{in}] \qquad d = [C_{i,in}] \tag{5b}$$

The estimation is indeed computed at discrete time step based on the sample rate in the control or monitoring system. The system (5) takes the following discrete step form:

$$x_{k+1} = F(x_k, u_k, d_k) = x_k + \int_{t_k}^{t_{k+1}} f(x(\tau), u(\tau), d(\tau)) d\tau \tag{6a}$$

$$y_k = G(x_k) + \nu_k, \quad \nu_k \in \mathrm{N}_{iid}(0, R_\nu) \tag{6b}$$

The observer is formulated as a CD-EKF filter as described by Price et al. (In Press). The main particularity of the CD-EKF in the present work is that output matrix C_k is not time invariant. C_k is the partial derivative of the output function $G(x_k, u_k, d_k)$with respect to the states. Commonly, C_k is time invariant as it represents the relation between the measurements and the states. In this case, as pH is one of the outputs:

$$C_k = \left. \frac{\partial G(x_k)}{dx} \right|_{\hat{x}_{k|k-1}} \tag{7}$$

Three possible configurations of the CD-EKF were tested considering different measurements and sampling rates, chosen following realistic implementation (Table 2). It is considered that the total holdup and the pH can be followed on-line and hence to a fast sampling rate. On the contrary, measuring glucose, xylose and ethanol content requires sample preparation and off-line analyses; the sampling rate is necessarily slow.

Table 2. Measured variables for three configurations of the CD-EKF

Configuration	Measurements	Sampling rate (Ts, min)
1	M, pH	20
2	M, Glu, Xyl, Eth	240
3	M, Glu, Xyl, Eth, pH	240

4. Simulation results

A first scenario was defined where the filter is assumed to dispose of perfect knowledge of the plant model (the only difference between the model and the plant is introduced by sensor noise). The performance of the three configurations is very similar when the performance metrics are compared (Table 3). As the space of this contribution is limited, we have decided to focus on the unmeasured states that have the highest influence on the plant evolution: X_{bio}, Fur, Ac and TIC. It can be seen (Table 3) that configurations 2 and 3 outperform configuration 1, as more information is available from the measurements.

A second simulation scenario was set where a certain and realistic model mismatch is assumed: there is contamination in the media by lactic acid bacteria (LAB), simulated by including 0.2% w/w of the yeast biomass in the inflow. The performance of the filter with the three configurations is compared to a simulation that does not take into account the LAB contamination. In this scenario (Figure 2), configuration 1 and 2 present a severe bias, in particular for X_{bio} and Ac. In contrast, X_{bio} is accurately estimated by configuration 3, demonstrating the importance of the information provided by pH. In

general, configuration 3 presents the smallest error of all the filter configurations and the system simulations except for Ac (probably because of the presence of lactic acid produced by the LAB). The performance metrics (Table 3) confirm these results. Additionally, the variance is smallest for configuration 3, showing that a good compromise between the use of measurements and model information was reached.

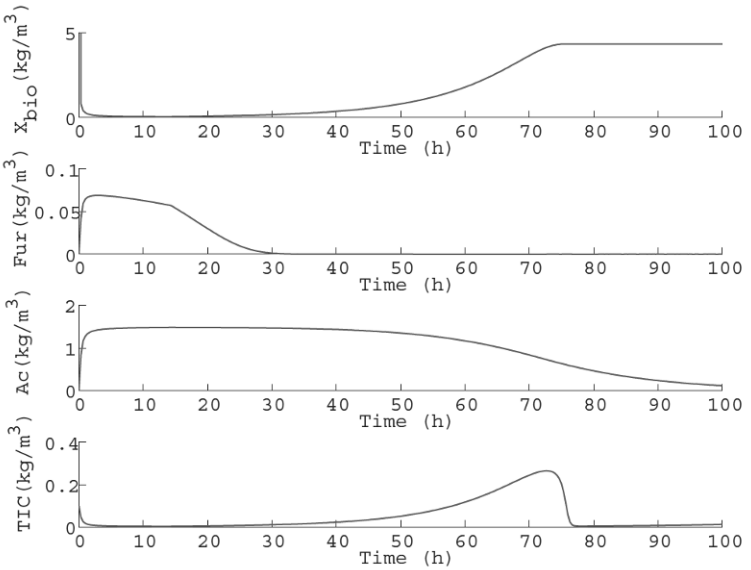

Figure 1. Simulation of the process with LAB contamination. Selection of key states.

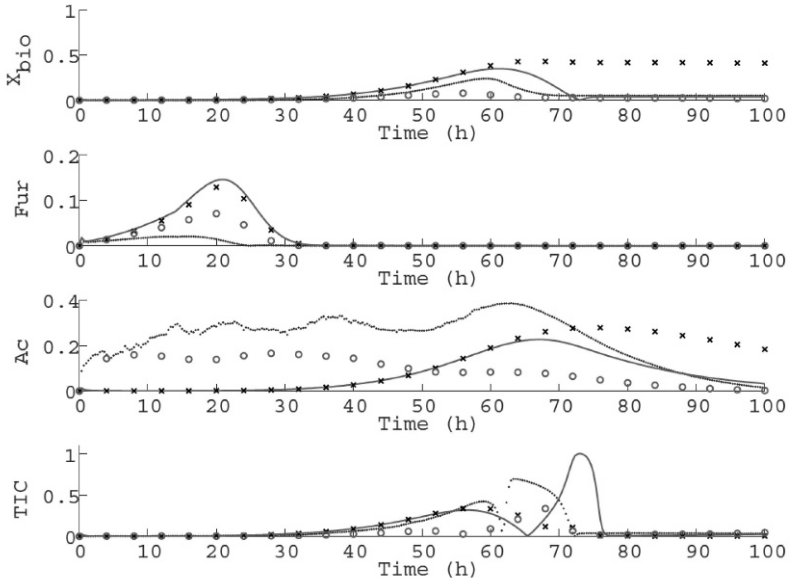

Figure 2. Absolute normalized prediction error of the CD-EKF in scenario 2 (LAB contamination) for pure simulation (line), configuration 1(dots), configuration 2 (crosses) and configuration 3 (empty circles)

Table 3. Estimation statistics: the mean and the standard deviation are given for the absolute estimation error on selected states based on the normalized data. Simulation stands for a simulation with the original plant model (not considering LAB contamination)

1	62.0	65.4	2.90	6.70	232	98.7	173	250
2	239	194	19.3	38.7	123	109	117	159
3	27.2	22.0	10.9	21.7	89.0	54.4	66.9	104

5. Conclusions

The CD-EKF was proven as a suitable tool for monitoring of biochemical processes. Its main drawback, i.e. requirement of significant computational resources, is of little relevance in these processes as sampling is relatively slow. Providing pH helps improving the prediction of the filter when comparing several configurations. The use of pH is of great interest for such processes since it is a ubiquitous measurement in biochemical processes, in particular in fermentation. Further application in contamination detection and real time optimisation will follow this study.

Abstract

Crude natural gas (NG) can contain a significant amount of contaminants that must be removed to guarantee safe transportation and sales specification. Water and hydrocarbon dew point (WDP and HCDP) adjustments are important for conditioning NG. In Brazil, Pre-Salt reservoirs have large amounts of NG with high CO_2 content, which also must be adjusted by a suitable operation like Membrane Permeation (MP). Furthermore, offshore processing requires reduced footprints, which minimize inventories and, consequently, intensify propagation of feed disturbances to downstream units. The dynamic scenario is inherently related to riser oscillations caused by slug flow, that may cause operational problems, losses and environmental and safety issues. Hence, the process control system must be sufficiently robust to ensure stability within such context. This work approaches the dynamical analysis of an offshore NG treating process for a typical Pre-Salt feed with the following operations: phase separation, dehydration with triethylene glycol (TEG) absorption, HCDP adjustment via Joule-Thomson (JT) expansion and CO_2 removal via MP. The objective is to assess the dynamic behaviour of the process and its control framework under slug flow oscillations within HYSYS simulation environment. As MP is not included in the simulator unit library, a dynamic unit operation extension (UOE-D) was developed. This UOE-D extension adequately reproduces MP response to disturbances allowing the entire process to be dynamically assessed. In general, results point to good process controllability and overall robustness despite the severe slug flow feed oscillations.

Keywords: Natural Gas, Slug Flow, Dynamic Simulation, Membrane Permeation.

1. Introduction

Recently, huge oil reserves have been discovered in Pre-Salt fields of Brazil, with high gas-oil ratio (Formigli, 2013) and impressive CO_2 content. The associated natural gas (NG) should be treated for adjusting water dew point (WDP), hydrocarbon dew point (HCDP) and for removal of CO_2, which reduces NG heat value and the transportation capacity of pipelines and, besides, is corrosive in presence of water (Dortmundt and Dosh, 1999). Considering the 300 km distance from coast to Pre-Salt fields, high NG flow rates have to be processed offshore for safe transportation to land facilities and sales specifications. However, high NG capacity requires large equipments, which configure a challenge for offshore rigs where space and weight are serious constraints. Due to its modularity, low weight and footprint, Membrane Permeation (MP) was chosen for CO_2 removal in Pre-Salt projects. Other design choices involve WDP

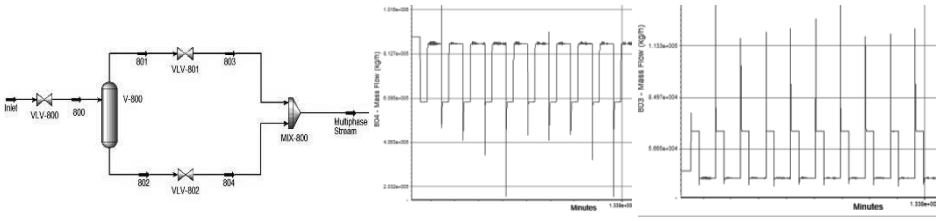
adjustment via NG dehydration by absorption with TEG (triethylene glycol) and HCDP adjustment via Joule-Thomson (JT) expansion. WDP is necessary to prevent hydrate formation under high pressure and low temperature, and HCDP is necessary to avoid condensation of heavier hydrocarbons in NG pipelines and processing.

Considering the offshore context, platforms are frequently vulnerable to flow and pressure oscillations of feeds caused by multiphase slug flow in production risers. Such instabilities configure a big challenge associated with oil and NG production in deep-water offshore fields. Slug flow is an intermittent flow in which liquid slugs are propelled by large bubbles of gas. The main types of slug flow are: Transient, Hydrodynamic and Severe Slugging (SS). The first one is induced by operational changes, such as start-up or pigging and can have impact on downstream processes. The second one occurs in near horizontal pipelines, being usually weak with limited effects on downstream facilities and is initiated by wave instabilities on gas/liquid interface with a sufficient velocity difference between phases. The third one, Severe Slugging (SS), may occur at low flow rates when a downwards inclined or horizontal pipeline is connected to a vertical riser. SS exhibits a cyclic behavior with characteristics steps: (i) liquid accumulates at the riser base blocking gas flow and increasing pressure upstream; (ii) pressure becomes sufficiently high, causing a sudden ejection of liquid, followed by gas blow-down; (iii) then, some liquid falls back, beginning a new cycle. Sagatun (2004) reported SS field data indicating periods between ≈10 min and ≈15 min. According to Godhavn (2005) SS in pipelines between Tordis field (North Sea) and Gullfaks C platform resulted in severe pressure and level oscillations in inlet separators, leading to instabilities and operational issues in the receiving facilities. Some consequences of SS to downstream facilities are: large disturbances in the separation area affecting oil/water separation; periods of low liquid flow, followed by high liquid production, occasionally causing flooding and shutdowns; impact on gas compression due to pressure variations from gas separation; increased flaring due to separator pressure oscillations, affecting the environment and destroying inventories (Sausen et al., 2012). Therefore, dynamic simulation becomes an important tool for offshore process design and operation, since it allows the analysis of the dynamical behavior of process under feed disturbances. Furthermore, reduced inventories dictated by space constraints in offshore rigs lead to rapid propagation of disturbances along downstream operations and render important the prediction of transient responses caused by SS. This work assesses the impacts of slug flow oscillations on a typical Pre-Salt offshore processing unit.

2. Methodology

The software used for process simulation is Aspentech HYSYS, with Peng Robinson equation of state. For simulation of the MP unit, a Dynamic Unit Operation Extension (UOE-D) was developed in Visual Basic. A base case was defined and simulated in steady state and process design parameters were defined through sensitivity analysis. In order to proceed to the dynamic mode, equipment sizing was performed employing literature correlations (Campbell, 2004) and the HYSYS Sizing tool. Last, the control structure was proposed and tuned in accordance with literature data and procedures (Nunes, Medeiros and Araújo, 2010). A slug flow emulator was developed using a vessel and two valves. The slug cycles were formed by coordinating valves opening and closing (Figure 1a), in a period of 9 minutes. The impact of slug flow on inlet gas and

liquid phases mass flow rates are presented in Figure 1 (b,c). The oil flow rate is reduced to approximately 50% of its base value in each cycle, while gas flow rate is increased to around 160% of base value.



(a) (b) (c)

Figure 1. Slug Flow: (a) Process Emulator, (b) Liquid Flow Pattern, (c) Gas Flow Pattern

3. Base Case

Process premises assumed a multiphase stream of 960 t/h, 75 bar and 40 ºC, with composition adapted from Vaz (2009) to represent a typical Pre-Salt feed (~20% molar base on gas phase - Table 1) similar to Lula field (Formigli, 2013). The treated NG specifications were defined according to ANP (Brazil National Agency of Oil, Gas and Biofuels): WDP ≤ -45 ºC at 1.01 bar; HCDP≤ 0ºC at 45 bar, CO_2 content ≤ 3%mol.

Table 1. Inlet Stream Gas Phase Composition (% mol.)

Component	Composition	Component	Composition	Component	Composition
Methane	59.98%	Water	5.00%	n-Pentane	0.18%
Ethane	6.00%	H2S	0.02%	n-Hexane	0.32%
Propane	4.97%	i-Butane	2.80%	n-Heptane	0.08%
CO2	18.99%	n-Butane	0.40%	n-Octane	0.01%
Nitrogen	0.43%	i-Pentane	0.83%		

3.1. Steady State Simulation

Plant scheme is based on Machado et al. (2012), with phase separation (Vaz, 2009), two MP stages (Pinto et al., 2009) and final NG compression. Fig. 2 shows the overall scheme on HYSYS. Table 2 shows the treated NG composition. Final NG conditions are 49.71 t/h, 94.29 ºC, 204.07 bar, WDP of -54.48 ºC at 1.01 bar, and HCDP of -4.9 ºC at 45 bar.

Table 2. Final Gas Stream Composition

Component	Composition	Component	Composition	Component	Composition
Methane	79.19%	Water	0.00%	n-Pentane	0.02%
Ethane	10.29%	H_2S	0.02%	n-Hexane	0.01%
Propane	5.12%	i-Butane	1.53%	n-Heptane	0.01%
CO_2	2.97%	n-Butane	0.17%	n-Octane	0.01%
Nitrogen	0.52%	i-Pentane	0.15%		

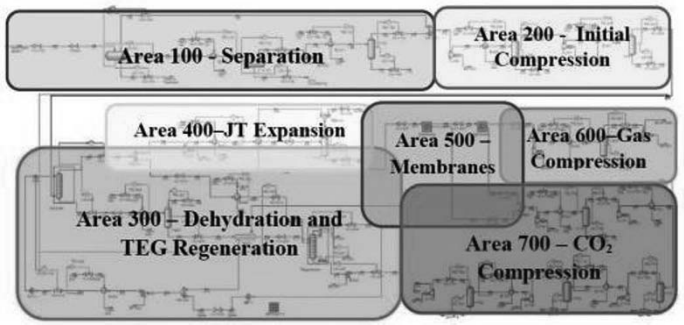


Figure 2. Process Flowsheet Scheme

3.2. Control Structure

Process control on offshore platforms is usually classic, presenting many simple loops with PID controllers in SISO configuration (Nunes et al., 2010). Controllers for the present process are selected in accordance with literature data for each unit operation (Mokhatab et al., 2006). Control loops dedicated to WDP and HCDP are: ratio controller between gas and TEG flow rates at the absorber and temperature controller at JT vessel. It is also important to control reboiler temperature to avoid TEG degradation (206 ºC). Control parameters suggested by HYSYS Dynamic Modelling Manual and by Luyben (2002) were used as base values for initial tuning. Then, process was initialized in dynamic state and a manual fine-tuning step was performed to reduce oscillations.

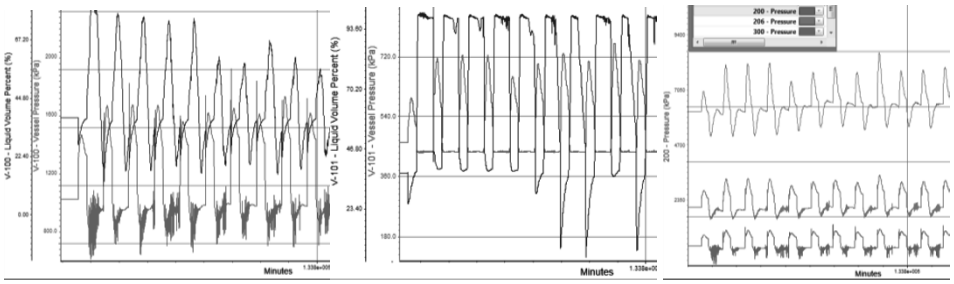
4. Dynamic Analysis

4.1. Membrane Separation Dynamic Extension

A UOE-D dynamic extension was developed to simulate MP modules for both steady and dynamic states. Extensions also provide customized interface options. The MP transient response is fast, so it was modelled as a first order transfer function with unitary gain. Permeate pressure is fixed, defined by user, according to its downstream application, while a fixed head loss of 1 bar is associated with the retentate product relative to the feed. Permeation rates vary with trans-membrane ΔP (Pinto et al., 2009). To validate the extension, simple MP cases were simulated and their responses were compared with the expected behaviour, resulting in a satisfactory representation.

4.2. Slug Flow Impact

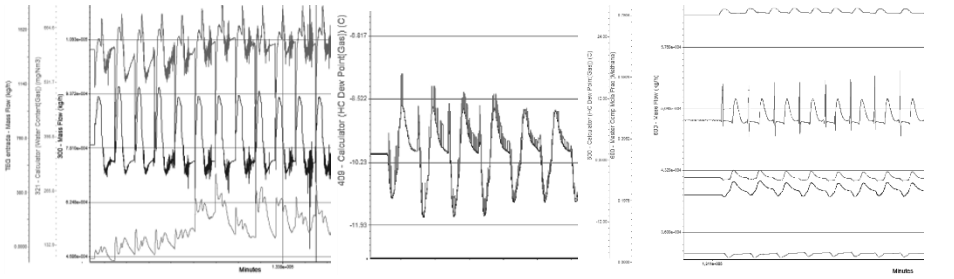
The separation area is responsible for absorbing the first impacts, so vessels pressures and levels are extremely affected (Figure 3a,b). Both separation pressures reach 150% of base case values. The tree-phase separator level fluctuates between 20 and 70%, while the two-phase separator reaches levels near 100% of full scale. The simulation did not identify any errors in this case, however, in a real plant it can lead to flooding and shutdown. Figure 3c shows stage pressure profiles on gas compression. The oscillations amplitude double in each step, reflecting the impact on compression ratio due to inlet pressure variations.



(a) (b) (c)

Figure 3. Slug Flow Impacts: (a) Three-Phase Separator, (b) Two-Phase Separator – level (blue), pressure (red), (c) Compression – inlet (red), 1st stage outlet (pink) and 2nd stage outlet (blue).

At the absorber, inlet gas mass flow rate fluctuations are of ~23 t/h and impact the absorption process. The ratio controller acts in TEG flow rate to maintain an optimum ratio for dehydration. Water content on dry gas still presents oscillations and may have affected gas specification at some points. Figure 4b depicts the strict relation between gas HCDP and JT vessel temperature, which is an expected behavior. The oscillations are of approximately 3 ºC, so it does not loose HCDP the specification. Figure 4c shows flow rate, dew points, methane and CO_2 contents of the final natural gas stream. Export gas properties and conditions presented variations, though dampened when compared to slug flow disturbances. Mass flow rate fluctuates with an amplitude of 10% of base case value. Dew point oscillations are of less than 5 ºC, so export gas can exceed specifications, but in not relevant levels.



(a) (b) (c)

Figure 4. Slug Flow Impacts: (a) Absorber – inlet gas flow rate (blue), TEG flow rate (red), water content (green), (b) JT – separator temperature (blue), HCDP (pink), (c) Final Gas Stream – gas flow rate (red), HCDP (blue), WDP (green), CO_2 content (light blue), methane content (pink).

5. Conclusions

A satisfactory representation of a NG processing plant on steady state was obtained, with the export NG stream complying with Brazilian ANP specifications for WDP, HCDP and CO_2 content. In general, the proposed control structure was properly tuned, since, despite the severe dynamic scenario, it performs adequately and promotes dampening of the inlet oscillations along downstream processing steps. Although the slug flow emulator is not a completely accurate representation of the real phenomenon, it successfully approaches its inherent intermittent profile. Furthermore, the MP

dynamic extension presents fast responses under system disturbances, according to the behavior expected for this unit operation.

The simulation further elucidates the impact of oscillations on gas dew points, which must be constantly monitored and controlled. It is worth noting that its increase may cause loss of specification and hence potential risk situations. It is relevant in validating the proposed control structure that such situation was not reached in the simulated scenario, in spite of the severe disturbances applied to the inlet stream. Finally, this study denoted the applicability of dynamic simulation in predicting the dynamic behavior in natural gas processing under severe slug conditions, and, hence, its potential application in the analysis and test of control strategies, operator training, HSE (Health, Safety & Environment) assessments, among others.

Automata Based Test Plans for Fault Diagnosis in Batch Processes

Chuei-Tin Chang, Wei-Chung Hsieh

Depratment of Chemical Engineering, National Cheng Kung University, Tainan 70101, Taiwan, R.O.C.

Abstract

Hardware failures are inevitable but random events in the useful life of any batch chemical plant. If such incidents are not efficiently diagnosed, the consequences may be very serious and sometimes even catastrophic. The present study aims to develop a systematic procedure-synthesis strategy for generating the test plans that minimize the chance of misjudgements. By modelling the components in the given system with timed automata, all possible fault propagation scenarios and their observable event traces (OETs) can be enumerated. The test procedure for every OET can then be conjectured by designing a supervisory controller to achieve the highest level of diagnostic resolution. One example is provided to show the feasibility of the proposed approach.

Keywords: Timed automata, Diagnostic tests, Model checking, Batch processes

1. Introduction

Various high value-added products, such as the specialty chemicals, foods, semiconductors and pharmaceuticals, etc., are manufactured in complex but flexible batch processes. Over the lifespan of any such plant, the hardware failures should be regarded as random but inevitable events. If these fault origins cannot be correctly identified in time, the consequences can be very serious and sometimes even catastrophic. Several studies have already been performed to address various issues concerning fault diagnosis in batch processes. Although satisfactory results have been reported, the available methods are mostly effective for applications in systems with relatively few interconnected units and, also, the diagnostic resolution in cases of coexisting failures may not always be acceptable.

In general, the diagnostic performance can be improved by capturing more online data so as to gain a clearer picture of the current system state and also a deeper understanding of the underlying fault propagation mechanism(s). This improvement is traditionally brought about by installing additional sensors. However, since adding new hardware inevitably requires extra spending and, also, the related issues have already been discussed extensively, there are incentives to consider a nonconventional means without capital investments. To this end, Yeh and Chang (2011) suggested to carry out extra control actions which are not included in the normal operating procedure. Kang and Chang (2014) later developed an effective method to synthesize diagnostic test plans according to untimed automata. However, due to the lack of time-tracking mechanisms in their models, the failure-induced abnormal plant behaviours cannot always be predicted accurately. To circumvent this drawback, it is the goal of present study to devise a procedure synthesis strategy for producing more practical test plans by using the timed automata.

2. Model construction principles

Since the modelling principles proposed by Kang and Chang (2014) are generic enough, their basic approach is also adopted to build time automata in the present study. For the sake of illustration clarity, this model construction method is illustrated here with a simple example. Specifically, let us consider a fictitious liquid transfer system represented by the piping and instrumentation diagram (P&ID) in Figure 1 and also the sequential function chart (SFC) in Figure 2. Notice that the components in this and any other batch process can always be classified into a hierarchy of 4 different levels: (1) the programmable logic controller (PLC); (2) the actuators, i.e., the three-way valves (V-1 and V-3) and the two-way valves (V-2 and V-4); (3) the processing units, i.e., Tank and (4) the online sensor(s). If a three-way valve is closed, the port connecting to the horizontal pipeline in Figure 1, i.e., P-2 in the case of V-1 or P-3 in the case of V-3, is assumed to be blocked. Otherwise, its inlet flow(s) should be directed to every outlet pipeline. It is assumed that all valves except V-4 are placed at the "close" position initially. Thus, it clear from the above SFC that, during the normal operation, the buffer tank is filled with liquid via P-1, P-3 and P-4 by manipulating V-3 and then drained via P-5 by gravity. For the sake of brevity, only four fault origins are considered in this example and they are denoted respectively by f_{1A} (or Tank_LEAK), i.e., a large leak develops in tank, f_{1B} (or Tank_leak), i.e., a minor leak develops in tank, f_2 (or V3SC), i.e., V-3 fails at the "close" position, and f_3 (or V3SO), i.e., V-3 fails at the "open" position.

The plant model can in general be obtained by first building automata to model all components in the given process and then integrating them via the standard parallel decomposition operation. In this work, the controller and the remaining components are modelled differently. Let us first outline the construction principles for the latter components, i.e., the valves, the tank and the sensors. In particular, a timed automaton is used to represent a finite set of identifiable states of the hardware item under consideration and also the specific events facilitating the state transitions. The prerequisite conditions of these events can be imposed with the so-called "guards", while the updated integer and clock variables may also be specified as the attributes of a transition (Behrmann et al., 2006).

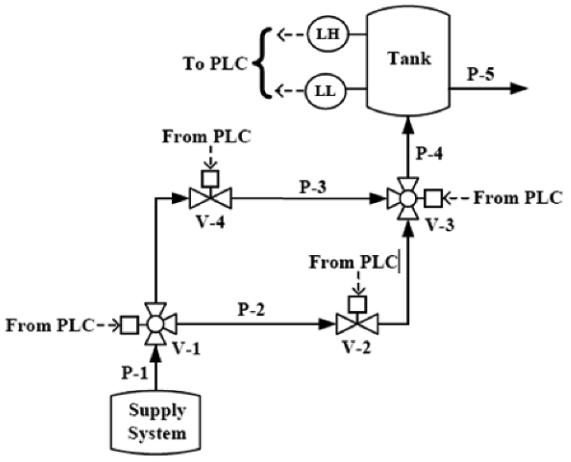

Figure 1. P&ID of a liquid transfer system.

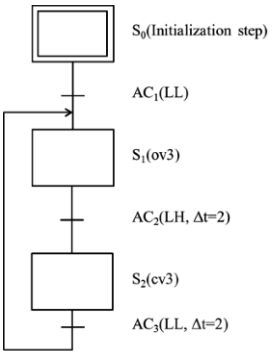

Figure 2. Normal SFC of a liquid transfer operation.

In this example, only the elapsed times of the transitions in tank model are assumed to be nonzero and the corresponding automaton is presented in Figure 3. Note that the places LL and LH are used to represent low and high liquid levels under normal conditions respectively, while LL_leak and LH_leak denote the corresponding liquid levels when a minor leak is present in the tank and LL_TEAK is the low level eventually reached after a large leak. For the sake of brevity, let us consider only the transition from LL to LH. To trigger this transition, three conditions (guards) are imposed with four binary variables (*v1 – v4*) and a clock variable *x*. The former are used to represent the corresponding valve states, i.e., 1 denotes open and 0 otherwise, and the latter is the time needed to complete the state transition. Tank_LH! is the LL-to-LH transition process and "!" denotes that it is an initiator or sender event. The last line is the reset condition, i.e., the liquid level is reset to high (*L=1*) after completing the transition. Finally, due to space limitation, the component models of valves and sensors are not presented here since they are essentially the same as the untimed counterparts given in Kang and Chang (2014).

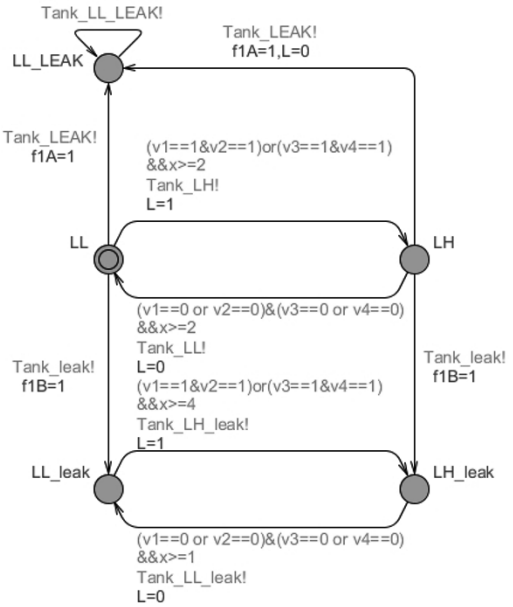

Figure 3. Tank model.

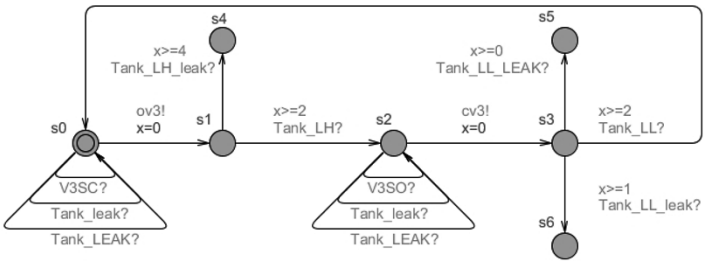

Figure 4. Controller model

The controller model can be constructed according to the normal system behaviours specified in SFC and also the failure-induced events (see Figure 4). The controller controlled actions in this model, i.e., open and close V-3 (*ov3*! and *cv3*!), should naturally be viewed as senders, while the failure induced events, e.g., V3SC?, V3SO?, Tank_leak? and Tank_LEAK?, are receivers.

3. Identification of fault propagation mechanisms

According to Clarke et al. (1986), "model checking" is essentially an algorithmic procedure for verifying whether a given system is compliant with the target specifications. A software verifier can be applied to determine if a set of timed automata conform to the desired system properties. If not, the verifier will provide a counter scenario, from which the user could find error(s) and then modify the models accordingly. In this study, the model checking tool provided in UPPAAL (Behrmann et al, 2006) was utilized for enumerating all fault propagation paths. The required deductive reasoning procedure is summarized in Figure 5.

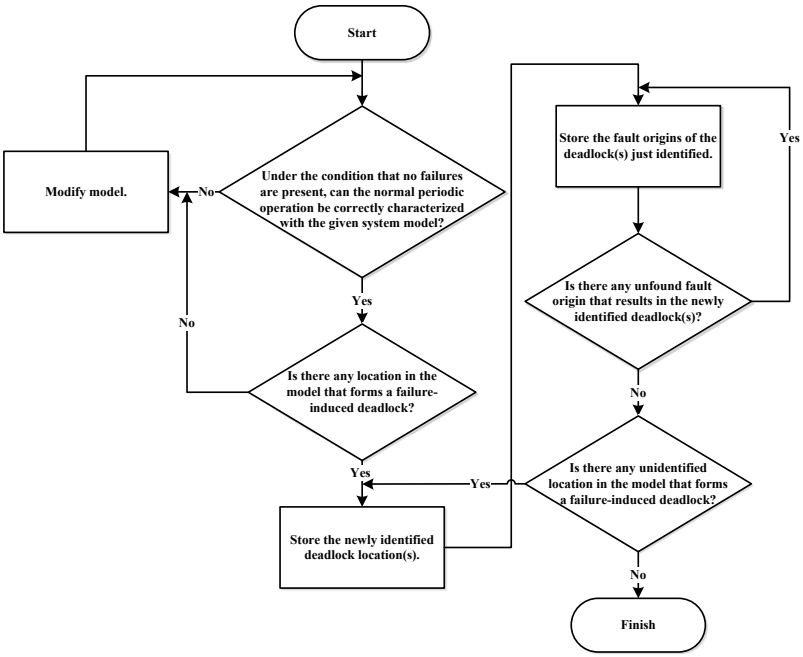

Figure 5. Deductive reasoning procedure for identification of fault propagation paths.

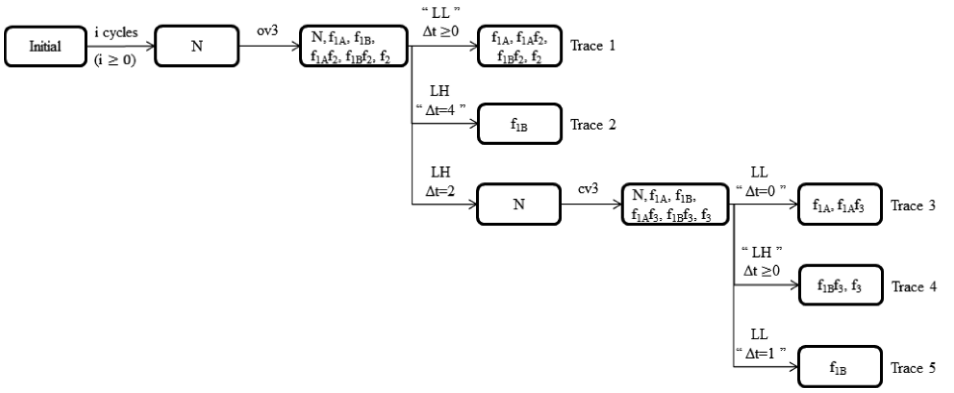

Figure 6. Observable event traces.

As mentioned before, failures may occur at any instance during the batch operation. Since these events are usually not directly observable, the fault origins can only be diagnosed with other available online information. By assuming that the sensor measurements, the actuator actions and the clock readings are observable online, all OETs in the present example can be identified and summarized in Figure 6. The rectangles in this figure are used to specify the implied system states, which may be either normal (N) or under the influence of one or more failure, while the arrows are transitions triggered by the corresponding *observable* events. Note also that every abnormal event is marked with double quote. For the sake of brevity, let us consider only Trace 1 in more detail. The first transition on this trace is used to represent the observable event sequence that may be experienced in *i* completed operation cycles. The subsequent action is the first operation step of SFC, i.e., *ov3*, which should normally result in a high liquid level (LH). However, if the abnormal state "LL" is detected instead, there should be four implied fault origins: (1) f_{1A}; (2) $f_{1A}f_2$; (3) $f_{1B}f_2$; (4) f_2. Note that two coexistent failures are present in the 2nd and 3rd scenarios respectively.

4. Synthesis of diagnostic test plans

If the implied fault origins are not unique after observing a fully developed OET during operation, additional tests should be performed to further enhance diagnostic resolution. The corresponding test plan can also be produced with the model checking tool mentioned above.

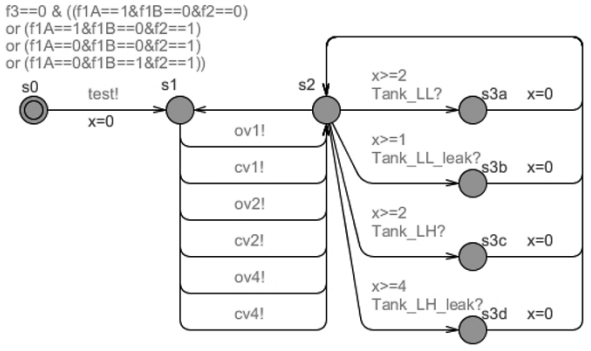

Figure 7. Test model.

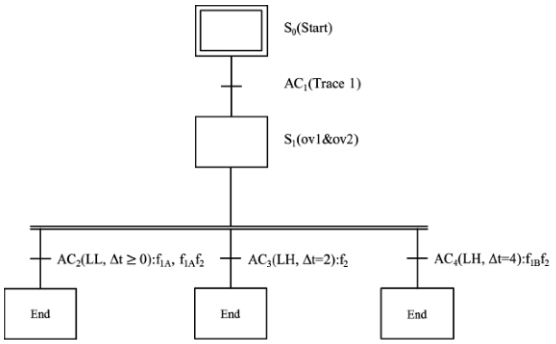

Figure 8. Optimal test procedure.

All component models can be adopted for synthesizing the test plans except that of the controller, which should be modified by introducing an additional transition which points away from a deadlock place reached after failure(s). This transition is activated by a receiver event "test" and terminated at an artificial place without outputs. An additional automaton should also be constructed to facilitate procedure synthesis (see Figure 7). The initial event "test" should be a sender, while its guards limit the scope of fault origins to those implied by the corresponding OET. All possible test actions are placed on the loops between s0 and s1, respectively. On the other hand, every admissible observable event triggers a unique outward transition from place s2 to a downstream place (i.e., s3a, s3b, s3c or s3d), which can then be brought back to the originating state s2 by resetting clock. It should be noted that the aforementioned loops are used mainly for creating multi-step procedures. By appropriately checking these models with UPPAAL, the SFC in Figure 8 can be generated for fault diagnosis after observing Trace 1. Note that the control actions *ov1* and *ov2* in the operation step S_1 are called for as soon as the activation condition AC_1 is satisfied. There may be three resulting scenarios depending on the sensor and clock readings, i.e., (1) AC_2 (LL, $\Delta t \geq 0$), (2) AC_3 (LH, $\Delta t = 2$), and (3) AC_4 (LH, $\Delta t = 4$), and the corresponding fault origins are: (1) f_{1A} or $f_{1A}f_2$; (2) f_2; (3) $f_{1B}f_2$.

5. Conclusions

A standardized methodology has been proposed in this work to construct timed automata for modelling all components in a given batch plant, and to establish the observable event traces accordingly. A generic synthesis procedure has also been developed for conjecturing the test plans of all undiagnosable traces. This diagnosis strategy is featured with the unique capability of differentiating various time delays caused by fault origins of the same type but with different intensities. Further enhancements should include a generalized method for more complex operations.

Modelling and Monitoring of Natural Gas Pipelines: New Method for Leak Detection and Localization Estimation

Xinghua Pan, M. Nazmul Karim*

Artie McFerrin Department of Chemical Engineering, Texas A&M University, 3122 TAMU, College Station, Texas 77843, United States
nazkarim@mail.che.tamu.edu

Abstract

Leakage of the chemicals from pipelines is the biggest safety concern about the transportation of the chemicals. Model-based fault detection method is one of the most widely used software solutions for fault identification. In this paper, a new leak detection method for a natural gas pipeline is proposed basing on the non-isothermal modelling of the process. The new software-based method is developed by designing an unknown input observer, which is able to deal with the disturbance from the temperature change and pressure drop from the pump station and estimate the boundary flow rate of the pipeline. A new adaptive model was updated towards the temperature and boundary pressure change for leak location estimation. A simulation of a natural gas pipeline with consumer connection was demonstrated.

Keywords: leak detection, natural gas pipeline, unknown input observer

1. Introduction

Pipeline is one of the most widely applied transportation methods for chemicals. However, the leakage accidents from the pipeline have generated great safety concerns. The software-based method generally use flow rate and pressure measurements at the boundary of the pipeline. Some software methods need temperature measurement such as Real Time Transient Modelling (Geiger, 2005). However, there are some limitations of the software method such as its high sensitivity to the process noise.

A natural gas pipeline is different from water and crude oil pipeline problems because of the change of gas thermal phase. Research have been reported for the leak detection of a natural gas pipeline without considering the thermal effect (Benkherouf and Allidina, 1988; Emara-Shabaik et al., 2002).The effect of the thermal property on the natural gas flow is demonstrated in this paper by non-isothermal modelling. A non-isothermal model of a natural gas pipeline without leak has been demonstrated (Osiadacz and Chaczykowski, 2001). Model-based software methods involve solving the partial differential equations (PDE) of the natural gas flow model both for isothermal and non-isothermal cases. The oscillation in boundary pressure changes the flow rate in the pipeline, further influences the leak detection decision.

In this paper, we designed a linear unknown input observer for the leak detection of a natural gas pipeline. The pipeline is featured with time-variant consumer usage at certain location. An unknown input observer is designed to eliminate the effect of

unknown input (Sename, 1997; Fu et al., 2004). The observer is able to identify the disturbance of pressure oscillation and temperature change without requiring the measurement and real-time modelling.

2. Modelling of the natural gas flow

2.1 Non-isothermal modelling of the natural gas flow in a pipeline

The non-isothermal modelling of a natural gas flow was demonstrated. Briefly, the composition of natural gas is assumed as 95 % methane, 2.5 % ethane, 1.6 % nitrogen, 0.7 % carbon dioxide, and 0.2 % propane. The pressure heat capacity is assumed constant at 2170 (J/kg K). The pipeline is 10 km in length (L = 10 km), and 0.3 m in diameter (D = 0.3 m). Heat transfer coefficient along the pipeline is assumed uniform. The inlet pressure (P_{in}) is 10 bar, and the outlet pressure (P_{out}) is 8 bar. The flow rate, pressure, and temperature across the pipeline cross-section were assumed constant as the flow is highly turbulent. A time-variant consumer usage is applied to the pipeline. The measurement frequency of the consumer usage is every 30 second. The non-isothermal models are developed based on mass, moment, and energy balance which are listed below.

$$\frac{\partial P}{\partial t}=\frac{-\frac{1}{A}\frac{\partial q}{\partial x}-\frac{1}{A\Delta x}q_L+\left[\frac{1}{ZC_P}\frac{\partial Z}{\partial T}+\frac{1}{TC_P}\right]\left[\frac{fq^3Z^2R^2T^2}{2DA^3P^2}-\frac{4U(T-T_g)}{D}-\frac{q}{A}C_P\frac{\partial T}{\partial x}+\left(\frac{T}{Z}\frac{\partial Z}{\partial T}+1\right)\frac{q}{AP}ZRT\frac{\partial P}{\partial x}\right]}{\left[\frac{1}{ZRT}-\frac{P}{Z^2RT}\frac{\partial Z}{\partial P}-\left(\frac{\partial Z}{\partial T}\right)^2\frac{T}{Z^2C_P}-\frac{2}{ZC_P}\frac{\partial Z}{\partial T}-\frac{1}{TC_P}\right]} \tag{1}$$

$$\frac{\partial q}{\partial t}=-A\frac{\partial P}{\partial x}-\frac{AP}{ZRT}g\sin\theta-\frac{fq^2}{2DAP}ZRT-\frac{1}{A}\frac{q_L}{\Delta x}\left(\frac{q}{P}\right)ZRT \tag{2}$$

$$\frac{\partial T}{\partial t}=\frac{\left(\frac{1}{ZRT}-\frac{P}{Z^2RT}\frac{\partial Z}{\partial P}\right)\frac{\partial P}{\partial t}}{\left(\frac{P}{Z^2RT}\frac{\partial Z}{\partial T}+\frac{P}{ZRT^2}\right)}+\frac{\frac{1}{A}\frac{\partial q}{\partial x}}{\left(\frac{P}{Z^2RT}\frac{\partial Z}{\partial T}+\frac{P}{ZRT^2}\right)}+\frac{q_L}{A\Delta x}\frac{1}{\left(\frac{P}{Z^2RT}\frac{\partial Z}{\partial T}+\frac{P}{ZRT^2}\right)} \tag{3}$$

Z is the compressibility factor and q_L is the leak mass flow rate.The isothermal models are developed using constant compressibility as shown in Eq. (4) and (5).

$$\frac{\partial P}{\partial t}+\frac{c^2}{A}\frac{\partial q}{\partial x}+\frac{c^2}{A\Delta x}q_L=0 \tag{4}$$

$$\frac{\partial q}{\partial t}+A\frac{\partial P}{\partial x}+\frac{fc^2q|q|}{2DAP}+\frac{c^2}{A\Delta x}\left(\frac{q}{P}\right)q_L=0 \tag{5}$$

2.2 Model reduction

The nonlinear isothermal model was reduced to a linear model which showed the relationship between consumer usage and boundary flow rate. The model reduction process starts from the isothermal model.

The reduction process is shown as followed. The overall pipeline is divided into three parts: the section before the usage (l_1), the section with the usage (l_2), and the section

after the usage (l_3). The isothermal nonlinear equation holds for each section. q_{usage} is zero for l_1 and l_3. With the assumption of fixed boundary pressure condition, equation becomes the following.

$$l_1 \frac{f(2q_1+\Delta q_1)\Delta q_1}{D} + (l_2+l_3)\frac{f(2q_1+\Delta q_0)\Delta q_0}{D} + \frac{1}{2}(\Delta q_1 - \Delta q_0)(q_1+\Delta q_0) = 0 \tag{6}$$

With the assumption that $(2q_1 + \Delta q_1) \approx 2q_1$ and $(2q_1 + \Delta q_0) \approx 2q_1$, the above equation can be simplified to the following equations with a/b as a constant.

$$q_{in} = q_{st.} + q_{usage} \cdot a \qquad q_{out} = q_{st.} + q_{usage} \cdot b \tag{7}$$

For a time-variant consumer usage, the dynamic of the boundary flow rate can be written as the following equations.

$$q_{in}(t) = q_{st.} + \sum_{i=1}^{n} a_i q_{usage}(t-i) \qquad q_{out}(t) = q_{st.} + \sum_{i=1}^{n} b_i q_{usage}(t-i) \tag{8}$$

3. Design of an unknown input observer with multiple time delays

Without loss of generality, a linear model was showed in Eq. (9). In which, x(t) is the state, y(t) is the measurement, $u(t-\tau_i)$ is the input (consumer usage), and w(t) is the unknown input.

$$x(t) = \sum_{i=0}^{n} A_i x(t-\tau_i) + \sum_{i=0}^{n} B_i u(t-\tau_i) + Ww(t) \tag{9}$$

$$y(t) = Cx(t) \tag{10}$$

The unknown input observer is designed as the following

$$\mathrm{z(t)} = \sum_{i=0}^{n} F_i z(t-\tau_i) + \sum_{i=0}^{n} TB_i u(t-\tau_i) + \sum_{i=0}^{n} G_i y(t-\tau_i) \tag{11}$$

$$\hat{x}(t) = z(t) + Ny(t) \tag{12}$$

Theorem 1: The observer will asymptotically estimate the state if and only if the following conditions hold:

1. $\mathrm{e(t)} = \sum \mathrm{F_i e(t-\tau_i)}$ is asymptotically stable
2. $T+NC=I$
3. $TW=0$
4. $\bar{G}_1 = G_i - F_i N,\ i = 0,1,2,\ldots n$
5. $F_i = TA_i - \bar{G}_1 C,\ i = 0,1,2,\ldots n$

(13)

The unknown input parameter matrix was set as $\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$, which corresponds to the pressure oscillation, process noise, and temperature change. The observer parameter synthesis is solved using the LMI method. The proof of the theorem is not shown here, which can be found in the reference (Keong et al., 2005).

Theorem 2: The observer estimation error will be asymptotically stable if and only if the following conditions hold: there exist matrices $P = P^T > 0;\ Q_i > 0$ satisfying the LMI.

$$\begin{bmatrix} -P+\sum_{i=1}^{4} Q_i & 0 & 0 & 0 & 0 & F_0^T P \\ * & -Q_1 & 0 & 0 & 0 & F_1^T P \\ * & * & -Q_2 & 0 & 0 & F_2^T P \\ * & * & * & -Q_3 & 0 & F_3^T P \\ * & * & * & * & -Q_4 & F_4^T P \\ * & * & * & * & * & -P \end{bmatrix} < 0 \tag{14}$$

The proof of the theory is to introduce a discrete type Lyapunov-Karsovskii function, which is not shown here. Another restriction for the parameter is that the eigenvalues of the parameter need to be restricted in a certain range. It satisfies the following LMI with λ_1 and λ_2 as constants as shown in the reference (Keong et al., 2005).

$$\begin{aligned} &Q_1 \sum \chi_i + (Q_1 \sum \chi_i)^T - \mathrm{U} \sum \beta_i - \left(\mathrm{U} \sum \beta_i\right)^T + 2\lambda_2 Q_1 < 0 \\ &Q_1 \sum \chi_i + (Q_1 \sum \chi_i)^T - \mathrm{U} \sum \beta_i - \left(\mathrm{U} \sum \beta_i\right)^T + 2\lambda_1 Q_1 > 0 \end{aligned} \tag{15}$$

4. Results and discussion

The effect of the temperature change and pressure drop at boundary of the pipeline was simulated in Matlab. A pattern of consumer usage in a time span is illustrated in Fig. 1, which shows a constant usage at midnight for heating and an increased usage for cooking in the morning.

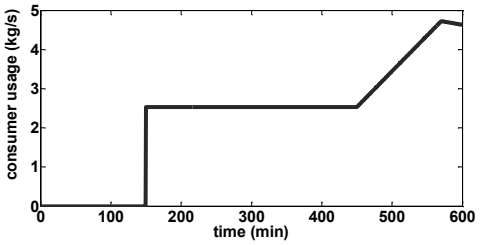

Figure 1. Time-variant consumer usage

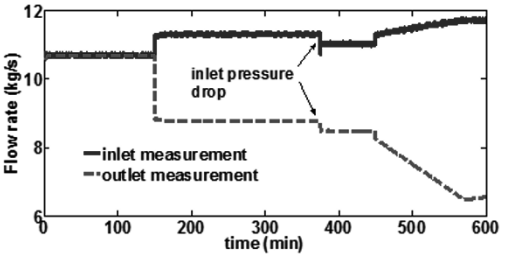

Figure 2. Effect of pressure drop on flow rate

The measurement data is generated by the non-isothermal model. The estimation data is from the unknown input observer which is based on the isothermal model. The measurement and estimation are only limited to flow rate. To study the effect of disturbance such as pump station pressure drop and temperature disturbance on the effect of flow rate, the simulation results are shown in Fig. 2 and 3.

Fig. 2 shows the effect of inlet pressure drop on the boundary flow rate. The inlet pressure drops from 10 bar to 9.9 bar in 30 s. As can be seen in the figure, both inlet and outlet drop, however, the inlet flow rate has a sharp drop and increases back. The effect of temperature change on flow rate is demonstrated in Fig. 3 with a 10 K temperature increase in 30 s. As shown in the figure, both inlet and outlet flow rate decrease after temperature change. The decrease of ground temperature will have the opposite effect which is not shown here.

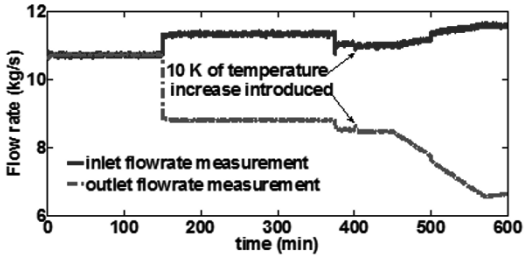

Figure 3. Effect of temperature change on flow rate

Fig. 4 compares the measurement and observer estimation of boundary flow rate. The observer was given an initial estimation error as seen in the figure. The observer is able to estimate the flow rate when disturbance occurs such as pressure drop and temperature change till a leak occurs.

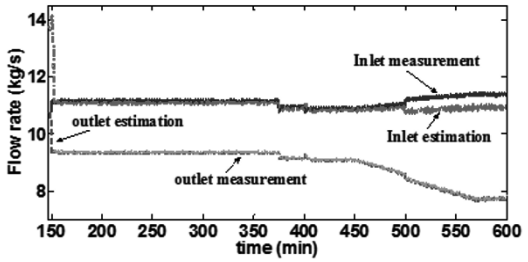

Figure 4. Comparison between flow rate measurement and observer estimation

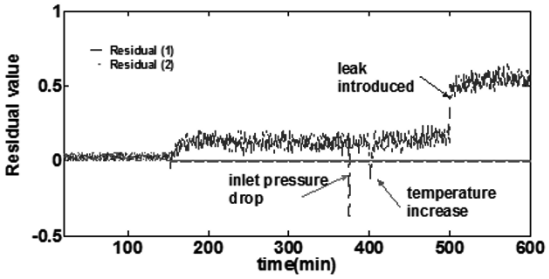

Figure 5. Residual signal of observer

The difference between measurement and observer estimation is defined as a residual. As pointed out in Fig. 5, the pressure drop will generate a sharp negative residual signal. The temperature increase also has a sharp negative residual signal. However, the leak accident creates a constant increase in the residual value, which is a different residual pattern for distinguishing the disturbance of pressure drop and temperature change.

A new location estimation scheme is proposed. The new method involves first identifying the disturbance and leaks basing on the residual signal shown in Fig. 5. If a disturbance was identified, the linear model of the natural gas flow was updated to include the information of disturbance. Once a leak event was distinguished from disturbance, the leak location was calculated based on the measurement and observer estimation. Fig. 6 demonstrated the leak location estimation result. The leak location was estimated using the Eq. (7) and (8).

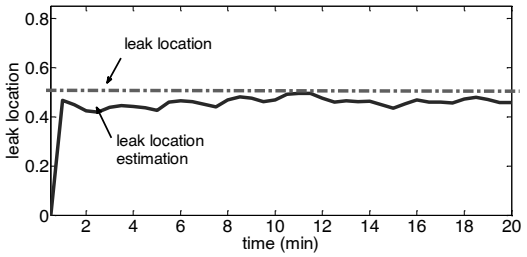

Figure 6. Leak location estimation

5. Conclusions

The non-isothermal modelling of a natural gas flow in a pipeline was developed. The unknown input observer can estimate the boundary flow rate of the pipeline, and also can distinguish the disturbance from the leak accident basing on the different residual signal. A new adaptive model was proposed to incorporate the temperature and pump pressure change for leak location estimation.

Abstract

Large numbers of variables are measured in typical chemical processes. In most of the fault detection and diagnosis methods, all the measured variables are selected. However, the incorporating measured variables that do not provide any additional information about faults degrades monitoring performance.

Dynamic artificial immune system (DAIS) is a new artificial intelligence methodology shows strong ability of self-learning and self-adaptability. Much work has been done on its application in process monitoring and fault diagnosis in chemical processes. However, there is little research in the variable selection in DAIS. In this paper, we propose an approach to select variable used for DAIS. The approach is based on the causal inference among the measured variables. Through causal inference, the cause-effect relations among variables can be found and then variables that do not reflect the main trends of changes of the processes can be picked out. Then the variable selection of the DAIS can be optimized and the performance of the fault diagnosis of DAIS can be improved. Case studies based on the Tennessee Eastman process are performed to illustrate the effectiveness of our approach.

Keywords: Fault diagnosis, artificial immune system, transfer entropy, variable selection

1. Introduction

It is of great importance to detect and diagnose process faults to ensure the stability and safety of chemical processes. The fault detection and diagnosis techniques can be divided into two categories: model-based techniques and data-based techniques (Venkatasubramanian et al., 2003). Model-based techniques require a reliable mathematical model and their application are often limited by the complexity of the chemical processes. On the other hand, data-based techniques mainly depend on the availability of process data, which are usually easy to obtain from modern chemical processes. Therefore, data-based techniques attract lots of focus from the fault detection and diagnosis study.

Among the data-based techniques, the multivariate statistical process monitoring (PSPM) techniques are very popular, such as principal component analysis (PCA), independent component analysis (ICA), partial least square (PLS). Besides PSPM, some methods based on pattern classification also draw much attention, such as artificial neural network (ANN), support vector machine (SVM). Compared with the data-based techniques above, artificial immune system (AIS) shows stronger self-adaptive and self-learning abilities and draws much attention recently (Dai and Zhao, 2011; Ghosh and Srinivasan, 2011; Zhao et al., 2014). In this paper, the fault detection and diagnosis (FDD) are based on dynamic artificial immune system (DAIS), which was proposed by

Dai and Zhao in 2011 to conduct FDD for batch processes as well as steady-state processes.

Although much work has been done in data-based fault diagnosis, few of them considered the selection of variables to be used in the diagnosis. As modern chemical processes are becoming larger and more complex, thousands of variables are measured to monitor the processes. However, for the FDD of a process, the measured variables aren't equally important. The introduction of unimportant variables will obviously increase the computing loads of the FDD techniques and, moreover, degrade the performance like the false alarm rate, the missed detection rate and the detection delay (Ghosh et al., 2014). Therefore, the variable selection is a critical issue of the FDD techniques.

In this paper, we propose a variable selection method based on the causal inference with transfer entropy, and apply it to improve the performance of FDD with AIS. The rest of the paper is organized as follows: Section 2 is a brief introduction of DIAS; Section 3 is the description of our proposed variable selection methods; Section 4 is the case study on Tennessee Eastman process; Section 5 is the conclusion.

2. Dynamic artificial immune system

Artificial immune system (AIS) is a method that tries to mimic the human immune system. As summarized by Timmis in 2008, AIS is a diverse area of research that attempts to bridge the gap between immunology and engineering and it is developed through the application of techniques such as mathematical and computational modeling of immunology, abstraction from those models into algorithm (and system) design and implementation in the context of engineering.

Recently, work on chemical process FDD has been reported (Aguilar in 2004; Wang and Zhao. in 2008; Ghosh and Srinivasan in 2011). To apply AIS in fault diagnosis of batch processes, Dai and Zhao integrated the clonal selection algorithm of AIS with dynamic time warping (DTW) in 2011and afterwards used the so-called dynamic AIS (DAIS) in an online fault diagnosis strategy for full operating cycles of chemical processes in 2014.

In this work, we use DAIS to diagnose faults. In DAIS, antibodies and antigens are represented by matrices of time-sampled data, instead of vectors of data, to reflect data changes in trend. The differences between them are calculated by the DTW algorithm. The details of DAIS can be found in Dai and Zhao's paper in 2011 and Zhao et al.'s paper in 2014. The main steps of DAIS are shown as below.

1) Initialization. Generate original fault and normal antibodies from historical samples. Then clone these antibodies with mutation to construct antibody library of normal state and each type of fault. The threshold of each of the antibody library should also be calculated.
2) Fault detection. Generate detective antigen from the incoming data and calculate the difference between the detective antigen and each antibody in the normal antibody library. If all of the differences are greater than the threshold of the antibody library, then a fault is detected.
3) Fault diagnosis. After a fault is detected, generate diagnostic antigen and calculate the difference between the diagnostic antigen and each antibody in antibody library of each type. If there exist fault antibodies in only one of the fault antibody libraries that have smaller difference degrees than the threshold of the fault antibody library, the fault is recognized of the fault type of the corresponding fault antibody library. If none of the fault antibody libraries contain an antibody that has a smaller

difference degree than the corresponding threshold, the fault is then diagnosed as a new fault.

4) Self-learning. After the fault diagnosis of DAIS, a manual diagnosis should be conducted to double check the diagnosis results by DAIS. According to the manual diagnosis result, a new original fault antibody is then generated and stored into the fault antibody library of the fault type of the manual diagnosis result. Afterwards the fault antibody library is updated through a new round of clone with mutation.

Although DAIS shows strong adaptation capability and independency on the number of training samples, there is still much work worth doing to improve its performance. One of the critical issues is the selection of variables to generate antibodies and antigens. In the next section, the issue of variable selection will be discussed.

3. Variable selection based on causal inference with transfer entropy

In pattern recognition, patterns are recognized based on a vector of features values, the selection of a subset of variables can have a significant effect on the classification performance and therefore feature selection have become an important step of data pre-processing in automated pattern recognition (Jain & Zongker, 1997; Raymer et al., 2000).

Although feature selection (or variable selection) is widely used in pattern recognition and data mining, it is rarely considered in multivariate statistical process monitoring (MSPM) or FDD. Two notable exceptions are: Verron et al. proposed a fault diagnosis method with variable selection based on mutual information in 2008; Ghosh et al. proposed a genetic algorithm (GA) based method for the variable selection in PCA in 2014. However, their method was based on a GA optimization and didn't consider the intrinsic relationships between variables. As a result, the optimized selection PCA may be useless for other FDD method. Verron's method is based on the mutual information between the data and the considered classes. Therefore, a large number of samples of each fault class to be considered are necessary for the variable selection, which may limit its application.

In our proposed selection approach, we utilize transfer entropy to infer the causal relationships between variables. According to the inferred causal relationships, the variables that closely relate to the root cause of a certain fault can be found. Then DAIS can be built with these related variables to diagnose the fault. In detail, our proposed DAIS fault diagnosis method with variable selection can be divided into three steps, which will be described separately as follows:

3.1. Transfer entropy calculation

Based on the concept of information theory and information entropy (Shannon and Weaver, 1949), Schreiber proposed the concept of transfer entropy in 2000 to measure the asymmetric interactions in a system. Transfer entropy is in an asymmetric form, which makes it possible to measure cause-and-effect relationships. To consider time delays, which are common in many practical situations, Bauer et al. in 2007 incorporated the prediction horizon in the transfer entropy. Shu and Zhao in 2013 proposed a modified transfer entropy to make the estimation of time delay more accurate. In this work we use the modified form to calculate transfer entropy that indicates the causal relations of y to x:

$$t(y \to x) = \int \cdots \int \hat{p}(x_{i+h}, x_{i+h-1}^{(k)}, y_i^{(l)}) \log \frac{\hat{p}(x_{i+h} \mid x_{i+h-1}^{(k)}, y_i^{(l)})}{\hat{p}(x_{i+h} \mid x_{i+h-1}^{(k)})} dx_{i+h} dx_{i+h-1}^{(k)} dy_i^{(l)} \quad (1)$$

x and y represent two variables while x_i and y_i represent their values at time i. $y_i^{(l)} = [y_i, y_{i-1}, \cdots, y_{i-l+1}]$ and $x_{i+h-1}^{(k)} = [x_{i+h-1}, x_{i+h-2}, \cdots, x_{i+h-k}]$. The probability density function (PDF) is estimated by a kernel estimator, which can be found in Bauer's work in 2007. As we change h, the value of equation (1) will change and we can find an h to maximize the value. Then the maximized value is the transfer entropy that presents the strength of causal relations from y to x and the corresponding h is the time delay.

3.2. Variable selection

With equation (1), the transfer entropy between variables of the process to be diagnosed can be calculated to measure the causal relations between variables with the normal data in steady state. Then for a certain fault type, pick out the measured variable that directly relates to the root cause of the fault. Afterwards examine the transfer entropy values from that variable to the other variables. Only those variables with transfer entropy values larger than the pre-set threshold, which means they are strongly affected by the fault, should be selected to be used in DAIS.

3.3. DAIS fault diagnosis

After the variables are selected for each fault type, the antibodies of each fault type can also be generated using only the variables selected for that fault type instead of all of the variables. On the other hand, different antigens should also be generated using different selection of variables for different fault types.

4. Case study

The case study is conducted on Tennessee Eastman (TE) process (Downs and Vogel, 1993), which is a benchmark model for studying fault detection and diagnosis. The process was simulated on Matlab Simulink using the control strategy proposed by Ricker in 1996.

In this case study we only use the continuous process measurements (XMEAS (1)-(22)) and the process manipulated variables (XMV (1)-(12)). The sampling interval is 1.8 seconds.

The transfer entropy calculation is based on 1000 sampling points of steady state normal data, with k=l=1 and the search range of h is from 0 to 5 sampling intervals. The threshold of transfer entropy to determine whether to select a variable is 0.1.

Totally 20 types of faults can be introduced into the simulated process to generate fault samples for the validations of FDD methods. In this case study, we choose to introduce fault 4 and 6 because the cause of each of these faults can be directed related to a measured variable. Then the related variables can be found using the results of transfer entropy calculation and selected to build DAIS. The descriptions and selected variables of the introduced fault are listed in Table 1.

Table 1. Fault description and selected variables

Fault No.	Fault description	Selected variable in DAIS
IDV (4)	reactor cooling water inlet temperature step change	Reactor Level; Reactor cooling water outlet temperature; Reactor cooling water flow valve
IDV (6)	A feed loss	A feed; A and C feed; A feed flow valve; A and C feed flow valve

For each fault type, two fault batches are simulated to generate training samples to construct the DAIS antibody libraries. Then two fault batches are simulated to provide test samples. The antibody length is set to be 30 sampling points and the antigen length is set to be 15 sampling points.

The diagnosis delays, which mean how long it takes DAIS to recognize the fault types of the type samples, are shown in Table 2. It can be found that variable selection reduced the diagnosis delays by 1 to 3 sampling intervals, or 1.8 to 5.4 seconds.

Table 2 Diagnosis delay of DAIS

Test sample	Diagnosis delay, all variables are used	Diagnosis delay, only selected variables are used
IDV (4) sample1	12.6 sec	10.8 sec
IDV (4) sample2	14.4 sec	10.8 sec
IDV (6) sample1	23.4 sec	21.6 sec
IDV (6) sample2	27.0 sec	21.6 sec

Then we generate diagnostic antigens from data of 15 sampling points after the fault introduced moment and calculate their difference degrees from the fault antibody libraries. The results are shown in Table 3. The antibody libraries of each fault type can correctly diagnose the two fault samples of its fault type and won't recognize the fault samples of other fault type by mistake, no matter whether the variable selection is implemented. But the variable selection will lead to a more obvious discrimination between antigens of different fault types. For example, when we use antibody library of IDV (6) to diagnose faults, the difference degrees between the antibody library and the samples of IDV (4) will be very close to the difference degrees between the antibody library and the samples of IDV (6) (0.5616 and 0.5083 v.s. 0.4418 and 0.4753). But if we use only the selected variables to diagnose, the differences will have a more significant disparity (0.0964 and 0.0963 v.s. 0.0248 and 0.0320).

Table 3 Difference degrees between antigens of test samples and the antibody libraries

Test sample	Antibody libraries, all variables are used		Antibody libraries, only selected variables are used	
	IDV (4) Threshold: 0.5085	IDV (6) Threshold: 0.4781	IDV (4) Threshold: 0.0661	IDV (6) Threshold: 0.0815
IDV (4) sample1	0.4457	0.5616	0.0457	0.0964
IDV (4) sample2	0.3772	0.5083	0.0401	0.0963
IDV (6) sample1	0.5596	0.4418	0.0691	0.0248
IDV (6) sample2	0.6030	0.4753	0.0766	0.0320

5. Conclusion

Because of the good availability data in modern chemical process, data-based techniques draw much attention from the chemical process fault detection and diagnosis (FDD) research. Although much work has been done on the data-based FDD methods, the selection of variable to be used in the FDD methods is rarely studied. Some research has shown that improper variable selection may degrade the performance of FDD methods. Variable selection is an important issue in FDD.

In this work, we propose a variable selection method based on the causal inference with transfer entropy. With causal inference, the variables that strongly relate to a certain fault type can be picked out. The FDD using only these variables will have a better

performance in diagnosis delays because irrelevant variables will no longer disturb the diagnosis.
The FDD method used in this work is dynamic artificial immune system because it is strong adaptation capability and independency on the number of training samples. However, it should be noted that our variable selection can also be used to improve other FDD methods because it depends on the causal inference rather than optimization of the performance of a certain FDD method.
A case study on TE process is performed to show the improvement of DAIS when our variable selection method is used.

Abstract

Conventional safety systems are designed to mitigate incidents, i.e., they aim to reduce the impact of failures using relief valves, rupture disks and, usually, cause a system emergency shutdown. The design of these systems is based on failure likelihood and the accident severity. However, this basis is normally obtained empirically, leaving the safety system vulnerable to process nonlinearities. To ensure the process safety, the control actions are conservative, so that small deviations from setpoints can lead to shutdown, generating large economic losses. This work proposes the periodic simulation of the reactor behaviour considering several component failures and, from these responses, determine the potential risk to which the system is subjected. Depending on this potential, preventive actions can be taken in order to guarantee the reactor safety and integrity and avoid a potential shutdown. These actions are calculated to provoke the least possible disturbance in order to reduce the impact on product quality, while keeping the process operating. The goal is to increase annual operating time of the plant without compromising the safety of the process and product quality. The results show that the proposal is feasible to real time applications and that, with a reliable model and an efficient fault detection system, unnecessary shutdowns can be avoided.

Keywords: process safety, nonlinear model predictive control

1. Introduction

Although the chemical industry operates on a large scale for tens of decades, only in the last two decades the subject of safety has gained the attention it deserves. Several accidents have marked the history of the chemical industry, such as Chernobyl, Bhopal, Seveso and Sandoz. Important lessons have been learned from these tragedies. Among them, the deep knowledge of the chemical process can be emphasized. In the synthesis of a new process, even after the tests on a pilot scale, the scale-up to industrial scale can bring serious changes in the dynamic behaviour of the system. Besides these changes, the control structure can modify the stability of the system at various operating points. In this case, the use of mathematical models is essential for reliable dynamic analysis. Moreover, with the rapid advancement of computing in recent years, the use of rigorous phenomenological models becomes increasingly feasible (Manenti, 2011). Their penetration in the industrial environment, however, is still limited. In security systems is no different. Despite the obvious gains that non-linear mathematical models can bring regarding the reliability of the analysis, their use still faces difficulties in implementation and hesitancy of industry replacing traditional linear models. In the area of process safety the scenario is even worse because, traditionally, the analyses are based on process empirical knowledge. Often qualitative models are used for that purpose, which are still quite lagged the proposals found in the scientific literature, which has suggested the use of more accurate models and techniques (Venkatasubramanian et al., 2003).

In addition to the difficulties faced during the design of safety systems, new obstacles arise during industrial operation. Detecting the origin of unwanted events can be a complex task, but once found, can be decisive in determining the actions of the security system (Venkatasubramanian et al., 2003). Another important issue is that many decisions involving hazardous situations are taken by operators, whose subjectivity considerably reduces the reliability of the security system. All of that makes these systems to be designed and operated conservatively under close tolerances in deviations from the setpoints and often using the emergency shutdown as a way to ensure safety (Luyben, 2012). These actions, however, lead to considerable loss of production and, consequently, financial losses, since the plant for days will idle until it is ready for the new startup.

This work focuses on industrial operation, putting the emergency shutdown as the last alternative in situations of risk to the integrity of the system. Before it, a step of system dynamics analysis is proposed. A feasible condition for safe operation is calculated in order to avoid an emergency shutdown while disturbing the system as little as possible. The goal is to increase annual operating time of the plant, reducing losses due to idleness without compromising the safety of the process and product quality. The strategy proposed in this work is not opposed to the techniques used in process safety. In other words, it represents a new security layer that can operate in harmony with the traditional layers.

2. Methodology

The smart safety system aims to test the actual responsiveness of the control system against critical failures and take preventive actions in case of risk. The risk in this case refers to a possible violation of the safety limits of the process as a result of a possible undesired behaviour. Thus there are two stages: one to evaluate risks and other to determine the safety action. The first consists of the dynamic simulation of the process in failure scenario. If any controlled variable violates safety limits, the operation is considered unsafe and new setpoints must be calculated. If not found a safe state of operation, the only alternative in case of failure would be the emergency shutdown. The integrated control, security and reconciliation system is outlined in Figure 1. The methodology proposed in this work to calculate these setpoints is to solve the optimization problem described below:

$$\min_{\mathbf{u}} \left(\mathbf{x}_0(k) - \check{\mathbf{x}}(k+P)\right)^T \chi \left(\mathbf{x}_0(k) - \check{\mathbf{x}}(k+P)\right) \tag{1}$$

Subject to:

$$\mathbf{x}(i+1) = f\left(\mathbf{x}(i), \mathbf{u}(i)\right) \qquad i = k, \ldots, k+P-1 \tag{2}$$

$$\mathbf{x}(k) = \mathbf{x}_0(k) \tag{3}$$

$$\check{\mathbf{x}}(j+1) = f\left(\mathbf{x}(j), \mathbf{u}(j), \omega\right) \qquad j = k+P, \ldots, k+P+H-1 \tag{4}$$

$$\check{\mathbf{x}}(k+P) = \mathbf{x}(k+P) \tag{5}$$

$$\check{\mathbf{x}}(k+P+H) - \check{\mathbf{x}}(k+P+H-1) < tol \tag{6}$$

$$\check{\mathbf{x}}(j+1) < \mathbf{x}^{max} \tag{7}$$

$$\left|\mathbf{x}(k+P) - \mathbf{x}(k+P-1)\right| < tol \tag{8}$$

$$\mathbf{u} \in \mathbb{U} \tag{9}$$

From state $\mathbf{x}_0(k)$, which is the current state of the plant (Eq.(3)), varying $\mathbf{u}$, a steady state $\check{\mathbf{x}}(k+P)$ (Eq.(5) and Eq.(8)) should be found such a way that from the initial condition $\check{\mathbf{x}}(k+P)$ a dynamic trajectory simulation with a failure scenario (Eq.(4)) must fulfil the defined safety limits (Eq.(7)). In addition, this dynamic trajectory must not be crescent at the end of prediction horizon H (Eq.(6)). Otherwise, after the prediction horizon H, the safety limits could be violated. The

state $\check{\mathbf{x}}(k+P)$ should be a steady state (Eq.(8)) because after changing the controller from SISO to MIMO the control actions $\mathbf{u}(k+P)$ are repeated. Only T_j remains manipulated. Thus, if $\check{\mathbf{x}}(k+P)$ is a point of a dynamic trajectory, then it is not possible to ensure the fulfilment of the safety limits.

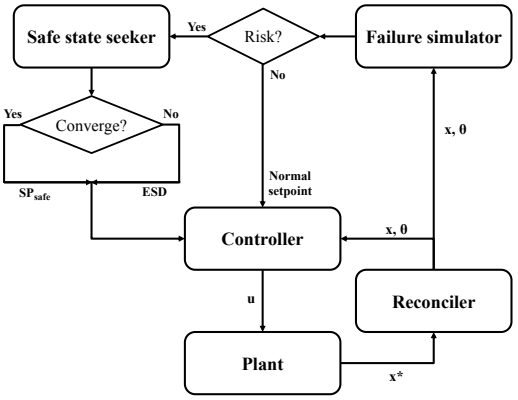

Figure 1: Structure of the proposed system.
ESD: Emergency shutdown. SP_{safe}: Safe setpoint.

In order to illustrate the methodology, the system under consideration consists of a jacketed stirred tank reactor fed by three independent inlet streams (monomer, solvent and catalyst) and an output that in addition to all components of the entry also carries the polymer formed in the chemical reaction. For illustration we consider an A $\rightarrow$ B chemical reaction which simulates a suspension polymerization, wherein the monomer reacts to form polymer in the presence of a solvent. Monomer, solvent, polymer and catalyst are in liquid phase. The mathematical model of this system consists of five differential equations, one related to energy balance (Eq.(14)) and the others relating to the material balance of monomer, polymer, solvent and catalyst (Eq.(10) - Eq.(13), respectively).

$$\frac{dM_{Mon}}{dt} = F_{in}^{Mon} - F_{out}^{Mon} - r \tag{10}$$

$$\frac{dM_{Pol}}{dt} = -F_{out}^{Pol} + r \tag{11}$$

$$\frac{dM_{Sol}}{dt} = F_{in}^{Sol} - F_{out}^{Sol} \tag{12}$$

$$\frac{dM_{Cat}}{dt} = F_{in}^{Cat} - F_{out}^{Cat} \tag{13}$$

$$\frac{dT}{dt} = \frac{F_{in}\,T_{in}}{M_t} - \frac{F_{out}\,T}{M_t} + \frac{\Delta H_r\,r}{M_t\,C_p} + \kappa_c(T_j - T) \tag{14}$$

$$M_t = M_{Mon} + M_{Pol} + M_{Sol} + M_{Cat} \tag{15}$$

$$\kappa_c = \frac{UA}{M_t\,C_p} \tag{16}$$

$$\mathrm{k} = \frac{\mathrm{k}_0\,M_t^2}{V} \tag{17}$$

$$r = x_{Mon}\,x_{Cat}\,\mathrm{k}\,exp\left(\frac{-E_a}{R\,T}\right) \tag{18}$$

$$F_{in} = F_{in}^{Mon} + F_{in}^{Sol} + F_{in}^{Cat} \tag{19}$$

$$F_{out} = F_{in} \tag{20}$$

$$F_{out}^{i} = F_{out}\,x_i,\ i = [Mon, Pol, Sol, Cat] \tag{21}$$

$$x_i = \frac{M_i}{M_t}, \qquad i = [Mon, Pol, Sol, Cat] \tag{22}$$

where F is flow in mol/h, M is amount of substance in mol, r is the chemical reaction rate in mol/h, T is temperature in K and x is molar fraction. The subindex j means jacket, t means total and Mon, Pol, Sol and Cat mean monomer, polymer, solvent and catalyst, respectively. The parameter k_0 is the Arrhenius pre-exponential factor, V is the reaction mixture volume, k is the equivalent kinetic

constant, E_a is the activation energy, R is the universal gas constant, ΔH_r is the reaction heat, C_p is the reaction mixture heat capacity, UA is the overall heat transfer coefficient and κ_c is the jacket equivalent heat transfer coefficient. The model parameters (Table 1) were adjusted empirically to represent a typical dynamics of a tank reactor. This mathematical model was used as a virtual plant and as model of the controller during the simulations.

The control strategy adopted in this work is known as Nonlinear Model Predictive Control (NMPC) an advanced control strategy based on nonlinear model. This controller is based on the concept of Model Predictive Control (MPC), conceived in the 60s, and basically consists of a dynamic optimization problem with multiple objectives and constraints. The NMPC has been gaining attention in the industry in recent years, especially because of three characteristics (Manenti, 2011): (i) is able to handle economical non-linearities and the process dynamics; (ii) can be based on phenomenological mathematical model or nonlinear semi-empirical models; (iii) is able to solve simultaneously the control problem and the problem of dynamic real-time optimization (economic problem), satisfying constraints for state variables and manipulated variables.

The controller was programmed to assume different configurations depending on the risk to which the process is subject. Under normal operating conditions (safe operation), the controller assumes the SISO (Single Input Single Output) configuration, where the manipulated variable is the jacket temperature and the controlled variable is the reactor temperature. When the algorithm detects an adverse safety situation (unsafe operation) new setpoints are calculated. To meet them the controller is reconfigured as MIMO (Multiple Input Multiple Output). In this case, the manipulated variables are: jacket temperature and monomer, catalyst and solvent flowrates. The controlled variables are: reactor temperature and the amounts of monomer, catalyst and solvent in the reactor. Due to the chemical reaction, monomer and polymer cannot be simultaneously controlled. Only one of them can be controlled while the other is given by the chemical reaction. It is noteworthy that the MIMO controller is retained until the safe setpoint is reached. After convergence, the controller returns to SISO, because the algorithm ensures that this configuration is able to keep the system safe.

In most chemical processes, parameter changes occur throughout the operation. To keep the accuracy of the controller model, this work uses a moving horizon data reconciliation algorithm to estimate parameters and states simultaneously in real time. The measured variables were the streams flowrates and temperatures. Only the reactor temperature measurements figure into the objective function of the reconciliation, so it was corrupted with zero mean Gaussian noise with standard deviation of 0.2. The other measurements were not corrupted with noise and were used to feed the prediction model; i.e., they do not contribute to the objective function of the reconciliation problem. The other states were estimated together with the parameter κ_c. The model of the controller is updated in each sampling time with the new estimates of the reconciler. This allows the adaptation of the controller to process changes (Souza et al., 2011).

3. Results and discussions

To test the efficiency of the proposed algorithm a scenario with an unwanted event was simulated. This event refers to a significant loss of reactor cooling capacity. The safety limit considered in the simulation is related to the reactor temperature, which should reach a maximum value of 385 K. The loss of cooling capacity is simulated by varying the parameter κ_c. This type of event is quite common during operation of reactors with jacket. Several failures may cause a decreased capacity for heat exchange between the reactor and jacket. For example, failure in the cooling fluid supply pumps, failure in stirring the reactor, increasing of viscosity of the reaction mixture (gel effect), and fouling.

The performance of the safety system to an abrupt drop in parameter κ_c from 1 to 0.1 is shown in Figure 2. Such an event would be able to raise the reactor temperature at 392 K, which represents

Table 1: Model Parameters

Parameters	Values	Units
k	5.0×10^7	mol/h
E_a	1.0×10^4	J/mol
R	8.32	J/mol.K
T_{in}	350.0	K
ΔH_r	2.5×10^4	J/mol
C_p	125.6	J/mol.K

Table 2: Comparison between initial setpoint and calculated by the security system

States	Initial	Safe
M_{Mon}	36.2	50.21
M_{Pol}	77.2	62.05
M_{Sol}	200.0	201.20
M_{Cat}	0.10	0.09
T	380.0	380.16

security risk to the process. For $t \leqslant 1$ h the system operates normally in SISO mode. At time 1 h, a simulation is performed for the failure in question, whose trajectory is represented by gray x markers in Figure 2. A violation of the safety limit is observed in Figure 2a, and immediately, the safe state seeker is activated. The safe state found is shown in Table 2. The observed good proximity between the variables is a result of the optimization scheme proposed. The dynamic trajectory predicted by the algorithm for the same failure, which has the safe state as the initial condition is represented by gray diamonds markers from the time of 4 h. This trajectory was calculated at time 1 h, but for ease of comparison with the actual trajectory of the plant it was moved graphically to the instant 4 h. Found the safe state, the controller is reconfigured to the MIMO mode in order to pursue the new setpoint. This configuration remains active in the interval $1 \text{ h} < t \leqslant 4$ h. Although not shown, other states follow perfectly to their new setpoints. At time 4 h, the controller returns to the SISO mode and the simulated failure is applied effectively in the plant, in order to test the effectiveness of the algorithm. As it can be seen in Figure 2a, the final reactor temperature remains around the safety limit and the actual trajectory of the plant is similar to the trajectory predicted by the algorithm.

Figure 2b shows the estimated parameter κ_c. The solid line represents the estimated values during operation. The gray "x" markers leaving at time 1 h, are the result of failure simulation. Besides considering the behaviour of the controller, this simulation also considers the behaviour of the reconciliation system, by adding noise to the simulated temperature. The gray diamonds markers in the interval $t > 4$ h are the κ_c values used to predict the trajectory of the system, represented by the same marker in Figure 2a.

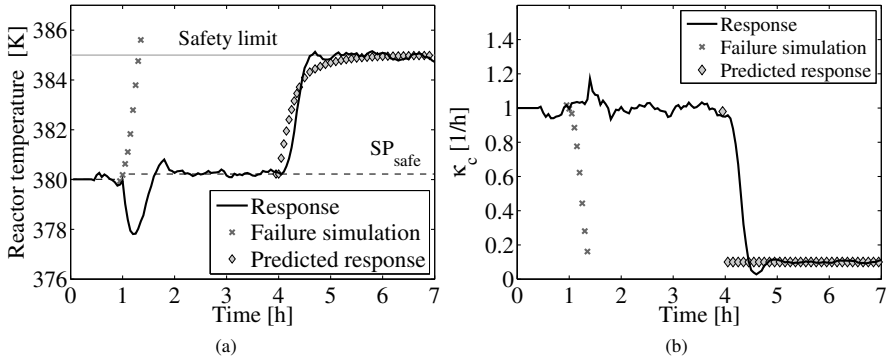

Figure 2: Performance of the safety system (a) to an abrupt drop in parameter κ_c (b).

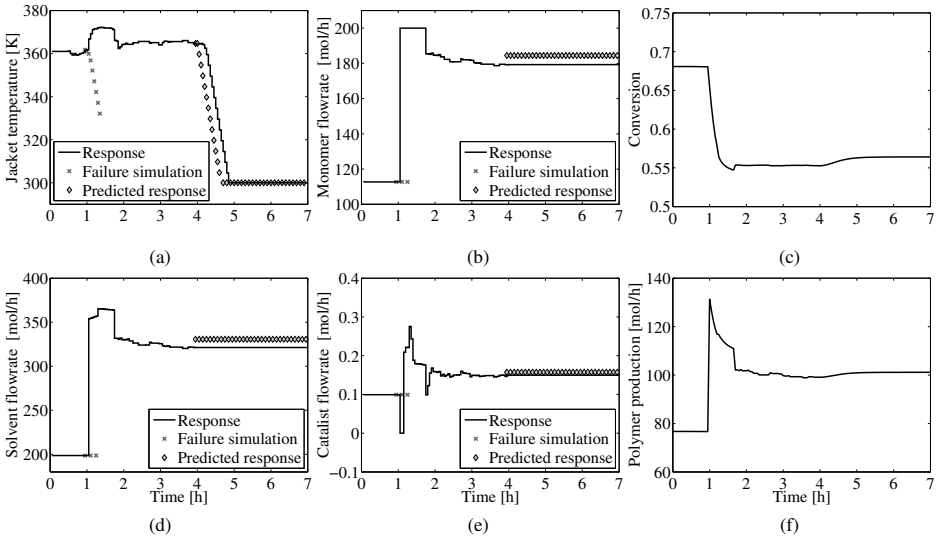

Figure 3: Dynamic trajectories of the manipulated variables, conversion and production.

For this case, therefore, the intelligent safety system was able to reverse a failure which could raise the reactor temperature at about 392 K, well above the safety limit. This failure would activate the emergency shutdown and consequently cause a huge economic loss. The system began operating with a lower conversion but with increased production (Figures 3c and 3f), showing that the losses caused by the preventive security action are questionable. The trajectories of the control actions are also shown in Figure 3.

4. Conclusions

This paper proposes a new security layer, leaving the emergency shutdown as the last alternative in terms of safety actions. The goal is to avoid unnecessary shutdowns, and increase the annual operating time of the plant. The results have shown that the proposed algorithm may be feasible if there is a reliable model of the process. For the discussed case of loss of cooling capacity, the algorithm was effective. It was able to prevent a violation of the safety limit which possibly would cause a system shutdown, thus preventing economic losses as well.

Shape Constrained Splines with Discontinuities for Anomaly Detection in a Batch Process

Kris Villez[a] and Jonathan Habermacher[a]

[a]*Department of Process Engineering, Eawag, Swiss Federal Institute of Aquatic Science and Technology; Dübendorf, Switzerland*
kris.villez@eawag.ch

Abstract

A previously developed technique for qualitative trend analysis (QTA) based on shape constrained splines (SCS) has been favourably compared to pre-existing techniques for the purpose of batch process diagnosis. Thanks to the branch-and-bound algorithm, this approach leads to a deterministic and global solution for QTA. One limitation of this method is that local discontinuities in otherwise continuous derivatives of the fitted spline function are not permitted. Recent work however allows to relax the optimization problem further so that provable bounds can be computed for this more complicated case. In this contribution, the resulting shape constrained splines with discontinuities (SCSD) method is applied for anomaly detection in batch process data. Importantly, the QTA approach to anomaly detection proves worthwhile because *(i)* tuning of the SCSD method is limited to setting an upper control limit, *(ii)* the resulting sum of squared errors statistic shows almost no drift for SCSD in contrast to the similar Q-statistic computed by principal component analysis (PCA), and *(iii)* true positive rates by means of SCSD are over 80% while the PCA method delivers at most 70% for false positive rates up to 5% based on a data set consisting of 410 batches.

Keywords: Anomaly detection, Fault diagnosis, Batch process monitoring, Statistical process control, Qualitative trend analysis

1. Introduction

Qualitative trend analysis (QTA) consists of a rather wide set of techniques for segmentation of data series. Such segmentation is popularly used for fault diagnosis applications. For such applications, QTA offers the possibility of an intuitive fault diagnosis mechanism. Its advantages include *(i)* that coarse-grained information about the faults symptomatic effects on measured data is sufficient to characterize and recognize a fault, *(ii)* that the required coarse-grained information corresponds to intuitive notions by human plant operators, and *(iii)* that consequently sparse occurrence of faults can effectively be dealt with. Despite these advantages, available techniques are often based on heuristic rules or greedy optimization schemes tuned for a particular application only. The lack of theoretical optimality makes it challenging to transfer such techniques from their original application context as was observed in Villez et al. (2012). This motivated the conception of a globally optimal approach to QTA based on shape constrained splines (SCS, Villez et al., 2013). This SCS method is limited in a number of ways. One important limitation is that any derivative of a degree smaller than or equal to $o-2$, in which o is the order of the spline function (for cubic splines: $o=4$), must be continuous over the whole function domain. Indeed, knots with multiplicity are not permitted. This is critical for QTA purposes as this means that certain shape constraints are not permitted. For example, one cannot fit a spline function which

is characterized by a segment which is decreasing (negative 1st derivative) and concave (negative 2nd derivative) followed by a segment which is increasing (positive 1st derivative) and concave (negative 2nd derivative). Practically, this is solved by adding a knot of multiplicity $o-1$ when the exact location where the segments meet, a.k.a. transition, is known. This is however not the case in general. Unfortunately, the SCS method does not permit optimizing transitions which imply a discontinuity in one or more derivatives which are otherwise continuous. This paper discusses results obtained with a modified version of the SCS method which accounts for shape-implied discontinuities. The method is therefore further referred to as the shape constrained splines with discontinuities (SCSD) method. Similar to the SCS method, it is based on a combination of second order cone programming (SOCP) and the branch-and-bound algorithm. This algorithm enables the identification of all transitions. The method is successfully demonstrated by means of oxidation-reduction potential (ORP, redox) measurements obtained from a laboratory scale sequencing batch process for wastewater treatment.

2. Methods

2.1. Case study

The data used in this study stems from an experimental side-stream reactor (SSR) setup operated at Eawag for a period of two years by the second author of this contribution. This SSR setup consists of two connected tanks in which the first tank is a sequencing batch reactor (SBR). The second tank is the so called SSR and is operated as a continuously stirred tank reactor for sludge digestion. The SBR is operated with a fixed recipe which lasts 6 hours. Each SBR cycle starts with pumping of sludge from the SSR to the SBR (7 min.) followed by addition of fresh wastewater (10 min.) under anoxic conditions. A reaction phase follows in which air is supplied to provide aerobic conditions in the SBR (285 min.). The SBR cycle ends with excess sludge withdrawal, settling, and decanting (58 min.). Each new cycle starts right after decanting.

The SBR is equipped with an oxidation-reduction potential (ORP) sensor, amongst others. A typical profile of the first 513 data points (85.33 min.) is shown in Fig. 1 (top panel). The first phase corresponds to an almost linear decreasing trend, followed by a convex decreasing trend in the second phase. In the third phase, the trend roughly corresponds to a concave increasing trend. The ORP time series consisting of the first 513 data points of 410 consecutive cycles are studied in this work. The selected batch cycles represent a period of 3.5 months in which no changes were made to the SBR recipe, the installed sensors (e.g., no replacements), or the data acquisition and control system. Each of these time series were inspected visually by two operators which are familiar with the experimental setup and the use of ORP sensors, including the second author of this paper. These operators addressed the question *whether the observed time series can be explained by normal circumstances alone* by means of a simple yes or no. To this end, the time series were visually represented to these operators on separate occasions and in a randomized order. Following this initial classification of the ORP time series as normal or anomalous, batches for which the classification by the two operators was different were visualized again with both operators present so to find a consensus classification result. For 16 cycles out of 410, no consensus could be reached. Only the time series

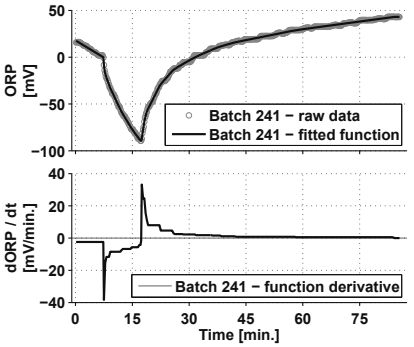

Figure 1: Exemplary time series corresponding to normal operation.

for which consensus was reached (394 batch cycles) are considered in the remainder of this study. The consensus classification is used as the ground truth or true class for each analysed time series.

2.2. Qualitative trend analysis (QTA): Definitions

The identification of so called *qualitative representations* (QRs) is the primary goal of QTA. Such QRs are defined as a sequence of *episodes*. Each of these episodes is completely characterized by means of *(i)* a start time, *(ii)* an end time, and *(iii)* a *primitive*. Such a primitive corresponds a unique combination for the signs of the measured variable and/or one or more of its derivatives with respect to time. A primitive is usually represented by means of a unique character, which can however be chosen arbitrarily. Fig. 2 shows the primitives and characters used in this study. Only the signs of the first and second derivatives are considered relevant. The episodes within a QR are contiguous, meaning that the end time of one episode is the start time of the next episode. The locations (in time) where two episodes meet are known as *transitions*. A sequence of primitives without specification of the transitions is known as a qualitative sequence (QS). Conform these definitions, the QS for a typical profile of ORP measurements as in Fig. 1 reads as EAC. The SCSD method explained in the next paragraphs allows to identify the values for the corresponding transitions.

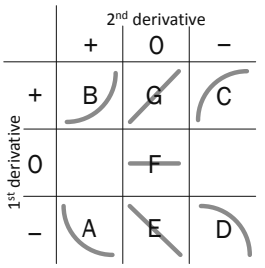

Figure 2: Primitives and associated characters.

2.3. Shape constrained splines (SCS)

In essence, the fitting of a shape constrained spline function can be written as the following mathematical problem:

$$\min_{\beta,\theta} J(\beta,\theta) = J(\beta,\theta,\mathbf{x},\mathbf{y}) \tag{1}$$

subject to:

$$\beta \in \Omega(\theta) \tag{2}$$

$$\theta \in \Theta \tag{3}$$

Table 1: Definitions of variables and parameters for SCSD.

Symbol	Definition
β	Function parameters
θ	Transitions
$\Omega(\theta)$	Feasible set for β
Θ	Feasible set for θ
$\mathbf{x}$	Argument vector
$\mathbf{y}$	Measurement vector
J	Objective function

with definitions given in Table 1. The spline function is defined by a number, m, of parameters represented by the vector β. In Villez et al. (2013), the parameters are the spline coefficients. Given a QR defining the shape constraints, the feasible set for these coefficients, $\Omega(\theta)$, is a convex subset of the real space ($\Omega(\theta) \subseteq \mathbb{R}$). This set depends on the values for the transitions, θ. In the context given by Villez et al. (2013) and this study, optimal values for θ are found by means of the branch-and-bound algorithm. Proofs for the applied bounds were given in Villez et al. (2013). The existing proofs are limited however in the sense that the bounding procedures only apply to spline functions without knot multiplicity and any associated discontinuities of the derivatives in such knots. This limitation is removed in the next paragraphs.

2.4. Shape constrained splines with discontinuities (SCSD)

To enable application of the branch-and-bound algorithm when discontinuities are implied by the imposed QS, the fitted function is now redefined by representing the spline function explicitly as a contiguous set of piece-wise polynomials. Once more, the problem is convex as long as θ

is given. To solve the non-linear search for θ the branch-and-bound algorithm can be applied again. The upper bound procedure is practically the same as in Villez et al. (2013). The lower bound procedure is fairly different however. In Villez et al. (2013) it was sufficient to implement only those constraints on β which are guaranteed to be included for any candidate solution for θ within a given solution set. In this case, one further needs to modify the objective function as well as set of implemented continuity constraints. The details of the lower and upper bounding procedures are given in Villez (2014). Apart from the modified bounding procedures, the branch-and-bound algorithm is applied exactly as in Villez et al. (2013). The branch-and-bound algorithm was solved until a resolution of 1 sampling interval (10 seconds) was reached for the location of the transitions. The fitted function is a natural cubic spline function ($o = 4$) with fixed spline knots placed at each sampling time. The resulting function is an interpolating spline function when no shape constraints are applied. As a result, any deviation of the SSE from zero is only due to a mismatch between the measured time series and the imposed shape (EAC).

2.5. Shape constrained function fitting as a method for process monitoring

To test the shape constrained splines methodology for process monitoring, the following strategy is applied. One optimizes the values for β and θ so to minimize the objective function value J. Importantly, there is no calibration phase for the SCSD method as long as the expected shape is known. In this study, this objective function is the sum of squared errors (SSE). In general, the optimized SSE, further referred to as SSE_{SCS}, will be high when the profile of the analysed data series does not correspond well to the imposed shape on the fitted function. As such, this SSE can be used as a lack-of-fit statistic to detect deviations from the expected shape. To this end, one defines a fixed upper limit, U_{SCS}, a priori and one classifies a data series as anomalous (normal) when the obtained SSE is higher (lower) than this limit. There are no theoretical distributions available for the SSE_{SCS} statistic. As such, an empirical evaluation is obtained by evaluating the false positive rate (FPR, fraction of normal cycles which are erroneously classified as anomalous) as well as the true positive rate (TPR, fraction of abnormal cycles which are correctly classified as anomalous) by varying the value for U_{SCS} between the lowest and highest value for SSE_{SCS} obtained. To this end, the ground truth classification as described above is used as a reference. This leads to the so called receiver operating characteristic (ROC, Fawcett, 2006).

2.6. Principal component analysis (PCA)

Principal component analysis (PCA) is by far the most commonly used method for process monitoring in a multivariate context. PCA is of use primarily when significantly large data sets are available and first principles modelling is impossible or cost-prohibitive. The successful application of classical PCA depends on a number of factors such as *(i)* whether relationships between measured variables are linear and time-invariant, and *(ii)* whether sufficient and representative data is available for PCA modelling of the normal process data variation. Despite these restrictive statistical requirements, PCA has been applied successfully to many processes. In this study, the batch process data is organized in a matrix with rows corresponding individual batches and columns to individual time instants in each of the analysed batches. A PCA model is then fitted to a subset of the data by *(i)* selecting a number of rows corresponding to normal process conditions, *(ii)* subtracting the column-wise mean, and *(iii)* computing a number of principal component loadings and associated scores by means of singular value decomposition. In this study, a simple scree plot is used as the device to select the number of principal components (PCs). Once the PCA model is identified, one projects the data not used for calibration and evaluation the so called reconstruction errors or residuals. Following this step, one computes the corresponding SSE, SSE_{PCA}, which is also known as the Squared Prediction Error (SPE, Kresta et al., 1991) and as the Q statistic (Jackson and Mudholkar, 1979). Theoretical and/or empirical confidence limits can be computed for this statistic (Jackson and Mudholkar, 1979). In this study, the ROC is computed as is done for the SCSD method to enable an effective comparison.

3. Results

3.1. Example

Fig. 1 displays the exemplary oxidation-reduction potential (ORP) time series, the optimized shape constrained spline function with EAC shape, and the 1st derivative of this fitted function. Finding the optimal transitions required 34 branching steps in the branch-and-bound algorithm which is equivalent to solving 69 SOCPs. This took 1.2 minutes on a dedicated desktop machine (Intel® Core™ i7-4770 CPU, 3.40 GHz, 16.0 GB RAM). The optimized SSE_{SCS} is equal to 332.

3.2. Benchmarking

All batch time series were analysed with the SCSD method on a dedicated desktop machine (as above). Computing the optimal transitions took less than 20 minutes in all cases. The PCA model was identified by means of the first 100 normal batch cycles and included two principal components which capture 86.9% and 9.6% of the variability (total: 96.5%). The statistics obtained with SCSD and PCA are shown in Fig. 3 as a function of batch index. The SSE_{SCS} is relatively stable with a number of outlying values sparsely present during the covered time span. In contrast, the SSE_{PCA} shows more variation and is generally higher. This is believed to be a result of non-linear parametric changes of the ORP profiles which are hard to capture by a linear PCA model. The SCSD method is robust to these variations because of a greater parametric flexibility of the spline function compared to PCA. In the top panel, an upper detection limit, U_{SCS}, is set at 610.33 which is the lowest value for which no false alarms (no false positives) result. Similarly, in the bottom panel, the upper detection limit, U_{PCA}, is set at 37659. With SCSD 38 of the 46 abnormal time series have an SSE_{SCS} which is higher than the set limit (TPR: 83%). With PCA only 30 positive detections result (TPR: 65%). Closer inspection reveals that 29 cycles are identified as abnormal by both methods. The SCSD method correctly flags 8 batch cycles as anomalous which are not detected by PCA. One batch cycle not identified with SCSD is identified as anomalous by PCA.

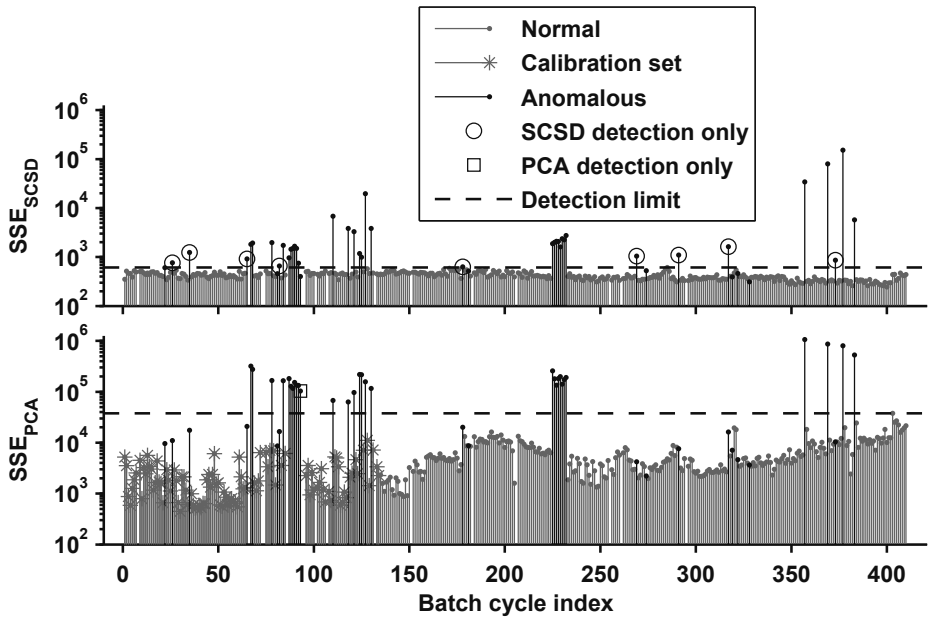

Figure 3: Sum of squared errors (SSE) statistics obtained with SCSD (top) and PCA (bottom).

Decreasing values of the upper limits for the SSR statistics increase both the FPR and the TPR. For example, at an FPR of 5% the TPR for SCSD is 85% while the TPR for PCA is 70%. The complete receiver operating characteristics (ROCs) are shown in Fig. 4. One can observe that the SCSD method performs better for FPRs up to 69%. PCA dominates only for FPRs ranging from 88% to 93%. In other sections of the curve, the methods are performing equally. In the present application as well as for most anomaly detection schemes, normal operating conditions are more frequent than anomalous conditions. It is thus reasonable to give larger weight to a low FPR than a high TPR. Selecting FPRs lower or equal than 5% is common. At such rates, the SCSD method clearly outperforms PCA-based detection.

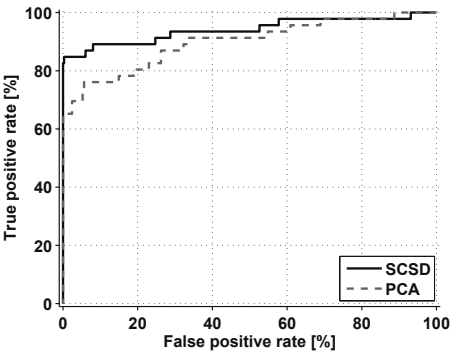

Figure 4: Receiver operating characteristics (ROC) showing the true positive rate (TPR) as a function of the false positive rate (FPR).

4. Conclusion

With this contribution, an extended version of the shape constrained spline (SCS) method for qualitative trend analysis (QTA) has been tested for batch process monitoring. The proposed extension allows to optimize the location of abrupt changes (discontinuities) in one or more derivatives of measured variable trends. Importantly, the identification of shape constrained splines with discontinuities (SCSD) is based on the optimization of the sum of squared errors which is has been successfully used as a lack-of-fit statistic for anomaly detection. A preliminary comparison with principal component analysis underscores the value of a qualitative approach to fault detection.

5. Acknowledgement

The authors want to thank Nicolas Derlon at Eawag for interpreting and classifying the studied data series and for his creative input and constructive feedback during execution and reporting of this study. All computations were executed by joint use of Matlab (The MathWorks Inc., 2012); the Functional Data Analysis software package accompanying Ramsay and Silverman (2002); and MOSEK (MOSEK ApS, 2012). The first author thanks O. Peth for everlasting inspiration.

Quantifying Model Uncertainty in Scarce Data Regions – A Case Study of Particle Erosion in Pipelines

Abstract

The transport of solids in multiphase flows is common practice in energy industries because of the unavoidable extraction of solids from oil and gas bearing reservoirs. The safe and efficient operation and design of these pipelines requires reliable estimates of erosion rates. The models used to calculate this rate have significant uncertainty due to the complexity of the underlying process. This uncertainty becomes especially important during the design phase for subsea applications, as erosion rate allowance, which is set using the erosion rate predictions and its uncertainty, directly impacts the integrity of the facility. Unfortunately, none of the models provide an estimate of this uncertainty. This paper introduced a systematic approach to quantify the model uncertainty for erosion rate predictions combining Gaussian Process Modeling (GPM) with data transformation and cross-validation techniques. The results reveal that given the available experimental data and the erosion rate prediction model considered, the model uncertainty is on average 3.61 times the model's predictions. Hence, our results suggest at least on average four order of safety factor when designing subsea systems.

Keywords: model uncertainty, erosion prediction, Gaussian Process Modeling

1. Introduction

The solid transport and management systems (STMS) are an integral part of the processes in energy industries, because of the unavoidable extraction of solids from oil and gas bearing reservoirs either onshore or offshore sites. If the amount and velocity of the solids in the fluids (oil and gas) in the transportation lines are too high, they might cause erosion in the pipelines resulting in facility integrity issues. These issues become more important for deep-water applications as these systems are "too costly to fail" due to limited availability of access for repairs and potential for devastating environmental consequences if failed. One of the essential design decisions is the expected erosion allowance for these systems and pipelines throughout their lifetime.

The erosion process, especially in flow systems, is a complex phenomenon and depends on many factors including fluid characteristic, particle characteristics, the construction material properties and the geometry of the flow lines. Given this complexity, most modeling work in this area focuses on developing empirical or semi-empirical models. Although all of these models have been compared to a limited set of experimental data, it has been reported that their predictions for the same input set can vary up to two orders of magnitude (Mazumder, 2004). Our preliminary comparisons of model predictions to experimental data revealed that the predictions may be up to 10 orders of

magnitude higher (resulting in considerable overdesign) for some input sets whereas up to one order of magnitude lower (causing facility integrity issues) for others. There are many sources of uncertainty in these models, e.g., in the model inputs, assumptions, and equations. However, none of the existing models include uncertainty analysis or quantify the confidence intervals in their predictions.

The goal of this paper is to introduce a framework capable of quantifying prediction uncertainty and confidence for erosion models under a wide range of input conditions especially focusing on regions where experimental data is scarce or not available. The framework, utilizing general model uncertainty quantification formulation (Kennedy and O'Hagan, 2001), estimates model bias and its confidence, and incorporates the effect of experimental uncertainty using Gaussian Process Modeling (GPM), and is capable of estimating model-prediction uncertainty due to extrapolation in sparse or no data regions. The framework is developed around 1-Dimensional Sand Production Pipe Saver (1-D SPPS) model (McLaury and Shirazi, 1999), which is used widely by oil and gas industry for predicting erosion rate when designing and operating pipelines and separation systems. A brief overview of 1-D SPPS model is given in the next section. Section 3 introduces the compiled experimental database that is used to train the GPMs for predicting model uncertainty. Section 4 contains the details of the systematic approach, followed by the results in section 5. Finally, conclusions are summarized.

2. The 1-D SPPS model

The 1-D SPPS model predicts maximum erosion rate given system geometry and materials, flow conditions, and particle properties (McLaury and Shirazi, 1999). It calculates the maximum erosion by defining how a hypothetical representative particle will impinge the target material. The abrasion caused by this particle is defined by length loss in the target material, and is calculated using the momentum of impingement, which requires the so-called characteristic impact velocity of this representative particle. Given flow conditions, particle and pipe properties, the model first calculates the characteristic impact velocity. The erosion ratio, which is defined as the ratio of measured target material mass loss to the mass of all particles in the carrier fluid, is calculated using a power law correlation of the characteristic impact velocity. Here, the carrier fluid can be single phase (liquid or gas), or multiphase (liquid/gas mixture). The maximum erosion rate empirical model in 1-D SPPS calculates the target material length loss per unit time, and uses erosion ratio and accounts for pipe geometry, size and material; fluid properties (density and viscosity) and rate; and sand sharpness, density and rate.

The multiphase carrier mixtures result in different flow patterns in the conduit depending on the relative ratios of liquid and gas flow rates, and liquid and gas densities and viscosities. These flow patterns are (1) Annular, (2) Mist, (3) Churn, (4) Slug, and (5) Dispersed Bubble (Zhang, 2006). The 1-D SPPS model can predict erosion rate considering or ignoring the effects of flow pattern in cases of multiphase (liquid/gas) carrier fluids. In the flow-pattern-dependent calculations, the input liquid and gas flow properties are first used to determine the flow regime, and erosion-rate-prediction models specifically developed for each flow pattern are used to calculate the erosion rate. Partly due to its semi-empirical nature and partly due to its efficient algorithm, 1-D SPPS calculates the erosion rate for a single input almost instantaneously.

3. Experimental database

For estimating erosion-rate-prediction uncertainty, we compiled an experimental database of erosion rate measurements from literature. It contains 544 data points in single or multiphase carrier flow. During experiments, the controlled variables were flow rate(s) and viscosity, particle size, and pipe geometry, size and material. The output or the measured variable was the erosion rate. According to the predicted flow regime from 1-D SPPS, eighty percent of the data in the database are collected for gas dominated flows (i.e., gas only, annular, mist and churn flow). For most experiments, the particle density is 2650 kg/m^3. Most experiments used one or more of the following particle types: Silica Flour with an average particle size of 20 µm, Oklahoma #1 with an average particle size of 150 µm, and California 60 Mesh with an average particle size of 300 µm. Superficial gas velocities range from 5 to 200 m/s, but experimental data at higher gas velocity region (>50 m/s) is limited. The superficial liquid velocities range from 0.0001 to 1 m/s. Pressure and temperature is used to change the density and viscosity of the gas phase. The viscosity of water is changed by adding CMC (Carboxy-methyl cellulose), which slightly changes the density of fluid but this effect is too small and is generally neglected (Okita, 2010).

4. Methodology

According to general model uncertainty quantification formulation (Kennedy and O'Hagan, 2001), the experimental response, y^e can be expressed with Eq.(1).

$$y^e = y^m + \delta + \varepsilon \tag{1}$$

In Eq.(1), y^m is the model response, δ is the model bias, and ε is the experimental uncertainty. In our case, the experimental response is the measured erosion rate, which is expressed as the sum of 1-D SPPS's prediction of erosion rate (y^m), a bias function which estimates 1-D SPPS bias (δ), and a random error, which assumed to follow a zero-mean normal distribution accounting for the experimental variability (uncertainty). The model bias includes the uncertainties associated with estimated model parameters in 1-D SPPS, the numerical errors and the model form discrepancies, and can be expressed as a Gaussian random process. As the experimental variability is assumed to follow a zero-mean normal distribution, the model bias and the experimental variability can be combined into one term, which we will refer as model discrepancy for the remainder of the paper. The model discrepancy can then be assumed to be a Gaussian random process (Jiang et al., 2013), and can be represented using Gaussian Process Modeling.

4.1. A Brief Overview of Gaussian Process Modeling (GPM)

The Gaussian process ($\mathcal{GP}(m,k)$) is a natural generalization of the Gaussian distribution, where the GP is fully characterized by its mean and covariance functions (Rasmussen and Williams, 2006). Let x denotes a point in multidimensional space, $m(x)$ is the mean function of the GP, and $k(x,x')$ is the covariance function of the GP, representing the spatial covariance between any two points (x and x') at the process. Once we specify the mean and covariance functions using the available data, the GP can be used to predict values at untested locations, and its prediction variance, i.e., uncertainty, can be calculated by the covariance function. The process of finding the mean and covariance function estimates using available data is referred to as the Gaussian Process Modeling.

In order to define GPM, prior information about the dataset is needed to specify prior mean and covariance functions. This prior information is normally represented by a hierarchical prior, where the mean and covariance functions are parameterized using hyper-parameters. Eq. (2) gives a constant mean and a squared exponential covariance functions for a Gaussian process as examples:

$$\begin{aligned} f &\sim \mathcal{GP}(m, k), \\ m(x) = a, \text{ and } k(x, x') &= \sigma_y^2 \exp\left(-\frac{(x - x')^2}{2l^2}\right), \end{aligned} \tag{2}$$

In Eq.(2), we have introduced hyper-parameters $\theta = \{a, \sigma_y, l\}$, where σ_y and l specify the characteristic length-scale and magnitude of the covariance function. The values of hyper-parameters are determined via maximum likelihood estimation approach, which is generally performed via a gradient based search algorithm (Rasmussen, 2004).

With the prior mean and covariance functions, the value of the function and its uncertainty for the unseen test location, *x*, is inferred by obtaining the posterior distribution using the training data set (*D*):

$$\begin{aligned} f|\mathcal{D} &\sim \mathcal{GP}(m_{\mathcal{D}}, k_{\mathcal{D}}), \\ m_{\mathcal{D}}(x) &= m(x) + \Sigma(X, x)^T \Sigma^{-1}(f - m), \\ k_{\mathcal{D}}(x, x') &= k(x, x') - \Sigma(X, x)^T \Sigma^{-1} \Sigma(X, x'), \end{aligned} \tag{3}$$

where $\Sigma(X, x)^T$ is the covariance vector between the training data (*X*) and x. The computational complexity in estimating Gaussian Process hyper-parameters scales cubically with the size of the dataset. For small problems (e.g. dataset size < 1000), storing and solving the associated linear system is not computationally expensive

4.2. Developing 1-D SPPS Prediction Discrepancy using GPM

In order to express 1-D SPPS discrepancy as a GPM, we need to estimate the hyper-parameters of mean and the covariance function. Based on our experience with the erosion dataset and the 1-D SPPS, a constant mean function and a squared exponential covariance function are deemed appropriate. The maximum-likelihood estimators of the hyper-parameters are determined using the experimental database, specifically, using the difference between experimental erosion rates and the corresponding erosion rate predictions of 1-D SPPS. We will refer to this difference as actual model discrepancy.

For training the GPM, we converted the categorical inputs, such as pipe geometry, to numerical values. The experimental database covers a wide range of input conditions resulting in significantly different erosion rates, and, at times, up to five orders of magnitude differences in actual model discrepancies. Such significant differences in training data may not suitable to train GPMs. Therefore, we applied a data transformation approach, Generalized Box-Cox transformation (Box, 1964) with θ = 1.5 (Eq. (4)), to reduce the range of actual model discrepancies.

$$\mathrm{f}(\mathrm{y}; \theta) = \frac{sign(y)|y|^{\theta} - 1}{\theta} \tag{4}$$

The transformed actual model discrepancy and the corresponding inputs are divided into two subsets: (1) a training set, and (2) a test set. The data in the training set is used to calculate the maximum-likelihood estimators of the GPM, and the test set is used to assess the performance of the GPM for unseen data points. A Matlab® based toolbox,

GPML (Gaussian Process for Machine Learning) (Rasmussen and Williams, 2006), is used to solve the resulting optimization problem for training the GMP. The same toolbox is used to calculate the expected mean and variance at the data points of the test set. Given the expected mean and the variance, the model discrepancy prediction is equal to the expected mean, and the 95% confidence interval of these predictions is equal to the two times of the standard deviation (i.e., square root of variance).

The suggested separation of training and test data sets is three to one (Mitchell, 1997), where around 75 % of the whole dataset is used to train the GPM. However, the maximum-likelihood estimates of the hyper-parameters, and hence, the performance of the GPM at data points in the test set differ based on the data points in the training set. To mitigate the influence of the training data subset on the GPM predictions and to obtain a robust GPM prediction, we applied a four-fold cross validation approach, and repeated this process 30 times. For one repetition of the four-fold cross validation, the dataset is separated to four distinct parts. Then, three of the four parts are randomly picked as the training data set, while the remaining part is used as the test data set. The procedure is repeated four times until all the parts have been used as the test data set. At one repetition of the four-fold cross-validation, we obtain the predicted mean and variance of each data point when it is used as a test point, i.e., as an unseen data point. The 30 repetitions, therefore, provide 30 predicted means and variances for each data point in our database when they are used as an unseen data point. Then, we calculate the average predicted mean and variance of model discrepancy at each data point. The average predicted mean is compared to the actual model discrepancy to assess the quality of the GMP predictions and the average variance is used to estimate the model uncertainty.

5. Results and discussion

Given the 545 data points in our database, 408 randomly selected points are used as training set and the rest as test set for each cross validation fold at each repetition. The performance of the resulting GPM predictions for all data points and for each flow regime data subset are summarized in Table 1. The average difference between the predicted and the actual model discrepancy, Di, is 116 %. If one defines the data points where the actual model discrepancy is outside the 95 % confidence interval predicted by the GPM, there are 53 outliers (O) in our database. If these outliers are ignored, the average difference, $Di_{w/oO}$, becomes 55.5 %. The average of the ratio (R) between the 95 % confidence interval and the model prediction is 9.9. The data points where there is a probability of 1-D SPPS under-predicting erosion, i.e., the points where the 95 % interval intersects the zero line, ($Da_{P<0}$), is of great interest for facility integrity and safe operation. Based on the GPM predictions, 71 % of the data points fall into this category. If we only consider these data points, average of the ratio between the 95 % confidence interval and the model prediction ($R_{Da_{P<0}}$) becomes 13.7. The safety factor at 95% confidence for designing these systems is defined as the ratio of average value of the lower bounds of the confidence intervals prediction by GPM to the average predicted discrepancy calculated using only the data points in $Da_{P<0}$. Our results reveal that this safety factor is equal to 3.61. This safety factor provides a measure of under-prediction ratio for the model and hence aid in avoiding integrity issues at the design stage.

As can be seen from Table 1, except for mist flow, other flow regimes exhibit a smaller average difference, $Di_{w/oO}$, and average ratio, $R_{Da_{P<0}}$, when compared to the whole data

set. We speculate that the large *Di* value and the safety factor yielded for mist flow stems from 1-D SPPS grossly under-predicting experimental erosion rates for a subset of data points. This results in wide range of actual discrepancies, and hence, reduces the reliability of the GPM predictions. Our results suggest caution may be taken when using our GPM approach with 1-D SPPS for erosion-rate-allowance estimates of mist flow.

Table 1. Summary statistical results obtained using the proposed approach

flow regime	Di	O	$Di_{w/oO}$	R	$Da_{P<0}$	$R_{Da_{P<0}}$	safety factor
total	116%	53	56%	9.9	71%	13.7	3.61
gas	71%	21	41%	4.4	62%	6.2	2.68
mist	2703%	27	83%	1.7	31%	19.9	4.97E+3
annular	59%	5	60%	6.2	82%	5.7	1.11
churn	42%	0	42%	4.9	100%	4.9	1.01
slug	358%	0	358%	27.9	100%	27.9	1.00

6. Conclusions

This paper introduced and demonstrated a model uncertainty quantification approach for erosion rate predictions using a well-known erosion model, 1-Dimensional Sand Production Pipe Saver (1-D SPPS), which is used extensively in oil and gas industry for erosion predictions. The results suggest using 3.61 as the safety factor when designing subsea systems, pipelines and auxiliary equipment if they would be exposed to solids. Future work will investigate different data transformation approaches, and consider data clustering approaches prior to GPM training.

Abstract

If it is desired to maintain uniform performance in the face of process faults, then it is important to diagnose them as they start developing. Kalman filter based fault diagnosis approaches are of particular interest in this work. Kitanidis (1987) has proposed a modified version of linear Kalman filter, which modifies the observer gain to make the estimated states insensitive to unknown input / faults of arbitrary character. An extended version of Kitanidis-Kalman filter (EKKF), which can directly employ a nonlinear mechanistic model for fault identification, is proposed in this work. The residuals generated by the EKKF are used to construct the fault magnitude estimates. Efficacy of the proposed EKKF is demonstrated using simulation studies on the benchmark quadruple tank system (Johansson, 2000). The proposed approach successfully identifies the leak type fault (modelled as changes in areas of the tank outlets) introduced either sequentially or simultaneously.

Keywords: Kalman Filtering, Nonlinear Systems, Fault Identification

1. Introduction

Engineered systems are susceptible to faults and failures. If it is desired to maintain uniform performance in the face of the soft faults, such as biases or drifts in system parameters or unmeasured disturbances, or hard faults, such as leaks in storage tanks, then it is important to diagnose them as they start developing and plan remedial measures. In particular, extended Kalman filter based fault detection and diagnosis approaches are of particular interest in this work. Wilsky and Jones (1976) originally proposed a method for identifying time, location and magnitude of a fault using the generalized likelihood ratio (GLR) method. Deshpande et al. (2009) have recently developed a nonlinear version of the GLR method. This approach is based on analysis of innovation or the model residual sequence generated by the extended Kalman filter after occurrence of a fault. One difficulty with the GLR method is that it is necessary to assume a model, such as step or ramp function, for all anticipated faults while carrying out the diagnosis. A commonly used approach for tracking arbitrary variations in fault / parameters is to assume the random walk model for the evolution of faults / parameters and carry out state and fault / parameter estimation simultaneously. This approach, however, requires *tuning* of the covariance matrix of artificially introduced noise in the random walk model. The covariance tuning is non-trivial exercise (Bavdekar et al., 2011).

Kitanidis (1987) has proposed an alternate version of linear Kalman filter (referred to as Kitanidis-Kalman filter or KKF in rest of the text), which modifies the observer gain calculation step to make the estimated states insensitive to unknown input / faults of arbitrary character. Madapusi and Goyal (2011) have recently used this approach to estimate magnitudes of the unknown inputs from the innovation sequence. The KKF, together with the input magnitude identification step, appears to be well suited for carrying out online fault identification. These developments, however,

have been carried out for discrete time linear systems. Majority of the engineered systems, on the other hand, exhibit nonlinear dynamics in the desired range of operation. Thus, an extended version of KKF (referred to as EKKF), which can directly employ a nonlinear mechanistic model for fault / parameter identification, has been proposed in this work. The residuals generated by EKKF are used to construct magnitude estimates of faults / parameters, which can exhibit relatively slow but arbitrary variations. A significant advantage of the proposed estimation scheme is that, despite model plant mismatch, it generates unbiased estimates of the states without requiring any *covariance tuning*. Efficacy of the proposed EKKF algorithm has been demonstrated using simulation studies on the benchmark quadruple tanks system (Johansson, 2000). Leaks occurring in the tanks are modelled as changes in area of the outlets for outflows from the tanks. The simulation study is carried out for sequential as well as simultaneous occurrence of the faults.

This paper is organized in four sections. The development of extended Kitanidis-Kalman filter is presented in Section 2. The simulation results are presented in Section 3 and main conclusions reached through the simulation studies are presented in Section 4.

2. Development of Extended Kitanidis-Kalman Filter

Kalman filter generates minimum variance estimates of states for linear time varying system under the perfect model assumption. However, if the plant dynamics is influenced by unmeasured inputs of unknown character, then the estimates are biased. Kitanidis (1987) proposed a variation of the Kalman filter, which generates unbiased estimate of the plant states even in the presence of unknown inputs. This approach is extended here to deal with fault identification in nonlinear dynamic systems.

The dynamics of systems under consideration in the work can be represented by the following nonlinear difference equation

$$\mathbf{X}(k+1) = F(\mathbf{X}(k), \mathbf{u}(k), \theta(k)) + \mathbf{w}(k) \tag{1}$$

$$\mathbf{Y}(k) = \mathbf{h}(\mathbf{X}(k)) + \mathbf{v}(k) \tag{2}$$

where, $\mathbf{X} \in \mathbb{R}^n$ denotes the system states, $\mathbf{u} \in \mathbb{R}^m$ denotes the manipulated inputs, $\theta \in \mathbb{R}^p$ denotes vector of faults / model parameters and $\mathbf{w}(k) \in \mathbb{R}^n$ represents a zero mean Gaussian white noise process with covariance matrix $\mathbf{Q}$. The measurements of the system outputs $\mathbf{Y} \in \mathbb{R}^r$ are assumed to be corrupted with zero mean Gaussian white noise process $\mathbf{v}(k) \in \mathbb{R}^r$ with covariance matrix $\mathbf{R}$. Moreover, $\mathbf{w}(k)$ and $\mathbf{v}(k)$ are assumed to be mutually uncorrelated. It is further assumed that $\theta(k) \in R^p$ can be represented as, $\theta(k) = \overline{\theta} + \Delta\theta(k)$, where, $\overline{\theta}$ represents the mean or the steady state value of the parameter at some desired operating point and $\Delta\theta(k)$ represent time varying perturbations of unknown characteristics. Moreover, the number of model parameters is less than or equal to the number of measurements, i.e. $p \leq r$.

Given the measurements up to time $(k+1)$, it is desired to construct an unbiased minimum variance estimate of $\mathbf{X}(k+1)$. Let us assume that an unbiased filtered estimate, $\hat{\mathbf{X}}(k|k)$, of $\mathbf{X}(k)$ is available at instant $(k+1)$. Defining estimation error, $\varepsilon(k+1) = \hat{\mathbf{X}}(k+1|k+1) - \mathbf{X}(k+1)$, it is desired to construct the estimate $\hat{\mathbf{X}}(k+1|k+1)$ such that it is unbiased, i.e. $\mathbf{E}[\varepsilon(k+1)] = 0$. Using Taylor series expansion in the neighborhood of $\hat{\mathbf{X}}(k|k)$ and neglecting terms higher than the first order terms, the R.H.S. of equation (1) can be approximated as follows (Soderstrom, 2002)

$$\mathbf{X}(k+1) = \Phi(k)\mathbf{X}(k) + \mathbf{G}(k)\Delta\theta(k) + \mathbf{M}(k) + \mathbf{w}(k) \tag{3}$$

where $\mathbf{M}(k) = \mathbf{F}(\hat{\mathbf{X}}(k|k), \mathbf{u}(k), \overline{\theta}) - \Phi(k)\hat{\mathbf{X}}(k|k)$ and

$$\Phi(k) = \left[\frac{\partial \mathbf{F}}{\partial \mathbf{X}}\right]_{(\hat{\mathbf{X}}(k|k), \overline{\theta})} \quad ; \quad \mathbf{G}(k) = \left[\frac{\partial \mathbf{F}}{\partial \theta}\right]_{(\hat{\mathbf{X}}(k|k), \overline{\theta})} \tag{4}$$

Following Kitanidis (1987), the predicted estimate of $\mathbf{X}(k+1)$ is constructed as follows

$$\widetilde{\mathbf{X}}(k+1|k) = \Phi(k)\hat{\mathbf{X}}(k|k) + \mathbf{M}(k)\left(= \mathbf{F}(\hat{\mathbf{X}}(k|k), \mathbf{u}(k), \overline{\theta})\right) \tag{5}$$

The state to output map can now be locally approximated in the neighborhood of $\widetilde{\mathbf{X}}(k+1|k)$ as follows

$$\mathbf{Y}(k+1) = \mathbf{C}(k+1)\mathbf{X}(k+1) + \mathbf{N}(k+1) + \mathbf{v}(k+1) \tag{6}$$

where

$$\mathbf{C}(k+1) = \left[\frac{\partial \mathbf{h}}{\partial \mathbf{X}}\right]_{\widetilde{\mathbf{X}}(k+1|k)} \quad \text{and} \quad \mathbf{N}(k+1) = \mathbf{h}(\widetilde{\mathbf{X}}(k+1|k)) - \mathbf{C}(k+1)\widetilde{\mathbf{X}}(k+1|k) \tag{7}$$

Following Kitanidis (1987), the predicted output at instant $(k+1)$ is defined as follows

$$\widetilde{\mathbf{Y}}(k+1|k) = \mathbf{C}(k+1)\widetilde{\mathbf{X}}(k+1|k) + \mathbf{N}(k+1)\left(= h(\widetilde{\mathbf{X}}(k+1|k))\right) \tag{8}$$

Using the predicted estimate and the predicted output, the updated state estimate at instant $(k+1)$ can now be constructed as follows

$$\hat{\mathbf{X}}(k+1|k+1) = \widetilde{\mathbf{X}}(k+1|k) + \mathbf{L}(k+1)\mathbf{e}(k+1) \tag{9}$$

$$\mathbf{e}(k+1) = \mathbf{Y}(k+1) - \widetilde{\mathbf{Y}}(k+1|k) = -\mathbf{C}(k+1)\xi(k+1) + \mathbf{v}(k+1) \tag{10}$$

where $\xi(k+1) = \widetilde{\mathbf{X}}(k+1|k) - \mathbf{X}(k+1)$. Using equation (9), the estimation error dynamics can be approximated as follows

$$\varepsilon(k+1) = [\mathbf{I} - \mathbf{L}(k+1)\mathbf{C}(k+1)]\xi(k+1) + \mathbf{L}(k+1)\mathbf{v}(k+1) \tag{11}$$

From equations (3) and (5), it follows that

$$\xi(k+1) = \Phi(k)\varepsilon(k) - \mathbf{G}(k)\Delta\theta(k) - \mathbf{w}(k) \tag{12}$$

and

$$\varepsilon(k+1) = [\mathbf{I} - \mathbf{L}(k+1)\mathbf{C}(k+1)]\,[\Phi(k)\varepsilon(k) - \mathbf{G}(k)\Delta\theta(k) - \mathbf{w}(k)] + \mathbf{L}(k+1)\mathbf{v}(k+1) \tag{13}$$

Taking expectation on both the sides under the assumption that $\mathbf{E}[\varepsilon(k)] = 0$, the unbiasedness condition is satisfied at $(k+1)$ if and only if an additional constraint is imposed

$$[\mathbf{I} - \mathbf{L}(k+1)\mathbf{C}(k+1)]\mathbf{G}(k) = [\mathbf{0}] \tag{14}$$

It may be noted that, matrix $\mathbf{C}(k+1)\mathbf{G}(k)$ is assumed to have full column rank at all k in this work.

To arrive at the minimum variance estimate of $\mathbf{X}(k+1)$, a scalar objective function $\varphi(k)$ is defined as

$$\varphi(k) = tr\left[\mathbf{P}(k+1|k+1) + 2[\mathbf{I} - \mathbf{L}(k+1)\mathbf{C}(k+1)]\mathbf{G}(k)\Lambda(k+1)^T\right] \tag{15}$$

where $\mathbf{P}(k+1|k+1) = \mathbf{E}[\varepsilon(k+1)\varepsilon^T(k+1)]$ and $\Lambda(k+1)$ denotes the matrix of Lagrange multipliers. Defining matrices $\mathbf{P}(k+1|k) = \Phi\mathbf{P}(k|k)\Phi^T + \mathbf{Q}$ and $\mathbf{V}(k+1)$ as

$$\mathbf{V}(k+1) = \mathbf{C}(k+1)\mathbf{P}(k+1|k)\mathbf{C}(k+1)^T + \mathbf{R} \tag{16}$$

the use of the necessary conditions for optimality reduces to the following matrix equation (Kitanidis, 1986)

$$\begin{bmatrix} \mathbf{V}(k+1) & -\mathbf{C}(k+1)\mathbf{G}(k) \\ \mathbf{G}(k)^T\mathbf{C}(k+1)^T & [\mathbf{0}] \end{bmatrix} \begin{bmatrix} \mathbf{L}(k+1)^T \\ \Lambda(k+1)^T \end{bmatrix} = \begin{bmatrix} \mathbf{C}(k+1)\mathbf{P}(k+1|k) \\ \mathbf{G}(k)^T \end{bmatrix} \tag{17}$$

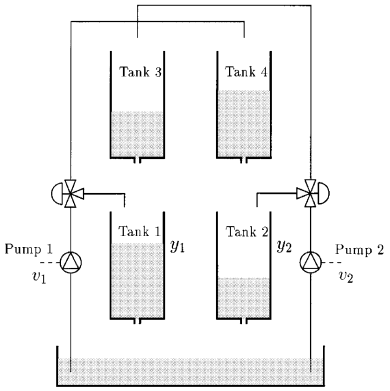

Figure 1: Quudruple Tank System: Schematic Representation (Johanson, 2000)

which can be used to compute $\mathbf{L}(k+1)$. Expressions for update of covariance matrix $\mathbf{P}(k+1|k+1)$ and discussion regarding the second order necessary conditions that ensure the minimality of the covariance can be found in Kitanidis (1987). It may be noted that the proposed EKKF reduces to the conventional EKF when $\mathbf{G}(k)$ equals the null matrix, i.e. in absence of any fault / parameter variations.

The extended Kitanidis-Kalman filter constructed such that the state estimate are insensitive to unknown drift in the parameter. In practice, however, the drifting value of the parameter / faults can be of interest from the viewpoint of monitoring. Estimates of the drifting parameters / faults can be constructed using the innovation sequence generated by EKKF. Consider innovation, $\mathbf{e}(k+1)$,which can be expressed as follows

$$\mathbf{e}(k+1) = \mathbf{C}(k+1)\mathbf{G}(k)\Delta\theta(k) + \upsilon(k+1) \tag{18}$$

where $\upsilon(k+1) = \mathbf{C}(k+1)\left[-\Phi(k)\varepsilon(k) + \mathbf{w}(k)\right] + \mathbf{v}(k+1)$ is a zero mean signal with covariance equal to $\mathbf{V}(k+1)$ given by equation (16). It is further assumed that variations in $\Delta\theta(k)$ are relatively slow and their value remains constant over a window in time $[k+1, k-N+1]$, i.e. $\Delta\theta(k-i) = \Delta\theta(k)$ for $i = 0, 1, ...N$. Under this simplifying assumption, by stacking equations for innovations over the window $[k+1, k-N+1]$, we arrive at $\mathscr{E}(k) = \mathscr{A}(k)\Delta\theta(k) + \mathscr{V}(k)$ where

$$\mathscr{E}(k) = \begin{bmatrix} \mathbf{e}(k+1) \\ ... \\ \mathbf{e}(k-N+1) \end{bmatrix}; \mathscr{A}(k) = \begin{bmatrix} \mathbf{C}(k+1)\mathbf{G}(k) \\ ... \\ \mathbf{C}(k-N+1)\mathbf{G}(k-N) \end{bmatrix}; \mathscr{V}(k) = \begin{bmatrix} \upsilon(k) \\ ... \\ \upsilon(k-N) \end{bmatrix}$$

Here, $E\left[\mathscr{V}(k)\right] = \overline{0}$ and covariance $Cov\left[\mathscr{V}(k)\right] = block\ diag\left[\begin{array}{cccc} \mathbf{V}(k+1) & ... & \mathbf{V}(k-N+1) \end{array}\right]$. Defining weighting matrix $\mathscr{W}(k) = \left[Cov\left[\mathscr{V}(k)\right]\right]^{-1}$, the maximum likelihood estimate of $\Delta\theta(k)$ can be constructed as

$$\Delta\theta(k) = \left[\mathscr{A}(k)^T\mathscr{W}(k)\mathscr{A}(k)\right]^{-1}\mathscr{A}(k)^T\mathscr{W}(k)\mathscr{E}(k) \tag{19}$$

3. Simulation Studies

The efficacy of the proposed EKKF is evaluated by conducting simulation studies on the benchmark quadruple tank system (Johansson, 2000). The system consists of four interconnected tanks as shown in Figure 1. Voltage inputs v_1 and v_2 to Pump 1 and Pump 2, respectively, represent the manipulated inputs and the liquid levels in Tank 1 and Tank 2 are the measured outputs. A

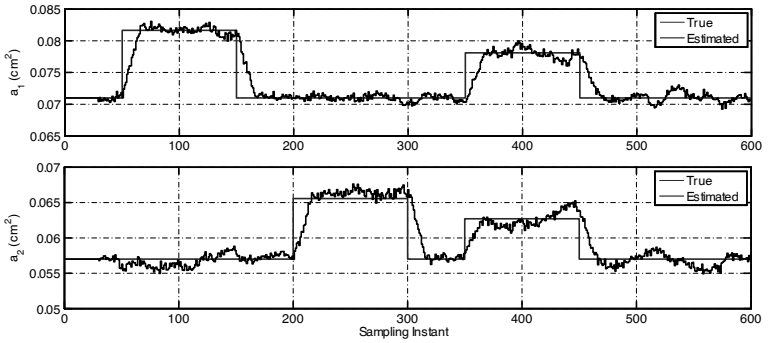

Figure 2: Comparison of variations of parameters a_1 and a_2 generated using EKKF with the true parameter variations

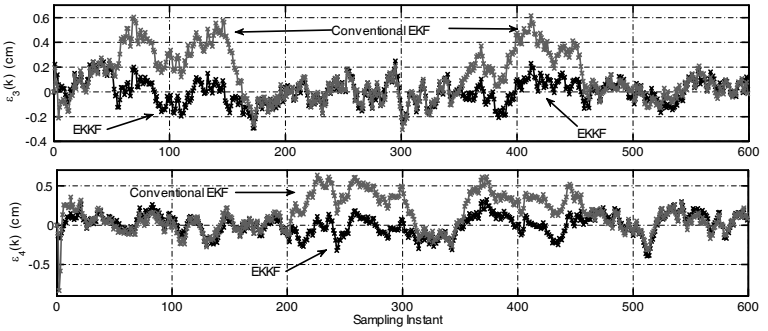

Figure 3: Comparison of state estimation errors generated by EKKF and EKF for the umeasured states h_3 and h_4.

mechanistic model governing the system dynamics, together with the model parameters, is given in Johansson (2000). The system is operated under the non-minimum phase conditions. The sampling interval is selected as 5 seconds. The system is operated in open loop and the manipulated input variations are introduced as random binary inputs (RBS) around the steady state values with amplitude of 0.5 V and in frequency range $[0, 0.05\pi/T]$. The state and the measurement noise covariances are chosen as $\mathbf{Q} = 0.05\mathbf{I}_{4\times4}$ and $\mathbf{R} = 0.05\mathbf{I}_{2\times2}$.

The faults considered here are leaks occurring at the bottoms of Tank 1 and Tank 2. Thus, they are modelled as changes in model parameters a_1 and a_2, i.e. changes in areas of bottom outlets of Tank1 and Tank 2, respectively. At instant $k = 51$, +15 % increase in area a_1 is introduced and a_1 is set equal to the nominal value at instant 150. Subsequently, at instant $k = 201$, +15 % increase in area a_2 is introduced and a_2 is set equal to the nominal value at instant $k = 300$. After introducing faults sequentially, areas a_1 and a_2 are simultaneous changed by 10 % between $k = 351$ to $k = 450$ and set equal to their nominal values subsequently. For fault magnitude estimation, the window size N is chosen as 30. The fault magnitude estimates generated using EKKF are shown in Figure (2). As evident from this figure, the proposed method for parameter / fault magnitude estimation generates fairly accurate estimates of variation in a_1 and a_2 for sequential as well as simultaneous faults. A comparison of the state estimation errors generated by the conventional EKF and EKKF is presented in Figures (3) and (4). The advantages of the proposed EKKF are highlighted by

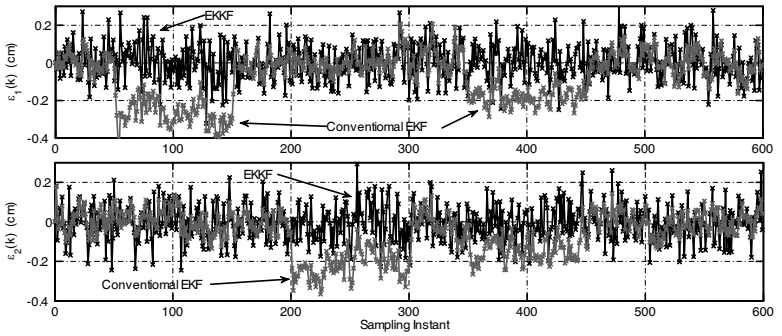

Figure 4: Comparison of state estimation errors generated by EKKF and EKF for the measured states h_1 and h_2.

Figure (3), which compares the estimation errors for the unmeasured states h_3 and h_4. When the faults are introduced, the estimates generated by the conventional EKF become biased. On the other hand, as can be expected from the design conditions, the estimates generated by EKKF remain unbiased throughout the simulation. The behavior of the estimation errors in h_1 and h_2 is qualitatively similar. Both the figures also underscore the fact that EKKF performance becomes similar to that of the conventional in the absence of any fault / parameter drift. However, under the no fault scenario, there is a relative loss of performance with respect to EKF as EKKF seeks a constrained optimum irrespective of occurrence of the faults.

4. Conclusions

In this work, an extended version of Kitanidis-Kalman filter (Kitanidis, 1987) has been developed, which employs a nonlinear mechanistic model for fault identification through successive linearization. The residuals generated by the EKKF are used to construct the fault magnitude estimates. Efficacy of the proposed EKKF is demonstrated using simulation studies on the benchmark quadruple tank system (Johansson, 2001). The proposed approach is able to generate reasonably accurate estimates of the leak type fault (modelled as changes in areas of the tank outlets) introduced either sequentially or simultaneously. Moreover, unlike the conventional EKF, the proposed EKKF formulation generates unbiased estimates of the states even in the presence of moderately large model plant mismatch.

Process Monitoring and Fault Detection in Non-Linear Chemical Process Based On Multi-Scale Kernel Fisher Discriminant Analysis

Norazwan Md Nor,[a] Mohd Azlan Hussain,[a] Che Rosmani Che Hassan[a]

[a]*Department of Chemical Engineering, University of Malaya, 50630 Kuala Lumpur, Malaysia*

Abstract

This paper presents a multi-scale kernel Fisher discriminant analysis (MSKFDA) algorithm combining Fisher discriminant analysis (FDA) and its nonlinear kernel variation with the wavelet analysis. This approach is proposed for investigating the potential integration of wavelets and multi-scale methods with discriminant analysis in nonlinear chemical process monitoring and fault detection system. In this paper, a discrete wavelet transform (DWT) is applied to extract the dynamics of the process at different scales. The wavelet coefficients obtained during the analysis are used as input for the algorithm. By decomposing the process data into multiple scales, MSKFDA analyse the dynamical data at different scales and then restructure scales that contained important information by inverse discrete wavelet transform (IDWT). A monitoring statistic based on Hoteling's T^2 statistics is used in process monitoring and fault detection. The Tennessee Eastman benchmark process is used to demonstrate the performance of the proposed approach in comparison with conventional statistical monitoring and fault detection methods. A comparison in terms of false alarm rate, missed alarm rate and detection delay, indicate that the proposed approach outperform the others and enhanced the capabilities of this approach for the diagnosis of industrial applications.

Keywords: multi-scale, Fisher discriminant analysis, wavelet analysis, process monitoring, fault detection

1. Introduction

Various modelling methodologies have been developed for achieving efficient monitoring and control system for chemical processes. These methodologies are broadly divided into three types: quantitative model-based methods; qualitative model-based methods; and process history based methods (Venkatasubramanian *et al*., 2003). The process history based or data-driven method concerns with the transformation of large amounts of data into a particular form of knowledge representation that will enable proper detection and diagnosis of faults. Availability of vast amounts of plant data has encouraged researchers to develop and improve the data-driven-based and multivariable statistical process monitoring based methods, which use statistic projection technique to extract key process information from theses massive process data. These methods including such as Principal Component Analysis (PCA), Partial Least Square (PLS), Independent Component Analysis (ICA) and Fisher Discriminant Analysis (FDA) have been widely applied to on-line continuous and batch process monitoring, fault detection and diagnosis.

In some context, fault diagnosis problems can be considered as classification problems when lots of historical data are obtained from various faulty conditions, and then feature extraction and pattern recognition or classification methods can be used for fault diagnosis. Linear supervised classification methods such as PCA, discriminant PLS (DPLS) and FDA can be used. PCA represents high-dimensional process data in a reduced dimension, which brings convenience for process monitoring. However, PCA aims at reconstruction but not classification, which degrades the performance in classification problems while FDA provides an optimal lower dimensional representation in terms of discriminating among classes, which is very useful for fault diagnosis. Though it has been proven that FDA outperforms PCA in the classification problems, it is still linear in nature, which degrades the performance of FDA in monitoring the nonlinear system.

Furthermore, a chemical process is often characterized by large scale and non-linear behaviour. When linear FDA is used for fault diagnosis in non-linear system, a lot of incorrect diagnosis results will occur. As solution to deal with the nonlinear system, and to improve the classification ability, kernel-based FDA, called kernel FDA (KFDA), is introduced. The basic idea of the KFDA is to map the input sample data into a kernel feature space by a nonlinear kernel function and then perform linear FDA in the nonlinearly mapped feature space to find the discriminant feature vectors for classification. KFDA has turned out to be effective in many real-world applications due to its power of extracting the most discriminatory nonlinear. However, application of KFDA in fault diagnosis of chemical and biological processes is still limited.

There were also limited application on multi-scale FDA and KFDA that integrates FDA and wavelet packet analysis (Vana *et al.*, 2011). Discrete wavelet analysis decomposes the high-frequency part further, which wavelet analysis not does, and adaptively selects relative frequency bond based on character of signal to be analysed. To further improve de-noising character of multi-scale KFDA, the paper describes a discrete wavelet transform KFDA, which combines the ability of KFDA to de-correlate the variables by discriminating a nonlinear relationship with that of discrete wavelet transform to extract auto-correlated measurements. Then, a novel multi-scale kernel FDA is proposed by combining FDA and its nonlinear kernel variation with the wavelet analysis. Finally, an individuals control charts (XmR charts) and Hoteling's T^2 statistics are used to monitor the fault data in process monitoring and fault detection. The proposed method is evaluated and compared with the T^2 statistical methods based on the PCA in terms of the average run length (ARL). The paper is organized as follows. In Section 2 the background of FDA, KFDA and the discrete wavelet transform (DWT) is introduced. Section 3 introduces the proposed fault diagnosis approach with kernel FDA and integrates it with the wavelet transform. The case study illustrates an application to Tennessee Eastman process is provided in Section 4, and Section 5 concludes the paper.

2. Background

2.1. Fisher Discriminant Analysis

Fisher discriminant analysis is a linear dimensionality reduction technique to find a direction for which data classes are optimally separated. The optimal discriminant direction is determined by maximizing the scatter within the classes (Wang and Romagnoli, 2005). Let the training data for all faulty classes be stacked into a n by m matrix $X \in R^{n \times m}$, where n is the observation number and m is the variable number. The

within-class-scatter matrices S_W and the between-class-scatter matrix S_B contain all the basic information about the relationship within the groups and between them as in Eq.(1) and Eq.(2) respectively.

$$S_W = \sum_{k=1}^{K} \sum_{n \in C_k} (x_n - m_k)(x_n - m_k)^T \tag{1}$$

$$S_B = \sum_{k=1}^{K} N_k (x_n - m_k)(m_k - m)^T \tag{2}$$

where N_k and m_k are the number and mean vector of the points assigned to class k, respectively; m is the total mean of all the samples, and K is the number of classes and x_n is the data sample. Maximizing Eq.(3) with w is the solution is equivalent to maximizing the between-class scatter S_B,and minimizing the within-class scatter S_W.

$$J(w) = \arg\max \frac{|w^T S_B w|}{|w^T S_W w|}. \tag{3}$$

2.2. Kernel Fisher Discriminant Analysis

The idea of KFDA is to solve the problem of FDA in the feature space F. However, since any solution $w \in F$ must lie in the span of all the samples in F, there exists coefficients $\alpha = \{\alpha, i = 1, 2, \ldots, n\}$ and the mapping of sample class, ϕ_i such that

$$w = \sum_{i=1}^{n} \alpha_i \phi_i. \tag{4}$$

K_B and K_W are the between-class kernel matrix and within-class kernel matrix, as in Eq.(5) and Eq.(6) respectively.

$$w^T S_B w = \alpha^T K_B \alpha \tag{5}$$

$$w^T S_W w = \alpha^T K_W \alpha \tag{6}$$

So the solution can be achieved by maximizing Eq.(7) following Fisher criterion

$$J(\alpha) = \arg\max \frac{|\alpha^T K_B \alpha|}{|\alpha^T K_W \alpha|}. \tag{7}$$

2.3. Discrete Wavelet Transform

Wavelets are basis functions that are localized in both time and frequency. Generally, the dyadically discretized form of wavelets is used and it can be represented as

$$\psi_{mk}(t) = 2^{-m/2} \psi(2^{-m} t - k), \tag{8}$$

where, $\psi(t)$ is the mother wavelet, and m and k are dilation and translation parameters, respectively. The translation parameter determines the location of the wavelet in the time domain, while the dilation parameter determines its scale and location in the frequency domain. By projecting a signal on the wavelet basis function, its contributions in different regions of the time-frequency space can be obtained. The

scaling and wavelet coefficients represented in terms of original measured data vector, x, take the form of

$$a_s = H_s x,\ d_s = G_s x \tag{8}$$

where, H_s represents projection m times on the scaling function, and G_s represents projection $(s-1)$ times on the scaling function and once on the wavelet. The sequences H and G are low-pass and high-pass filters derived from the corresponding basis function, respectively. The scaling coefficients represent the lower frequency approximation of the signal while the wavelet coefficients represent the higher frequency components of the signal (Maulud *et al.*, 2005).

3. Methodology

The detailed in multi-scale kernel FDA application procedure of fault diagnosis were discussed briefly in this section. First, each of the m variables is first decomposed individually by applying discrete wavelet transformation (DWT). Then, the Kernel FDA is performed on the wavelet coefficients for each selected scale. Appropriate numbers of component loading vectors are retained and the wavelet coefficients are reconstructed at each selected scale. In this work four scales (s=4) are used for discrete wavelet transformation (DWT) of the original signal. After that, the wavelet coefficients larger than a selected threshold corresponding to a significant event are retained. The variables consisting of deterministic components are reconstructed from the retained wavelet coefficients through inverse discrete wavelet transformation (IDWT) and the loadings of the extracted deterministic components are computed.

The new observations are projected into lower dimensional subspace. This subspaces measures the systematic or state variations occurring in the process. Meanwhile, the lower dimensional subspace corresponding to the $(m-a)$ smaller singular value describes the random variations of the process such as that associated with measurement noise are term as residual space. KFDA is used to search the optimal one-dimensional discriminant direction between the fault data and the normal data. Thus, individuals control charts, also known as XmR charts, are used to monitor the fault data on the optimal discriminant direction with contribution plot based on the optimal discriminant direction from KFDA is also used to improve its performance (Pei *et al.*, 2006). The proposed method is applied to the Tennessee Eastman process. Finally, the proposed method is evaluated and compared with the Hotelling's T^2 statistical methods.

4. Case study

Tennessee Eastman process (TEP) as described by Downs and Vogel (1993) in Figure 1was used as a case study. The process includes a total of 52 variables with 20 different faults were simulated (Yélamos *et al.*, 2006). The data set for the process and the details can be obtained from the Multi-scale Systems Research Laboratory (MIT, 2013).

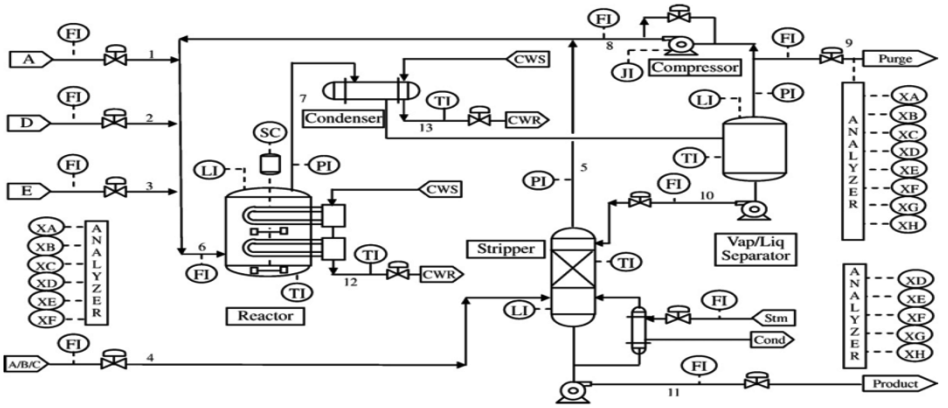

Figure 1 Tennessee Eastman process diagram

Table 1 Selected faults for four combination cases

	ID	*Fault description*	*Type*
Case 1	Fault 3	D feed temperature	Step change
	Fault 4	Reactor cooling water inlet temperature	Step change
	Fault 11	Reactor cooling water inlet temperature	Random variation
Case 2	Fault 8	A, B, C feed composition	Random variation
	Fault 12	Condenser cooling water inlet temperature	Random variation
	Fault 15	Condenser cooling water valve	Sticking
Case 3	Fault 2	B composition, A/C ration constant	Step change
	Fault 9	D feed temperature	Random variation
	Fault 13	Reactor kinetics	Slow drift
Case 4	Fault 9	D feed temperature	Random variation
	Fault 14	Reactor cooling water valve	Sticking
	Fault 17	Unknown	Unknown

These case studies and their respective faults were tabulated in Table 1, covering all fault types in the TEP simulation. Each case study combination includes three different types of faults and each of fault type sampling intervals is set to be 3 min with every sample data contains 52 process variables.

5. Results and Discussion

Table 2 Comparison among diagnosis success rates using different approaches

		Diagnosis success rate (%)		
		FDA	KFDA	MSKFDA
Case 1	Training data set	67.5	100	98.0
	Testing data set	41.7	84.7	92.7
Case 2	Training data set	89.1	100	100
	Testing data set	33.7	72.7	91.3
Case 3	Training data set	100	100	100
	Testing data set	86.7	100	100
Case 4	Training data set	93.7	100	100
	Testing data set	62.7	95.3	98.3

A summary of the classification results for MSKFDA, KFDA and FDA is listed in Table 2. Compared with the classification performance of KFDA, MSKFDA has a significant improvement. After fault data are decomposed by DWT wavelet analysis, KFDA is performed on these multi-scaled fault data, which offers important supplemental classification information to KFDA. Without proper variable weighting, all variables are used in a same level and the data sets are masked with irrelevant information. The integration of DWT with KFDA improved the extraction of features that are relevant to the abnormal operation in both time and frequency domain and lead to better classification. In addition, the high misclassifications rate for FDA shows the advantage of nonlinear technique when the fault data are highly overlapped.

6. Conclusions

In this paper, MSKFDA-based fault diagnosis for the Tennessee Eastman process is presented. The data discrimination and fault detection based on MSKFDA methodology enhanced the diagnosis proficiency by taking into consideration the multi-scale information compared to other methods that considered only single scale nature. Moreover, it can provide a better separation of the deterministic and stochastic features and improve the extraction of features that are relevant to a faulty situation from both time and frequency domain aspects. The application of the proposed MS-KFDA shows better fault diagnosis performance than KFDA and FDA. The high misclassification rate for FDA also shows the advantage of nonlinear technique when the fault data are highly overlapped.

Abstract

Although fault propagation scenario-based accident analysis can be an effective means to help operators to find the root causes of the current abnormal event, it has not yet been analyzed from the resilience engineering (RE) perspective. Resilience engineering is a new method that can control incidents and limit their consequences. This study introduces a hierarchical fault propagation model (HFPM) as an extension of the Infrastructure Resilience-Oriented Modelling Language (IRML), considering the dynamic behaviour of fault propagation. The method involves two parts: the first part is static analysis for system structure feature and the second part is dynamic analysis for fault evolution mechanism. The performance of the proposed model has been tested on a petroleum refining system with the characteristics of complex, non-linear and multivariate.

Keywords: fault propagation; process safety; resilience engineering; Infrastructure Resilience-Oriented Modeling Language.

1. Introduction

The complexity of the process plants which can be considered as systems of systems, has increased due to extensive heat and mass integration. Thus, the plant operation becomes more demanding with multiple unit operation interactions. It is their scale, nonlinearities, interconnectedness, and interactions with humans and the environment that can make these complex systems fragile, when the cumulative effects of multiple abnormalities can propagate in numerous ways to cause systemic failures. Therefore it is often difficult to develop nonlinear models that accurately describe the system as well as the fault propagation features in all regimes.

Various methods and models for systems of systems have been proposed. The main aim is to reveal fault propagation features, to estimate the process risk or to make resilience analysis. According to previous accidents and disasters, Utne (2011) plotted a cascade diagram to describe the cascading failures process under a specific initiating event. It is a logical method to model the dependencies. Johansson et al (2010) proposed an agent based approaches for vulnerability analysis in critical components. Kjølle et al (2012) proposed an across-sector approach for analysis of critical components and interdependencies between components. Functional Resonance Analysis Method

(FRAM) (Belmonte, 2011) was proposed to establish a fault evolution model in systemic functional perspective. To uncover process variables' interactions, Gabbar et al (2014) employed fault semantic network (FSN) as a novel method for fault diagnosis and fault propagation analysis by using techniques like genetic programming (GP) and neural networks (NN).

Although above fault propagation scenario-based accident analysis can be an effective means to help operators to find the root causes of the current abnormal event, it has not yet been analyzed from the resilience engineering (RE) perspective. Resilience engineering is a new method that can control incidents and limit their consequences. This study introduces a hierarchical fault propagation model (HFPM) as an extension of the Infrastructure Resilience-Oriented Modelling Language (IRML) (Filippini, 2014), considering the dynamic behaviour of fault propagation. It can be used for fault propagation and control strategy analysis from the resilience engineering perspective and also be beneficial to the design and modifications of process plants which will enhance the process safety.

2. Hierarchical fault propagation model (HFPM)

HFPM is an optimization method based on IRML for fault propagation analysis for systems of systems. The core of the method is a network formed by nodes and links, where nodes represent different components and links mimic the functional connections among them. This method is aimed at analyzing the system structure and the fault scenarios to capture the fault propagation behaviors and evaluate the resilience of systems of systems. HFPM has two modules: static analysis module, dynamic analysis module.

2.1. static analysis

Static analysis, i.e. structure analysis, captures the system structure features for fault propagation in a specific system, which includes following steps:

Setp (1): Draw the network. The network can be drawn based on the process flowchart, where nodes are classified into two types, i.e. the subsystem node and secondary node. The subsystem nodes are decided according to the process units, and the devices in subsystems are called the secondary nodes.

Setp (2): Simplify the network. The simplified network is the overall representation of all the relevant functional dependencies with the secondary nodes omitted. Criticality, vulnerability and interdependency node sets are obtained to judge the criticality and vulnerability degree of each subsystem.

Setp (3): Complicate the network. The most critical and vulnerable subsystem nodes determined in step (2) are chosen as the analysis object. The criticality and vulnerability degree of the devices is determined as step (2).

2.2. dynamic analysis

Dynamic analysis module quantifies the fault propagation behavior under different fault modes and working conditions in systems of systems. The procedure used to develop the dynamic analysis is described as: fault propagation scenarios analysis, determination of modeling parameters and state function definition.

Setp (1): Fault propagation scenarios analysis: Combining "what…if…" method, HFPM analyzes the fault propagation scenarios to obtain the event sequences of each subsystem and device in the certain fault mode.

Setp (2): Determination of modeling parameters, which contains disturbance duration (T_D), node buffering time (T_F) and node recovery time (T_R).

Setp (3): State function definition: Resilience is the ability of the network to resist a disturbance and recover back to the initial state. A simple metric of network resilience is the sum of the node's state. HFPM defines the node's state function R, which has two values. If the node operates normally, R=1, otherwise, R=0. If a subsystem node contains n secondary nodes, the subsystem node's state function $R=(r_1+r_2+...+r_n)/n$. The system's state function R is determined based on the fault propagation scenarios and modeling parameters. It can be calculated as the sum of the affected subsystems.
Setp (4): Map the system's state function graph. The fault propagation behavior is reflected in the graph.

Petroleum refining system is an automatic and nonlinear system of systems. Its process parameters are controlled by DCS (Distributed Control System). When parameters fluctuate beyond the threshold due to fault, it will be adjusted to the normal levels. The detected parameter's value has fluctuation in a certain period and eventually returned to the normal value. Therefore, the state function R with two values in HFPM can express the parameter fluctuation in petroleum refining system. Fault acts as the disturbance of the detected parameters. In case study, "Fault" is expressed as "Disturbance".

3. Case study

In petroleum refining system, the atmospheric and vacuum distillation process is a complicated information and mass transfer process. It has many variables, between which there exist a large amount of correlations, intercouplings and interactions among units. It is a typical system of systems. According to the principle technological process, HFPM network is developed and shown in Fig 1.

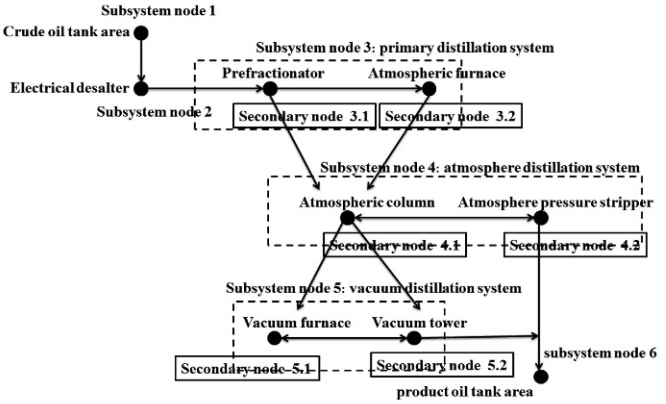

Figure 1 Structure diagram of atmospheric and vacuum system (HFPM network)

3.1. HFPM static analysis

The criticality, vulnerability and interdependency of each subsystem node are achieved by static analysis in table 1 to show that node 1 is the most critical node and node 6 is most vulnerable node. Node 1 represents crude oil tank area and node 6 represents product tank area. The two subsystem nodes determined both contain only one secondary node. Static analysis on the two subsystems is unnecessary.

3.2. HFPM Dynamic analysis

Fault can be detected on devices or product in petroleum refining system. Thus, the disturbance mode is classified into device disturbance mode and product disturbance mode. Taking Device disturbance as an example, the considered fault is prefractionator

disturbance, which triggers fault propagation in an atmospheric and vacuum distillation system.

Table 1: the criticality/vulnerability/interdependency set

	criticality set	vulnerability set	interdependency set
node 1	C(1)={2，3，4，5，6}	V(1)={}	I(1)={}
node 2	C(2)={3，4，5，6}	V(2)={1}	I(2)={}
node 3	C(3)={4，5，6}	V(3)={1，2}	I(3)={}
node 4	C(4)={5，6}	V(4)={1，2，3}	I(4)={}
node 5	C(5)={6}	V(5)={1，2，3，4}	I(5)={}
node 6	C(6)={}	V(6)={1，2，3，4，5}	I(6){}

If the system is under multi-device disturbance, the system's state function is also the sum of the effected subsystems' state functions, which is the sum of the involved secondary nodes' state functions. When *n* devices are disturbed at initial moment, the disturbances from different source reach device *i* in different time points. Device *i* is disturbed at the moment that the first disturbance reaches and recovers at the moment that the last disturbance withdraws. The disturbance affected nodes are *node 3*, *node 4*, *node 5* and *node 6*. Under different working conditions and disturbance modes, the system's state function graphs are drawn according to section 2.2 steps (1) - (4), which represent the fault propagation.

Scenario 1: T_D=2.5; Buffer time parameter and recovery time parameter of each node are set as 1.

The prefractionator (node 3) is disturbed at time=2 for 2.5 time units. Fig 2 (a) shows the system's state function graph. It means that the system will recover to normal state after a period of disturbance. The system resilience can deal with the disturbance of such strength.

Scenario 2: T_D=3.5. Buffering time parameter and recovery time parameter are set the same as scenario 1.

The prefractionator (*node 3*) is disturbed at time=2 for 3.5 time units. Fig 2 (b) shows the system's state function graph. It means that the system will break down after a period of disturbance. The disturbance imposed exceeds the system resilience.

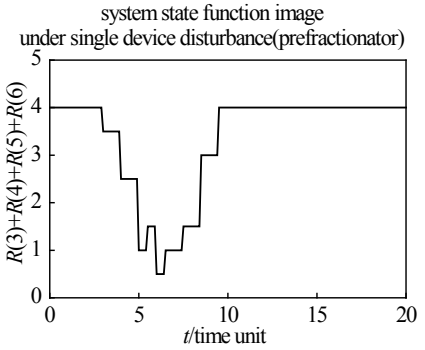

Figure 2(a) single device disturbance in scenario 1

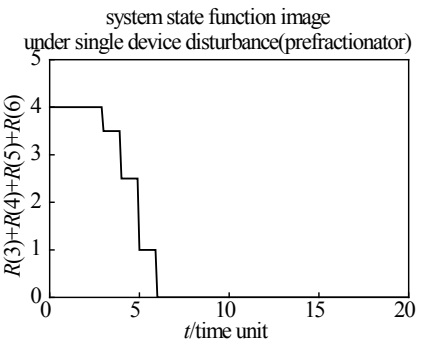

Figure 2(b) single device disturbance in scenario 2

Comparing **scenario 1** and **scenario 2**, it is concluded that the system may recover to the normal state or break down after a period of disturbance and it depends on the

system resilience and the modelling parameters determined by disturbance mode and working condition. The system response varies for different disturbance duration (T_D) in **scenario 1, 2**. In **scenario 3, 4**, buffering time (T_F) or recovery time (T_R) is changed based on scenario 2.

Scenario 3: T_D=3.5; Longer buffering time is set as 1.5 and constant recovery time as 1.

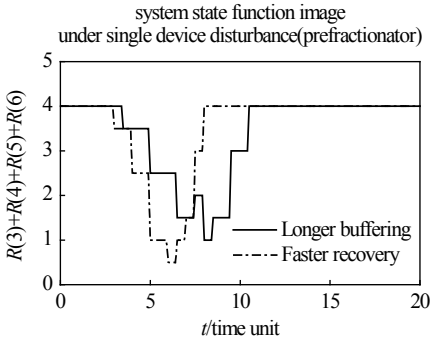

Figure 3: system state function image under single device disturbance in scenario 3/4

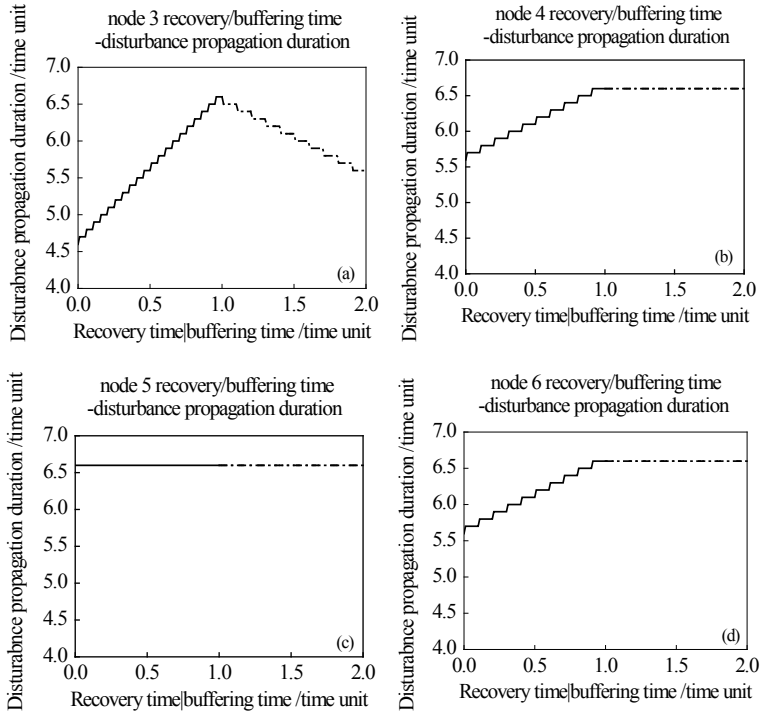

Figure 4: recovery time/buffering time-disturbance propagation duration
(——Recovery time; - - - - -Buffering time)

Scenario 4: T_D=3.5; Constant buffering time is set as 1 and faster recovery time as 0.5.

As Fig 3 shows, in a single device disturbance (prefractionator), longer buffering time or faster recovery may make the break-down resolved. In the case study, faster recovery is more efficient than longer buffering for intervening.

The quantitative relation between recovery time/buffering time and disturbance propagation duration of each effected subsystem node is shown in Fig 4. Each node's sensitivity to disturbance is various. The disturbance propagation duration remains constant when some time parameter of some node is changed, such as buffering time parameters of *node 4, 5, 6* and recovery time parameter of *node 5*. But faster recovery of *node 3, 4, 6* and longer buffering time of *node 3* accelerate the disturbance propagation.

4. Conclusions

Resilience engineering provides a new way to control incidents and limit their consequences. This study introduces a hierarchical fault propagation model (HFPM) as an extension of IRML, involving two parts: static analysis for system structure feature such as the interdependency between nodes; and dynamic analysis for fault evolution mechanism based on the fault scenario simulation. Due to the dynamic and highly nonlinear characteristics of petroleum refining system, the HFPM is applied in the case study, which can not only analyze structure features about the fault propagation, but also can capture quantitative fault propagation features in various fault modes and changeable working conditions.

Abstract

Production of anhydrous ethanol in large scale has been made by extractive distillation using solvents such as ethylene-glycol or glycerol. In this work, azeotropic distillation is studied to dehydrate bioethanol using n-octane as entrainer. We use a procedure to account for risk and safety, in addition to economic evaluations, in the process design. A probabilistic methodology is applied for the evaluation of a distance likely to cause death as a risk index. The safety assessment combines a frequency and consequence analysis to calculate process total risk. The approach is applied to the design of ethanol dehydration processes, for which azeotropic and extractive distillation systems are compared. The properties of the solvents affect the inherent process safety. The comparison between the two alternatives is done in terms of individual risk, CO_2 emissions and total annual cost. The results show that the azeotropic distillation using n-octane as entrainer presents lower total energy consumption and risk compared to the purification process with extractive distillation using ethylene glycol. The product of the proposed separation scheme is a dehydrated mixture of ethanol and n-octane with 81 % mol (61% vol) ethanol, which can be used to produce gasohol.

Keywords: Safety; Anhydrous ethanol; Azeotropic distillation; Bio-ethanol

1. Introduction

Anhydrous ethanol demand has been increasing in response to environmental policies that promote the use of gasohol. Thus, bio-refineries have gained significant interest. The bioethanol production process has three main steps: pre-treatment, fermentation, and purification. Purification steps have been investigated especially because most of the energy requirements are spent at this point of the process. Ethanol and water form an azeotrope, which makes dehydration process costly, and complex configurations are needed to achieve dehydrated ethanol for fuel use. The selection of an adequate dehydration configuration requires a multi-criteria approach.

Complex distillation systems have been tested for bioethanol dehydration (Luyben, 2013). Azeotropic and extractive distillations employ a separating agent to obtain anhydrous bioethanol. Both distillation schemes require the addition of an external component to the separation process, which implies additional risk and cost. Then, this added agent plays an important role in safety and economics of the dehydration process. In this work, we analyze azeotropic distillation and we compare the results with

extractive distillation in order to select a proper configuration and entrainer considering safety, CO_2 emissions and economics.

2. Methodology and case study

After the fermentation step, ethanol is highly diluted in water, among other components. The first step of the purification process is the concentration of ethanol close to the azeotrope composition using simple distillation. After pre-concentration, a dehydration process is needed, which is the focus of this work. Extractive distillation and azeotropic distillation processes are considered.

Heterogeneous azeotropic distillation is used when there is an immiscibility zone in the ternary diagram that can be used to attain the desired separation. Then, a decanter is used for the liquid-liquid separation. Figure 1 shows the proposed azeotropic distillation flowsheet, where C0 is the preconcentrator column, C1 is the azeotropic distillation column, C2 is the entrainer recovery column and T1 is a decanter.

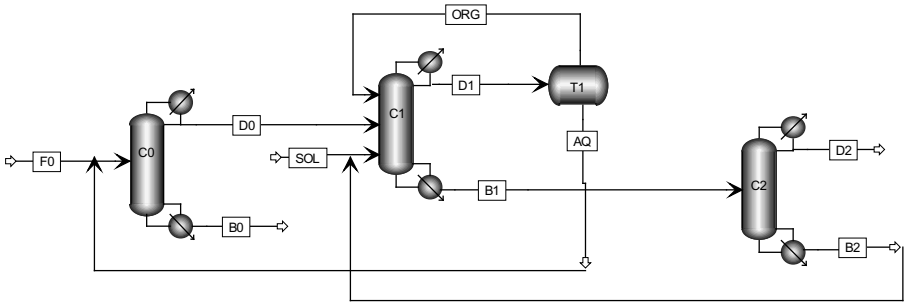

Figure 1. Azeotropic distillation flowsheet.

The dehydration processes are simulated using rigorous models with the ASPEN Plus process simulator. The feed stream for the azeotropic distillation process is 800 kmol/h with a composition of 90% mol water and 10% mol ethanol, which is a typical yield from fermentation of first generation raw materials for biofuels. UNIFAC was used as the thermodynamic model for the vapor-liquid and the liquid-liquid equilibrium. The conventional column C0 was initially designed using the Winn-Underwood-Gilliland method (DSTWU model) and manipulating the reflux ratio until a composition of about 80% mol ethanol was reached. Then, the RadFrac model was used to simulate C0 and C1. The initial design for C1 is assumed to recover the ethanol in F0, and initial guesses are needed for the composition of the organic phase recycle, which is a ternary mixture; the degrees of freedom (number of stages, reflux ratio, solvent to feed ratio, feed stages) are varied one by one aiming to minimize the energy requirements and to separate all of the water in the distillate stream. After the parameters for C1 were determined, C2 was designed applying first the DSTWU model to concentrate the ethanol-n-octane mixture to a composition near the binary azeotrope, and then the three columns with recycles were simulated with RadFrac. Once the simulation is done, risk, CO2 emissions and economic evaluations are carried out.

The methodology proposed by Medina-Herrera et al. (2014) is used to evaluate risk. This probabilistic methodology combines a frequency and consequence analysis to calculate risk. A distance likely to cause death is used as a risk index. The total annual

cost (TAC) is estimated using the Aspen Cost Estimator. A depreciation factor of 0.2 for equipment cost annualization was assumed. The utilities considered are saturated steam at $4.1x10^5$ N/m^2 ($4.7/10^6$ USD / KJ) and water with a cooling cost of 33.44 KJ/Kg (0.0251$/t). The carbon dioxide emission is reported considering the CO_2 emission factor data source US-EPA-Rule-E9 5711. The analysis provides an understanding of safety, environmental and economics behavior. This configuration is then compared with extractive distillation.

Gasohol is a mixture of gasoline and ethanol, which is used as a substitute for pure gasoline. The focus of this work is the dehydration of ethanol for its potential use in the production of gasohol. The main compound of gasoline is octane. Therefore we use n-octane as an entrainer for the azeotropic configuration. The challenge found in this ternary system (see Figure 2) is that n-octane forms azeotropes with water and ethanol. Three binary azeotropes and one ternary heterogeneous azeotrope provide three distillation regions. Therefore, if the mixture to separate is located on the upper left side of the triangle, below the azeotrope ethanol-water (D0), there are two possible regions to explore in order to get dehydrated ethanol. Operating in the top region enables the total purification of ethanol, with the disadvantage that recycle streams with high ethanol composition and relatively high flow rates are required to achieve the purification. On the other hand, operating in the right distillation region presents lower flow rates and thus low energy requirements. Even though the product is not pure ethanol, it is a dehydrated mixture of ethanol and n-octane, which can then be used for gasohol production.

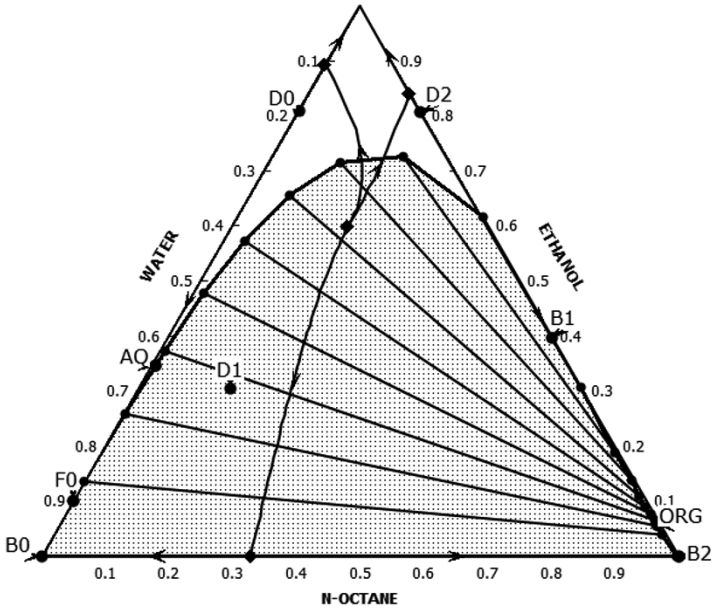

Figure 2. Ternary diagram with stream compositions (mol basis), obtained with the UNIFAC model at 1 atm.

3. Results and Discussion

The stream from the fermentation step enters the column C0 (see Figures 1 and 2) to concentrate the diluted mixture to a composition near the azeotrope composition (D0). The distillate stream is the feed to the azeotropic column C1, where the dehydration step

takes place and the top product (D1), containing mostly water, is located in the immiscibility zone of the ethanol-water-n-octane system. The product is condensed and sent to a liquid-liquid separator to obtain an n-octane rich phase (ORG) that is recirculated to the azeotropic column. The aqueous phase is recycled to the column C0 because it still contains ethanol. The bottom C1 product is an n-octane-ethanol mixture that enters the column C2 to recover the entrainer and obtain the final product, an ethanol-n-octane mixture (B2). The results of the design for the columns and mass flows are presented in Tables 1 and 2.

For risk calculations, five catastrophic scenarios are considered. There are two types of mass releases, instantaneous and continuous. In the case of an instantaneous release, the outcomes are boiling liquid expanding vapour explosion (BLEVE), unconfined vapour cloud explosion (UVCE), and flash fire due to instantaneous release (FFI). The other two scenarios correspond to a continuous release, jet fire and flash fire due to continuous release (FFC). The calculations were carried out considering only n-octane within the process. The estimated total distance likely to cause death (DD) was 0.1446371 m/y, which represents the total individual risk of the process considering the extractive and recovery columns. The corresponding risk of the five events can be seen in Figure 3 for columns C1 and C2.

Table 3 shows the distances of impact obtained for all events. Although BLEVE scenarios have the greatest distances, we can see in Figure 3 that flash fire due to a continuous release represents the worst-case scenario for both columns. This is because FFC has a higher probability of occurrence. The probability of occurrence for FFC is 2.48×10^{-4}/y in contrast to the BLEVE probability of occurrence of 5.75×10^{-6}/y, a difference of two orders of magnitude.

As mentioned above, the approach is based on a multi-criteria analysis. Therefore, Table 4 shows the cost of dehydrating the product, with a flow of 800 kmol/h and a composition of 90% mol water. The total purification cost is 0.0752 US$/kg ethanol. Carbon dioxide emissions were estimated assuming crude oil as fuel. The value reported in Table 4 shows CO_2 emissions of 0.007639 Kg/s per kmol of ethanol dehydrated.

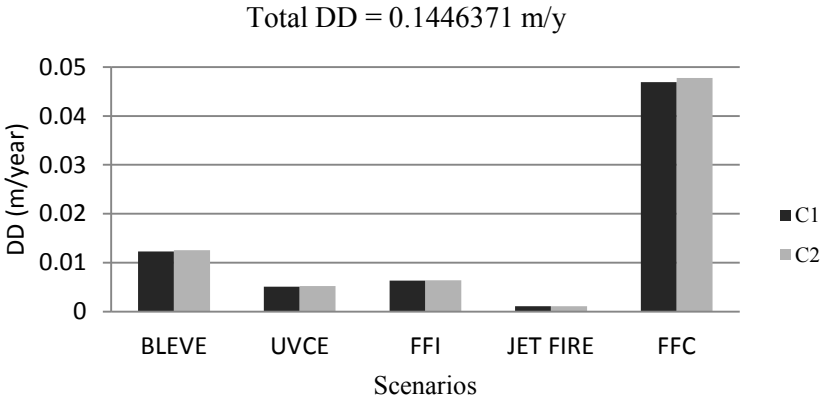

Figure 3. Total distance likely to cause death for the azeotropic distillation scheme.

Equipment	1,116,920.00
Utilities	1,309,450.00
Total Annual Cost	2,426,370.00
CO_2 Emissions	2200 Kg/hr

In order to compare the results with the extractive distillation process to dehydrate bioethanol, we considered the works reported by Avilés-Martinez et al. (2012) and Medina-Herrera et al. (2014), in which extractive distillation was used to obtain anhydrous bioethanol. Using the same ethanol production rate as in this work, Medina-Herrera et al. (2014) minimized the total individual risk in the extractive column and in the ethylene-glycol recovery column, and reported a distance likely to cause death of 0.2052 m/y, which is higher than the result obtained here of 0.1446 m/y. In the work by Avilés-Martinez et al. (2012), glycerol was considered as entrainer. Based on the design parameters reported in their work, we simulated their extractive distillation process for the diluted water-ethanol mixture considered here. The results include a higher TAC of 3,148,340 US$/y, equivalent to 0.0996 US$/kg ethanol, and a total heat duty of 0.010931 GJ/kg-ethanol. The CO_2 emissions were estimated at 3096.23 kg/h, equivalent to 0.011 Kg/s for every kmol of ethanol purified. Figure 4 summarizes the results obtained for the economic, safety, energy and environmental terms analyzed for the

separation schemes; it can be observed that all of these factors favor the use of azeotropic distillation over extractive distillation for the case study considered here.

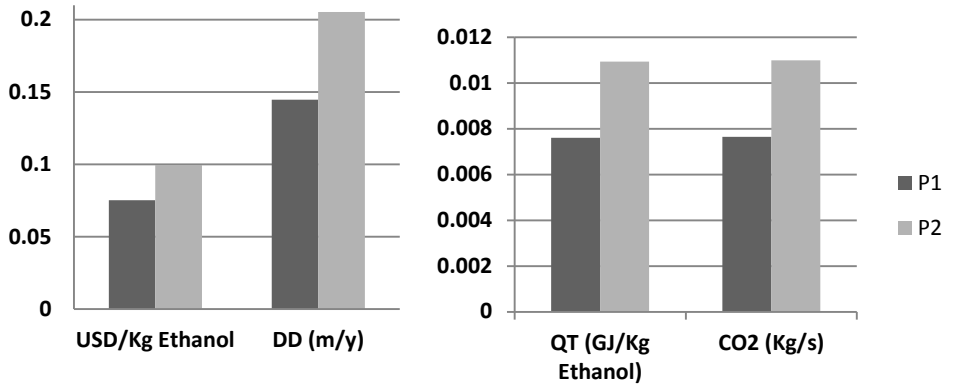

Figure 4. Comparison of total cost, total distances likely to cause death, energy requirements and CO_2 emissions for the azeotropic (P1) and extractive distillation (P2) processes.

4. Conclusions

Two alternatives for the ethanol dehydration process have been considered. The results for the azeotropic distillation option suggest that n-octane is a promising entrainer. Although the product is not highly purified ethanol, the product blend of ethanol and n-octane is dehydrated (with composition near the binary azeotrope of 84% mol of ethanol), which can then be mixed directly with gasoline to produce gasohol. The comparison between extractive and heterogeneous azeotropic distillation has shown that the latter is a promising alternative to the conventional extractive distillation scheme in terms of both safety and economics. Both processes, however, are suitable for dehydration of ethanol because the energy requirements are lower than the ethanol heat of combustion.

Abstract

In this work, a multi-objective mixed integer linear programming (moMILP) model is presented for the design and planning of sustainable closed loop supply chains. It includes strategic decisions such as facility location, definition of transportation modes, technology selection and allocation, as well as tactical decisions. The model includes four objectives: 1) The economic pillar, measured through the net present value (NPV); 2) the environmental pillar, which includes Life Cycle Assessment (LCA), through the application of the ReCiPe methodology; 3 and 4) The social pillar measured using two socio-economic indicators applied by the European Union in its Sustainable Development Strategy. The applicability of the model is demonstrated through a representative supply chain case study. Results show that the different objectives influence the supply chain structure and translate in significantly different and conflicting decisions, showing the importance of such type of models to better understand the decisions implications on the different dimensions of sustainability.

Keywords: sustainable supply chain, environmental impact, socio-economic indicators

1. Introduction

The growing pressure from both customers and governments towards sustainable development is redirecting strategies focused on profit to strategies that account for the triple bottom line, where profit, planet and people are considered (Bojarski et al., 2009). However, the complexity inherent to the integration of such decisions has been delaying the growth in both research and implementation of sustainable development practices. A number of different and interdependent factors are involved and have an impact on the economic, environmental and social performances of the supply chains, resulting in highly complex models. Facility location decisions for instance directly influence the costs and environmental impact of transportation, which is often the activity responsible for the major share of both costs and environmental impact within supply chains. However, these decisions also have an impact on the community where facilities are located. Decisions such as transportation policy also have an impact on the three pillars of sustainability. Depending on the transportation mode selected, costs may be higher but compensated by a lower environmental impact or additional job creation. There is also the possibility of selecting either unimodal transportation, in which a single transportation mode is used to distribute the product to its final destination, or intermodal transportation, where the product is carried by a combination of at least two transport modes (e.g. road, rail, sea, air). Another decision variable of significant impact is the technology selection as different technologies might have different operating costs, may use different quantities of raw materials or even different raw materials,

which may result in different environmental impacts, and may require a different workforce. Closing the loop by recovering end-of-life products opens an even more complex path that needs to be carefully designed and planned so as to actually translate a more sustainable supply chain. In addition is the difficulty in quantitatively measuring environmental and social impacts, where a significant research gap is found (Mota et al., 2014). Hence, decision support tools that adequately address such complex problems, both at a strategic and tactical level, are required to help companies adjust to these current and growing sustainability pressures. This work aims to be a step forward in this direction by presenting a model for the design and planning of closed loop supply chains, which introduces the discussed decision variables and incorporates the three pillars of sustainability.

2. Problem definition and mathematical formulation

The proposed model aims at determining the supply chain structure, transportation network, and technology allocation, along with planning decisions (supply and product recovery) that maximize profit, minimize environmental impact and maximize the social benefit of a closed loop supply chain. The modelled supply chain structure is the one depicted in Figure 1, which shows a four-echelon structure where suppliers send the raw materials to the factories, the factories transform them into final products and then send these products to other factories, to distribution centres or directly to the clients. End-of-life products are then recovered at the clients and can be sent back to the distribution centres or directly to the factories. Transhipment is also allowed between distribution centres. In the factories the end-of-life products are remanufactured and sold as final products. Transportation between all facilities can be performed using only one transportation mode (unimodal transportation) or using intermodal transportation. In this latter case a new entity is installed, a hub terminal, where the transfer of cargo from one transportation mode to the other is performed.

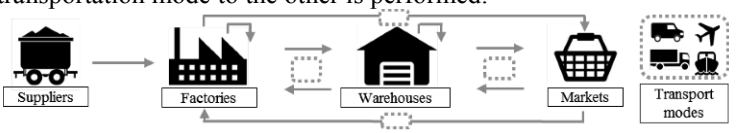

Figure 1. Modelled supply chain structure.

The problem is modelled through a moMILP formulation, evolving from the work presented by Mota et al. (2013, 2014) in three ways. Firstly it moves from a 3-echelon to a 4-echelon structure that includes suppliers. Secondly it incorporates technology selection and allocation decisions as well as transportation network definition, to which an intermodal transportation option is added. Thirdly the social impact indicator is redesigned to consider Gross Domestic Product (GDP) and unemployment rate as socio-economic indicators. The economic objective function is obtained from the maximization of the NPV as described in Cardoso et al. (2013). The net earnings (*NEt*) are given by the difference between the incomes, defined by the amount of products sold, and the costs per time period (Eq. (1)). The costs include:

- raw material costs (first term, where X_{maijt} is the flow of product *m* through transportation mode *a* between entities *i* and *j* in time period *t*);
- production costs (second term, where Ψ_{mgit} is the amount of product *m* produced through technology *g* in entity *i* in time period *t*);
- product recovery (third term) and remanufacturing costs (fourth term, where Φ_{mgit} is the amount of product *m* remanufactured through technology *g* in entity *i* in time period *t*);

- transportation costs for air (fifth term) and for road transportation (sixth term, where Q_{aijt} is the number of trips with transportation mode *a* between entities *i* and *j* in time period *t*), and handling costs at the hub terminal (seventh term);
- inventory costs (eighth term, where S_{mit} is the inventory of product *m* in entity *i* in time period *t*; and
- labour costs at entities (ninth term, where Y_i is a binary variable for entity installation in location *i*), at production and remanufacturing technologies (tenth term, where Z_{gmi} is a binary variable for technology allocation) and at transportation (eleventh term, where K_{aij} is a binary variable for transportation link establishment).

The last term describes the depreciation of the capital invested (*DPt*) with *tr* being the tax rate.

$$
\begin{aligned}
NE_t = (1-tr)\Bigg[& \sum_{m,i,j:(m,i,j)\in F_{INCFP}} psu_m \sum_a X_{maijt} \\
& - \Bigg(\sum_{m,i,j:(m,i,j)\in F_{OUTSUPRM}} rmc_m \sum_{a\in A} X_{maijt} \\
& + \sum_{m,g,i:(m,g)\in G_{PROD}\wedge i\in I_f} opc_g \Psi_{mgit} \\
& + \sum_{m,i,j:(m,i,j)\in F_{OUTCRP}} rpc_m \sum_{a\in A} X_{maijt} \\
& + \sum_{m,g,i:(m,g)\in G_{REM}\wedge i\in I_f} opc_g \Phi_{mgit} \\
& + \sum_{a,m,i,j:(a,m,i,j)\in NetP\wedge a\in A_{plane}} tc_a . pw_m . d_{ij} . X_{maijt} \\
& + \sum_{a,m,i,j:(a,m,i,j)\in NetP\wedge a\in A_{truck}} vtc_a . d_{ij} . Q_{aijt} \\
& + \sum_{a,m,i,j:(a,m,i,j)\in NetP\wedge a\in A_{plane}} hhc . X_{maijt} + \sum_{m,i:(m,i)\in V} sc_m . S_{mit} \\
& + \sum_{i\in I_f \cup I_w \cup I_{air}} w_i . lc_i . mwh . Y_i \\
& + \sum_{m,g,i:(m,g)\in G_{PROD}\cup G_{REM}} w_g . lc_i . mwh . \mathrm{Z}_{gmi} \\
& + \sum_{a,i,j:(a,i,j)\in Net} w_{aij} . lc_i . mwh . K_{aij} \Bigg) \Bigg] + tr . DP_t
\end{aligned}
\tag{1}
$$

The fixed capital investment (FCI) is defined in Eq. (2) and is given by the investment in facilities (first and last term), investment in production and remanufacturing technologies (second term) and investment in transportation links (third term).

$$FCI = \sum_{i \in I_f \cup I_w} ec_i . Y_i + \sum_{m,g,i:(m,g) \in G_{PROD} \cup G_{REM} \wedge I_f} tec_g . \mathrm{Z}_{gmi} + \sum_{a,i,j:a \in A_{truck} \wedge (a,i,j) \in Net} ftc_a . \frac{\mathrm{K}_{aij}}{2} + \sum_{i \in I_{air}} hub_i \, Y_i \quad (2)$$

The environmental objective function is modelled using the ReCiPe methodology as described in Mota et al. (2014). For each midpoint category c the environmental impact of production (first term), transportation (second term) and entity installation (third term) is determined, summed and normalized as shown in Eq. (3).

$$\min EnvImpact = \sum_{c} (\sum_{t \in T} \sum_{m,g,i:(m,g) \in G_{PROD} \cup G_{REM} \wedge I_f} I_{mgc} (\Psi_{mgit} + \Phi_{mgit}) + \sum_{t \in T} \sum_{a,m,i,j:(a,m,i,j) \in NetP} I_{ac} pw_m d_{ij} X_{maijt} + \sum_{i \in I_f \cup I_w} I_{ic} a_i Y_i) \eta_c \quad (3)$$

The social objective function is designed taking into account socio-economic indicators applied by the European Union to its Sustainable Development Strategy, namely GDP and the unemployment rate of each country. These two indicators are applied through μ_i, a regional factor. Hence, two social objective functions are in fact given. One where μ_i results from GDP statistics and the other where the regional factor results from unemployment rate statistics. In this way the models prefers the location of entities (first term), the allocation of technologies (second term) and the establishment of transportation links (third term) in regions of higher unemployment rate or of lower GDP, according to the selected regional factor. Additionally these social objective functions are designed to balance these regional indicators with the maximization of the number of jobs created ($w_i / w_g / w_{aij}$), as shown in Eq. (4).

$$\min SocialAssess = \sum_{i \in I_f \cup I_w \cup I_{air}} \mu_i \frac{Y_i}{w_i} + \sum_{m,g,i:(m,g) \in G_{PROD} \cup G_{REM} \wedge i \in I_f} \mu_i \frac{Z_{gmi}}{w_g} + \sum_{a,i,j:(a,i,j) \in Net} \mu_i \frac{K_{aij}}{w_{aij}} \quad (4)$$

The constraints account for the mass balances, supply capacity, flows of products at entities, inventory levels, production, remanufacturing and transportation capacities.

3. Case-study

The model was applied to a European case-study where decisions regarding facility location, technology selection and allocation, product recovery and transportation modes/network establishment are to be taken, so as to satisfy the demand. Model inputs include:

- Entities: The suppliers location is set in the United Kingdom and Italy, the same two possible locations are available for factories. Seven possible locations exist for warehouses: United Kingdom (UK), Italy (IT), Spain (ES), Germany (DE), Portugal (PT), Hungary (HU) and Bulgaria (BG). All locations are characterized in terms of their socio-economic indicators: GDP and Unemployment rate.

- Markets: The target markets are located in Portugal, Spain, Italy, the United Kingdom and Germany, as shown in Figure 2.
- Products and technologies: Two final products are modelled. Each can be obtained through production or remanufacturing. For product 1 (P1) there are two alternative production technologies and one for remanufacturing. For product 2 (P2) there is one production and one remanufacturing technologies. All technologies are characterized in terms of cost, capacity, environmental impact and workers.
- Product recovery: a minimum product recovery of end-of-life products is imposed per time period.
- Transportation: There are three transportation modes available, two types of trucks and one by airplane. All modes are characterized by different costs, capacities, environmental impact and number of workers. Three airports for intermodal transportation can be used, one in France, one in Spain and one in Belgium. In case a hub terminal is installed, it is also characterized in terms of economic, environmental and social performance.

Figure 2. Superstructure considered for the case-study.

4. Results and discussion

Table 1 summarizes results obtained when considering different sustainability pillars.

Table 1. Summary of results considering the different sustainability pillars.

	Sustainability pillar			
	Economic	**Environmental**	**Social (GDP)**	**Social (Unemployment)**
Entity location	Factories: UK, IT Warehouses: HU, BG	Factories: UK, IT Warehouses: UK, PT	Factories: UK, IT Warehouses: HU, BG	Factories: UK, IT Warehouses: ES, PT
Technology selection and allocation	Only one production technology for product 1	Only one production technology for product 1	Combination of both production technologies for product 1	Combination of both production technologies for product 1
Product recovery and remanufacturing	Minimum imposed	Maximum allowed	In-between limits	In-between limits
Transportation network	Unimodal + Combination of two types of trucks	Intermodal with three airports + Combination of two types of trucks	Unimodal + Combination of two types of trucks	Unimodal + Combination of two types of trucks

When maximizing profit the model installs two factories in the UK and Italy, and two warehouses in Hungary and Bulgaria. This solution minimizes the costs with human resources, which is the largest contributor to this supply chain total cost, by selecting the countries with the lowest hourly labour costs and reducing the number of established transportation links. This implies increasing the number of trips and the labour intensity for truck drivers (even though a maximum is respected). The technology chosen for production of P1 is the one that even though having higher installation costs, has a higher production capacity and lower operating costs. Product recovery is minimized since it is less expensive to produce from raw materials than from recovered products.

Unimodal transportation is selected and a combination of the two types of trucks is used, according to the corresponding capacities.
When minimizing environmental impact the same factories as before are installed but the two warehouses are now installed in the UK and in Portugal. Product recovery and remanufacturing are maximized since the environmental impact of remanufacturing is lower than that of production, even with the necessary increase in transportation. Intermodal transportation is implemented in this case with all the three available airports given the lower environmental impact of air transport. These options translate in a 40% profit reduction.
When optimizing for social performance the structure obtained considering GDP is different from the one obtained considering unemployment rate. In the first case the structure is identical to the one obtained for profit maximization since the countries are the ones with the lowest GDP. In the latter case the warehouses are opened in Spain and Portugal, the countries with the highest unemployment rate, contributing to the decrease in profit by 50%. However, in both cases a combination of both production technologies is used for P1, product recovery is between the imposed limits and unimodal transportation is preferred. A smaller number of workers is obtained in either of these solutions when compared to the number of workers obtained when minimizing environmental impact. This indicates that these social indicators attribute a higher importance to the regional factor than to the number of jobs created. Does more social benefit arise from the creation of jobs in socio-economically challenged regions or from the maximization of job creation throughout the supply chain? This type of questions evidence the importance of such models to better understand the implications of the decisions on different dimensions of sustainability.

5. Conclusions and future work

The presented work proposes a decision support tool to study how sustainability can be introduced in supply chain design and planning. The model allows to understand the impact of decisions such as facility location, technology selection and allocation, and transportation modes choices, on the three pillars of sustainability. Through the model application to a European case-study results show how the different indicators return conflicting solutions. Future work will include the determination of the Pareto front through the augmented ε-constraint method, allowing to address the trade-offs inherent to these conflicting objectives. Further case-studies will also contribute to a better understanding of the implications of the proposed environmental and social indicators.

Abstract

Pipelines play an important role in the oil supply chain linking different supply chain echelons and acting as one of the most sustainable, safe economical transportation mode. In this context, multiproduct pipeline scheduling is a key issue to be addressed in an optimized form, namely when integrating pipeline operation with the operations of the connected entities. In this paper a MILP discrete time formulation is developed for multiproduct distribution scheduling linking both sides of the pipeline, refinery and distribution centre, so as to generate the best product pumping sequence accounting for material availability at the refinery blending process and delivery needs at the distribution centre. The model was applied to a case based on a real world oil supply chain.

Keywords: oil industry, scheduling, multiproduct pipeline, activities integration, MILP.

1. Introduction

Typically, downstream distribution in the oil industry can be accomplished via road, railway and pipelines. Pipelines are widely used since they may connect several refineries, depots and terminals transporting crude oil as well as final products in large quantities for long distances in a more sustainable form. The pipeline operator must decide what products and what quantities should be pumped, operational timing range, and how to distribute all products among several destinations (Rejowski and Pinto, 2008). Additionally, this problem often presents some restrictive requirements associated with the pipeline operational conditions such as reverse operation, pumping rate limits, inventory levels, interfaces and lot sizes. All these aspects taken simultaneously make this operation quite complex and decision support tools to help the solution of such complexity are required. Therefore, according to MirHassani, Abbasi and Moradi (2013), distribution scheduling arises as a modeling tool that should be able to determine the transport details and the best way to fulfill several demands at the right time.

Several works may be found in the literature addressing pipeline scheduling integrated with either up or downstream operations. Rejowski and Pinto (2004) presented a discrete MILP problem composed by a refinery, pipeline and depots considering

intermittent pumping time and logical constraints, adding a set of integer cuts and special interface constraint that resulted in better solutions. The same problem was later improved by the same authors (Rejowski and Pinto, 2008) to develop a MINLP continuous time formulation with pumping cost dependent on booster stations yield rate. Magatão et al. (2012) developed a hierarchical decomposition to solve a planning and assignment\sequencing pipeline network model composed by refineries, harbors, depots and clients applied to a real scenario. More recently, Ghaffari-Hadigheh and Mostafaei (2014) proposed a model which provides input and output pipeline sequences to satisfy different terminals simultaneously with minimum operating costs.

Pipeline scheduling alone has derived over the last years an intense field for publication, consisting in a complex scheduling problem. These complexities are related with the need to model time and volume decisions efficiently and additionally build flexible models aiming to address multiple i) topologies, ii) products iii) operational and cost issues so as to represent any pipeline-based system. Recent works on the area include the work of Cafaro et al. (2015), where pumping costs are detailed, MirHassani and BeheshtiAsl (2013), who use heuristic procedures as solution method for pipeline scheduling and Relvas et al. (2013) where inventory management at destination depots is tackled along with pipeline scheduling.

From the literature review it can be seen that the integration of pipeline scheduling with operations in input and output entities is not widely studied, given the complexity of integrating the pipeline scheduling problem with additional decisions in different echelons. The purpose of this work is to address this problem and to integrate information on product availability at both sides of the multiproduct pipeline (blending and distribution centre) so as to produce an optimal product sequence with minimum operational costs while guaranteeing service levels. The inventory management at the blending and distribution centre is integrated with the pipeline pumping sequence.

2. Problem description

The system considers a single unidirectional multiproduct pipeline that connects a product tank farm at the refinery, blending section, and a distribution centre that has to satisfy the local market, as illustrated in Figure 1. Three different products (gasoline, diesel and jet fuel) are produced and stored at the refinery and transported through a multiproduct pipeline to a distribution centre and to storage tanks with fixed service. When a batch of product arrives at the distribution centre a settling period is required due to regulatory quality assessments.

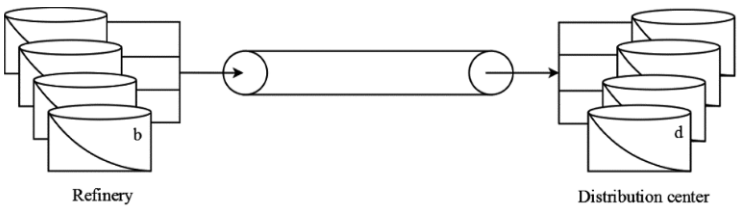

Figure 1 - Schematic system.

Given:

- The scheduling horizon;
- The inventory limits (minimum/maximum storage capacities);
- Initial volume available at each tank and pipeline;
- The feeding flow rate from the refinery blending;
- The pipeline volumetric capacity and batch size limits;
- The minimum settling period;
- The matrix of possible/forbidden products sequence;
- The daily demand;

The goal is to determine the products sequence pumped into the pipeline, which satisfy the demand while controlling the inventory tanks at the refinery blending centre and distribution centre.

3. The mathematical formulation

A discrete time Mixed Integer Linear Programming (MILP) model is formulated which is an extension of the previous work developed by Relvas et al. (2013). This extension links the previous developed model to the blending tank farm where inventory management is also performed. The main assumptions for this problem are:

1. There is a set of dedicated tanks teach product at refinery and distribution centre;
2. A tank at the refinery is not allowed to load and unload simultaneously;
3. The pipeline should be full at any time;
4. At most one tank can be connected to the pipeline at any time;
5. Changeovers time from one tank to another are disregarded;
6. Not all products sequences are allowed in the pipeline;
7. Settling periods are accounted for at the destination depot, making unavailable the settling product for dispatching to local market;
8. The flowrate is assumed to be variable within an acceptable operational range.

This operation is controlled by several constraints that are summarized as follows:

1) Material balance –to determine that the amount of products available in each tank;
2) Timing – to define the initial and final pumping and receiving time of each batch;
3) Inventory control – the minimum and maximum storage tanks limits;
4) Operating rules –referred to allocation constraints;
5) Forbidden sequences – the contact between some products inside the pipeline is prohibited;
6) Demand – to satisfy the local market demand values on time;
7) Batch limits – the volumes pumped should be bounded by the pipeline capacity;
8) Initial conditions –inform on the initial products at each tank and inside the pipeline;

Due to space limitations, we will only present the timing constraints and the objective function. Timing constraints are responsible for connecting the blending to the distribution centre, given the pipeline operation, using a reduced amount of problem information.

3.1 Timing constraints

These constraints are used to synchronize the operations between refinery, pipeline and distribution centre since these operations are continuous. Then, when a tank b start to feed a pipeline with product p simultaneously a tank d begins to receive a product already pumped at previous time. In this way, at the distribution centre the receiving time for batch i (TDS_i) is determined based on the previous receiving time plus the time required to unload the product from the pipeline, as expressed in constraint (1).Similarly, at the refinery the pumping time for batch i (TBS_i) depends on the

transportation time to the distribution centre and the receiving time at the distribution centre, as shown in constraint (2). Both timings are calculated within an interval given by minimum and maximum pipeline flow rate.

$$TDS_{i-1} + \left(\frac{1}{v_{max}}\right) * \sum_{d \in D_p} \sum_{p} \sum_{k} W_{d,i,p,k} \leq TDS_i \leq TDS_{i-1} + \left(\frac{1}{v_{min}}\right) * \sum_{d \in D_p} \sum_{p} \sum_{k} W_{d,i,p,k} \quad \forall\, i \tag{1}$$

$$\frac{pipe}{v_{max}} * \sum_{b \in B_p} \sum_{p} \sum_{k} XR_{b,i,p,k} - TDS_i \leq TBS_i \leq \frac{pipe}{v_{min}} * \sum_{b \in B_p} \sum_{p} \sum_{k} XR_{b,i,p,k} - TDS_i \quad \forall\, i \tag{2}$$

Where v_{min}/v_{max} are the minimum/maximum pipeline flowrate, *pipe* is the pipeline volume, $W_{d,i,p,k}$ is the volume of batch *i* with product *p* received in tank *d* at time *k* and $XR_{b,i,p,k}$ a binary variable that indicates if a batch *i* with product *p* is unloading from tank *b* to pipeline at time *k*.

3.2 Objective Function

The objective function is based in operational indicators and is composed by four terms. The first one corresponds to the difference between the total amount received at the distribution center and the total demand. The second term is used to maximize the pipeline usage so as to avoid stoppages/idle times. The third and last terms represent the lowest inventory level at refinery blending and distribution centre, respectively.

$$\min \; w_1 * \frac{dif}{\sum_p \sum_k Dem_{p,k}} - w_2 * \frac{TDS_{|I|}}{h^{max}} - w_3 * minid - w_4 * minib \tag{5}$$

$$minib \leq \frac{InvR_{b,p,|K|}}{InvR_{b,p}^{max}} \quad \text{and} \quad minid \leq \frac{InvT_{d,p,|K|}}{Inv_{d,p}^{max}} \tag{6}$$

Where $InvR_{b,p,|K|}$ and $InvT_{d,p,|K|}$ are the inventory of each tank at end of the time horizon as well as their maximum limits, *dif* is the difference between the volume arrived at the tank at the distribution centre and the volume sent to clients, $Dem_{p,k}$ is the demand of each product *p* at time *k*, h^{max} is the time horizon and w_1-$w_4$are weights for each of the normalized objective function terms.

4. Results and discussion

Having presented the problem at hand, an example to illustrate the model applicability was built based on data reported by Rejowski and Pinto (2008). The input data are detailed in Table 1 regarding inventory limits and initial conditions for each tank. Note that there are two equal tanks for each product at the refinery, since a tank cannot load and unload simultaneously. The product demands for each day for all products are:

Gasoline=2000m^3, Jet Fuel=2500m^3 and Diesel=6500m^3.The pipeline capacity is 18000 m^3 and pipeline flowrate range is 450-650 m^3/h. A time horizon of 7 days was considered.

Table 1 - Input data.

	Max – Min capacities (m^3)		Initial Inventory (m^3)	
Product	Refinery	Distribution centre	Refinery	Distribution centre
Jet Fuel (A1)	100,000-15,000	14,000-3000	31,500	9000
Diesel (GO)	250,000-40,000	40,000-3000	105,000	10,000
Gasoline (U8)	225,000-40000	19,000-5000	100,000	10,000

The model was implemented using GAMS 23.7.3 system version with CPLEX solver on an Intel(R) Core(TM) i7 platform with 6GB of RAM. The model contains 1614 continuous variables, 1008 binary variables and 1547 constraints. The objective function value obtained was -3.4781after 1.061CPU seconds with a gap of 0.0 %.
The model solution provides the inventory management in both centres as well as the pipeline scheduling that are shown in Figures 2 and 3, respectively.

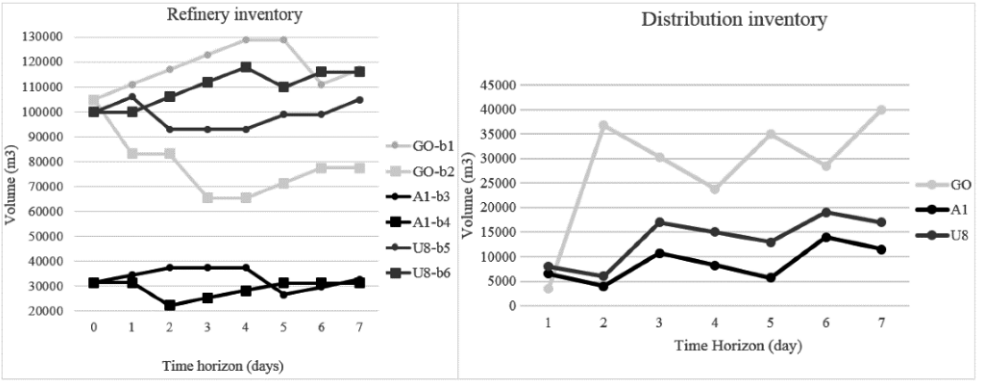

Figure 2 - Inventory at the refinery (left) and distribution centre (right)

Refinery Tank	i=1	i=2	i=3	i=4	i=5	i=6	i=7	
TBSi	0.24	1.08	1.67	2.74	4.01	4.69	5.84	
Day	1	2		3	5		6	7
Distribution tank	pipe	i=1	i=2	i=3	i=4	i=5	i=6	i=7
TDSi		1.39	2.23	2.82	4.41	5.15	5.84	7.0
Day	1	2	3		5	6		7
		GO		A1		U8		

Figure 3 - Pipeline sequence (input/output of the pipeline).

It can be seen in Figure 2 that the first product delivered from the refinery at the beginning (k = 0) is diesel followed by gasoline and jet fuel (when analysing the slopes). When we look to the distribution centre, it is observed that during the day 1diesel volume is increasing, this corresponding to the volume received from the initial pipeline volume and the volume sent by refinery. This is similar for all products and it demonstrates the synchronization operations. All pumping sequences can be seen through Figure 3. In this figure is shown in different colours the product sequence and the transference time due to the pipeline operation. The time variables values, TBS and TDS, represent the exact moment that the last "volume" of batch *i* finished its' pumping or receiving. It is important to note that some products, e.g. in batches 2 and 3, are sent

at the same day but not at the same time. The constraints which do not allow simultaneous products dispatch as well as loading and unloading simultaneous tanks operations are both satisfied, translated into positive or negative slopes. Additionally, between days 3 and 4 the refinery tanks are loading or stopped and, consequently, there is no pipeline operation and the distribution tanks are just delivering the products.

5. Conclusions

This work has presented a model that integrates storage tanks at the refinery blending centre and distribution centre. The scheduling model is capable to coordinate pipeline and the tanks operation at the refinery and distribution centre, while guarantee the demand. Settling periods are considered so as to ensure product quality prior to market delivery. A scenario based on real world data was built to test the model feasibility. This problem allowed testing the model performance even when both pipeline ends are modelled and require having a careful operation with some restrictions. As future work, the model has to be extended in order to include more real world problem features such has blending procedures at the refinery integrated with the market demand, intermediate pipeline inputs/outputs, operational rules at the distribution centre as well as longer time horizons, so as to improve the integration of operations that have different timings along the distribution network.

Abstract

The techno-economic potential for new technologies in pulp mills is conventionally studied assuming annual averages, based on the assumption that the pulp mill is continuously operated at a constant production rate close to its design capacity. Recent work has shown, however, that a technology, such as lignin extraction, which can improve the operating flexibility of the pulp mill utility system, has a value associated with its flexibility that is not captured in such average-value models. These previous results indicated a risk of significant errors if heat load variations were not properly modelled. This paper presents a multi-period optimization model for the planning of design and operating decisions connected to pulp mill utility systems, which in this work has been extended with back-pressure and condensing turbine models. The model optimizes technology selection, equipment capacities and operating loads under the influence of demand variations, considering part-load efficiencies and operating load limits. Application of the model to an illustrative example showed that lignin extraction can compete with electricity production already at a lignin price of 22 €/MWh in the presence of variations due to poor off-design performance for the turbines. This demonstrates the usefulness of the proposed modelling approach.

Keywords: multi-period, utility system, pulp mill, lignin extraction, steam turbine.

1. Introduction

The pulping process is typically continuous and designed for maximization of quality and throughput of one core product. The operational objective is to maintain the production as close to the design capacity as possible. Consequently, pulp mill energy systems are traditionally modelled using annual averages representing values close to design conditions. However, changes in wood, pulp and energy market conditions motivate a shift towards producing a larger variety of products including traditional pulp mill energy by-products such as electricity and heat, and emerging lignocellulosic biorefinery products such as different kinds of materials and chemicals (Moshkelani et al., 2013). The transition from the traditional pulp mill towards a biorefinery concept will connect the pulp mills to an increased number of external markets. Also for the traditional by-products of heat and electricity, an increased implementation and production rate can be expected when energy prices rise. Pulp mills that are connected to district heating systems, which is common in Scandinavia today, can be strongly affected by large variations in heat demand over the day and over the year. In a typical Nordic district heating grid with an average heat load of about 130 MW, the winter peak load can be over 300 MW while the summer minimum load is about 30 MW (Gadd and Werner, 2013). In combination with the opportunities connected to the diversified product portfolio of a pulp mill biorefinery, there is no lack of incentives for better modelling of variations in investment analyses connected to pulp mill utility systems.

Methodologies for the design optimization of utility systems with varying demands need to simultaneously consider both design and operational decisions. Most published methods rely on a multi-period, mixed-integer linear programming (MILP) formulation. For example, Marechal and Kalitventzeff (2003) optimized the synthesis and operation of the utility system using a multi-period MILP model, after having used a genetic algorithm to identify the minimum number of operating periods needed in the model. During the last decade, the focus has primarily been directed towards the modelling of energy equipment performance. Varbanov et al. (2004) proposed improved models for steam and gas turbines in part-load operation. Shang and Kokossis (2005) considered the performance of turbines and boilers to depend on size, load and operating conditions in their approach, in which they rely on thermodynamic targeting to achieve a reasonably sized MILP formulation. Aguilar et al. (2007) also considered part-load operations and varying energy demands and obtain linearity by starting from the development of linear models for boilers and turbines. Recent advances also include the modelling of variations in steam header properties, either as predetermined parameters (Aguilar et al., 2007) or as variables to be optimized (Chen and Lin, 2011).

The present work suggests a multi-period approach for the specific application to a chemical pulp mill retrofit. The aim is to illustrate the potential advantage and importance of applying this kind of methodology also in an industrial sector such as the pulp and paper industry that traditionally has been served well by simpler approaches. In addition to boilers and turbine, the model proposed in this paper includes the option to invest in lignin separation, an emerging technology for the pulping industry. Previous work has shown that lignin extraction may provide a great opportunity for indirectly increasing the flexibility of the pulp mill utility production in response to demand variations (Svensson, 2014). However, the previous study did not consider competing technologies, such as condensing power generation, which may have similar advantages. The aim of the present work is to extend the previous model with turbine models and investigate to what extent the lignin extraction can compete with the alternative of electricity generation.

2. Studied pulp mill

An overview of the utility system of the pulp mill is shown in Figure 1. The main steam producer is the recovery boiler for which the load is determined by the demand for recovering chemicals from the black liquor, which in turn is set by the pulp production rate. Variations in steam demand are therefore normally controlled by varying the steam production in a supplementary boiler, typically fired with bark. However, for typical market Kraft pulp mills, the steam production from the recovery boiler alone is sufficient for covering the steam demand under most operating conditions. Under such conditions, which can occur during long periods of the year, excess steam will be vented to atmosphere. There are, however, opportunities to reduce the steam production also in the recovery boiler. This can be achieved by extracting lignin from the black liquor in the evaporation plant, thereby reducing the heating value of the black liquor fired in the recovery boiler. During periods of excess steam production, electric power production in a condensing turbine can be an alternative to lignin extraction.

The studied mill is connected to a district heating network. The heat-load variation curve used for the pulp mill has been constructed to represent the typical steam demand of a mill that is the dominant heat supplier in a district heating network (see Figure 2).

The average heat load is approximately the same as in the mill studied by Persson and Berntsson (2009) and the relation between maximum and minimum district heating demand is approximately the same as for a typical medium-sized district heating system as defined by Jönsson et al. (2008). The few days with top-load demand are, however, assumed to be covered by alternative heat supply. The combined heat demand of the mill and district heating system create a demand for the bark boiler. Because of the minimum load limit on the bark boiler and the constant load in the recovery boiler, there will be a steam excess during parts of the year, but the amount is fairly small. However, without any investments to enable reduced steam production or to make use of a potential steam excess, there are few incentives for steam demand savings in this mill, since this would mainly lead to increased steam venting.

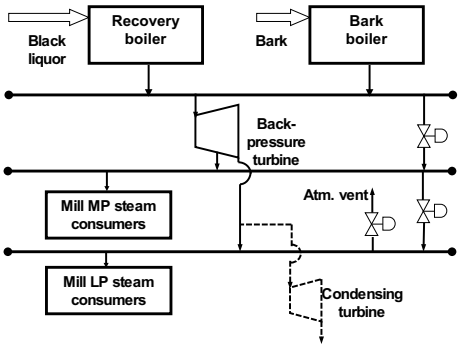

Figure 1. Utility system at a chemical market pulp mill (cond. turbine = investment option).

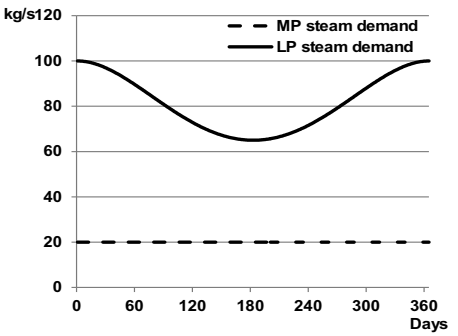

Figure 2. Current steam demand of the pulp mill (incl. district heating).

3. Optimization model

The MILP model is used to identify the optimal steam production and turbine operation at the pulp mill, typically as a response to a steam savings retrofit. The steam header data for high-pressure (HP), medium-pressure (MP) and low-pressure (LP) steam are pre-determined. Potential costs or difficulties associated with daily variations in the operation of the studied processes and steam production units are neglected (see discussion in Svensson, 2014). For the boilers, part-load operation is represented by the use of marginal efficiencies that are estimated to be valid as long as the boiler load is kept above the minimum load limits set in the model. Finally, part-load efficiency effects of the lignin extraction plant are assumed to be negligible.

The objective of the optimization is to minimize the net annual investment cost and the bark costs, and maximize the revenues from lignin exports and electricity production:

$$\text{Minimize} \quad InvCost + BarkCost - LigRev - ElecRev \tag{1}$$

The investment costs $InvCost$ for the lignin extraction plant (Lig) and the condensing turbine (CT) are annualized by the annuity factor r (Eq.2). The cost function $Cost_x(Y_x)$ for investment in technology x is expressed by a piecewise linear function of the capacity, Y_x, of the technology (Eq.3). $C_{inv,x}(i)$ is the investment cost at the breakpoints, $bp_x(i)$, between the segments of the piecewise function and $k_x(i)$ is the linear slope between $bp_x(i)$ and $bp_x(i+1)$. The binary variable z_x is 1 if investment is made in technology x, and 0 otherwise. Eq.(4) represents the valid linearization range.

$$InvCost = \mathrm{r}\big(Cost_{\mathrm{LIG}}(Y_{\mathrm{LIG}}) + Cost_{\mathrm{CT}}(Y_{\mathrm{CT}})\big) \quad (2)$$

$$Cost_x(Y_x) = \begin{cases} 0, & Y_x = 0 \\ \mathrm{C}_{inv,x}(i) + \mathrm{k}_x(i)\big(Y_x - \mathrm{bp}_x(i)\big), & \mathrm{bp}_x(i) \le Y_x < \mathrm{bp}_x(i+1) \end{cases} \quad (3)$$

$$z_x\ \mathrm{bp}_x(1) \le Y_x \le z_x\ \mathrm{bp}_x(\mathrm{n}) \quad (4)$$

$BarkCost$ is the annual bark cost as a function of the bark price, $\mathrm{p}_{\mathrm{bark}}$. The bark use, $Q_{\mathrm{Bark},t}$, is given by the steam production in the bark boiler $M^{\mathrm{prod}}_{\mathrm{BB},t}$, the boiler efficiency η_{BB} and the enthalpies of HP steam and feed water, h_1 and h_{FW}. T_t is the operating time in period t. Similarly, the annual lignin revenues, $LigRev$, associated with lignin exports, $Q_{\mathrm{Lig},t}$, are a function of the lignin price $\mathrm{p}_{\mathrm{lignin}}$ and the recovery boiler's marginal lignin efficiency, $\eta_{\mathrm{RB-LIG}}$. Lignin extraction reduces the steam production in the recovery boiler from its previous level $M^{\mathrm{max}}_{\mathrm{RB}}$. $ElecRev$ represents the annual revenues from electricity produced in the steam turbines, E_t, at an electricity price of p_{el}; E_t is given by the sum of the power output $W_{st,t}$ from all turbine stages *st*.

$$BarkCost = \mathrm{p}_{\mathrm{bark}} \sum_t T_t Q_{\mathrm{Bark},t} = \mathrm{p}_{\mathrm{bark}} \sum_t T_t (\mathrm{h}_1 - \mathrm{h}_{\mathrm{FW}}) M^{\mathrm{prod}}_{\mathrm{BB},t} / \eta_{\mathrm{BB}} \quad (5)$$

$$LigRev = \mathrm{p}_{\mathrm{lig}} \sum_t T_t Q_{\mathrm{Lig},t} = \mathrm{p}_{\mathrm{lig}} \sum_t T_t\,(\mathrm{h}_1 - \mathrm{h}_{\mathrm{FW}})\big(\mathrm{M}^{\mathrm{max}}_{\mathrm{RB}} - M^{\mathrm{prod}}_{\mathrm{RB},t}\big)/\eta_{\mathrm{RB-LIG}} \quad (6)$$

$$ElecRev = \mathrm{p}_{\mathrm{el}} \sum_t T_t E_t = \mathrm{p}_{\mathrm{el}} \sum_t T_t \sum_{st} W_{st,t} \quad (7)$$

The turbine model (Eqs.8-12) is adapted from Aguilar et al (2007). The parameters A_{st}, B_{st} and L_{st} are coefficients calculated from regression and thermodynamic data, $\Delta\mathrm{h}^{\mathrm{is}}_{st}$ is the estimated isentropic enthalpy difference over the turbine stage *st* and $\mathrm{w}^{\mathrm{min}}_{st}$ defines the minimum load of the turbine as a fraction of the design load. $M^{\mathrm{turb}}_{st,t}$ represents the steam flow through a turbine stage. If a turbine stage is in operation, the binary variable $\gamma_{st,t}$, which is introduced in Eq.(8) to avoid a flow through a non-existing turbine, takes the value one and the virtual design output of this turbine stage, W^{VD}_{st}, is set to the design output. If not in operation, both these variables are zero. The existing turbine is assumed to always be in operation (Eq.10) and its virtual design output is a parameter set to the existing design output. For the condensing turbine, the virtual design output, $W^{\mathrm{VD}}_{3\to\mathrm{c},t}$, will instead be a decision variable subject to constraints (Eqs.11-12).

$$W_{st,t} = (\mathrm{L}_{st} + 1)\big(M^{\mathrm{turb}}_{st,t}\Delta\mathrm{h}^{\mathrm{is}}_{st} - \gamma_{st,t}\mathrm{A}_{st}\big)/\mathrm{B}_{st} - \mathrm{L}_{st}W^{\mathrm{VD}}_{st,t} \quad (8)$$

$$\mathrm{w}^{\mathrm{min}}_{st}\ W^{\mathrm{VD}}_{st,t} \le W_{st,t} \le W^{\mathrm{VD}}_{st,t} \quad (9)$$

$$\gamma_{1\to2,t} = \gamma_{2\to3,t} = 1 \quad (10)$$

$$\mathrm{bp}_{\mathrm{CT}}(1)\gamma_{3\to\mathrm{c},t} \le W^{\mathrm{VD}}_{3\to\mathrm{c},t} \le \mathrm{bp}_{\mathrm{CT}}(\mathrm{n})\gamma_{3\to\mathrm{c},t} \quad (11)$$

$$Y_{\mathrm{CT}} - \mathrm{bp}_{\mathrm{CT}}(\mathrm{n})\big(1 - \gamma_{3\to\mathrm{c},t}\big) \le W^{\mathrm{VD}}_{3\to\mathrm{c},t} \le Y_{\mathrm{CT}} \quad (12)$$

Mass balances for steam pressure headers p are formulated in Eqs.(13-15). The process steam demands are given by $\mathrm{M}^{\mathrm{proc}}_{p,t}$, but there will also be an extra LP steam demand S in the evaporation plant if lignin is extracted. $M^{\mathrm{turb}}_{st,t}$, $M^{\mathrm{vlv}}_{st,t}$ and M^{vent}_{t}denote the steam flows through the turbine, expansion valves and atmospheric vent, respectively; $M^{\mathrm{qw}}_{p,t}$ denotes quench water added to steam header p and $M^{by}_{3\to\mathrm{c},t}$ represents a bypass flow around the condensing turbine that preheats the turbine outlet before the feedwater tank.

$$M^{\mathrm{prod}}_{\mathrm{RB},t} + M^{\mathrm{prod}}_{\mathrm{BB},t} = \mathrm{M}^{\mathrm{proc}}_{1,t} + M^{\mathrm{turb}}_{1\to2,t} + M^{\mathrm{vlv}}_{1\to2,t} \quad (13)$$

$$M^{\mathrm{turb}}_{1\to2,t} + M^{\mathrm{vlv}}_{1\to2,t} + M^{\mathrm{qw}}_{2,t} = \mathrm{M}^{\mathrm{proc}}_{2,t} + M^{\mathrm{turb}}_{2\to3,t} + M^{\mathrm{vlv}}_{2\to3,t} \quad (14)$$

$$M^{\mathrm{turb}}_{2\to3,t} + M^{\mathrm{vlv}}_{2\to3,t} + M^{\mathrm{qw}}_{3,t} = \mathrm{M}^{\mathrm{proc}}_{3,t} + \mathrm{S}\ Q_{\mathrm{Lig},t} + M^{\mathrm{turb}}_{3\to\mathrm{c},t} + M^{\mathrm{by}}_{3\to\mathrm{c},t} + M^{\mathrm{vent}}_{t} \quad (15)$$

Energy balances for the MP and LP steam headers are given by Eq.(16). $Q_{p,t}^{\text{ext}}$ represents the estimated heat flow discharged by the turbine to steam header p calculated from estimated inlet enthalpies at each turbine stage, $\text{h}_{j-1}^{\text{in}\prime}$ (Eq.17) (see Aguilar et al., 2007). An energy balance is also set up around the condensing turbine (Eq.18).

$$M_{j-1\to j,t}^{\text{vlv}}\text{h}_{j-1} + Q_{j,t}^{\text{ext}} + M_{j,t}^{\text{qw}}\text{h}_{\text{QW}} = \left(M_{j-1\to j,t}^{\text{vlv}} + M_{j-1\to j,t}^{\text{turb}} - M_{j\to j+1,t}^{\text{turb}} + M_{j,t}^{\text{qw}}\right)\text{h}_j \quad j = 2,3 \tag{16}$$

$$Q_{j,t}^{\text{ext}} = \left(M_{j-1\to j,t}^{\text{turb}} - M_{j\to j+1,t}^{\text{turb}}\right)\left(\text{h}_{j-1}^{\text{in}\prime} - 0.838\Delta\text{h}_{j-1\to j}^{\text{is}}\right) + 0.8097 \quad j = 2,3 \tag{17}$$

$$M_{3\to\text{c},t}^{\text{turb}}(\text{h}_{\text{c}} - \text{h}_{\text{FW}}) + M_{3\to\text{c},t}^{\text{by}}(\text{h}_3 - \text{h}_{\text{FW}}) = 0 \tag{18}$$

A boiler in operation must operate within the limits $\text{M}_b^{\min}$ and $\text{M}_b^{\max}$ (Eq.19). The binary variable $y_{b,t}$ is one if the boiler is in operation, and zero otherwise; it is always one for the recovery boiler (Eq.20). Lignin exports are limited by extraction capacity (Eq.21):

$$y_{b,t}\text{M}_b^{\min} \le M_{b,t}^{\text{prod}} \le y_{b,t}\,\text{M}_b^{\max} \tag{19}$$

$$y_{\text{RB},t} = 1 \tag{20}$$

$$Q_{\text{Lig},t} \le Y_{\text{Lig}} \tag{21}$$

Model data are shown in Tables 1-4. The process steam demand equals the steam demand shown in Figure 2, with the LP steam demand reduced by 15 kg/s after a steam savings retrofit. The year is divided into 365 periods with T_t=24 h. The prices are set to p_{Bark} = 20 €/MWh and p_{elec} = 60 €/MWh, while two levels for lignin price have been analyzed: p_{Lignin} = 20 €/MWh (≈ wood fuel) and p_{Lignin} = 30 €/MWh (≈ oil). Operating costs for lignin extraction are included in the lignin price. The extra steam demand in the evaporation plant when lignin is extracted is S=0.0229 kg/MW.

Table 1. Investment cost data

Investment cost parameter	Lignin extr. plant (LIG)	Cond. turb. (CT)
r [1/y]	0.2	
$\text{bp}_{\text{x}}(i)$[MW], $(i = 1..10)$	$10 + 8(i-1)$	$4 + 2(i-1)$
$\text{C}_{\text{inv,x}}(i)[10^6€]$	$1.02\ \text{bp}_{\text{LIG}}(i)^{0.6}$	$2.38\ \text{bp}_{\text{CT}}(i)^{0.6}$
$\text{k}_x(i)$ [€/MW]	$\frac{(\text{C}_{\text{inv},x}(i+1)-\text{C}_{\text{inv},x}(i))}{(\text{bp}_x(i+1)-\text{bp}_x(i))}$	

Table 2. Performance data for the boilers

Boiler parameters	Rec. boiler (RB)	Bark boiler (BB)
η_{b} $[\frac{\text{MW steam}}{\text{MW "fuel"}}]$	0.92[a]	0.88
$\text{M}_{\text{b}}^{\min}$ [kg/s]	65	8
$\text{M}_{\text{b}}^{\max}$ [kg/s]	90	30

[a] Marginal lignin-to-steam efficiency = Steam output decrease / heat content of extracted lignin

Table 3. Steam and water enthalpies

Steam/water	Enthalpy [MJ/kg]
HP steam, h_1	3.300
MP steam, h_2	2.822
LP steam, , h_3	2.745
Feed water, h_{FW}	0.42
Quench water, h_{QW}	0.084
Cond. turb. out, h_{cond}	0.147

Table 4. Turbine data (see Aguilar, 2007)

Property/ coefficient	Turbine stages 1→2	2→3	3→c
$\Delta\text{h}_{\text{st}}^{\text{is}}$	0.4349	0.1814	0.6581
$\text{h}_{\text{st}}^{\text{in}\prime}$	3.300	2.930	2.776
A_{st}	0.6442	0.2601	0.0343
B_{st}	1.230	1.280	1.418
L_{st}	0.1540	0.1966	0.0276
$\text{W}_{\text{st}}^{\text{D}}$	41.0	13.8	*var*
$\text{w}_{st}^{\min}$	0.25	0.25	0.25

4. Results

The model was formulated in Cplex Optimization Studio and solved in 4–7 seconds on a standard desktop computer. Figure 3 shows the optimal operation of the plant for different levels of the lignin price. At p_{Lignin} = 20 €/MWh, lignin extraction is not competitive, but for p_{Lignin} = 30 €/MWh, the lignin extraction rate is high.

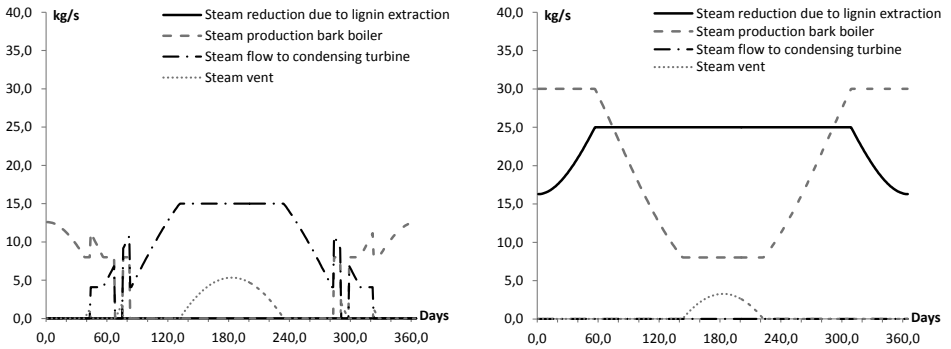

Figure 3. Optimal operation: a) p_{Lignin}=20 €/MWh, b) p_{Lignin}=30 €/MWh

In fact, investment in lignin extraction becomes more profitable than the condensing turbine already at a lignin price of 22 €/MWh. The low value is explained by the poor off-design performance of the condensing turbine.

5. Conclusions

A model has been formulated for optimal investment decisions in lignin extraction and turbine capacity at a pulp mill affected by demand variations. Results indicate an advantage for lignin extraction already at lignin prices above 22 €/MWh due to poor off-design performance of condensing power generation. Further research is needed to investigate the influence of varying operating conditions on the lignin extraction and evaporation plant and the recovery boiler.

Scenario-Based Price Negotiations vs. Game Theory in the Optimization of Coordinated Supply Chains

Kefah Hjaila, Luis Puigjaner and Antonio Espuña

Chemical Engineering Department, Universitat Politècnica de Catalunya, ETSEIB, Av. Diagonal 647, 08028 Barcelona, Spain.

Abstract

A scenario-based negotiation (SBN) win-to-win approach is proposed for the optimization of coordinated decentralized multi-site multi-product Supply Chains (SCs) in a competitive environment. Based on non-symmetric roles, the leader aims to settle its offer taking into account the uncertain reaction of the follower, which behavior is represented by a probability of acceptance. Different negotiation scenarios, based on considering Standalone, Cooperative, and Non-Cooperative SCs are analyzed for the negotiation, resulting in different MINLP tactical models, which are illustrated using a case study with different "follower" SCs around an industrial production SC "leader". On the other hand, a Stackelberg non-cooperative bi-level MINLP game model is built and solved for the same case study. The Non-Cooperative Negotiation Scenario (NCNS) proves to be more adequate, leading to higher individual profits expectations.

Keywords: Tactical management, Supply Chain coordination, Game Theory

1. Introduction

The competitiveness among chemical industries is shifting the interest of Process Systems Engineering (PSE) towards SCs coordination based on individual and global benefits. Many works have been carried out to analyze different ways of coordination among SCs, such as the integration of different SCM levels (Varma et al., 2007); or the coordination of suppliers' and producers' SCs at the tactical level (Hjaila et al., 2014). But, these works support decisions through the use of centralized objectives, disregarding the goals of individuals SCs, and thus conflicts of interests may arise.

Solving these conflicts by negotiations has been studied through Game Theory (GT), and specially through the "revenue sharing" based on Stackelberg's-game for one manufacturer and many competing retailers (Cao et al., 2013), or through developing a bi-level MINLP design and planning model under the leading role of the manufacturer (Yue & You, 2014). Price negotiations as a way to prepare a coordination agreement has been also proposed as a form of "timing" between producer and customer (Moon et al., 2011). Nevertheless, most of the negotiation mechanisms focus on the competitiveness among the retailers disregarding the supplier's competitive behavior. Furthermore, the aforementioned approaches are based on dominance leadership, without considering the uncertain behavior of the other partner/s, leading to insufficient coordination.

Accordingly, this work aims to establish the best conditions for the coordination contract through quantitative negotiations built on win-to-win principles considering the uncertain behavior of the follower conditions when optimizing the leader SC. A

scenario-based negotiation approach is developed taking into account the individual and global profits at the tactical level. Furthermore, a Stackelberg-game model is also developed to solve the same negotiation problem.

2. Problem statement

2.1. Scenario-Based Negotiation (SBN)

Based on non-symmetric roles, the SBN is held between two independent SCs: supplier SC (follower), and client SC (leader); actually, both have been considered production SCs with their own independent suppliers/markets. The leader decides to improve its benefits by buying internal product/s (negotiation item) from the follower SC. The negotiation procedure is divided into two main steps: i) analyzing the negotiation scenarios, and ii) the coordination agreement.

2.1.1. Analyzing the negotiation scenarios

Standalone Scenario (SS)"pre-negotiation": based on the individual objectives, this step aims to establish benchmarks for all negotiation methods.

Non-cooperative negotiation scenario (NCNS): based on individual objectives, this scenario considers the contract to be offered to maximize the profit of the leader SC.

Cooperative negotiation scenario (CNS): based on establishing a global objective.

2.1.2. The coordination agreement

In order to push the negotiation towards a win-to-win policy, the benefits of any reduction in the uncertainty of the production scenario associated to the signature of a collaboration agreement are considered. This includes the calculation of a probability of acceptance of this agreement by the follower SC, taking into account the risk associated to the uncertain behavior of the external conditions. Then, the contract proposed by the leader will be the one driving to the most profitable leader's expected profit.

2.2 Game Theory (GT)

The interaction between the leader and the follower is modelled as a single-leader–single-follower no-cooperative non-zero-sum Stackelberg-game, resulting in a bi-level MINLP model. The idea of the bi-level is that the follower (lower-level SC) objective function is represented as constraints in the leader problem (upper-level SC). In this paper, the bi-level model is solved by building the Stackelberg-payoff matrix considering constraints in both leader and follower SCs. The reaction function is identified (price vs. quantity) and, based on complete information "dynamic game", the leader designs its moves by offering prices, and the follower responds by offering the amounts to be supplied according to its best conditions.

3. Mathematical Model

A generic MINLP tactical model is developed as a basis for this paper. A set of supply chains (sc1, sc2… SC) is considered with their new subsets linking each SC to its corresponding negotiation partner (follower F or leader L). The total sales include internal and external markets (M), at different prices ($p_{r',sc',t}$ and $pr_{r,m,t}$ respectively).

$$SALES_{sc} \le \sum_{t\in T}\sum_{r\in R}\sum_{m\in M} pr_{r,m,t}\cdot xdem_{r,sc,m,t} + \sum_{t\in T}\sum_{r'\in R} p_{r',sc',t}\cdot Q_{r',sc',}\forall sc\in SC; sc'\in F \quad (1)$$

The SC Cost along the planning time horizon T is (RM purchase, transport, storage, production, and the negotiation resource total costs, respectively (Eq. 2).

$$COST_{sc} = \sum_{t\in T}(CRM_{sc,t} + CTR_{sc,t} + CST_{sc,t} + CPRD_{sc,t}) + \sum_{t\in T}\sum_{r'\in R} p_{r',sc',t}\cdot Q_{r',sc',t} \quad (2)$$

$\forall sc \in SC; sc' \in L$

$$PROF_{sc} = SALES_{sc} - COST_{sc} \qquad \forall sc \in SC \qquad (3)$$

3.1. Application of negotiation scenarios:

SS: the negotiation resource quantity $Q_{r',sc',t}$ will be substituted by zero.

CNS: the independent SCs seek to optimize the global SC profit (*Tprofit*) (Eq. 4),

$$Tprofit = \sum_{sc \in SC} PROF_{sc} \qquad (4)$$

NCNS: the negotiation resource demand is equal to a constant value $E_{r',sc',t}$ resulted from maximizing the leader SC profit:

$$Q_{r',sc',t} = E_{r',sc',t} \qquad \forall r' \in R; sc' \in L; t \in T \qquad (5)$$

Within the expected leader SC profit expression, $ExPROF_{sc'}$, the uncertainty reduction cost is represented as an "abridged" uncertainty risk, to be represented by a probability of acceptance (Eq. 7)

$$ExPROF_{sc'} = PROF_{sc'} - uncertainty\ risk_{sc'} \qquad \forall sc' \in L \qquad (6)$$

$$prob_{sc'} = \frac{No.\ of\ scenarios\ of\ improved\ profits_{sc'}}{Total\ No.\ of\ scenarios_{sc'}} \qquad \forall sc' \in F \qquad (7)$$

3.2. Application of Game Theory

Mathematically, the Stackelbergy game forms a bi-level model (Chu and You, 2015), which can be represented in Eqs. (8 &9), where Z and z are the upper-level and lower levels objective functions; *X* and *Y* stands for the upper-level and lower-level decision variables; *G* and *H* are the upper-level inequality and equality constraints; while *g* and *h* are the lower-level inequality and quality constraints.

$$\max_{x \in X, y \in Y} Z_{sc' \in L}(x, y) \text{ , subject to } G_{sc' \in L}(x, y) \le 0 \text{ , and } H_{sc' \in L}(x, y) = 0 \qquad (8)$$

$$\text{Where } y \in \max_{y \in Y} z_{sc' \in F}(x, y) \text{ subject to } g_{sc' \in F}(x, y) \le 0 \text{ ,and } h_{sc' \in F}(x, y) = 0 \qquad (9)$$

4. Case Study

The negotiation models have been implemented and solved for a real data case study (Figure 1) modified from Zamarripa et al. (2014). The partners involved are a production/distribution SC (leader), and the Energy generation SC (follower); the energy supplied/demanded represents the negotiation item.

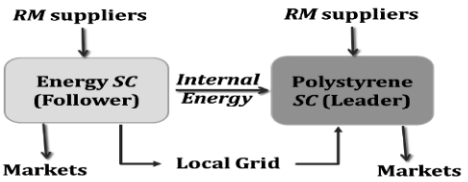

Figure 1- The decentralized global SC network

5. Results and discussion

5.1. Scenario-Based Negotiations (SBN)

The resulting MINLP models have been solved using GloMIQO (Misener & Floudas, 2013). The negotiation starts from the total profit ensuing from the SS (Figure 2 –

purple line). Obviously, if coordination will not allow improvement over this total profit, there is nothing to negotiate. It is worth noticing that the NCNS leads to 10.77 M€ total profit at the contract price 0.21 €/kWh, with a difference of 8.7% and 3.3% comparing with the SS and the CNS, respectively. Furthermore, the NCNS mathematical formulation is less complex and so allows to identify better solutions with less computational effort (32% less than SS and 63% less than CNS).

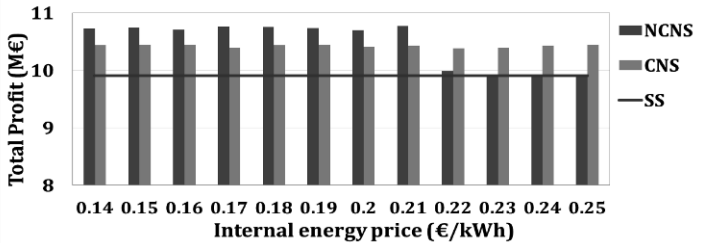

Figure 2- Negotiation scenarios total profits

In turn within the NCNS scenario the leader designs its final offer taking into account the follower uncertain reaction; then, the follower has to assess this offer based on its probability distribution curves (accept or reject):

5.1.1. From the leader side:

The Production SC assesses its expected profit for each contract offer based on the follower probability of acceptance (Figure 3). In general this probability increases as the contract price increases, but at 0.22 €/kWh the leader decides to buy higher energy amounts from the local Grid, resulting in a sudden probability reduction.

The difference between the Production SC contract profit and the expected profit represents the uncertainty cost. The total energy amount needed for the Production SC during the established long term planning horizon is 24.71GWh; 36% of this amount (8.84 GWh) is expected to be supplied from the energy SC, while the rest (15.86 GWh) is to be covered by the local Grid. It is worth mentioning that before considering the uncertainty reduction cost, the contract price 0.14€/kWh was the best option for the leader SC (9.24 M€), but after considering the uncertain reaction of the supplier, the leader offers higher price (0.15 €/kWh), resulting in a 15.5 % profit reduction.

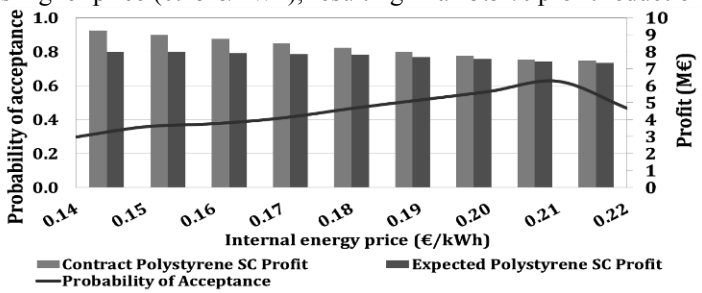

Figure 3- Polystyrene SC contract/expected Profit vs. Probability of acceptance

5.1.2. From the follower side:

The Energy SC seeks to optimize its expected benefit based on the leader offer (8.84 GWh at 0.15€/kWh). This results in 2.29M€ profit. In spite of an initially calculated SS profit of 2.44 M€, based on the Energy SC profit probability curves (Figure 4), the probability from accepting the contract seems to be higher.

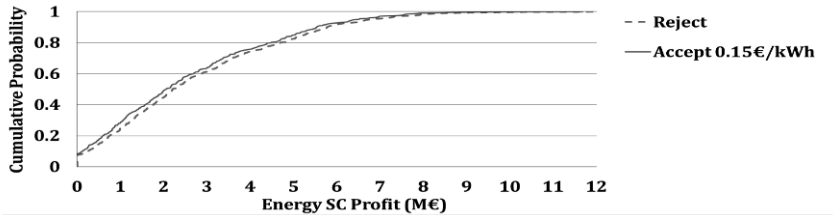

Figure 4- Cumulative probability curves

5.2. Results of Game Theory

The non-cooperative single-leader/single-follower Stackelberg payoff matrix has been built (Table 1), highlighting the follower optimal quantities for each leader offer.

5.2.1. From the leader side:

Stackelberg initial point results in 9.16 M€ profit for the Leader, but this solution is not considered (not win-to-win: The Energy SC Profit is 1.57M€). The final point corresponds the leader SC profit of 7.92 M€ (6% profit improvement vs. the SS). The leader Stackelberg strategy then is to buy 24.71GWh at contract price 0.19 €/kWh.

Table 1- Stackelberg-Payoff Matrix

L (Leader) → action (€/kWh)	0.14		(…)	0.17		0.19		0.20		0.21	
F (Follower) response (GWh)↓	F	L		F	L	F	L	F	L	F	L
0	2.44	7.47		2.44	7.47	2.44	7.47	2.44	7.47	2.44	7.47
(…)											
12.00	2.10	8.29		2.46	7.93	2.70	7.69	2.82	7.58	2.94	7.45
(…)											
23.00	1.69	9.06		2.38	8.37	2.84	7.90	3.07	7.68	3.30	7.45
24.71	1.57	**9.16**		2.31	8.42	2.81	**7.92**	3.06	7.67	3.30	7.43

5.2.2. From the follower side:

The leader contract results in 2.81 M€ Energy SC profit (13 % higher than SS: 2.44M€). The follower then analyses its expected benefits in order to accept or reject. The expected follower SC profit with the coordination contract is 2.99 M€, 8.4% higher than the expected profit resulting from rejecting the contract (2.74 M€). So the follower is expected to accept the coordination contract.

5.3. Scenario-Based-Negotiations (SBN) vs. Game Theory (GT):

Table 2 shows the final SCs coordination contract using the SBN and GT. The SBN results in higher leader SC profit than GT method, with a difference of (74.61 k€).

Table 2- Coordination contract

Negotiation method	Contract price (€/kWh)	Contract amount (GWh)	Leader profit (M€)	Follower profit (M€)
Scenario-Based (SBN)	0.15	8.84	8.00	2.29
Stackelberg Game	0.19	24.71	7.92	2.81

6. Conclusions

A Scenario-Based Negotiation (SBN) approach is proposed to set the best conditions for the coordination of independent multi-site multi-product SCs in a highly competitive

environment. Under the leading role of the client SC, different negotiation scenarios have been analyzed based on Standalone, Non-cooperative, and Cooperative SCs. An uncertainty reduction cost is modelled within the expected leader SC profit as a form of probability of acceptance. From the other hand, a single-leader-single-follower Stackelberg Bi-level MINLP model is developed. Both methods have been illustrated using a case study which coordinates different suppliers' SCs and client "industrial production SC" (leader) through a global scenario. The results show that the Non-Cooperative Negotiation scenario (NCNS) proves to be the most adequate scenario leading to higher global profits (8.7% and 3.3% than the Standalone and Cooperative scenarios). Furthermore, the SBN results in higher profit (1%) than GT, in favor of the leader SC. The proposed approach allows to contemplate the different mechanisms a SC may use to modify its relationships with its clients and suppliers during the optimization procedure, which can be used for further second stage agreements, in a generic and flexible way, so it can be applied in practice to real cases, including centralized/decentralized simple/global SCs, as illustrated in the presented case study.

Acknowledgements

Financial support received from the Spanish Ministry of Economy and Competitiveness and the European Regional Development Fund, both funding the Project SIGERA (DPI2012-37154-C02-01), and from the Generalitat de Catalunya (AGAUR FI program and grant 2014-SGR-1092-CEPEiMA), is fully appreciated.

Abstract

The manufacturing of pharmaceutical products is preceded by complex development phases where process design, planning, and scheduling problems must be considered as deeply linked, fact that has not yet been adequately handled by the existing literature. In this perspective, this work discusses the role of the production planning and scheduling decisions in the pharmaceutical industry. It starts by analysing the main aspects that influence planning and scheduling, and defines an extended scope of the related problems, as a way to account for higher levels of integration between process design and operational decisions. We propose a novel conceptual representation, the *Delivery Trade-offs Matrix* (DTM) to help managing the trade-offs occurring in the drug development process and to expose the factors that affect the performance of these manufacturing systems.

Keywords: Planning; scheduling; pharmaceutical industry

1. Introduction

The pharmaceutical industry can be viewed as a complex system of processes, operations, and organizations involved in the discovery, development, and manufacturing of drugs. Companies operating in this industry are responsible for: a) research and development (R&D) activities; b) development and manufacturing of active pharmaceutical ingredients (APIs); and c) drugs manufacturing. Federsel (2009) recognized that, although the pharmaceutical industry has historically tolerated total time investments of more than 10 years from idea to market, the current worldwide paradigm imposes a significant reduction of this time. The pharmaceutical industry is therefore confronted with several challenges that are related to increasing R&D costs, long cycle times, and low probabilities of success (Hynes III, 2009). Additionally, over the years, manufacturers and regulators have created an environment for operations management that strongly conditions the planning and scheduling functions. In this work, we have looked into the literature addressing planning and scheduling problems in the sector, and tried to derive some general principles for defining and extending the scope of these functions, and to identify some current and future research and industrial challenges.

The rest of the paper is structured as follows. Section 2 presents the critical factors that determine how planning and scheduling are done in the pharmaceutical industry.

Section 3 discusses the planning and scheduling functions and proposes an extension of the scope for the related problems, to account for higher levels of integration between process design and operational decisions. In section 4, the *Delivery Trade-offs Matrix (DTM)* is introduced. Finally, in section 5, some concluding remarks are presented.

2. Critical factors for planning and scheduling

Planning and scheduling are functions that primarily aim at reducing costs and improving responsiveness of the manufacturing systems. One recent review on planning and scheduling has been written by Harjunkoski et al., (2013). The critical factors that drive the planning and scheduling functions, in the particular context of the pharmaceutical industry, can be grouped in three categories: market, processes, and plants. Market factors are related to the specific contextual factors of this industry. Process factors have to do with the structure of the chemical processes. Plant factors relate to the operating strategies and resources characteristics of the manufacturing systems. Note that some of the process and plant characteristics discussed in the following subsections are more general and not specific to the pharmaceutical industry.

2.1. Market

The market context has a direct influence on the planning and scheduling functions. First of all the pharmaceutical market is highly fragmented. There is a large variability on the demand, that is also a result of the pressure created by generic drugs, and that leads to larger production mixes in the manufacturing sites. Operations flexibility is therefore required to fit the systems to this heterogeneous demand, and for that reason efficient planning and scheduling methods are required. Manufacturing in a high regulated market has to deal with additional complexities that do not exist in less regulated markets. In fact chemical processes are executed under a close supervision of the regulatory agencies that define rigorous procedures to monitor process changes. Globally, the time-to-market issue and the pressure to reduce costs are imposing operations to run more efficiently and therefore advanced planning and scheduling methods are necessary (Moniz et al., 2014).

2.2. Processes

The production process topology strongly determines the scheduling models that can be applied. The work of Mendez et al. (2006) provides a comprehensive review on the different types of scheduling models. In the manufacturing of APIs, for example, processes require numerous production steps with tasks having short and long processing times, usually spanning across several working shifts. Regulatory and quality procedures define the *lot size* and the *changeover* requirements that must be rigorously followed in the manufacturing sites, thus introducing additional time to the effective production time. Stable intermediaries and final products are produced in lots, and therefore lots traceability must be ensured. The first batches after a *scale-up* are usually more difficult to produce, since this may involve the use of different processing units or even performing changes in the process. For that reason, these processes impose frequent revisions of the production schedule.

2.3. Plants

The plant structure has also implications on how planning and scheduling are performed. Note that, although the modelling approach strongly depends on the process topology (as discussed above), the characteristics of the plants (such as resources, plant structure, operating mode, and batch/continuous manufacturing) lead as well to specific

planning and scheduling problems. Continuous manufacturing of pharmaceuticals is an emergent process mode that relies on flow reactors and is currently being evaluated for the production of drugs. A consequence of using flow reactors, instead of batch reactors, is that the production process moves from a batch mode to continuous operating conditions (Buchholz, 2010). Finally, it is important to mention that for aiming the full operational efficiency the integration with advanced control systems should be performed. However, here there are significant practical and theoretical integration challenges, Engell and Harjunkoski (2012).

3. Extending the scope of planning and scheduling problems

In the context of process development and manufacturing of drugs, R&D, and Operations Management (OM) departments perform critical activities that determine how planning and scheduling are effectively done (see Figure 1).

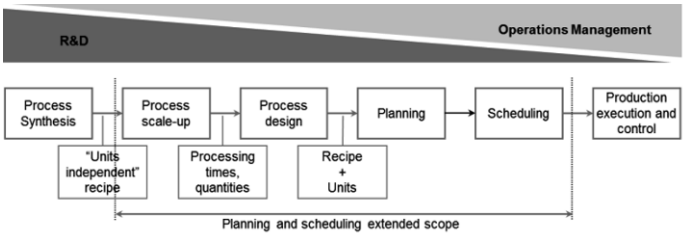

Figure 1 – Scope of the planning and scheduling problems.

We argue that the planning and scheduling functions must be extended in order to integrate decisions made in the *process scale-up* and *design* steps. The planning process, whether long-term or short-term, will clearly benefit from considering decisions taken at the scale-up and process design levels, as these decisions have a direct impact on the determination of the processing units suitable for the process, this leading to different production routes (alternative processes). On the contrary, after schedules have been released to the shop-floor, changes on planning and scheduling decisions can only be very limited, although *rescheduling* is a common practice. The same happens with changes in process design decisions that may not be possible or are not desirable to perform. In summary, we propose that the scope of the planning and scheduling functions is extended to account for design decisions (Barbosa-Povoa (2007)), especially for chemical manufacturing processes that are under development. This will increase the solution space of planning and scheduling decisions, hopefully leading to more globally optimized operations.

4. The Delivery Trade-offs Matrix

The ultimate goal of planning and scheduling is to deliver the right amounts of product at the right time, cost, and quality. Thus, in order to provide guidance on the issues that determine the effectiveness of manufacturing a new drug to the market, we propose a conceptual representation, named the *Delivery Trade-offs Matrix* (DTM) that is depicted in Figure 2. The relative importance of *costs* and *uncertainty* on the manufacturing activities that support the development and delivery of APIs or final products can be assessed in the DTM. It is important to notice that the proposed DTMs were built taking into account a set of estimated values available in the literature. To the best of our knowledge, there are no reliable figures regarding the cost structure and uncertainty associated to the R&D, trials I-III, and commercialization phases. However, the huge development and manufacturing costs in the pharmaceutical industry clearly justify a discussion on the path to follow towards manufacturing efficiency.

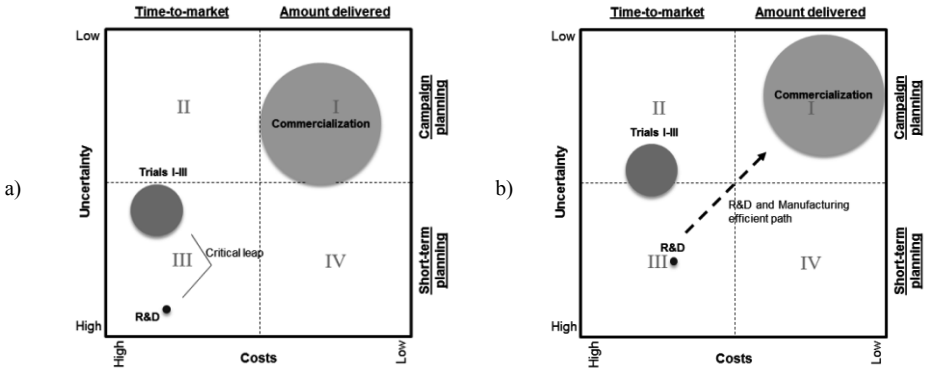

Figure 2 – Delivery Trade-offs Matrix (DTM) of the pharmaceutical industry: a) current state, b) future scenario.

The matrix depicts three phases of the drug development cycle (R&D, trials I-III, and commercialization). The R&D phase accounts for discovery, safety, and toxicology research activities and clinical supplies. Trials I-III relate to clinical studies performed on humans. The commercialization phase includes the manufacturing activities required to deliver the right amounts of product to the market, after approval by the regulatory agencies. Uncertainty and costs are represented in a continuous scale from *high* to *low*. The proportion of the production lot size at each phase is indicated by the size of the associated bubble. The DTM of Figure 2.a) shows the current trade-offs of the industry, while b) depicts a future scenario, as a possible response to the challenges the pharmaceutical industry is facing and needs to overcome. These aspects are next discussed in more detail.

4.1. Uncertainty and costs

At the start of a research program, products and processes have not yet been developed, and therefore there is a high uncertainty associated to the drug structure and to the production process. Uncertainty makes planning decisions more complex, since it is more difficult to estimate the required times and resources. For example, in the development and manufacturing of APIs it is common to allocate production resources 6 to 12 months in advance. Thus, changes in the plans may have a significant impact in manufacturing costs and delivery time. With drug development the uncertainty tends to decrease as product and process characteristics are better understood. In fact at the laboratory scale, only small amounts are produced (around few hundred grams). The delivery of the first scaled up batch (usually between 1 to 5 kg), used to support toxicological and formulation studies, along with phase I trials, is on the critical path of the development process This scale-up is particular difficult to perform since the knowledge obtained at the laboratory scale is seldom sufficient to guarantee a successful process at a plant scale (Federsel, 2009). Moreover, the drug development process requires a series of scale-ups so as to develop an efficient production process.

At the commercialization stage, the need for API or drug products is normally in the order of hundreds of kilograms. The processes are well defined, thus the uncertainty is mainly associated to market parameters such as demand, and to the processing time of the complex production tasks. The current practice demonstrates that there are large costs and high uncertainty at the R&D and trials I-III phases (see Figure 2 a), with the total estimated cost of bringing a new drug to market being larger than 1 billion dollars (Kessel, 2011). In terms of the total cost structure, pharmaceutical R&D costs are

around 30% to 35%, and clinical trials (typically representing the most significant cost) can be between 35% to 40% of the total (Suresh & Basu, 2008).

4.2. Time-to-market and amount delivered

It should be noted that from the planning and scheduling perspective, the delivery of products to Trials I-III phases is of extreme importance. Shah (2004) and Buchholz (2010) pointed out that time-to-market is a critical driver of the pharmaceutical industry. Additionally, Buchholz (2010) highlighted that fast and robust scalability of the production processes is another relevant driver for this industry. In fact it is quite often to have more than one company developing similar drugs, and therefore the importance to respect due dates is even more crucial.

On the other hand, at the commercialization phase there is more flexibility concerning delivery dates, if there is inventory on the supply chain. According to Shah (2004), the whole pharmaceutical chain stock can represent 30% to 90% of the annual demand in quantity. Therefore, at this phase, we can say that delivering the right product amounts is relatively more important than respecting delivery dates. Remember that the production lot sizes at the Trials I-III phases are in the order of few kilograms, while after several scale-up and validation steps, the lot sizes are around hundreds of kilograms. After drug development, the manufacturing costs are lower and tend to decrease with the reduction of the root causes of variability in the production process.
Concerning the operating mode, manufacturing sites run in *short-term mode* to fulfil a small product demand, or run preferably in *campaign mode* to respond to a regular demand. Sometimes the short-term mode is also used for manufacturing products that are in commercialization, this naturally resulting in the production of a smaller number of lots. However, in all cases the process must run with the same lot size as approved by the regulatory agencies.

4.3. The path to efficient R&D and manufacturing activities

All the above issues led the pharmaceutical industry to recognize the need for reducing time-to-market, the costs of new drug development, and the manufacturing costs. The path to efficient R&D and manufacturing activities requires new ways to address uncertainty and reduce costs (see Figure 2 b). This will involve the introduction of new production technologies (Suresh & Basu, 2008), as well as the adoption of innovative process design, planning, and scheduling decision-making tools. For example, according to Roberge et al. (2005), 50% of the reaction tasks in the chemical-pharmaceutical industry could benefit from the adoption of continuous processes based on the micro-reactor technology. In what concerns decision-making, the relevance of applying optimization tools and deploying more integrated decision-making processes is being recognized by the industry, despite the challenges that still exist (Grossmann, 2012). A new path must then be followed as represented in Figure 2 b. Such path must focus on improving the reliability of the drugs delivery by dealing with the uncertainty and the associated costs. The challenge here is to address in a systematic way the huge uncertainty present in the supply chain, so as to decrease the delivery times and meet the delivery quantities, thus improving the delivery reliability and response time. In the manufacturing sites, a more effective utilization of the resources can be achieved by integrating process design, planning and scheduling decisions and reducing the production lot sizes, but without increasing the costs, particularly the ones related to the long production changeovers.

5. Conclusions

This work analyses the main aspects that influence planning and scheduling decisions in the context of the pharmaceutical industry. Extending the traditional scope of planning and scheduling functions is particularly interesting, if drug development and manufacturing activities are simultaneously considered. The critical factors that determine planning and scheduling were identified and grouped in three categories: market, processes, and plants. In our view, comprehensive optimization methods for this sector must take into account these factors. Finally, we propose a conceptual representation, the Delivery Trade-offs Matrix, as a contribution to better managing uncertainty and costs issues, in the drug development and manufacturing activities. The matrix shows that the pharmaceutical industry should focus on the manufacturing and delivery issues knowing that each phase of the development cycle has different challenges. The integration of design decisions in the planning and scheduling is fundamental to do in the early stages of the drug development cycle. While the implementation of high flexible and high efficient manufacturing systems will then require the integration of planning and scheduling and control, especially during the commercialization phase.

Flare Minimization of Ethylene Plant Start-up via Resource-Task Network Approach

Guang Song, Tong Qiu*, Bingzhen Chen

Department of Chemical Engineering, Tsinghua University, Beijing, China

Abstract

Energy utilization and environment protection has received increasing attention over the last few decades. Therefore, flare minimization has become one of the main concerns for ethylene industry. Currently, the research of flare minimization has two major approaches, which are the experience-based approach and the dynamic simulation approach. The former has some limitations when it has to confront dynamic operations. The latter adopts dynamic simulation to validate the proposed start-up plans, which lacks optimization for the start-up plans. The start-up process of an ethylene plant can be considered as a semi-continuous process. Thus, the short-term scheduling approach based on resource-task network (RTN) is firstly used in this paper to depict the super-structure of the start-up process and optimize the start-up plans. This work developed a flare minimization model for the start-up process of ethylene plant, which could overcome the aforementioned shortcoming. We established the mathematical formulation of the flare minimization model, whose reliability and adaptability was validated by 5 significant case studies. The results showed that the flare minimization model also could effectively reduce start-up durations.

Keywords: flare minimization, ethylene plant, start-up, scheduling, resource-task network

1. Introduction

Energy utilization and environment protection has gotten more and more attention during the last few decades. The complicated start-up operations of ethylene plant would generate huge amounts off-spec product streams that have to be sent to flare systems (Q. Xu, 2009). Flare minimization has become one of the main concerns for the ethylene industry. Currently, the research of flare minimization has two major approaches, which are the experience-based approach and the dynamic simulation approach.

In the experience-based approach, the flare emission sources are firstly identified. Based on this, some improvements have been presented to reduce flare emissions, such as starting charge gas compressors with starting working medium(SWM) before feeding the furnace (A. Shaikh, 1995). However, the experience-based approaches have some limitations when they have to confront dynamic operations. Therefore, a “three step” methodology for flare minimization by using dynamic simulation tools is proposed (Q. Xu, 2008). This methodology is used to study start-up performance of a multistage compression system (X. Yang, 2009) and integrated cryogenic separation system (Y. Zhao, 2014). However, the above methods use dynamic simulation to validate the proposed startup or shutdown plan, which lack optimization for operating parameters. Thus, a flare minimization model of an ethylene splitter system based on the simulation data for different operating situations have been built, which optimizes the operating

* Corresponding author: Tong Qiu. qiutong@tsinghua.edu.cn.

parameters in the shutdown plan (G. Song, 2013). Notwithstanding, the model only involved the ethylene splitter system, and also lacked the optimization for the whole plant. In this work, the start-up process of an ethylene plant is considered as a semi-continuous process. The short-term scheduling approach based on resource-task network (RTN) is firstly utilized to model the flare minimization problem, which includes the whole plant.

2. Resource-Task Network Approach

RTN approach has been implemented to definitely model the main features encountered in ethylene plant start-up process such as the choice of SWM, inventories of products, start-up operations and procedures and units' state, etc. The main characteristic of RTN approach is the entirely uniform description of available resources, such as materials, processing and storage equipment, utilities, and different states of the same equipment. The other concept involved in the RTN approach is that of a task, which can be viewed as an abstract operation that consumes or/and produces a specific set of resources. In this work, not all resources and tasks will be treated in the same manner. The following subsections will describe the semantic elements in detail.

2.1. Equipment Resources.

The equipment resources include all of the equipment units, such as furnace and compressors. An example of an equipment resource is given in Figure 1 as "J1". One equipment resource, at a given time, can be used by a single processing task at most, meaning that any two tasks cannot be executed simultaneously in the same equipment resource.

2.2. Cumulative Resources.

The cumulative resource represents a resource that, at a given time, can be shared by multiple processing tasks. So, they include materials and utilities. The material resources are raw materials, intermediate and finished products that are consumed or produced during the start-up operation. The utility resources represent steam under different pressures. An example of a cumulative resource is given in Figure 1 as "R2", in which the initial stock and the capacity are given.

2.3. State Resources.

The state resource represents a state of an equipment. Some equipment have different operating states. For example, the furnace has three states and needs to follow this sequence: 1) "shutdown"; 2) "steam running"; 3) "feed running". The state resource can be used to manage transitions between modes. An example of a state resource is given in Figure 1 as "R1", in which the initial state and the capacity are given.

2.4. Task.

A task node represents a processing operation that consumes and/or produces a specific set of resources. An example of a task is given in Figure 1 as "T1". The maximum and minimum batch size are given as V_{max} and V_{min}. Moreover, the duration of the task equals to $pf+pv*B$, where B is a variable equal to the batch size of the task.

3. Mathematical Formulation

During the last decade, the research on RTN-based scheduling formulations has made great progress. Castro et al proposed several formulations for batch and continuous processes (P. M. Castro, 2010). Thery et al extended the RTN approach to integrate the production and utility system (R. Thery, 2012). In view of the aforementioned formulation, a continuous time mixed integer linear programming (MILP) model is

presented in this paper based on the global time point representation. The type of event representation and constraints of the formulation are given below.

3.1. Event Representation.

The continuous-time formulation uses a uniform time gird to keep track of events taking place. The time horizon is divided into *n-1* time slots. The boundaries are named event points and global time points, where the events take place. The absolute time of event point is a variable, which needs to be determined via the optimization.

3.2. Allocation constraints.

The three index binary variable $W(i,n,n')$ defines the assignment of task i that starts at event point n and ends at event point *n'* ($n < n'$). A parameter, Δn, is defined as $n < n' \leq n + \Delta n$, to control on the maximum number of event points allowed between the beginning and end of a given task. The allocation constraints have the three following parts.

In every equipment unit *j* ($j \in J$), at most, one task *I* ($i \in I$) can start at each event point *n* ($n \in N$) as given by constraint 1.

$$\sum_{i \in I_j} \sum_{\substack{n' \in N \\ n < n' \leq n + \Delta n}} W(i,n,n') \leq 1 \qquad \forall j \in J, n \in N \tag{1}$$

Similarly constraint 2 states that, in every equipment unit *j* ($j \in J$), at most, one task *i* ($i \in I$) can end at each event *n* ($n \in N$).

$$\sum_{i \in I_j} \sum_{\substack{n \in N \\ n' - \Delta n \leq n < n'}} W(i,n,n') \leq 1 \qquad \forall j \in J, n' \in N \tag{2}$$

Constraint 3 states that, in a given equipment unit a new task can start only if the total number of tasks that started earlier matches the total number of tasks ending.

$$\sum_{\substack{n' \in N \\ n < n' \leq n + \Delta n}} W(i,n,n') \leq 1 - \sum_{\substack{n' \in N \\ n' < n}} \sum_{\substack{n'' \in N \\ n' < n'' \leq n' + \Delta n}} \sum_{i \in I_j} W(i',n',n'') + \sum_{n'' \in N} \sum_{\substack{n' \in N, n' \leq n \\ n'' < n' \leq n'' + \Delta n}} \sum_{i \in I_j} W(i',n'',n') \tag{3}$$

$\forall i \in I_j, j \in J, n \in N, n > 1$

3.3. Capacity constraints.

Constraint 4 states that the amount *R(r, n)* of resource *r* stored at event point *n* should never exceed its maximum storage capacity C_r^{max}.

$$0 \leq R(r,n) \leq C_r^{max} \qquad \forall r \in R, n \in N \tag{4}$$

3.4. Batch size constraints.

For each task, constraint 5 states that the batch size $B(i,n,n')$ is bound by the maximum V_i^{max} and minimum V_i^{min} value.

$$W(i,n,n')V_i^{min} \leq B(i,n,n') \leq W(i,n,n')V_i^{max} \qquad \forall i \in I, n, n' \in N, n < n' \leq n + \Delta n \tag{5}$$

3.5. Cumulative resource mass balance.

In the mass balance eq. 6, the amount $R(r,n)$ of resource *r* stored at event point *n* equals to that at previous event point *n-1* adjusted by the materials coming into and out of the resource at the current *n*. Constraint 6 represents the generalized mass balance that is applicable to all the cumulative resources, in which *I*(*r, i, n*)/*O*(*r, i, n*) defines the amount of cumulative resource *r* ($r \in RC$) entering in/leaving task *i* ($i \in I$) at event point *n* and

governed by a mass balance, and *UI*(*r, i, n*)/*UO*(*r, i, n*) defines those not governed by a mass balance.

$$R(r,n) = R(r,n-1) + \sum_{i\in I} O(r,i,n) - \sum_{i\in I} I(r,i,n) + \sum_{i\in I} UO(r,i,n) - \sum_{i\in I} UI(r,i,n) \qquad \forall r \in R^C, n \in N, n > 1 \tag{6}$$

The initial amount $R0_r$ of resource *r* is given as constraint 7.

$$R(r,1) = R0_r - \sum_{i\in I} I(r,i,1) - \sum_{i\in I} UI(r,i,1) \qquad \forall r \in R^C \tag{7}$$

The demand in resource needs to be constrained as constraint 8.

$$R(r,N) \geq D(r) \quad \forall r \in R^C \tag{8}$$

3.6. Processing of cumulative resource.

Tasks can transform cumulative resources in known or unknown proportions of batch size. In the latter case, the proportions are calculated through the resolution of the optimization problem. Constraint 9~10 state that the batch size *B*(*i, n, n'*) is equal to the sum of the amount *I*(*r, i, n*) of resource r entering in task i as well as the amount *O*(*r, i, n'*) of resource *r* leaving task *i*.

$$\sum_{\substack{n'\in N \\ n<n'\leq n+\Delta n}} B(i,n,n') = \sum_{r\in R_i^{cons}} I(r,i,n) \qquad \forall i \in I, n \in N \tag{9}$$

$$\sum_{\substack{n\in N \\ n'-\Delta n\leq n<n'}} B(i,n,n') = \sum_{r\in R_i^{prod}} O(r,i,n') \qquad \forall i \in I, n' \in N \tag{10}$$

The amount of input flows into a task *i* needs to be constrained as given by constraint 11~12. The amount of output flows out of a task *i* constraint is similar, that is omitted.

$$I(r,i,n) \leq \left(\rho_{i,r}^{cons} + \mu_{i,r}^{cons}\right) \cdot \sum_{\substack{n'\in N \\ n<n'\leq n+\Delta n}} B(i,n,n') \quad \forall i \in I, r \in R_i^{cons}, n \in N \tag{11}$$

$$I(r,i,n) \geq \rho_{i,r}^{cons} \cdot \sum_{\substack{n'\in N \\ n<n'\leq n+\Delta n}} B(i,n,n') \quad \forall i \in I, r \in R_i^{cons}, n \in N \tag{12}$$

3.7. Production/consumption of cumulative resource.

The consumption and production of cumulative resources needs to be constrained as given by constraint 13~14.

$$UI(r,i,n) = u_{i,r}^{cons} \cdot \sum_{\substack{n'\in N \\ n<n'\leq n+\Delta n}} W(i,n,n') \qquad \forall i \in I, r \in R^C, n \in N \tag{13}$$

$$UO(r,i,n') = u_{i,r}^{prod} \cdot \sum_{\substack{n\in N \\ n'-\Delta n\leq n<n'}} W(i,n,n') \quad \forall i \in I, r \in R^C, n' \in N \tag{14}$$

3.8. State resource balance.

Be similar as cumulative resource balance, constraint 15~16 represent the transition among states of a resource.

$$R(r,n) = R(r,n-1) + \sum_{i \in I}\left(\alpha_{i,r}^{prod} \cdot \sum_{\substack{n' \in N \\ n-\Delta n \le n' < n}} W(i,n',n)\right) - \sum_{i \in I}\left(\alpha_{i,r}^{cons} \cdot \sum_{\substack{n' \in N \\ n < n' \le n+\Delta n}} W(i,n,n')\right) \quad (15)$$

$\forall r \in R^S, n \in N, n > 1$

$$R(r,1) = R0_r - \sum_{i \in I}\left(\alpha_{i,r}^{cons} \cdot \sum_{\substack{n' \in N \\ 1 < n' \le 1+\Delta n}} W(i,1,n')\right) \qquad \forall r \in R^S \quad (16)$$

3.9. Duration constraints.

The finish time and start time of a task are constrained by the duration constraints as given by constraint 17~18.

$$T(n') - T(n) \ge pf_i \cdot W(i,n,n') + pv_i \cdot B(i,n,n')$$
$$\forall i \in I, n, n' \in N, n < n' \le n + \Delta n \quad (17)$$

$$T(n') - T(n) \le M\big(1 - W(i,n,n')\big) + pf_i \cdot W(i,n,n') + pv_i \cdot B(i,n,n')$$
$$\forall i \in I, n, n' \in N, n < n' \le n + \Delta n \quad (18)$$

The absolute time of the first time point should be assigned to the start time of time horizon, and similarly that of the last time point should be assigned to the ending time as given in constraint 19.

$$T(1) = 0;\ T(n) = H \quad (19)$$

4. Case Study

In this section, the modeling of an ethylene plant's start-up process is presented to illustrate the use of the proposed flare minimization model. The RTN representation of the start-up process of the ethylene plant is shown in Figure 1, in which the problem data related to resources and tasks are also given. The detailed description of the resource node and task node is given in the list.

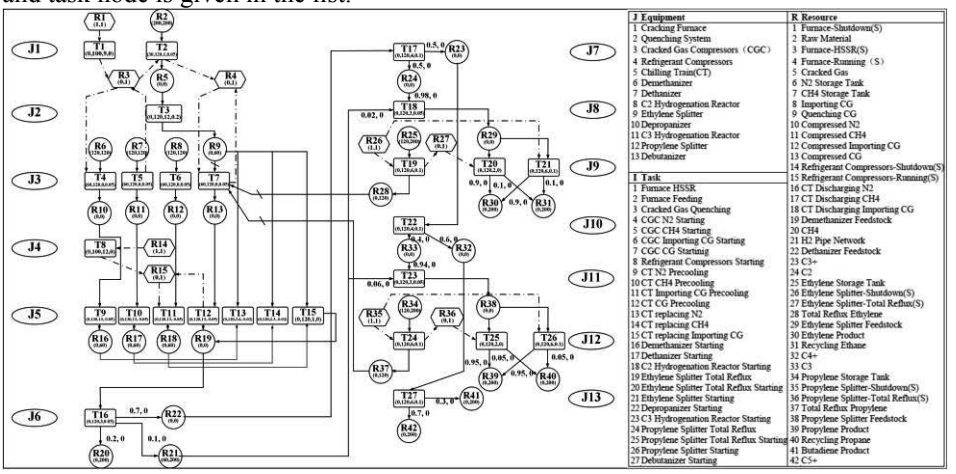

Figure 1. RTN representation of the start-up process of the ethylene plant.

Five case studies with different raw material inventories are presented, and case 5 is the general start-up process. Note that the reduction of starting time means not only the increase of normal manufacturing time and but also the saving of raw materials from flaring. Therefore, the optimal objective is to minimize the start-up duration. Table 1 gives the raw material inventories of each case and computational results. For case 1 and case 2, it can be observed that one more time point could obtain shorter duration but require more computer time. For case 3 and case 4, the reduction of the ethylene and propylene inventories caused the longer durations, because the total reflux operation of product splitter could not be executed. Case 1~4 all require less durations than case 5, thus the flare minimization model could effectively reduce the start-up duration.

Table 1 Case study features and computational results

Case	R6	R7	R8	R21	R25	R34	Duration/h	Time point	Δn	Cplex time[a]

3	120	120	120	0	30	30	82.16	15	4	407.09
4	120	120	120	0	0	0	91.30	15	4	48.08
5	120	120	0	0	0	0	91.78	15	4	57.48

a. Seconds on Intel(R) Core(TM) i7-3770 CPU @3.40GHz 3.90GHz Ram 8GB with CPLEX 12.5

5. Conclusion

This paper firstly used the short-term scheduling approach based on RTN to optimize the start-up plans. The RTN approach was used to depict the super-structure of the start-up process. We developed a flare minimization model for the start-up process of ethylene plant. As shown in computational results for five case studies, the flare minimization model could effectively reduce the start-up duration. Therefore, raw materials are saved from flaring during start-up process.

Abstract

We propose a mixed-integer nonlinear optimization for process design synthesis of oil-refinery units that includes crude-oil mixing, unit processing and product blending. The quantity-logic-quality phenomena involving a non-convex mixed-integer nonlinear problem is decomposed into a two-stage stochastic programming model with complete recourse considering, in a first stage, quantity and logic variables in a mixed-integer linear model and, in a second stage, quantity and quality variables in a nonlinear programming formulation. Iteratively, nonlinear models of each demand scenario are restricted by the multi-scenario process design results. An industrial-sized example that is not solved in a full space model demonstrates our tailor-made decomposition scheme, which yields within 5% gap between the first and the average second stage results.
Keywords: Oil-refinery design synthesis, strategic planning, stochastic programming

1. Introduction

Multi-period and multi-scenario process design synthesis models integrating logic variables and quantity-quality relations gives rise to large scale non-convex mixed-integer nonlinear (MINLP) models that are often difficult to solve. In order to overcome this problem, a method denoted here as the phenomenological decomposition heuristic (PDH) partitions MINLP models into two simpler submodels namely logistics (quantity and logic) and quality (quantity and quality) problems. The logistics model solves a mixed-integer linear (MILP) problem with quantity and logic variables subject to quantity and logic constraints. Quality optimization solves a nonlinear (NLP) model for quantity and quality variables subject to quantity and quality constraints after the logic variables have been fixed at the values obtained from the solution of the logistics optimization.

The PDH algorithm resembles the well-known approach suggested in generalized Benders decomposition where complicating variables (in this case, binary) are fixed such that a simpler problem may be solved, which are later freed again for the new iteration of the master problem (Geoffrion, 1972). A similar method has also been applied for a different purpose, namely that of integrating decentralized decision-making systems through a hierarchical decomposition heuristic (HDH) (Kelly and Zyngier, 2008). In the context of the integration between logistics and quality problems, the coordinator (logistics problem) would send what we call logic pole-offers to the cooperator (quality problem), which would send back logic pole-offsets to the coordinator. This procedure continues until convergence is achieved, hopefully providing a good globally feasible MINLP solution.

A phenomenological decomposition example considering an MINLP crude-oil scheduling problem (Mouret et al., 2009) compares the full space solution and its decomposed MILP-NLP problem by neglecting the pooling or blending nonlinear constraints in the MILP model, and then composing the model in an NLP problem by relating quantity and quality variables for the binary results found in the MILP model. In their work, the full space solution becomes intractable for industrial-sized examples, but they are solved in an MILP-NLP decomposition gap lower than 4%. Only a small example considering low number of time slots is solved using an MINLP formulation, which yields the same result found in the decomposed solution but with higher computational expense.

Another decomposition method, applied in large scale MILP process industry problems (You et al., 2011; Corsano et al., 2014) and relying on relaxations and primal bounding information, is the bi-level decomposition (Iyer and Grossmann, 1998) that requires smaller computational times leading to solutions that are much closer to the global optimum when compared to the full space solution and to Lagrangean decomposition (Guignard and Kim, 1987). A cross-decomposition algorithm (Mitra et al., 2014), combining Benders and scenario based Lagrangean decomposition in two-stage stochastic MILP problems with complete recourse, demonstrates a reduction of iterations and stronger lower bounds compared to pure Benders decomposition.

2. Problem statement

Given future scenarios *sc*, the full design problem (*FDP*) consists of determining the expansion of existing units and installation of new units in petroleum refineries, which are defined by binary variables y_t related to the investment decision and continuous variables x_t that are the size of the new capacities to be expanded and installed.

The objective function (1) maximizes the net present value (NPV) and consists of cash flows (*CF*) from operational gains $\sum_{sc} \pi^{sc} CF_{op}(x_t^{sc})$ and investment costs $CF_{in}(x_t, y_t)$, where π^{sc} is the probability for the scenario *sc* with $\sum_{sc} \pi^{sc} = 1$.

$$(FDP)\ \max NPV = \sum_t \left(\sum_{sc} \pi^{sc} CF_{op}(x_t^{sc}) - CF_{in}(x_t, y_t) \right) \tag{1}$$

$$s.t. \quad A_t x_t + B_t y_t \leq b_t \quad \forall\ t \tag{2}$$

$$D_t y_t \leq d_t \quad \forall\ t \tag{3}$$

$$x_t^{sc} \leq x_t \quad \forall\ sc, t \tag{4}$$

$$h_t^{sc}(x_t^{sc}) = 0 \quad \forall\ sc, t \tag{5}$$

$$x_t, x_t^{sc} \in \mathbb{R}^+, y_t \in \{0,1\} \tag{6}$$

The investment layer in constrains (2) and (3) controls the capacity increase linked to the operational layer by (4), e.g. if capacity is expanded/installed, additional decisions over the scenarios are available in x_t^{sc}. Eq. (5) specifies linear and nonlinear constraints for each scenario *sc*. The PDH algorithm for the *FPD* problem considering scenarios is a two-stage stochastic programming model with the first stage problem (*FS*) comprising the investment and operational layers in an MILP model (logistics optimization), and

the second stage problems (SS^{sc}) in an NLP model (quality optimization), in which the complete recourse in crude-oil diet, processing, and imports permits the problem to match the different demand scenarios despite the first stage investment decisions. To the best of our knowledge, there is no work in the process design synthesis literature handling the following: (i) oil-refinery optimization including the mixing of crude-oils, processing units, and blending of the product streams, (ii) expansion and installation of existing and new units with consideration to their time of execution, and (iii) the decomposition of the oil-refinery process design problem along the phenomenological dimensions of quantity, logic, and quality in order to find good solutions in reasonable time. The need to improve the strategic decision-making to address issues in a quantitative manner rather than the usual qualitative approaches is acknowledged by the industry and still remains an active field of research (Shapiro, 2001).

3. Phenomenological decomposition heuristic algorithm

To formulate the MILP and NLP objective functions, the time horizon comprises investment t and operational t_0 time periods as seen in Figure 1. After project executions over each t with time duration of several years (ΔT_t), a new production framework is considered in the following time periods to determine new operational gains given by throughputs $QF_{u,t}^{sc}$ of crude, imports, and fuel sales ($u \in U_G$). These gains are considered fixed within the investment time period t; otherwise there would be the need to optimize the problem for every t_0, which results in a combinatorial explosive problem with small or no influence in the discrete decisions. Prices pr_{u,t_0} are considered varying annually to improve the accuracy of the NPV calculation. The gains are brought back to the initial time t_i (t_{i1}, t_{i2},…; see Figure 1) for every t_0 at an interest rate ir_t to reflect future gains when they are considered at the present. The investment amounts are withdrawn in t_i for the t with investment under consideration.

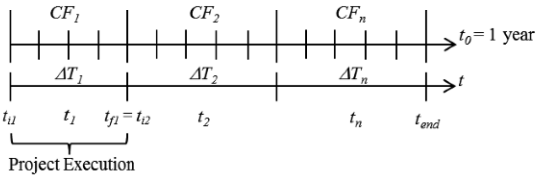

Figure 1. Investment t and operational t_0 time horizon.

The FS problem maximizes the NPV_{MILP} function (7) considering revenues from operational scenarios and costs from investments $y_{u,t}$ (expansions and installations) to among the process units u ($u \in U_I$). Constraints (8) to (12) are the capacity planning equations for adding new capacity $QN_{u,t}$ only once until the next-to-last time period ($t < t_{end}$) considering capital CAP_t, lower and upper bounds of the additions ($QN_{u,t}^{L}$ and $QN_{u,t}^{U}$), and varying and fixed cost coefficients, $\propto_{u,t}$ and $\beta_{u,t}$, respectively. Eq. (12) represents integer constraints to reduce the tree search related to investment in groups of units with the same functionality and considers process unit sequence-dependency investment based on the possible connectivity in the oil-refinery design. Eq. (13) is the linking constraint, where unit throughputs $QF_{u,t}^{sc}$ despite sc is lower than its current capacity $QC_{u,t}$. Eq. (14) represents linear operational constraints, by neglecting the nonlinear relations or linearizing them.

$$(FS)\ \max NPV_{MILP} = \sum_{t}\left(\sum_{t_0=t_i}^{t_0=t_f}\sum_{sc}\sum_{u\in U_G}\frac{\pi^{sc} pr_{u,t_0} QF_{u,t}^{sc}}{(1+ir_t)^{t_0}} - \sum_{u\in U_I}\frac{\propto_{u,t} QN_{u,t} + \beta_{u,t} y_{u,t}}{(1+ir_t)^{\sum_t \Delta t - \Delta t_t}}\right) \quad (7)$$

$$s.t. \quad \sum_{u\in U_I} \propto_{u,t} QN_{u,t} + \beta_{u,t} y_{u,t} \le CAP_t \ \ \forall\ t < t_{end} \quad (8)$$

$$QC_{u,t+1} = QC_{u,t} + QN_{u,t} \ \ \forall\ u \in U_I, t < t_{end} \quad (9)$$

$$QN_{u,t}^{L} y_{u,t} \le QN_{u,t} \le QN_{u,t}^{U} y_{u,t} \ \ \forall\ u \in U_I, t < t_{end} \quad (10)$$

$$\sum_{t<t_{end}} y_{u,t} \le 1 \ \ \forall\ u \in U_I \quad (11)$$

$$D_{u,t} y_{u,t} \le d_{u,t} \ \ \forall\ u \in U_I, t < t_{end} \quad (12)$$

$$QF_{u,t}^{sc} \le QC_{u,t} \ \ \forall\ u, sc, t \quad (13)$$

$$\tilde{h}_{u,t}^{sc}\left(x_{u,t}^{sc}\right) = 0 \ \ \forall\ u, sc, t \quad (14)$$

$$QC_{u,t}, QN_{u,t}, QF_{u,t}^{sc}, x_{u,t}^{sc} \in \mathbb{R}^{+}, y_{u,t} \in \{0,1\} \quad (15)$$

The second stage SS^{sc} problem of each scenario maximizes the NPV_{NLP}^{sc} function (16) for fixed investment decisions $\overline{QN}_{u,t}$ and $\bar{y}_{u,t}$ and unit throughputs lower than the capacities from the *FS* problem, so it means $QF_{u,t}^{sc} \le \overline{QC}_{u,t}$ for existing units ($u \in U_E$) (both previously existing and those installed). Eq (17) represents linear and nonlinear equations for crude-oil mixing, processing, and blending that can be found in Menezes et al. (2013) for the improved swing-cut distillation modeling and in Menezes et al. (2014) for the other equations, in which is also given overall data such as price, crude assay, and product specification. The number of these equations and its variables varies every each MILP-NLP iteration depending on the binaries $y_{u,t}$ found in the *FS* problem. Figure 2 shows the PDH algorithm flow. For the second or later MILP iteration (*FS*), yields and rates are taken from the past NLP or quality optimization (SS^{sc}), which brings processing changes into the MILP problem. The algorithm details is in Menezes (2014).

$$(SS^{sc})\ \max NPV_{NLP}^{sc} = \sum_{t}\left(\sum_{t_0=t_i}^{t_0=t_f}\sum_{u\in U_G}\frac{pr_{u,t_0} QF_{u,t}^{sc}}{(1+ir_t)^{t_0}} - \sum_{u\in U_I}\frac{\propto_{u,t} \overline{QN}_{u,t} + \beta_{u,t}\bar{y}_{u,t}}{(1+ir_t)^{\sum_t \Delta t - \Delta t_1}}\right) \forall\ sc \quad (16)$$

$$s.t. \quad h_{u,t}^{sc}\left(x_{u,t}^{sc}\right) = 0 \ \ \forall\ u \in U_E, sc, t \quad (17)$$

$$QF_{u,t}^{sc}, x_{u,t}^{sc} \in \mathbb{R}^{+} \quad (18)$$

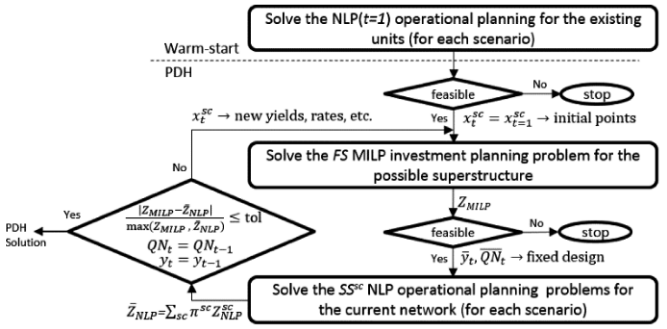

Figure 2. PDH algorithm flowchart.

4. Illustrative example

We apply the proposed decomposition to capacity planning of the São Paulo State supply chain refineries in Brazil, where the investments in new capacities for both expansion and installation of units over a 15-years time horizon (3 periods of 5 years each) are defined in the first stage with the same scenario probability π^{sc} and the operations including the nonlinearities are defined in the second stage.

As shown in Table 1, the decomposition solution converged after 4 iterations, when the investment results between consecutive iterations are nearly identical (4th iteration in Table 2) within a 5% gap between the NPV_{MILP} and the average-NPV_{NLP}^{sc} ($\overline{NPV}_{MILP}$) solutions. The indices r, u, and n in Table 2 correspond to refinery, unit, and number of the unit, respectively. The full space MINLP problem was tested with several solvers, but it was found to be infeasible in the root relaxation. Table 3 shows the model statistics of the problems. Note that the number of equations and variables in the NLP problems change over the time because of different investment decisions. The NLP solver used is CONOPT (v. 3.15P) and the MILP solver is CPLEX (v. 12.6.0.0).

5. Conclusion

We have described how to iteratively solve an MINLP capital investment optimization in a two-stage programming problem using MILP and NLP sub-solvers configured in a coordinated manner that resulted in an MILP-NLP solution gap within 5%. This same technique can be applied to any advanced planning and scheduling MINLP problem in the process industries given our assertion that these problems can be phenomenologically modeled using the QLQP (quantity-logic-quality phenomena) attributes to concatenate the sub-problems. The major advantage of the PDH approach is that each sub-problem can be decomposed and thoroughly investigated to debug inconsistencies and unexpected solutions when they exist. In contrast to existing MINLP and global optimizers that may fail to even obtain feasible solutions, the PDH approach is computationally much more efficient and robust, and yields optimal or near optimal solutions.

Abstract

There is a movement towards implementation of 2nd generation biorefineries producing chemicals from renewable sources or residual feedstock such as woody biomass or woodchips. Value chain optimisation is used as a decision making tool to aide in the development and implementation of biorefining. To this end, an optimisation model for the value chain assessment of a lignocellulosic biorefinery was developed using mixed integer linear programming and verified with a softwood case study. The model allows for the comparison of different feedstock sources with different characteristics such as moisture content and size. Each source may be subjected to alternate pre-processing prior to biorefining to up to three product streams. Optimisation identified the most profitable locations for each process stage, including, collection points and intermediate storages, pre-processing locations, biorefining locations and customers for different production pathways according to the associated transport as well as capital and operational costs. The scene was set in Scotland, UK, with two source streams, logged softwood versus the chipped by-products from the sawmill industry. The biorefinery was based on a technology developed by Bio-Sep Ltd which converts the lignocellulosic feedstock into three product streams, cellulose, hemicellulose and lignin. The results demonstrate the significant effect of moisture content on drying and transportation costs. Overall, it was demonstrated that decision making tools for biomass processing must allow for the consideration of different pre-processing stages with respect to overall costs and/or profit

Keywords: biorefining, lignocellulose, optimisation, value chain,

1. Introduction

Biorefinery value chain analysis from lignocellulosic feedstock has traditionally focussed on ethanol or heat production for fuel (Sharma, Ingalls et al. 2013). However, increasingly, alternative product streams are being considered. Therefore, as biorefining for non-biofuel purposes become more inevitable, tools to evaluate the economic viability of various operations are increasingly needed. It is evident that previous supply and/or value chain works have focussed on the distribution of processing hubs, (Bowling, Ponce-Ortega et al. 2011) comparison of biomass sources, (van Dyken, Bakken et al. 2010) first and second generation bioethanol (Akgul, Shah et al. 2012) and feedstock properties such as moisture content (Dunnett, Adjiman et al. 2007). In addition, transport cost and distance was demonstrated to be an important consideration for biofuel supply chain networks (Yu, Cecelja et al. 2013).

Lignocellulose consists of three main polymeric materials, lignin, hemicellulose and cellulose which undergo further conversion to monomer sugars and aromatic alcohols with potential use across industry. Sources of lignocellulose include woody biomass,

fast growing crops and agricultural residue such as wheat straw, sugar bagasse, rice husks and corn stover.
In this work a mixed-integer linear model is described for the optimisation of the value chain associated with biorefining. The value chain allows for consideration of different moisture contents, biomass sources and indicates the optimal locations and configuration of the value chain. The optimisation is performed relative to maximising the profit received from the sale of three product streams, cellulose, hemicellulose and lignin. The value chain assessment is based on a novel technology which utilises ultrasound to treat the lignocellulose prior to final separation into lignin, cellulose and hemicellulose.

2. Technology description

The technology used in the model is a low capacity technology developed by Bio-Sep Ltd. with three main stages: slurry preparation, sono-assisted fractionation and separation. The slurry preparation involves mixing mechanically reduced biomass with a dilute organic acid solution prior to the addition of appropriate amounts of ethanol and MIBK. The fractionation stage involves treatment at elevated temperature of the slurry with ultrasound prior to centrifuging to separate the liquid and solid streams. Separation involves further treatment of the liquid and solid streams to extract the lignin, hemicellulose and cellulose. The biorefinery is based on a capacity of 1540 ton/y with operational time and labour costs based on 7 days/week, 20 h/day and 44 a week year.
Assuming a solvent recovery percentage of 99%, the key contribution to the cost of the technology is heating. A techno-economic assessment demonstrated significant savings are obtained with a reduction in heat energy price. With a reduction in price from £0.05/ kWh to £0.01/kWh, the contribution of heat energy cost to total operational cost is reduced from around 40% to 10%. Therefore, the base case considered for the technology for the optimisation scenario is to assume the solvents are recycled with >95% efficiency and as a starting point the heating cost was assumed to be £0.05/kWh. This gives a total fixed cost (in both cases) of £753 000 and an operational cost of £358 and £257 y/ton for heating at £0.05 kWh and £0.01 kWh, respectively.

3. Optimisation model formulation

As shown in Figure 1, the value chain model is based on two different feedstock routes, namely the softwood log source and chipped feedstock source from the sawmill. These were pre-processed before refining into three product streams, lignin, hemicellulose and cellulose. A summary of the parameters, objective function and constraints is presented in Table 1 and Table 2. In brief, the total profit was maximised according to the costs, income and constraints. The model optimises the locations of storages, pre-processing sites, biorefining site, selection of customers satisfying the capacity of the biorefinery, as well as the transportation routes and modes. The number of biorefineries available for use is set by the user and the location of each biorefinery is chosen by the model.

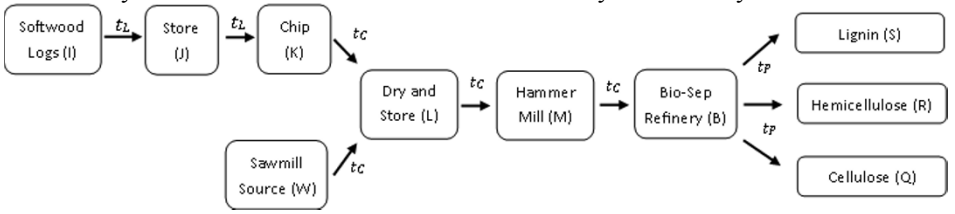

Figure 1. Value chain outline for the Bio-Sep biorefinery

Table 1. Parameters used in the optimisation model

Log source points	$i \in I$	Pre-processing stage	$\{J, K, L, M\} \in O$
Storage locations	$j \in J$	Capacity of pre-processing	$A_p(O)$
Chipping locations	$k \in K$	Fixed cost of pre-processing	$P_{pf}(O)$
Sawmill source points	$w \in W$	Operating cost of pre-processing	$P_{po}(O)$
Dry and store locations	$l \in L$		
Milling locations	$m \in M$	Existence of pre-processing	$E_P(O)$
Biorefining locations	$n \in N$	Conversion rate of pre-processing	$C_p(O)$
Cellulose buyer	$q \in Q$		
Hemicellulose buyer	$r \in R$	Set of biorefineries	$b \in B$
Lignin buyer	$s \in S$	Fixed cost of biorefinery	$P_{bf}(B)$
Feedstock source	$\{I, W\} \in F$	Operational cost of biorefinery	$P_{bo}(B)$
Availability of feedstock	$A_F(F)$	Existence of biorefinery at N	$E_B(N, B)$
Cost of feedstock	$P_p(F)$	Conversion to cellulose	$C_Q(B)$
Material transported	$x \in X$	Conversion to hemicellulose	$C_R(B)$
Transport distance cost	$Pt(T)$	Conversion to lignin	$C_S(B)$
Transport load cost	$Pl(T)$	Capacity of the biorefinery	$A_N(B)$
Capacity of transport	$T_c(T)$	Product buyer	$\{Q, R, S\} \in Z$
Transportation type	$t \in T$	Price of product	$P_z(Z)$
Distances between stages	$d \in D_t$	Capacity of buyer	$A_z(Z)$

Table 2. Functions within the value chain model.

Objective Function:	**Maximise Σ Profit – Σ Cost**	
Cost Functions		
Feedstock purchase	$\sum P_p(F) \cdot X(F)$	(1)
Transportation cost (travelling)	$\sum Pt \cdot X \cdot D_t$	(2)
Transportation cost (loading)	$\sum Pl \cdot X$	(3)
Pre-processing operational cost	$\sum P_{po} \cdot X$	(4)
Pre-processing fixed cost	$\sum P_{pf} \cdot E_P$	(5)
Biorefinery fixed cost	$\sum P_{bo} \cdot X$	(6)
Biorefinery operational cost	$\sum P_{bf} \cdot E_B$	(7)
Income from product sales	$\sum P_z \cdot X(Z)$	(8)
Constraints		
Amount of feedstock used cannot exceed capacity: $\sum X(F) \leq A_F(F),\ \forall i, w \in \{I, W\} \in F$		(9)
Transported material cannot exceed capacity: $\sum X \leq T_c\ \forall t \in T$		(10)
Pre-processing capacity cannot be exceeded: $\sum X(O) \leq A_p(O), \forall j, k, l, m \in \{J, K, L, M\} \in O$		(11)
What is transported away from an operation cannot exceed what is transported to an operation, considering conversion: $\sum X(O_{n+1}) \leq \sum X(O_n) \cdot C_p(O_n), \forall j, k, l, m \in \{J, K, L, M\} \in O$		(12)
There can only be one of each type of pre-process at each location: $\sum E_P(O) \leq 1, \forall j, k, l, m \in \{J, K, L, M\} \in O$		(13)
There can only be one biorefinery at each location: $\sum E_B(N, B) \leq 1, \forall b, n \in B, N$		(14)
What is transported away from the biorefinery is less than what was produced: $\sum X(Z) \leq \sum X(M) \cdot C_Q(B) + \sum X(M) \cdot C_R(B) + \sum X(M) \cdot C_S(B), \forall m, z \in M, Z$		(15)
The buyer capacity cannot be exceeded: $\sum X(N, Z) \leq A_z(Z) \forall q, r, s \in \{Q, R, S\} \in Z$		(16)
The capacity of the biorefinery must be filled $\sum X(M) \geq A_N(B), \forall b \in B$		(17)

Key
Log sources = $\{I_1, I_2, I_3, I_4, I_5\}$
Chip sources = $\{W_1, W_2, W_3\}$
Log storages = $\{J_1, J_2\}$
Biorefinery location options = $\{N_1, N_2, N_3\}$
Customer locations = $\{Z_1, Z_2\}$

Figure 2. Map of candidate points considered

4. Example scenario

The example scenario is set in Scotland with the use of softwood either as logs or as chips from the sawmill by-product. The prices in the model are based on the pound sterling 2012. A summary of the candidate points is presented in Figure 2. The pre-processing operations, chipping, drying and milling could either be located at the log storage sites, the sawmill sources or the biorefinery locations. The data for each route type was made on collation of information collected for the Road Haulage Association (Table 3) (Road-Haulage-Association 2013). Diesel fuel cost was averaged over 2012, as reported by the UK government, (1.4216 £/L).

4.1. Feedstock sources

Trees are bought as sawlogs at an average price of £47.60 per green ton (Forestry Commission 2012) with a moisture content of 60% (wet basis) for Sitka Spruce (Rolls 2009). However if any tree is allowed to air dry, the moisture content can be reduced to 30% in 18 months (Price 2009). Here the price per cubic metre is converted using the mass ratios to a related price of £92/ ton (30% moisture content), with a nominal 10% added to incorporate cost of passive drying.

The sawmill availability is based on three different sawmills in Scotland, considering their annual production of by-products. The sawmills were assumed to provide green chips with 55% (wet basis) moisture content (Price 2009). The wet wood price taken for woodchips was £30 which was an average of public and private sources provided which was corrected for any dryer prices using a mass conversion and adding 10% nominal additional holding cost per ton.

Table 3. Transport costings calculated according to UK data. (Road-Haulage-Association 2013)

Transport Type	**Distance** (£/ton/km)	**Load** (£/ton)	**Capacity** (km.ton/ year)
Forest logs	0.53	6.57	2.42×10^6
Highway logs	0.25	6.57	2.42×10^6
Chips and milled feed stock	0.15	1.88	2.51×10^6
Products - large trucks	0.31	4.37	4.34×10^5
Products – small trucks	0.46	6.59	2.53×10^5

Table 4. Fixed costs and capacities of different pre-processing stages.

Pre-process	Capacity (ton/y)	Fixed cost (£/y)	Operational cost (£/ton)
Storage (J)	20 000	200	1
Chipping (K)			
At log store	23500	48300	0.95
At BioSep Facility	44000	64000	0.95
Milling (M)			
At Dry/Store	5040	20 100	3
At Bio-Sep Site	18000	31800	3

Table 5. Drying Costs. Variations per moisture content to reduce to 10% moisture

Moisture content (MC) (%)	Operating cost (£/ ton(wet))	Capacity (wet ton/y)	Conversion rate
60	125	19000	0.44
55	100	19000	0.50
50	80	19000	0.56
40	50	21100	0.67
30	29	27000	0.78
10	0	30000 (nominal)	1

4.2. Pre-processing stages (J,K,M)

The figures for capacity, fixed cost and operational cost of the various pre-processing costs are summarized in Table 4. Estimates were made for the cost of a storage facility with capacity of 1200 tons. The chipping scenario costs were based on chipping costs with respect to forest logs (Webster 2007). Two different milling capacities were considered (Zhangqiu Yulong Co. Ltd), with an assumed conversion rate of 95%.

4.3. Chip dry and store (L)

Woodchip drying can normally be facilitated to 10% moisture content (MC) based on woodfuel drying, and pelletisation reports (Crown 2001, Price 2009, Price 2011). The calculated cost per dry ton per percent reduction in moisture content was £0.87, and this value was translated into a cost per input (wet ton), as displayed in Table 5. Then the cost of dryers was estimated, with an additional land and labour cost which gave a total of £22600/year (Alibaba, accessed February 2014). The capacity of each drying site was then based on 0.56 h/dry ton/% which correlated to 4704 dry ton/ year.

4.4. Product values

There are three main products for consideration in the value chain, namely; lignin, cellulose and hemicellulose. Mid-range values for cellulose, lignin and hemicellulose were used at £2600, £460 and £1200, respectively. This was based on the organosolv lignin valorisation (Gosselink 2011), cellulose values from the National Non-Food Crops Centre (NNFCC), (Higson 2011), and alibaba.com, and an approximation for hemicellulose using xylose values (alibaba.com).

5. Results

The main cost to the value chain was the biorefining, (>50%) followed by drying (up to 25%) and feedstock transport (5-20%). Overall, sawmill by-products (55% MC) were cheaper overall than green saw logs (60% MC) and the southern sawmill (W3) was the preferred option for a feedstock source due to proximity to the processing sites.

However, passively dried sawn logs were the cheaper option once they reached 40% MC due to transportation and drying cost reduction. Drying was done at either the log storage or collection location to minimise transportation costs. Due to the additional transportation costs and requirements in log processing, the change in moisture content is a more significant factor for the log source compared to the sawmill source. The biorefineries were placed next to potential sources of waste heat and the effect of heating cost on the overall value chain was only 3% when going from £0.05/kWh to £0.01/kWh.

6. Conclusions

The flexibility of the model allowed for analysis of key parameters such as moisture content, feedstock size and hence subsequent downsizing and drying options. Thus the model provides a generic framework for a flexible scenario where one technology may consider more than one simultaneous feedstock type and hence pre-processing route. The significant variation in costs given the alternative scenarios demonstrated the importance of this flexibility in consideration of different feedstock characteristics.
Moreover the availability of various product streams provides a generic framework, useful for the evaluation of a variety of lignocellulosic products. These may be alternatives to heat energy and ethanol or co-production biorefineries where ethanol or heat energy are produced alongside other by-products of lignocellulose processing. With regards to decision making for a biorefinery with multiple options for feedstock sources and products the model can be useful for comparing and identifying the key factors to consider with respect to profitability.

Abstract

Design and planning of petroleum supply chains (PSC) present significant opportunity as financial crunches and variability in crude oil prices continue augmenting volatility among the petroleum product prices, costs, margins and demand. To deal with this challenge, we present a stochastic mixed integer linear program (MILP) that maximizes the expected net present value (ENPV) while simultaneously minimizing a risk measure the conditional value-at-risk (CVaR) under demand uncertainty. The bi-objective MILP model determines the design decisions relating to installation, sizing and operation of infra-structures, the fair price strategic cost and tariffs and tactical decisions concerning periodic depot and route product affectations and inventory levels. Pareto optimal solutions are obtained for the retrofit network design of the Portuguese PSC, wherein computational results are presented and identified opportunities for further research.

Keywords: petroleum supply chain, strategic design, tactical planning, mathematical programming, uncertainty management

1. Introduction

The PSC is a complex network that can be divided into upstream involving exploration and production; and downstream involving refining, transportation, storage and distribution. While world economies struggle amidst financial crunches and volatile crude oil prices, the strain on the reduction of the petroleum products' costs has increased for companies to stay competitive and sustain sales. Market condition adjustments have created volatility among the petroleum prices, margins and product demand. Consequently, inefficiencies resulting from crude oil price fluctuations that are transferred down to the final product prices and customer demand misbalances that scale up the distribution, inventory, production and procurement stages have adversely affected PSC profitability. This presents an opportunity for downstream networks to improve the PSC efficiency and perform well in spite of price and demand uncertainty.

PSCs have always been under focus for supply chain optimization. Lately, considerable research has focused refinery and the distribution network planning, specifically related to process design and operational planning including some references on network design. Nevertheless, the integrated downstream PSC design and planning under uncertainty although less explored, presents an increasing potential. Fernandes et al. (2011) surveyed the supply chain and PSC risk management literature on risk planning in petroleum prospection, exploration, production, refinery process design, scheduling and network design. Interesting directions for the strategic, tactical and operational planning levels under several types of uncertainties were identified.

The crude oil supply chain management has been identified in Sahebi et al. (2014) as a flourishing research area, requiring vertical integration of strategic and tactical decisions and horizontal integration of the complex crude oil supply chain. Uncertainty with global factors such as international taxation, transfer prices, environmental impacts involving multi-stage stochastic and nonlinear modelling still remain unaddressed.

Uncertainties relating to demand and cost were modelled in Lakhanawat and Bagajewicz (2008) using a non-linear program for refinery operations planning, in order to determine the final product prices and the crude purchase and production quantities that maximize profits. The stochastic model incorporates the upper-bound risk curve, opportunity value, and value-at-risk (VaR) to provide higher expected gross margin and lower risks. Later, Conejo et al. (2010) model production, cost, demand and price uncertainty for electrical markets, maximizing net profits and simultaneously minimizing a risk measure. The risk measures included mean variance, variability index, probabilistic financial risk, downside risk, risk premium, VaR and CVaR.

Recently, Oliveira et al. (2014) proposed a two-stage stochastic MILP to make the downstream PSC investment, transportation and inventory decisions that minimize the investment and logistics costs under demand uncertainty. Network design and discrete capacity expansion are modelled using the L-Shaped method (Benders decomposition), for varying demand scenarios, to improve the solution quality and performance. However few works have analysed so far the presence of uncertainty in oil supply chains when dealing with many important aspects that characterize these chains.

In order to contribute to the reduction of this gap we extend our previous work (Fernandes et al. 2014) where several characteristics of the downstream oil supply chain have been considered. Namely, a PSC collaborative design is studied to determine depot locations, transport modes, routes and shared resource capacities under an uncertain context. Tactical decisions are also considered that include the periodic multi-stage importation, exportation, refinery, storage, transportation and inventory volumes for crude oil and petroleum products, for current, grassroots and retrofit redesign considering single-entity and multi-entity networks. Company financial participations determine the resource sharing and incorporation of refinery, transport infrastructure and distribution depot profits. Entity tariffs are determined using piecewise linearization, to ensure economies of scale and efficient sharing of self and competitor installation capacities. The multi-stage and multi-period crude oil and derivative price variations are captured and the procurement, exportation, refining and inventory costs optimized. The stochastic model developed generates Pareto-Optimal network design solutions by varying demand scenarios for the Portuguese PSC. On one side we consider the maximization of the Net Present Value (NPV) while on the other side we minimize the conditional value-at-risk (CVaR).

2. Problem Description and modelling

PSC networks are comprised of petroleum companies that purchase crude oil, import and export or produce petroleum products through refineries, which they commercialize and distribute through distribution depots using different transportation modes and routes to retail customer districts. Considering that multiple entities operate in a market with self-owned or participated installations, the mission of the petroleum companies is to design, construct and manage PSC networks that maximize the profits and reduce risks for the entire PSC. The problem here is to determine the right company participations, depot locations, resources, capacities, transport modes and routes to install and operate per product; the crude importation, production, primary and

secondary distribution volumes, the product inventories at multi-stage nodes and the entity tariffs and prices, in order to construct efficient collaborative networks.
Figure 1 represents the Portuguese downstream PSC where two refineries R1 and R2 produce the petroleum products. The companies purchase the oil products from the local refineries or import them from external sources at a premium of insurance and freight. The product is then transported using the primary distribution to eleven storage depots, D1-D11, where it is stored and distributed using the secondary distribution to the retail stations. The depot capacities as the number of typical capacity tanks are determined for each of the 8 products (C3, C4, U5, U8, GO, FU, A1, B5). The retail stations are aggregated into customer zones corresponding to the eighteen districts of Portugal.

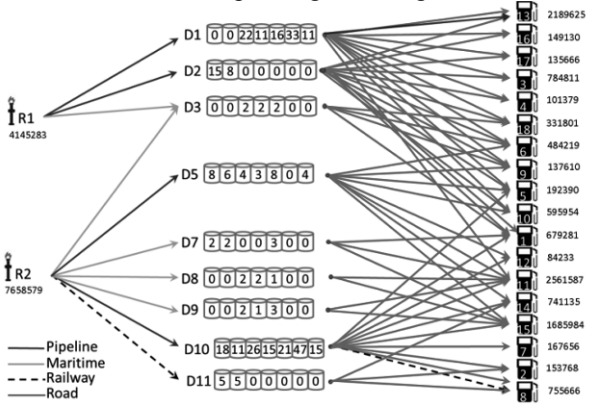

Figure 1. The PSC network in Portugal

The stochastic MILP determines 1) strategic decisions for installation, operation and closure of multi-entity infrastructures and capacities; 2) tactical decisions for crude and product inventories and transfer volumes per PSC stage, entity, time period and scenario. The objective function is an aggregation of value components determined per PSC stage, location, transportation route, product, entity, time period and scenario:

$$= \textit{Refinery Margin} = \textit{(Refinery profits – Exportation costs – Importation costs – Crude Oil, refined product, depot and retail inventory costs)}$$

$$+ \textit{Gross retail margin} = \textit{(Retail profits – Depot tariffs – Transportation tariffs – Shortage costs + Depot profits + Transportation profits)}$$

The PSC collaborative model may consider a current network, a retrofit network or a grassroots network. Hence the network initial conditions for the infrastructure may begin with the existing depots and transport infrastructures with known entity participations which may not change (Current), may begin with the current and are allowed to change (Retrofit), or need to be constructed from scratch (Grassroots).

3. Uncertainty Management

The stochastic scenario dependent MILP simultaneously maximizes ENPV (Expected NPV) and minimizes one risk measure including variance, variability index, downside risk, VaR and CVaR and uses the compact node-variable formulation as explained in Conejo et al. (2010). The authors identify the first four measures as non-coherent risk measures, presenting drawbacks of "fat tail" profit distributions, discouraging diversification and not distinguishing the different levels of losses below the threshold

whereas CVaR is a coherent risk measure ward of such drawbacks. The CVaR is the likelihood that an ENPV will be lower than the NPV given by the VaR with a specific confidence level and can be expressed using a linear formulation.
The ENPV is determined in equation (1) as the aggregate of the product of probability and NPV for all scenarios where the NPV per scenario is given by equation (2) as the summation of the discounted profits per time period, using an arbitrary interest rate. The MILP implements the linear approximation of CVaR for discrete distributions as defined in Rockafellar and Uryasev (2002). Equation (3) derives the CVaR where $a \in (0,1)$ represents a confidence level defined by the decision maker and ΔV_s is a positive difference between the VaR and NPV obtained per scenario in equations (4).

$$Max(ENPV) = \sum_s \psi_s \times NPV_s \tag{1}$$

$$NPV_s = \sum_t \text{Profit}_{ts} / (1+irr)^{t-1} \tag{2}$$

$$CVaR_a = VaR + 1/(1-a) \times \sum_s (\psi_s \times \Delta V_s) \tag{3}$$

$$\Delta V_s \geq VaR - NPV_s \tag{4}$$

$$\Delta V_s \in R_0^+ \tag{5}$$

$$Max(f_1 + 10^{-6}(slack/r)) \qquad | f_2 + slack = f_{2Max} - k(r/n_k) \tag{6}$$

The stochastic model is combined with the improved augmented ε-constraint algorithm from Mavrotas and Florios (2013) to determine the Pareto optimal solutions and the trade-off between the two objective functions f1 = ENPV and f2 = CVaR. Both objective functions are individually optimizing to obtain f1=z1* and f2=z2*. By adding constraint f2=z2*, is optimized F1 to obtain the extreme points of the Pareto curve. The remaining points of the curve are obtained by solving the problem in equation (6) where f_{2Max} is the upper bound of f_2, slack is a non-negative surplus variable, r is the range of objective function f2 and k is the number of efficient solutions between 1 and n_k.

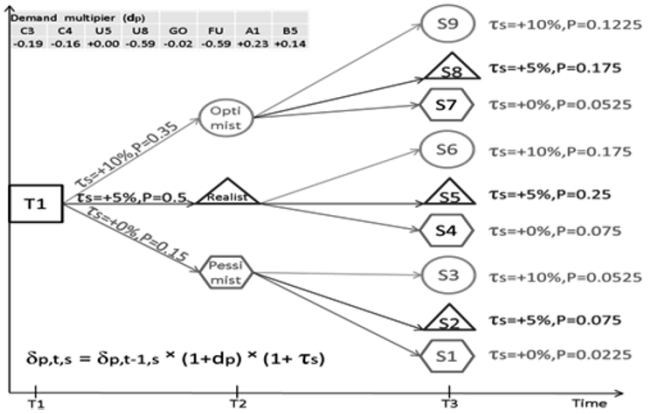

Figure 2. Demand scenario tree construction.

Figure 2 presents the scenario tree for the demand uncertainty which is constructed based on the market demand evolution in recent years, which has increased for some products and decreased for others. After the recent economic crisis, the market evolution is expected to be favourable, so the scenarios are constructed considering an optimistic growth of 10% with 0.35 probability, a realistic growth of 5% with 0.5

probability and a pessimistic growth of 0% with 0.15 probability. The product demand per period and scenario $\delta_{p,t,s}$ is given by expression $\delta_{p,t-1,s}\times(1+dp)\times(1+\tau s)$ where *dp* is the product trend per period and τs is the market tendency per scenario.

4. Computational Results

The MILP model is implemented using GAMS 24.3.3 64-bit and solved with MILP commercial solver CPLEX 12.6 using 4 parallel threads on a dual-core Pentium 2.4 Ghz CPU with 8GB RAM. The stopping criterion is 0.1% optimality gap or 24 hours of CPU time. The MILP models the current, grassroots and retrofit designs for single and multi-entity networks of the Portuguese PSC maximizing ENPV while minimizing CVaR.

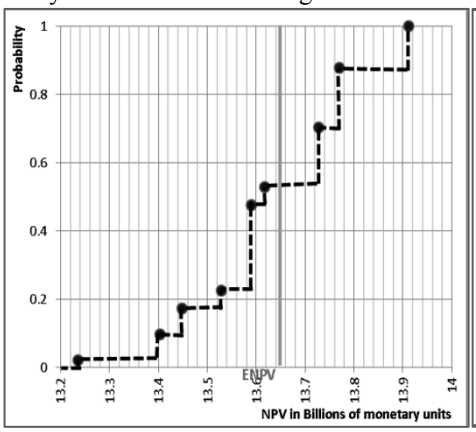

Figure 3. ENPV maximization solutions

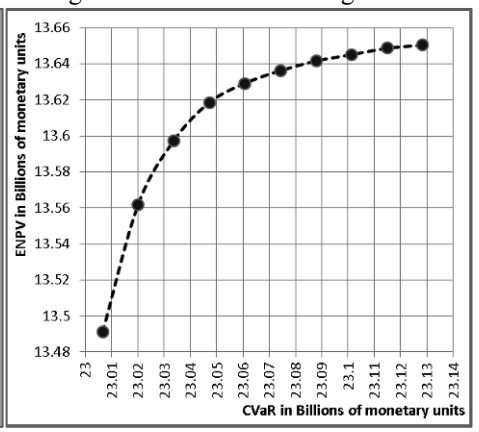

Figure 4. Pareto optimal solutions ENPV/CVaR

Figure 3 presents the cumulative probability distribution for the ENPV maximization problem of the single-entity retrofit. The PSC designs for the 9 scenarios generate NPVs between 13.23 to maximum 13.91 billion monetary units (bmu). The cumulative probability distribution shows that the MILP generated network design has 0.5275 probability of generating NPVs higher than the ENPV which is 13.65 bmu.

Figure 4 presents the Pareto optimal solutions for the Portuguese PSC considering ENPV maximization and CVaR minimization. By fixing the VaR to 13.65 bmu which is the result of the max(ENPV) problem and using a confidence level of 95%, are obtained the minimum CVaR of 23.01 bmu and maximum CVaR of 23.13 bmu. The CVaR range is then calibrated into 10 equidistant grid points and solved the max(ENPV) problem for these CVaR grid points deriving the ENPV values which vary between a minimum of 13.49 up to a maximum of 13.65 bmu. The min(CVaR) problem contrasts with the Max(ENPV) problem where a higher ENPV implies a higher CVaR risk as seen in the Pareto-Optimal curve. The MILP and augmented ε-constraint methodology is seen to adequately model the downstream PSC design and planning under uncertainty.

The methodology may also be used to minimize variance, variability index or downside risk. While variance is the summation of the modulus of the differences between ENPV and NPV per scenario multiplied by its probability, the variability index only considers the positive differences. The downside risk is similar to the variability index, however the reference is not ENPV but a NPV target value defined by the decision maker. The bad news for the variance is that negative differences will nullify positive differences whereas NPVs higher than the target value will be discarded for the variability index and downside risk measures. Hence, the use of CVAR besides the fact that it considers

both the expected profit and the profit variability where the trade-off between the two is modelled using a weighting parameter.

Table 1 – Model Statistics

	Total Variables	Binary Variables	Equations	Gap (%)	CPU(s)
ENPV	433397	4591	101501	0.1	59556
CvaR	433414	4591	101515	0.1 - 3.5	8402 – 86400

Table 1 presents the model statistics for the PSC example. The MILP is executed four times to obtain the payoff table: 1) the maximum ENPV; 2) the minimum CVaR; 3) the minimum ENPV which is max(ENPV) when z2*= min(CVaR); 4) the maximum CVaR which is min(CVaR) when z1*= max(ENPV). These are the extreme points of the Pareto-Optimal curve. The MILP is then executed 10 times to obtain the efficient solutions of max(ENPV) for 10 equidistant CVaR values derived from the payoff table. Each run considered 9 scenarios with execution times varying between 8402 and 86400 seconds. The model statistics demonstrate the problem complexity and the computational load for solving such problems even when considering only 9 scenarios.

5. Conclusions

The current paper presents a stochastic MILP for collaborative strategic and tactical planning of downstream PSC networks where uncertainty management and economies of scale are considered. Besides ENPV, the risk measure CVaR is incorporated using the augmented ε-constraint method, in order to improve planning under demand uncertainty. As result, are obtained improved network designs with stable expected profits, and therefore lower risk for the real-case Portuguese PSC network. These designs improve costs, tariffs, revenues and total profits. As the PSC planning under uncertainty is a large scale problem, our future research will focus decomposition strategies and robust optimization as alternative methods that may better explore time performance difficulties.

Abstract

To meet the quality requirements in the production of cement, samples are taken in the production process, transported to a central lab and analysed partially automatically. The measurements are used to adjust the parameters of the production process. An optimal management of the laboratory system can lead to significant throughput gains and shorter analysis times. In this contribution, we describe the optimal scheduling of the robots-based laboratory automation system a cement plant. The TA-based approach is embedded into a reactive scheduling approach to handle the different uncertainties in the system, e.g. manually inserted jobs. We show that compared to a priority-based dispatching rule, this approach leads to significant throughput gains while meeting all process-related timing restrictions.

Keywords: Process operations, Reactive scheduling, timed automata, laboratory automation.

1. Introduction

The increasing demand for high quality cement in construction calls for an efficient integrated quality analysis process in cement production plants. To analyse the quality of the cement, small samples of material are collected online in several stages of the cement production process, and the composition and the properties of the samples are analysed in a central laboratory. Based on these measurements, various control parameters of the production process are adjusted. In advanced cement plants, the sample collection, transportation and analysis is partially automated. In the automated lab, human operators and robots interact in a cooperative setup. In the automated analysis process, the time between the sample collection and the adjustment of the control parameters is strictly restricted but the actual time depends on the load on the lab and on material composition and quality. Additionally, the human workers can insert new samples that have to be analysed at any point in time and are allowed to switch analysers that are required to process the samples to a manual mode thus disconnecting them from the automatic system. The assignment, sequencing, and timing decisions that are required to execute the automated sample handling and analysis process are taken by a scheduling solution, either in the form of a dispatching rule (He

and Hui (2012)) or by an optimization-based technique, e.g. mathematical programming (Mendez and Cerda (2006)) or TA-based scheduling (Subbiah et al. (2011)). One of the crucial characteristics that make a scheduling problem challenging, especially if strict time limits have to be met, is the presence of uncertainty in the information on the operational level, e.g. varying analysis times, insertion of new samples, decoupling of idle analysers from the automatic system, etc. Such highly dynamic environments demand optimization techniques that can compute new decisions within small amounts of computation time when reacting to unforeseen events.

In this contribution, it is shown that a real-time optimization of the sample handling and analysis system can lead to significant efficiency increases in the shuttle-based laboratory automation system that is connected to a cement production plant. The sample scheduling problem is modelled using timed automata (TA). To handle the different kinds of uncertainties in an efficient and robust fashion, the TA-based approach is extended to a reactive scheduling approach that combines the idea of a moving window approach in which schedules are computed one after the other for temporally overlapping windows with an explicit event handling procedure to quickly cope with unforeseen deviations in the schedule execution and the insertion of new jobs. We show that this approach can successfully handle the different uncertain events and can lead to significant throughput gains compared to priority-based dispatching rules while meeting all process-related timing restrictions.

2. The laboratory Automation System

The industrial case study considered is the shuttle-based laboratory automation system (LAS) of a cement production plant located in Solnhofen, Germany. The layout of the LAS is shown in Fig. 1. The LAS is equipped with seven collectors which are located in different parts of the continuous cement production plant and collect sample material from the production process. The collectors are connected by a single-capsule pneumatic tube system that transfers the material samples - one at a time - to the laboratory. The laboratory itself consists of a cup filling machine, three storage areas, four analysers and two material crushers which are connected by a single-track shuttle lane and one shuttle robot. All parts of the laboratory, except of the cup filling machine, can also be accessed by human workers. In this case they are decoupled from the automatic system. Furthermore the workers can insert additional samples in the storage areas that must be analysed.

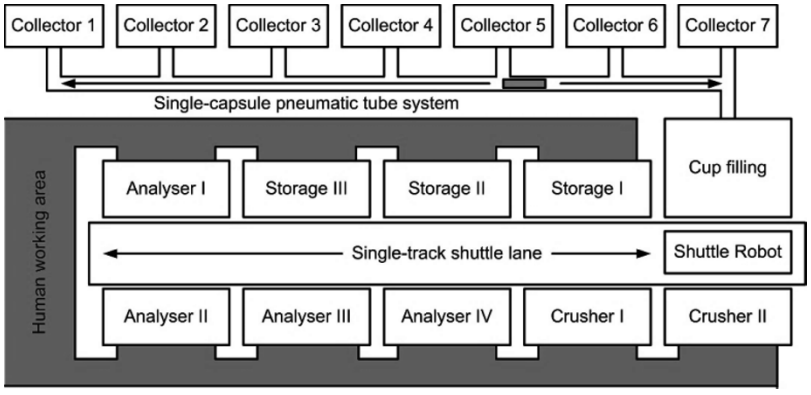

Figure 1: Layout of the laboratory automation system (LAS).

The cyclic sample analysis process starts with the collection of material in one of the collectors. When the collection of the material is finished, the capsule of the pneumatic tube system is sent to the corresponding collector, filled with the material and sent back to the cup filling machine. Once the material has been poured into up to three different cups, each cup can be picked up by the shuttle robots and has to be transported to different units in the laboratory based on a predefined sample route. The time required by the shuttle robot to transport a cup from one of the unit to another is in the range of a few seconds to tens of seconds and depends on the current position of the shuttle robot, hence it is sequence-dependent. Furthermore, the time required to process the sample in one of analysers depends on the material composition and the quality of the current sample, and may vary. In total, 340 different sample routes exist including the transportation from the seven collectors to the laboratory, the splitting into up to three subsamples.

In the current control system, the samples and the shuttle-robot movements are dispatched using a problem-specific algorithm implemented on a programmable logic controller. The complexity of dozens of priority rules makes it challenging to improve the existing algorithm and to implement new features. It can happen that deadlines are missed or that manually inserted samples suffer from starving which means that these samples are not started for a long period of time.

3. Timed Automata-based Scheduling

A relatively new method to model and to solve scheduling problems is by means of reachability analysis of timed automata (TA). Timed automata are finite state automata extended by the notion of clocks. They are used to model and to analyse real time systems with discrete dynamics. The timed automata framework offers a transparent graphical problem representation, and models can be built in a modular fashion, making the approach intuitive and comprehensible also for inexperienced users. Due to the modular nature of the framework, changes in the model formulation can easily be implemented. For a detailed introduction to timed automata, see Behrmann et al. (2005).

The model of the case study was built in a generic fashion taking advantage of the modular framework of the TA formalism. Following the standard modelling approach for batch scheduling problems, see Panek et al. (2008), for each sample route a separate recipe automaton was created. If the material that was collected is split and poured into more than one cup in the cup filling machine, for each of the subsamples a separate recipe automaton was created. Similarly, for each unit in the laboratory, for each collector, for the pneumatic tube system and for the shuttle robots, separate resource automata were created. The movements of the shuttle robot were modelled according to the modelling procedure for sequence-dependent changeovers (Subbiah et al. (2011)), similar to the shuttle management of a high-rise warehouse in a polymer production plant described in Schoppmeyer et al. (2014a).

The large number of 340 different sample and subsample routes made it impossible to create all recipe automata by hand. Therefore the generation of the recipe automata is done online in an automated fashion based on the current state of the system including the current execution state of all samples in the system, the current position of the robot and the current operating mode of the units in the laboratory, i.e. available or decoupled. The automatic procedure developed in Gajjala (2014) works as follows: first, a recipe

automaton for the sample collection and the transportation using the pneumatic tube is created. In a second step, additional subsample recipe automata are created including the shuttle movements to transport the samples in the laboratory.

Once the TA model has been created, the sets of job automata and resource automata are combined on-the-fly by the technique of parallel composition to form a composed global automaton that represents the complete scheduling problem as a directed graph. Every path from the initial node of this graph to a leaf node represents a feasible schedule and the shortest path according to a given cost criterion represents the optimal schedule. To compute the shortest path, the cost-optimal reachability algorithm for TA models is used that was presented in Panek et al. (2008). To enhance the efficiency of the search, different graph search and state space reduction techniques were introduced, see Panek et al. (2008) and Schoppmeyer et al. (2012).

4. Reactive Scheduling Approach

As mentioned in the description of the case study above, the material composition and hence the duration of the operations, the insertion times of manually started samples, and the times at which human workers disconnect idle units from the automatic system are not known to the shuttle management system in advance. To tackle the problem of optimizing the sample scheduling problem with online information on the processing duration and insertions and decoupling times, a reactive scheduling approach has been developed.

The reactive scheduling approach combines the idea of a moving window approach (Schoppmeyer et al., 2014a) in which schedules are computed one after the other for overlapping windows with an explicit event handling procedure to quickly cope with deviations in the execution of the schedule from the nominal schedule. Fig. 2 shows the structure of the reactive scheduling approach. , The monolithic problem is decomposed into overlapping windows where the decisions in later windows are not taken at the beginning of the scheduling horizon but at later points in time. Hence, it is possible to incorporate new information on the execution status and new job arrivals in the later decisions.

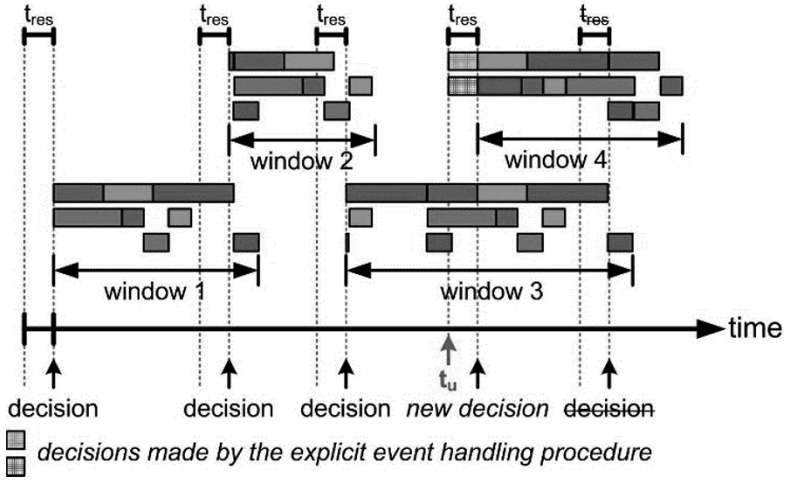

Figure 2: Schematic structure of the reactive scheduling approach.

The response time t_{res} denotes the time that is required to calculate a new decision. In a dynamic production environment where new decisions have to be taken quickly, the response time should be as short as possible. The actual response time of any algorithm does not only include the calculation time to compute new decisions but also the time required for data handling and communication. Hence not all unexpected events can be handled by a re-computation of the schedule in a new window. The moving window approach is therefore combined with a lightweight explicit event handling procedure based on pre-calculated dependencies between operations. Dependencies are defined following the principles introduced in Schoppmeyer et al. (2014b). Dependencies exist between operations of the same recipe, so-called recipe-based dependencies, requiring to stick to the sequence of the recipe, between operations that are scheduled on the same resource (unit), so-called resource-based dependencies, and between operations that share or require a common utility, so-called utility-based dependencies. Based on these dependencies and using the currently valid schedule, the explicit event handling procedure can quickly – in the range of a few milliseconds - determine upon recording of an unexpected event that occurred at time t_u in Fig. 2 which operations can continue, which operations can start as planned and which operation have to be delayed or aborted. Of course, the capabilities of the event handling procedure are limited to re-decide on the operations that were planned in the current window. At the same time at which the event handling procedure is started, a new window in the moving window approach is created and a new schedule is computed. In other words, the explicit event handling procedure only has to bridge the response time t_{res} to avoid that the systems stops while waiting for the computation of a new schedule.

In principle, the reactive scheduling solution can be used with any scheduling algorithm that solves the static problems within the individual windows. The advantages of selecting the TA-based scheduling approach are that good and feasible schedules are found within seconds, even for larger scale problems, and that the developed automatic model builder can adapt the model easily to the current state of the system, exploiting the modular nature of the TA formalism.

5. Numerical Results

To test the performance of the developed approach, a 24 hours scenario that had been recorded in the real plant was simulated. The scenario includes 82 automatically collected samples with strict timing restrictions and 20 additional samples that were inserted at random points in time by human workers – counting the individual subsamples, the total number of orders is 415. Additionally, the scenario includes several delays in the operations that are executed in the analysers caused by the varying material composition and a few disconnections of units by the human workers. In case of any of the uncertain events, the explicit event handling procedure of the reactive scheduling approach is called and a new window is created and scheduled.

Table 1 shows the comparison of the results for the 24 hours scenario between the existing dispatching rule and the proposed reactive scheduling approach. It can be seen that the dispatching rule is not able to meet the timing restrictions for all samples while the proposed approach not only meets these constraints but also reduces the average execution time required to process the samples as shown in the last column. For the manually inserted samples, the proposed approach is able to reduce the average execution time by up to 47%.

Table 1. Comparison of results for the 24 hours scenario.

Recipe type	Time limit	Dispatching rule			Reactive scheduling approach			Perf. difference
		Av. ex. time	Max. ex. time	Constr. vio.	Av. ex. time	Max. ex. time	Constr. vio.	
Raw meal	30	26.55	46.40	5	25.01	28.33	0	+7.1%
Kiln feed	60	28.59	36.46	0	28.56	34.25	0	+0.2%
Hot meal	60	49.37	55.27	0	50.44	51.35	0	-2.3%
Clinker	60	53.58	61.55	1	49.15	53.55	0	+8.8%
Manually inserted	-	124.52	255.01	-	66.11	122.41	-	+47.0%

Times in minutes, av. – average, ex. – execution, t. – time, max. – maximum, constr. – constraint, vio. – violations, perf. - performance

6. Summary

In this paper, a reactive scheduling approach for the sample handling and analysis in the shuttle-based laboratory automation system of a cement production plant was developed. The reactive scheduling approach combines a moving window approach with an explicit event handling procedure to provide an instantaneous reaction to unforeseen events. To solve the scheduling problems in the moving window approach, the TA-based schedule optimization is used, exploiting the advantages of the modular modelling formalism and its performance in calculating good and feasible schedules quickly. The numerical results show that the reactive scheduling approach is able to meet all crucial process-related time restrictions while handling the different uncertain events in a robust fashion. The performance in terms of the throughput of the system is increased by serving all additional samples inserted by the human workers within the required time.

Abstract

The development of new techniques to the management of industrial water resources has become increasingly necessary in the last years. Many efforts in the field of algorithmic approaches have been made to achieve the minimum fresh water consumption. A common issue to most of those methods is the determination of a reference contaminant when dealing with processes presenting multiple contaminants. An assertive choice of it is crucial, because the calculations of all other contaminants are based on the reference contaminant and all of them require the same flow rate to meet the process constrains. Not only that, but the structure obtained based only on the reference contaminant can lead to violations of concentration limits. One of those techniques is the Water Source Diagram (WSD), which also requires a reference contaminant to deal with multiple contaminants. This work presents a novel and robust algorithm to determine the reference contaminant when applying WSD in Water Using Networks (WUN) problems. The proposed approach can also be used in conjunction with other methods based on the Water Pinch Analysis (WPA). We also present a violation prediction method that informs which contaminant violates (or may violates) the concentration limits and its respective operation. The presented results show the effectiveness and robustness of the algorithm when applied to a process plant example from the literature with four operations and three contaminants.

Keywords: Water Source Diagram, Reference Contaminant, Violation Prediction, Multiple Contaminants, Water Using Networks.

1. Introduction

The world is facing a faster and increasing demand for water resources. The water scarcity has reached regions that are traditionally known for its abundance in the availability of water. This fact has concerned environmental government agencies, private and state-owned companies and motivating them to provide changes in the use and regulation of resource (UNEP, 2008). The increasing demand associated with climate changes and agricultural and industrial sectors are the major responsible for this situation.

In the industrial sector, especially in the chemical process industries, there is a requirement of great amount of water that is distributed to several usages such as vapour generation, cooling water, washing, etc (UNESCO, 2012). Most of this water is loaded with contaminants making it difficult to be reused.

To consider reusing wastewater in a process, the presence and behaviour of multiple contaminants must be investigated. To perform mass transfer calculations, it is necessary

to choose a contaminant to be the reference for the others. This choice involves some assumptions and one of them is to presume that the mass transfer between contaminants presents a linear relation, as shown in Eq. (1) .

$$\Delta \mathrm{m}_{\mathrm{u,c}} = f_u\left(C_{u,c,out}^{max} - C_{u,c,in}^{max}\right) \quad (1)$$

Where $\Delta \mathrm{m}_{\mathrm{u,c}}$ is the mass load of contaminant *c* transferred in the unit *u*, f_u is the flow rate in unit *u* and $C_{u,c,in}^{max}$ and $C_{u,c,out}^{max}$ are the maximum inlet and outlet contaminant concentrations, respectively.

Gomes et al., (2013), in a recent work, proposed a procedure to identify the reference contaminant when dealing with many processes and contaminants in WUN. Some difficulties found by Gomes et al., (2013) are intimately associated with the choice of the reference contaminant.

This paper proposes a novel algorithm to determine the reference contaminant and operation, focusing on improving the procedure developed by Gomes et al. (2013). Moreover, we present a method to identify previously, which contaminant will present violations in its limiting concentrations, and the unit where this occurs. This identification procedure represents an important role to solve not only the WSD but also other methods based on WPA and to remove violation concentration in the network evolution step. This algorithm contributes to most targets achievement procedures in the literature when dealing with multiple contaminants.

2. Reference Contaminant and Operation

The reference operation is the unit, which demands the use of the cleanest external fresh water available and the reference contaminant is the one, which calculations of all other contaminants are based on, and all of them require the same flow rate to meet the process constraints.

Even defining steps to properly use the WSD, they were not enough to avoid the presence of violations. To escape of such problems, Savelski and Bagajewickz (2003) proposed optimality conditions, and one of them is related with a rule of monotonicity used to define the reference contaminant, which can be analysed using the following parameter.

$$G_{u,c}^{w} = \frac{\Delta m_{u,c}}{C_{u,c,out}^{max}} \quad (2)$$

Where *w* indicates the fresh water source as the basis. The reference contaminant is then the one with the highest $G_{u,c}^{w}$ value. In other words, this contaminant reaches first its maximum inlet concentration in a process unit when fresh water is used. This contaminant with the highest $G_{u,c}^{w}$ has a specific nomenclature:$G_{u,c_{ref}}^{w}$.

2.1. The choice of the reference operation

The criteria presented herein to choose the reference operation are based only on the analysis of the maximum inlet contaminants concentration. The reference operation is then the one whose some contaminant requires the cleanest water, i.e., water at a maximum inlet concentration of 0 ppm.

As can be seen in Figure 1, if more than one operation present all of its contaminants with the maximum inlet concentration equal to zero, then to choose the reference operation among them, it is necessary to select the one which presents the lowest outlet concentration. It allows a greater possibility of reuse between operations. The operation having this characteristic is the reference. Furthermore, if no operation present any

contaminants with the maximum inlet concentration equal to zero, the reference operation will be the one with the lowest inlet concentration among all contaminants.

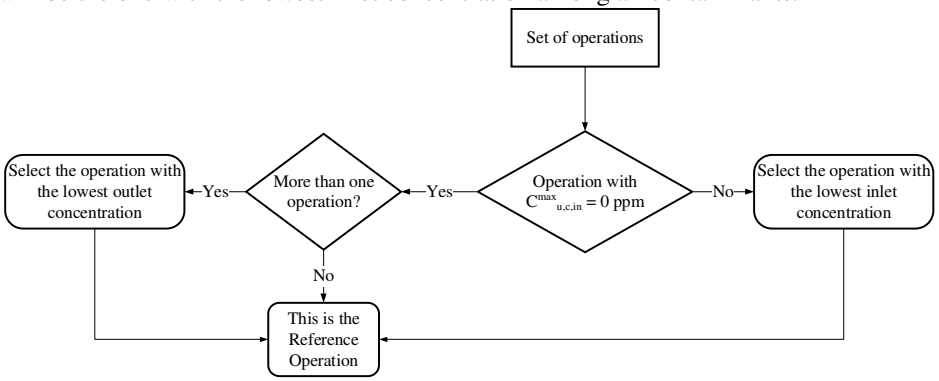

Figure 1. Algorithm for the choice of the reference operation.

2.2. The choice of the reference contaminant

The criteria to choose the reference contaminant are also initially based on the verification of the maximum inlet concentration of all contaminants in the process. However, we now analyse if the contaminants meet the criterion of monotonicity, as it is presented in previous work (Savelski and Bagajewickz, 2003). Figure 2 shows the algorithm to define the reference contaminant. We analyse if there is some contaminant with the maximum inlet concentration equal to zero. If so, then the monotonicity of the contaminant(s) is (are) verified, i.e. the concentration must be rankable and sortable in an ascending order.

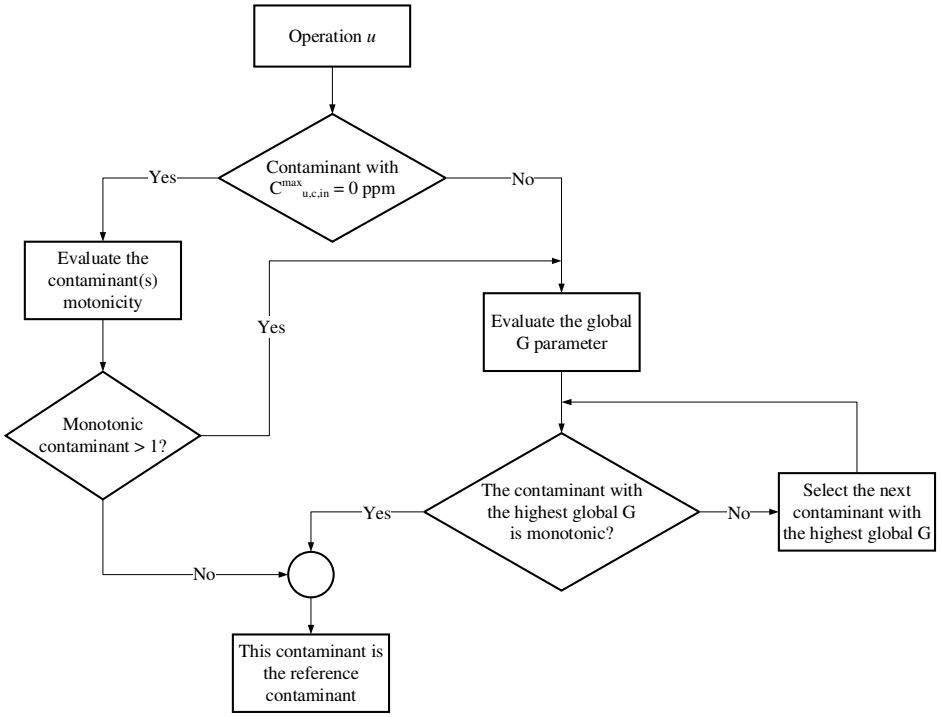

Figure 2. Algorithm for the choice of the reference contaminant.

If only one contaminant is monotonic then it is the reference, otherwise, if more than one is monotonic, the parameter $G_{u,c}^{w}$ presented in Eq. (1) is evaluated. The monotonicity is now verified for the contaminant with the highest $G_{u,c}^{w}$ value among all operations. If this contaminant is monotonic, then it is the reference contaminant, but if is not, the next contaminant with a higher $G_{u,c}^{w}$ is select, and its monotonicity is evaluated. This process continues until find a contaminant that respect the monotonicity criterion.

3. A Method to Predict Concentrations Violations

In order to avoid unnecessary effort in the preparation of the WSD and generation of the WUN and, to identify where will (or may) occur concentration violation, a prediction method is presented. Before introduce the algorithm, it is important to define other parameter as follows.

$$R_{u,c} = \frac{C_{u_{ref},c,out}^{max}}{C_{u,c,in}^{max}} \tag{3}$$

Where $C_{ref,c,out}^{max}$ is the maximum outlet concentration of contaminant c in the reference operation unit u_{ref} and $R_{u,c}$ is a relation that represents the amount of water saved in an operation unit u. Figure 3 shows the steps of the algorithm. Given the set of all operations in the process, the reference operation and contaminant are defined. However, it is possible to have one contaminant in the operation u, which its respective $G_{u,c}^{w}$ is greater than the $G_{u,c_{ref}}^{w}$ of the reference contaminant in that operation. If so, then we evaluate $R_{u,c}$ for it. The contaminant with the highest $R_{u,c}$ will have its concentration violated. Otherwise, if such contaminant does not present the highest $R_{u,c}$, then it is not confirmed the violation, but it is possible to have a one in that contaminant. The $R_{u,c}$ parameter is also evaluated in the case of the operation presents the highest $G_{u,c}^{w}$. If the reference contaminant presents the highest $R_{u,c}$, the violation will not be present in that operation.

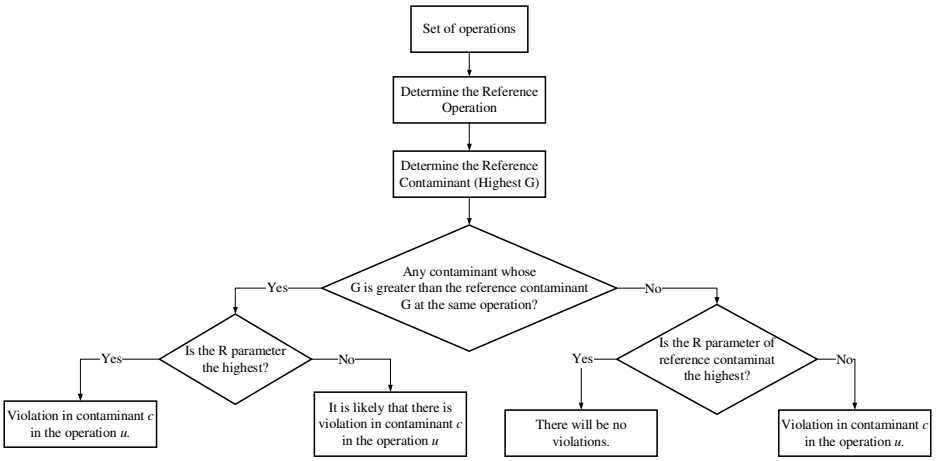

Figure 3. Algorithm to predict violations.

However, if its respective $R_{u,c}$ is not the highest one, then a violation will occur for that contaminant in the operation under evaluation. To make it clear, the three algorithms presented herein will be applied in a case study.

4. Case Study

To a better understanding of the presented algorithms, a problem provided by Doyle and Smith (1997) with four operations and three contaminants will be tested. The limiting data, as well as $G^w_{u,c}$ and $R_{u,c}$ are showed in Table 1. The WSD construction will not be explained here and for more detail, we recommend a reading of the work of Gomes et al. (2013). The first step is to define the reference operation. Using the algorithm given in Figure 1, the operation 1 is the reference, because it is the only one that requires freshwater at 0 ppm. The second step relates to the choice of the reference contaminant. The algorithm in Figure 2, points out that all the three contaminants can be the reference. All of them present the inlet concentration equal to 0 ppm, which increases monotonically. When this happens, the contaminant with highest $G^w_{u,c}$ will be the reference. In this case, the contaminant A is the reference ($G^w_{4,A}$ = 50.00 in operation 4).

Table 1. Data for the Case Study.

Operation (OP_i)	Limiting water flow rate (t/h)	Contaminant (c)	C^{max}_{in} (ppm)	C^{max}_{out} (ppm)	$\Delta m_{u,c}$ (kg/h)	$G^w_{u,c}$	$R_{u,c}$
1	34	A	0	160	5,440	34.00	NA
		B	0	450	15,300	34.00	
		C	0	30	1,020	34.00	
2	75	A	200	300	7,500	25.00	0.80
		B	100	270	12,750	47.22	4.50
		C	500	740	18,000	24.32	0.06
3	20	A	600	1,240	12,800	10.32	0.27
		B	850	1,400	11,000	7.86	0.53
		C	390	1,580	23,800	15.06	0.08
4	80	A	300	800	40,000	50.00	0.53
		B	460	930	37,600	40.43	0.98
		C	400	900	40,000	44.44	0.08

The third step refers to identify which contaminant will present violation. This is made looking at $G^w_{u,c}$, where the contaminant that presents $G^w_{u,c}$ bigger than $G^w_{u,c_{ref}}$ will present violations in its limiting concentrations.

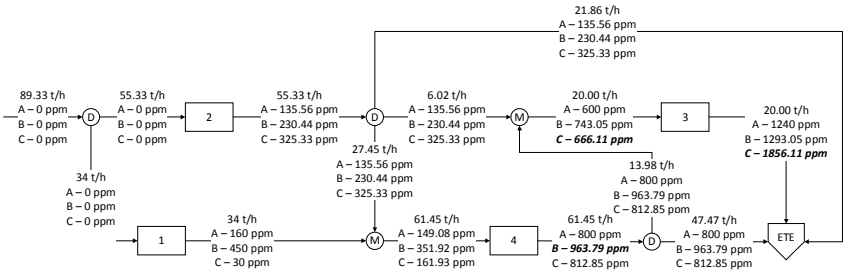

Figure 4. Water Network with concentration violations.

After identifying this contaminant, the concentration of the reference contaminant is adjusted with respect to the reference operation. This modification will be made only in contaminant B in operation 2, because it is the only operation that cannot receive

wastewater from the reference operation to allow reuse. It can be noted that contaminant C in operation 3 has a $G_{3,C}^{w}$ bigger than the reference contaminant and the lowest value of $R_{3,C}$. Therefore, it may occurs violation of contaminant C in this operation. For operation 4, the reference contaminant has the highest value of $G_{u,c}^{w}$ and only the $R_{u,c}$ is important to evaluate whether or not occurs violation in this operation.

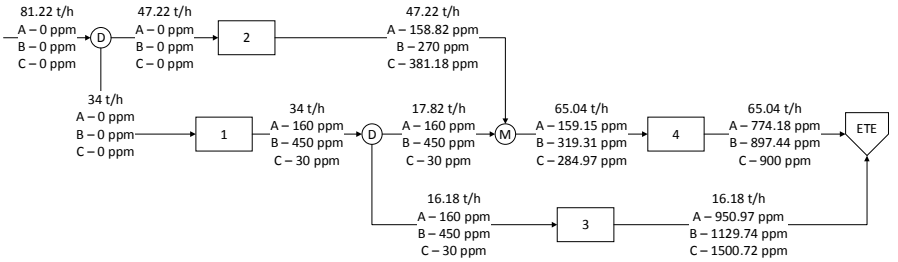

Figure 5. Final Water Network.

The $R_{4,B}$ for contaminant B is the highest, so it will violate its concentration limiting value. Figure 4 shows the WUN with violations and a total water consumption of 89.33 t/h, which is bigger than the one reported by Doyle and Smith (1997). The violations are marked in bold and italic. As expected for the operation 4, the contaminant B presents violation. For operation 3, there was violation in contaminant C that could be occurred or not. Using some rules and heuristics (Gomes et al., 2013), the network evolution is made to remove all the violations and to achieve the minimum water consumption. The new network is showed in Figure 5, with a total water consumption of 81.22 t/h.

5. Conclusions

This work presented a novel way to choose the reference operation and the reference contaminant, as well as to identify where may occur violation(s) in the limiting concentration of the others contaminants. To show this new method, a case study with four operations and three contaminants was analyzed using WSD. The proposed procedure can be employed to other targeting methods based on WPA. It does not guarantee the global optimum, but the monotonicity rule presented herein is the criterion to establish an optimum system. The violations occurred as predicted by the algorithm giving a water network with violation of constraints. Some rules and heuristics are used to remove these violations and to achieve the better water network. The $R_{u,c}$ parameter can be used to avoid computational effort in a future computer package implementation.

Abstract

Supply chain of a manufacturing system contains various functional activities including procurement of raw materials from suppliers considering demands of intermediate products. One of the most important issues for the inventory management is that various sources of supply and demand uncertainty should be considered. In general, these order decisions cannot be made effectively by intuition or heuristic approaches because they oftentimes involve multiple suppliers and competing criteria for their selection. Therefore, in this study, we apply a systematic approach to consider diverse criteria for supplier selection and to incorporate possible realizations of uncertainty into the decision-making process. This multi-period decision problem is formulated as a Markov decision process (MDP) with supply and demand uncertainty. Decision policies are obtained from solving the MDP problem through exact value iteration, as well as approximate approaches intended to overcome the 'curses of dimensionality.' We compare the results from applying them with those from the popular (s, S) policy for a simple benchmark problem.

Keywords: inventory planning, supply and demand uncertainty, Markov decision process

1. Introduction

Supply chain (SC) of a manufacturing system includes the following functional activities: procurement of raw materials from suppliers, transformation of raw materials into valuable products, blending and storage of final products, and distribution of final products to warehouses or customers. Decomposition of the overall SC planning into sub-problems is a common practice in refinery or chemical plants due to the complexity involved in different operations throughout the SC. To optimize the overall production system, it is important to manage the inventories of raw materials effectively.

For a sustainable long-term operation, supply and demand uncertainty should be considered. According to an excellent review of planning under uncertainty by Peidro et al. (2009), many models exist for a random demand, whereas the case of supply uncertainty has been studied far less, despite its significance. Another issue of inventory management for the raw materials is that multiple external vendors are oftentimes used; one should determine which suppliers to choose, and how much order is released to each one. In almost all cases, these decisions involve multiple criteria. Because the criteria for supplier selection often tend to conflict with one another, decision made by intuition or heuristic approaches can be significantly suboptimal.

The above argues for a systematic approach that can consider diverse, conflicting criteria for the supplier selection and incorporate possible realizations of supply/demand uncertainty into the decision-making process. Cheng et al. (2003) state that there are two

modelling approaches to address the problem of "multi-period decision under uncertainty": multistage stochastic programming (SP) with recourse and Markov decision processes (MDP), which is naturally solved by dynamic programming (DP). Since the SP formulation is limited to the problem of only a modest number of scenarios, it is difficult to apply to multi-period decision problems of practical significance (Lee, 2014). On the other hand, since a state-oriented formulation of MDP allows for a sequential decision making capturing both the physical dynamics and the flow of information, it can prove to be more convenient for handling many practical problems.

In this study, the inventory control problem is formulated as a MDP with two exogenous information variables: lead time (delay time from order release to delivery) and demand. By formulating the MDP problem considering both demand and supply uncertainties, a more general inventory system that better reflects the reality can be constructed and serve as a basis for future research. On the demand side, Markovian demands are used to capture the time-correlations that often exist in randomly changing economic and market condition (Cheng and Sethi, 1999). The formulated MDP problem is solved through approximate value iteration with linear separation form of the value function as well as exact value iteration. By employing the approximate solution method, we can alleviate the 'curse of dimensionality' associated with DP, and thus increase the range of applications but performance loss due to the approximation should be evaluated.

The rest of the paper is organized as follows. Section 2 provides a general background of MDP, and solution algorithms. The system and decision problem for the inventory management problem are described and formulated as an MDP in Section 3. In Section 4, usefulness of the MDP formulation is verified by comparing its performance against the popular (s, S) policy for a simple benchmark problem. Section 5 concludes the paper.

2. Markov Decision Process (MDP)

A formal MDP formulation requires following specifications with time index k:

1) State variables, s_k and finite state space S
2) Decision variables, a_k and finite action space A
3) Exogenous information variables, W_k and finite exogenous space Ω
4) Stage-wise cost function, $c(s_k, a_k)$
5) Transition function, $s_{k+1} = S^M(s_k, a_k, W_{k+1})$

A state variable is the minimally dimensioned function of history that is sufficient to compute all the future dynamics of the system (Powell, 2011). Exogenous information, which models uncertainty and becomes realized only at each corresponding time period, forces us to make decisions before all the information is known. It is expressed in the form of random variables governed by probability distributions or an exogenously provided file of scenarios (Powell et al., 2011). Decision is made by decision policy π, which is a map indicating which action to take for any given state should be found by the decision maker. The decision maker receives a cost corresponding to the given state and taken decision. The system state at the next period is determined by the given transition function. The problem of finding the best policy to minimize the overall cost over the entire infinite horizon would be written by Eq. (1). Here, discount factor $\gamma < 1$ is used to ensure the convergence of the infinite horizon cost.

$$\min_{\pi \in \Pi} E\left[\sum_{k=0}^{\infty} \gamma^k c\left(s_k, \pi(s_k)\right) \middle| s_0\right] \quad (1)$$

For convenience, we can represent the optimal infinite horizon cost to as $V(s_0)$, which is also referred to as the value function. Note that it is a function of the starting state.

2.1. Dynamic programming (DP)

We do not have to solve the entire problem (Eq. (1)) at once. Invoking the Markov property of the system, meaning that future state depends on the only current state and decision, the multi-period decision problem can be decomposed into sequential one-period decision problems. The optimality equation includes both the current and future cost of being in the current state (Eq. (2)). In a case of infinite horizon problem, this equation cannot be solved by backward induction. One of the most widely used algorithm for solving this problem is value iteration, of which details can be found in Powell (2011).

$$V(s_k) = \min_{a_k \in A} \{c(s_k, a_k) + \gamma E[V(s_{k+1})|s_k]\} \tag{2}$$

The fact that the value function is a function of the state complicates the calculation significantly. The exact value iteration algorithm essentially has to enumerate over the entire state space for each iteration, thus causing the 'curse-of-dimensionality'.

2.2. Approximate Dynamic Programming (ADP)

A common strategy for alleviating the curse of dimensionality associated with solving the optimality equation is to replace the exact value function with some sort of approximation. In the problem of inventory management, the linear separable function approximation (Eq. (3)) with appropriate basis functions (ϕ_f) is known to be efficient due to only minimal interaction between the states (Kleywegt et al., 2002). Another source of computational complexity is the computation of the expectation in Eq. (2). To facilitate this computation, a sample set of outcomes $\widehat{\Omega}^n$ (in iteration n) is randomly generated for realization of exogenous information. Let $p^n(\widehat{\omega})$ be the probability of outcome $\widehat{\omega} \in \widehat{\Omega}^n$. If we choose M realizations in the set $\widehat{\Omega}^n$, $p^n(\widehat{\omega}) = 1/M$. Then the expectation of values at a future state, $s' = S^M(s^n, a, W)$ could be approximated using a sample average approximation, as in Eq. (4). Estimating the coefficient vector (θ) in a linear form of the value function using batch methods (a whole set of data processed together) such as the conventional least squares would be very expensive and can even be infeasible because of the singularity problem. Therefore we compute the parameters in a recursive manner with an observed value ($\hat{v}^n$) at a visited state (s^n). Refer to Powell (2011) for details of the algorithm of approximate value iteration (AVI).

$$V_k(s) \approx \bar{V}(s) = \sum_{f \in F} \theta_f \phi_f(s) \tag{3}$$

$$\mathrm{E}[\bar{V}^{n-1}(s')] \approx \sum_{\widehat{\omega} \in \widehat{\Omega}^n} p^n(\widehat{\omega}) \bar{V}^{n-1}\left(S^M(s^n, a, \widehat{\omega})\right) \tag{4}$$

3. Problem Formulation

3.1. Problem description

Different types of suppliers are considered together as candidates for providing raw materials to a single manufacturer (Figure 1). A single-echelon system is studied. The inventory level of the raw material is stochastic because of the random lead times and demand. We consider a periodically renewed inventory model under a backorder and assume that the decisions are made sequentially for each period in an infinite horizon. Replenishment costs and inventory holding costs are imposed, and the inventory shortage is controlled by a penalty cost. Exogenous suppliers are assumed to be always available and have infinite capacity. All suppliers are independent of each other, and may have a minimum or maximum order constraint. Replenishment cost for each supplier is known and fixed. Order released for supplier i must arrive within u_i time periods, i.e., lead time (L_i) is a random variable distributed among $\{1, \dots, u_i\}$. At decision epoch k, the sequence

of events occur in the following manner: Stocks being delivered arrive at the beginning of the period, and demand of intermediate products are realized. With these information, the state of the inventory is renewed. Then, by predicting the next state based on the current information, a decision about placing a new replenishment order is made.

3.2. MDP formulation

We model the inventory system, described in the previous section, as a discrete-time infinite horizon Markov decision process (MDP). In our system, s_k consists of three categories: on-hand inventory level (x_k), on-order inventory (o_k), and demand (d_k). Non-negative x will represent items at a storage point and negative x will correspond to a backorder. And o is on-order inventory indicating the items are in the process of being delivered, whose elements are made of orders to supplier i released j periods ago ($o_{k,j,i}$), where $i = 1, \dots, n$, and $j = 1, \dots, (u_i - 1)$. a_k is a vector containing the order amount to each supplier placed at time k. ω_k is new information resulting of items arrival ($r_{k,j,i}$) and demand realization ($\hat{d}_k$). $r_{k,j,i}$ is a binary random variable that is 1 if the corresponding order arrives at time k and 0 otherwise. The probability of order arrival is calculated from $P(L_i = j | L_i \geq j)$ for positive o_k. With the overall number of arrival stocks (N_k) and evolving demand by $d_k = d_{k-1} + \hat{d}_k$, the state of the inventory is reviewed following:

$$x_k = x_{k-1} + N_k - d_k, \qquad o_{k,j,i} = o_{k,j,i}\left(1 - r_{k,j,i}\right) \tag{5}$$

The state transition probability $p(s'|s_k, a_k)$ from the current state $s_k = (x_k, o_k, d_k)$ to the future states $s' = (x', o', d') \in S$ is specified in Eq. (6). The first term is calculated by product of all probability of on-order inventory transition by random arrival $p\left(o'_{j,i} \middle| \tilde{o}_{j,i}\right)$ where $\tilde{o}_{j,i} = a_{k,i}$ if $j = 1$; and $\tilde{o}_{j,i} = o_{k,j-1,i}$ otherwise. In the case of corresponding order arrival, $\left(o_{j,i}{}' = 0 \middle| \tilde{o}_{j,i} > 0\right) = P_r\left(r_{k+1,j,i} = 1\right)$. The second term of Eq. (6) is for the probability of demand evolution by random demand. The last term $p(x'|s_k, o', d')$ is 1 if $x' = x_k + N' - d'$; and 0 otherwise. Here, N' is the number of ordered items arrival at next period.

$$p(s'|s_k, a_k) = p(o'|o_k, a_k)p(d'|d_k)p(x'|s_k, o', d') \tag{6}$$

In this work, one-period cost consists of the replenishment cost and the inventory handling cost as shown in the following:

$$c(s_k, a_k) = \sum_i \left(c_{setup,i}\delta(a_{k,i}) + c_{rep,i}a_{k,i}\right) + h(x_k)^+ + b(-x_k)^+ \tag{7}$$

where c_{setup} is setup cost (a fixed cost incurred for any size order); c_{rep} is the unit replenishment cost; h is unit holding cost; b is unit backorder cost; $\delta(\cdot)$ is the step function which is 0 for zero input and 1 otherwise; and $(\cdot)^+$ is a function defined as $(\cdot)^+ = \max(0, \cdot)$. The first two terms represent the replenishment cost and the last two terms represent the inventory handling cost.

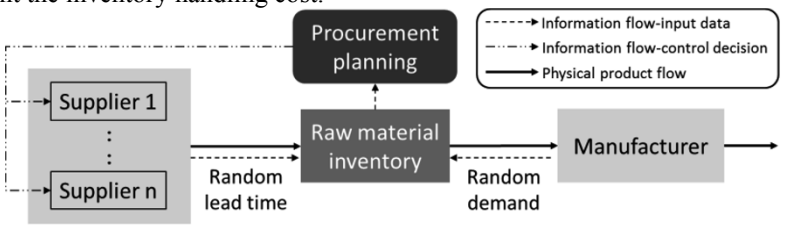

Figure 1. The studied raw material inventory system with multiple suppliers

4. Case Study

We defined a benchmark problem with three different types of suppliers; Supplier 1 and 2 have longer lead time but offer cheaper replenishment costs, while the orders released to Supplier 3 arrive right after the period but the cost is higher. Detailed parameter values are given in Table 1. On-hand inventory and demand space are defined as: $X = \{-7, \dots, 7\}$ and $D = \{2, \dots, 5\}$. We assume that lead times are uniformly distributed with $(1, \dots, u_i)$, and $\hat{d}$ follows a normal distribution, $N(0,\ 1)$. Unit inventory holding cost and backorder cost are specified as 1 and 5, respectively. The problem is formulated as a MDP, and solved by exact VI with γ=0.99. The converged value function from the VI is graphed in Figure 2 (left). In overall, the value function can be approximated as a piecewise linear function with respect to the on-hand inventory (dashed line). The slope on the negative on-hand inventory side is steeper than that on the positive side due to the higher penalty for backorder than the inventory holding cost. By the values of 1 ~ 64 states, which have a same on-hand inventory, we can check that local fluctuations are caused by the differences in the on-order inventory and demand; the values are linearly increased by the demand, and decreased by the sum of the on-order inventories over i and j, $\mathrm{sum}(o) = \sum_i \sum_j o_{j,i}$. Based on these analysis, a basis set for a linear model can be constructed as in Eq. (8). Another significant point is that the effects of on-order inventory and demand become more important as the on-hand inventory value decreases. To reflect this impact, the basis set for the linear approximation can be revised to that in Eq. (9). Coefficient vectors for the different basis sets are calculated by AVI, and the resulting linearly approximated value functions are shown in Figure 2 (right). We can check that ϕ_2 represents a more accurate choice of approximate basis for the value function. In this result, on-order inventory has little marginal effect on the value function when the system has sufficient inventories (x=5~7), whereas it becomes important in the case of severe inventory shortage (x=-5~-7). Thus the significant factors that affect future values change according to the current state.

$$\phi_1 = [1\ \ (-x)^+\ \ (x)^+\ \ \bar{o}\ \ d]^T \text{ where } \bar{o} = \max\{sum(o)\} - sum(o) \tag{8}$$

$$\phi_2 = [1\ \ (-x)^+\ \ (x)^+\ \ \bar{o}\bar{x}^2\ \ d(\bar{x} + \mathrm{c})\ ]^T \text{ where } \bar{x} = x_{max} - x \tag{9}$$

The policies obtained from VI, and AVI with different basis sets are compared with a rule-based (s, S) policy, one of the most widely used inventory policies (Axsater, 2007); if the inventory level is at or below a reordering point (s), a replenishment order will be placed up to S. Table 2 shows the computational time to obtain each policy, and the average cost incurred under the policy. Average cost of the (s, S) policy is much higher than those of the other policies from the MDP formulation because it does not account for the information regarding the on-order inventory and demand of the system. Henceforth it is vulnerable to environmental variability. While the average cost of the policy from exact VI is the lowest, its computational burden is significant even for this simple problem. In addition, it does not scale well with problem size. In this sense, AVI with basis ϕ_2 represents an attractive tradeoff between optimality (average cost) and computational time.

Table 1. Problem parameters for different suppliers

	u_i	O_i	$c_{setup,i}$	$c_{rep,i}$
Supplier 1	2	{0,2,3,4}	0.4	0.5
Supplier 2	2	{0,1,2,3}	0.5	0.6
Supplier 3	1	{0,1,2}	0.8	0.9

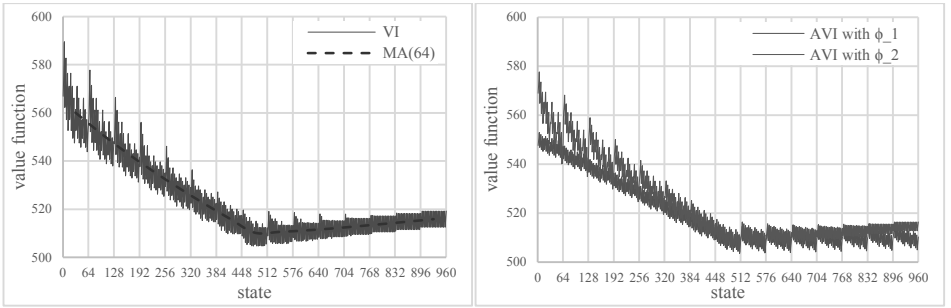

Figure 2. Converged value function (left), and linear approximated value functions (right).

Table 2. Results

	Rule-based (s, S) policy	Policy from VI	Policy from AVI with $\boldsymbol{\phi_1}$	Policy from AVI with $\boldsymbol{\phi_2}$
CPU time (s)	1.56	1007.36	4.72	5.41
Average cost	635.64	515.16	566.88	539.28
Improvement (%)	-	18.95	10.82	15.16

5. Conclusions

In this study, a general inventory control problem for supplying raw materials to manufacturers has been formulated as a MDP to incorporate supply and demand uncertainty. MDP formulation enables the use of both the physical dynamics and the flow of information in sequential decision making. The problem was solved by the dynamic programming method of VI. The performance gain from employing the more rigorous MDP formulation compared to the popular (s, S) policy was verified through a case study. The results showed that the proposed method can reduce the costs by capturing uncertainties, and considering multiple criteria for supplier selection such as lead time, replenishment cost, and limits on the order quantity. Additionally, an approximation framework using stochastic simulations and linear function approximation was tested to reduce the computational burden of exact VI. It can be an excellent alternative to the exact dynamic programming to broaden the applicability of the MDP approach to practically sized problems at minimal performance loss.

Abstract

This paper introduces a general mathematical programming framework that employs an innovative supply chain network (SCN) composition coupled with forward and reverse logistics activities. The work addresses a multi-product, multi-echelon and multi-period Mixed-Integer Linear Programming (MILP) problem in a closed-loop supply chain network design solved to global optimality using standard branch-and-bound techniques. Applicability, benefits, and robustness of the proposed model are illustrated by using a medium size case study.

Keywords: Supply chain network design; Multifunctional nodes; MILP;

1. Introduction

Over the last years, closed-loop supply chains (CLSC) have gained considerable attention in global organizations, as well as in academic fields. Researchers emphasize that focusing on both forward and reverse logistics, can be achieved maximization of the value creation over the entire life-cycle of a product. Therefore, in order to ensure high profit margins, it is necessary for companies to cope with the design, control and operation of the whole network system while managing different types of products. Some of the recent works found in the literature aiming to optimize both direct forward and reverse supply chain processes are those of Salema et al. (2010) who presented a generic model for coping with the simultaneous design and planning of supply chains with reverse flows using two level of decisions that corresponds into two time scales, macroscale for supply chain network design and microscale for the planning activities, In the same perspective, Cardoso et al. (2013) developed a mixed integer linear programming for the design and planning model for CLSC considering simultaneously all processes and uncertain product demand. Pishvaee et al. (2011) proposed a robust optimization model for handling both opened-loop and closed-loop structures coping with uncertainty in return products, demands and transportation costs while, Ramezani et al. (2014) addressed a multi-period problem in a closed-loop supply chain network design under a fuzzy environment with intergrading activities considering the transportation option, the quality and hybrid processing facilities.

Regarding the existing literature this is the first paper that presents a general mathematical programming framework that employs an innovative SCN composition coupled with forward and reverse logistics activities by introducing a generalized node with fourfold role. The function of the proposed Multifunctional nodes are optimally

defined rather than selected from a set of potential alternatives providing flexibility options to the model on designing and operating SCNs.

2. Mathematical formulation

2.1. Problem description

The problem addresses the design of a multi-product, multi-echelon and multi-period supply chain for closed-loop networks consisting of a set of distributed first class and second class markets whose location is known, and a set of facilities, whose locations are to be determined. The model proposes an innovative configuration to network's structure by entering a level consisted of multifunctional nodes with fourfold role. The generalized Production/Distribution/Recovery/Re-distribution (PDR) nodes will substitute the traditional plants and distribution centers at the forward flow and the traditional collection and re-distribution centers at the reverse flow of the materials. The model permits intra-layer material flow connections that occur in the PDR level.

The objective is to minimize the overall capital and operational cost and determine the optimal structure of the network. The model defines: (i) generalized node's location and role; (ii) suppliers; (iii) recycle centers and disposal sites; (iv) material flow among SCN's levels; and (v) functional elements (capacity, material flow, inventories, purchases etc.).

2.2. Mathematical model

A deterministic MILP model is formulated where each product can be produced at several generalized PDR nodes in different location with known and time-variant product demand. All transportation flows determined are considered to be time-averaged quantities whereas customer zones are single sourced. We denote the set of all nodes and materials in the network as $n \in N$ and $i \in I$ respectively. This includes not only the generalized nodes $n \in PDR$ but also suppliers nodes $n \in S$, first customers nodes $n \in C$, second customers nodes $n \in CC$, recycling centers $n \in Re$ and disposal sites $n \in Di$. Also, the set of raw material will be demonstrated with the set $i \in is$, likewise the set of final and return products with the set $i \in ir$. Overall we have $N = S \cup PDR \cup C \cup CC \cup Re \cup Di$ and $I = is \cup ir$. The objective (Eq.(1)) is to minimize the overall capital and operational cost of the network and is as follows:

$$
\begin{aligned}
&\min \sum_{t\in T} DT(t) \Big\{ \sum_{n\in PDR} \Big(C_n^P Y_n^P + \gamma_n^D D_n + C_n^D Y_n^D + C_n^R Y_n^R + C_n^{DR} Y_n^{DR} + \sum_e \delta_{en}^P \sum_{i\in ir} \lambda_{ine} P_{int} + \\
&+ \sum_{i\in ir} C_{in}^{DH} \Big(\sum_{n'\in S, i'\in is} Q_{i'n'nt} + \sum_{n'\in PDR} Q_{in'nt} + \sum_{n'\in PDR} QR_{inn't-1} + \sum_{n'\in CU PDR} Q_{inn't} \Big) + \\
&\sum_{i\in ir} C_{in}^{DRH} \Big(\sum_{n'\in PDR} QR_{in'nt} + \sum_{n'\in CC} Q_{inn't} \Big) + \sum_{i\in ir} \Big(\sum_{n'\in S, i'\in is} C_{i'n'n}^T Q_{in'nt} + \sum_{n'\in PDR} C_{inn'}^T Q_{inn'} + \\
&\sum_{n'\in C} C_{inn'}^T Q_{inn't} + \sum_{n'\in C} C_{in'n}^T QR_{in'nt} + \sum_{n'\in PDR} C_{inn'}^T QR_{inn't} + \sum_{n'\in CC} C_{inn'}^T QR_{inn't} + \\
&\sum_{n'\in Re} C_{inn'}^T QR_{inn't} + \sum_{n'\in Di} C_{inn'}^T QR_{inn't} \Big) + \sum_{i\in ir, n\in PDR} C_{int}^{IP} \frac{I1_{int} + I1_{in(t-1)}}{2} + \\
&\sum_{i\in ir, n\in PDR} C_{int}^{IDR} \frac{I2_{int} + I2_{in(t-1)}}{2} + \sum_{i\in ir, n'\in C} C_{in}^{RV} QR_{in'nt} + \sum_{i\in ir, n'\in C} C_{in}^{RP} (QR_{in'nt}) RCC + \\
&\sum_{i\in ir, n'\in C} C_{in}^{RM} (QR_{in'nt}) RM \Big) + \sum_{n\in Di} (C_n^{Di} Y_n^{Di} + \sum_{i\in ir, n'\in PDR} C_{in}^{Di} QR_{in'nt}) + \sum_{n\in Re} (C_n^{Re} Y_n^{Re} + \\
&\sum_{n'\in S, i\in ir} C_{i'nn'}^T QR_{i'nn't} + \sum_{i\in ir, n'\in PDR} C_{in}^{Re} QR_{in'nt}) + \sum_{n\in S} (C_n^S Y_n^S + \sum_i C_{in}^S S_{int}) \Big\}
\end{aligned}
\tag{1}
$$

Capital cost is consisted of infrastructure cost whereas handling, production, transportation, purchasing, recovery, remanufacturing, repairing, recycling, disposing and inventory cost contribute to operational cost.

Infrastructure cost is related to the establishment of all capabilities at $n \in PDR$ node, recycling center and disposal site ($C_n^P Y_n^{DP}, C_n^D Y_n^D, C_n^R Y_n^R, C_n^{DR} Y_n^{DR}, C_n^{Re} Y_n^{Re}, C_n^{Di} Y_n^{Di}$) that is the annualized fixed cost required to establish the node (C_n^n) with the binary variable that expresses the establishment of this node (Y_n^n). If a distribution capability is established at a node $n \in PDR$ then its infrastructure cost has also a variable element ($\gamma_n^D D_n$), that is a coefficient expressing the unit cost associated with the distribution capacity (γ_n^D) with the continuous variable expressing the distribution capacity (D_n). Regarding operational cost, handling cost is expressed as a linear function of the total throughput at node $n \in PDR$ both at forward and reverse flow. At the forward direction the total throughput is the sum of the continuous variables expressing the rate of flow of material $is \cup ir$ that arrives at node $n \in PDR$ from node $n \in S$ or/and from other node $n \in PDR$ at time period t ($\sum_{n' \in S \cup PDR} Q_{in'nt}$) whether it is coming from forward or reverse flow and the sum of the continuous variables expressing the rate of flow of material ir that leaves node $n \in PDR$ to node $n \in C$ or/and to other node $n \in PDR$ at time period t ($\sum_{n' \in C \cup PDR} Q_{inn't}$). We apply the same at reverse direction. By multiplying the aforementioned total throughputs with the unit handling cost for material i ($C_{in}^{DH}, C_{in}^{DRH}$) and summarising the resulting products we obtain the handling cost. Production cost is related to the unit cost of consumption of resource e at node $n \in PDR$ multiplied with the total utilization of each resource e at time period t ($\sum_{i \in ir} \lambda_{ine} P_{int}$). Transportation cost is related to the amount of material i transferred between all nodes occurred in the forward and reverse network. This cost summarizes the products of unit transportation cost of material i from a node n to another node n' ($C_{inn'}^T$), and vise versa ($C_{in'n}^T$), and the corresponding continuous variables expressing the rate of flow of material i that arrives at a node n from another node n' ($Q_{inn'}$), and vise versa ($Q_{in'n}$). Purchasing cost is consisted of the cost required to establish a relationship (supplier management costs, technology integration investments, hedging costs for financial risk, etc.) with supplier $n \in S$ ($C_n^S Y_n^S$) plus the sum of the cost for purchasing amounts of raw material i from the selected supplier ($\sum_i C_{in}^S S_{int}$) during time period t, that is the product of the unit purchase price of material i from node $n \in S$ (C_{in}^S) and the continuous variable expressing the purchased amounts of raw material i from the selected node $n \in S$ at time period t (S_{int}). Inventory cost occurred over a given time period t is assumed to be proportional to the average amount of inventory held over this time period. The average amount of inventory held over a time period is expressed as an arithmetic mean of the starting and ending inventories($\frac{I1_{int} + I1_{in(t-1)}}{2}$) for this period and by multiplying with the unit inventory cost for material i in case of established forward (C_{int}^{IP}) or reverse capabilities (C_{int}^{IDR}) we gain inventory cost. Recovery cost is related to the cost of returned or recoverable products at the recovery center $n \in PDR$ and is the product of unit recovery cost ($C_{in'}^{RV}$) with the continuous variables expressing the rate of flow of recoverable materials. Remanufacturing ($C_{in}^{RM}(QR_{in'nt})RM$), repairing ($C_{in}^{RP}(QR_{in'nt})RCC$), recycling ($C_{in}^{Re} QR_{in'nt}$) and disposing ($C_{in}^{Di} QR_{in'nt}$) costs are dealt in the same fashion.

The MILP optimization model has six sets of constraints that formulate the structure of the network, the flow of materials within the network, the core operations in the network (purchasing, operating multifunctional node, recycling and disposing), and customer satisfaction. Constraints (2) to (5) demonstrate the conditions for the establishment of a node $n \in PDR$. In specific, constraint (2) states that if a production capability is established at a node $n \in PDR$ ($Y_n^P = 1$) then the corresponding node

$n \in PDR$ should be established as the binary variable that expresses its establishment is forced to take the value of one ($Y_n = 1$). In the same fashion, constraint (3), (4) and (5) for distribution, recovery and redistribution capability respectively.

$$Y_n \geq Y_n^P, \forall n \in PDR \tag{2}$$

$$Y_n \geq Y_n^D, \forall n \in PDR \tag{3}$$

$$Y_n \geq Y_n^R, \forall n \in PDR \tag{4}$$

$$Y_n \geq Y_n^{DR}, \forall n \in PDR \tag{5}$$

As shown in constraint (6) and (7), considering the forward flow, if a node $n \in PDR$ is established ($Y_n = 1$) should receive material from at least one other node $n' \in S \cup PDR$ and should provide material to at least one other node $n' \in C \cup PDR$. For this reason the binary variable that expresses the establishment of a material transportation link ($X_{n'n}$) or ($X_{nn'}$) is forced to take the value one for at least one pair of $n' \in S \cup PDR$ or $n' \in C \cup PDR$ with $n \in PDR$ and provided that $n \neq n'$.

$$Y_n \leq \sum_{n' \in S \cup PDR \setminus \{n\}} X_{n'n}, \forall n \in PDR \tag{6}$$

$$Y_n \leq \sum_{n' \in C \cup PDR \setminus \{n\}} X_{nn'}, \forall\, n \in PDR \tag{7}$$

Similarly considering reverse flow, if a node $n \in PDR$ is established it should receive material from at least one other node $n' \in C \cup PDR$ and should provide material to at least one other node $n' \in CC \cup PDR \cup Re \cup Di$. Constraint (8) forces the binary variable expressing the contracting of node $n' \in S$ ($Y_{n'}^S$) to be unity when the material transportation link, between a node $n' \in S$ and a node $n \in PDR$, is established ($X_{n'n} = 1$). On the other hand, constraint (9) forces the binary variable expressing the establishment of node $n \in PDR$ to be unity when the material transportation link, between a node $n' \in S$ and a node $n \in PDR$, is established ($X_{n'n} = 1$).

$$X_{n'n} \leq Y_{n'}^S, n' \in S, n \in PDR, n \neq n' \tag{8}$$

$$X_{n'n} \leq Y_n, n' \in S, n \in PDR, n \neq n' \tag{9}$$

In the same manner, we manage all the constraints that force to build links between all permitted nodes occurred in the network. The binary variable ($X_{nn'}, XR_{nn'}$) is fixed to zero, in cases when the model does not allow intra-layer flows between nodes except node $n \in PDR$, flows from suppliers to first/second markets or to recycle centers, from first markets to other nodes, from PDR nodes to suppliers, from disposal sites or recycle centers to PDR nodes. Moreover, the flow of materials at time period t ($Q_{inn't}, QR_{inn't}$) lies between upper and lower bounds provided that the corresponding transportation connection has been established. Constraint (10) states that the available inventory of product $i \in ir$ held in production facility at node $n \in PDR$ at the end of period t is equal to

$$I1_{int} = I1_{in(t-1)} + \left(\sum_{n' \in PDR \setminus \{n\}} Q_{in'nt} + \sum_{n' \in PDR \setminus \{n\}} QR_{in'nt-1} + P_{\text{int}} - \sum_{n' \in C \cup PDR \setminus \{n\}} Q_{inn't} \right) \Delta T_t, \forall t, i, n \in PDR \tag{10}$$

the inflow from other nodes $n \in PDR$ including the remanufacturable products from reverse flow at the end of period *t-1*, plus the rate of production of product $i \in ir$, plus the inventory held at the end of period *t-1* minus the outflow to other nodes $n \in PDR$ at forward flow and to first markets.

The rate of production (P_{int}) of product *i* is limited between a maximum and minimum production capacity while, the usage of manufacture resources *e* must not exceed the total availability of the resource *e*. Additionally, appropriate constraint force to satisfy the demand at first markets. At the reverse direction, provided that a recovery capability is established at node $n \in PDR$, constraint (11) states at period *t* the flow of recoverable material $i \in ir$ exiting from each customer $n \in C$ to all recovery centers is equal to the flow that enters to first markets multiplied with a return ratio (*RC*).

$$\sum_{n' \in PDR} Q_{inn't} = \left(\sum_{n' \in PDR} Q_{in'nt} \right) RC, \forall t, i \in ir, n \in C \tag{11}$$

After collecting and inspecting the return products, repaired products are shipped by recovery center to node $n \in PDR$ provided re-distribution capability it is established, remanufacturable to node $n \in PDR$ with production capability, recycled products to recycled centers and scrapped products to disposal sites. The flow of recyclable products entering recycling centers is re-processed to raw materials. Provided that a re-distribution capability is established at node $n \in PDR$, constraint (12) depicts that the inventory of repaired product $i \in ir$ held at the end of period *t* is equal to the inflow from other $n \in PDR$, plus the inventory held at the end of period *t-1* minus the outflow to second markets.

$$I2_{int} = I2_{in(t-1)} + \left(\sum_{n' \in PDR \setminus \{n\}} QR_{in'nt} - \sum_{n' \in CC \setminus \{n\}} QR_{inn't} \right) \Delta T_t, \forall t, i, n \in PDR \tag{12}$$

Finally, distribution, recovery and re-distribution capacity (D_n, Rc_n, RD_n) lies between higher and lower limits, provided that the capabilities are established while it is approached as linear function of handled material flow that enters/leaves the node.

3. Case study

The applicability of the Generalized SCN design and operation model is illustrated by using a medium-size case study in the European area. This network is comprised by five potential suppliers, ten potential generalized nodes ten first markets, three recycle centers-disposal sites and 5 second markets. The number of materials/products provided by the suppliers is ten. The proposed model (GSCN) is compared with a counterpart model with fixed-echelons (FSCN), both of which were implemented in GAMS 24.1.3 software, using CPLEX 12 solver. Identical data were used for both models while the production process is approached in the same way.

4. Results

Figure 1, presents the optimal network for GSCN and FSCN, respectively. The former establishes 1PDR node with production-distribution-recovery capability (BE) and 1 PDR node with production-distribution-redistribution capability (CH) both of which are provisioned from the same supplier (RO), 1 recycle center (FR) and 1 disposal site (IT), while the latter establishes 3 plants (FI,BE,CH) which are provisioned from two suppliers (RO, TR), 2 distribution centers (BE,CH), 1 recycle center (IT) 1 disposal site (IT). Both models employ the same objective function that was counted 5,323,075 and 6,169,743 relative money units for GSCN and FSCN, respectively. Cost saving of about 15% is due to the fact that FSCN model is forced by the a priori structure to build more facilities (sum of plants, distribution, recovery and re-distribution centers) resulting also in higher inventory (94%) and production (13%) cost. Moreover the GSCN model resulted to lower transportation cost due to the network's flexibility.

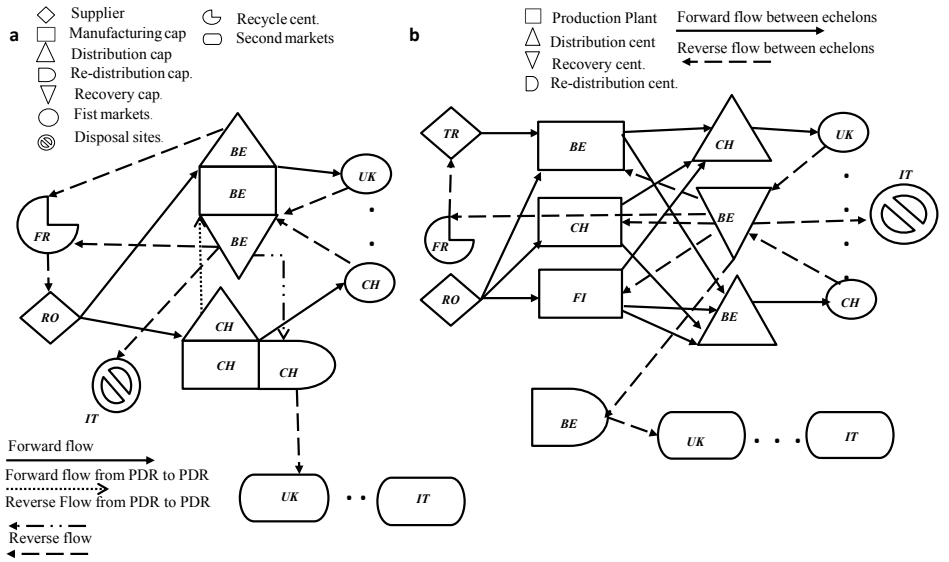

Figure 1. Optimal GSCN configuration (a) against the optimal FSCN configuration (b).

5. Conclusions

This paper introduces a mathematical model that provides flexibility options on designing and operating CLSCNs. The model is capable of deciding the appropriate suppliers and material flow connections including intra-layer flows but mainly the location and role/capability of the generalized nodes. It is concluded that, giving the network the option to have multifunctional nodes (or choose among them) and simultaneously to avoid having separated processes, significant cost savings can be achieved.

Abstract

Processing plants are often required to be capable of turndown or increased production depending on the demand for their products or changes to the raw materials supply and the design of the process should take into account of these considerations in determining additional capital that may be required to provide this additional flexibility. In this paper the economic and environmental performance of a natural gas combined cycle (NGCC) power plant fitted with post combustion capture (PCC) is optimised under a number of different scenarios using a time-integrated multi-objective optimisation (MOO) framework.

In the base case scenario, the plant is operated in a base-load continuous mode and just accepts the electricity price available. The economic performance of the plant will be modelled and optimised for each day throughout the year accepting the electricity price for that year. The results are provided on a Pareto front multi-objective basis as annual net operating profit plotted against the average fraction of CO_2 captured. This general modelling framework can be applied to a wide range of industries where there are similar economic and/or environmental dynamics.

Keywords: Carbon capture and storage, Multi-objective optimisation, Dynamics, Surrogate Modelling.

1. Introduction

In order to address the problem of global warming, swapping coal fired power plants for natural gas will be insufficient to achieve the emission reduction required for the 2 °C temperature rise scenario (IEA, 2012). Fossil fuel use is also predicted to continue to play a major role in energy production throughout the 21st century (IEA, 2013) and as result carbon capture and storage (CCS) will be required to mitigate the CO_2 equivalent (CO_{2e}) emissions.

CCS is economically detrimental to power plant performance not only due to the capital and operating expenses incurred by the CCS plant, but also from the loss of revenue incurred due to reduction in power plant output. Work by Berstad et al. (2011) showed that although NGCC had a lower efficiency penalty compared to coal fired power

stations the specific work required for capture was higher. This is due to lower CO_2 flue gas concentration in NGCC power plants thus requiring more specific work to capture the CO_2. Exhaust gas recirculation (EGR) has been used to increase the CO_2 concentration in the flue gas by recycling a portion of the flue gas around to the air inlet. Sipöcz et al. (2011) showed a reduction in energy requirement and levelised cost of electricity (LCOE) with the use of EGR. ElKady et al. (2009) showed the maximum EGR rate without turbine modification was 35 %. An additional problem with gas turbine post combustion capture is the high O_2 concentration in the flue gas stream. As shown in work by Supap et al. (2006) the presence of O_2 degrades monoethanolamine (MEA), the most common solvent currently used for solvent based post combustion capture. Similar to Pandit et al (2014) a potassium carbonate (K_2CO_3) solvent process is selected for this work.

Most studies of integration of CCS with the power station have been based on calculating the LCOE using design conditions. Work by Wiley et al. (2011) showed that by adjusting capture rate within the demand cycle, up to 50 % of the CO_2 could be captured for a coal fired power plant without affecting the net power supplied to the grid. Manaf et al (2014) analysed different dynamic post combustion carbon capture control strategies. Whereas Pandit et al (2014) studied the improvements obtained from EGR and heat integration and Harkin et al (2012) studied the economic performance under design conditions, is the current study has applied the first MOO model for dynamic capture based on real market electricity power prices.

2. Methodology

The power plant and capture process were modelled using the Aspen Plus® V8.4 processing modelling software. The steam cycle performance and simple heat integration were calculated from the grand composite curve (Harkin et al., 2012). The gas turbine modelled was a combined cycle Alstom GT26 (Alstom, 2007). Gas turbine performance is shown in Table 1. A simplified flow sheet for the gas turbine with PCC-CCS is shown in Figure 1.

The detailed Aspen model was then used to produce a surrogate model (SUMO) (Gorissen et al., 2010), which takes the inputs to the Aspen simulation and uses an artificial neural network to generate an empirical formula for the simulation outputs. The SUMO is used to reduce CPU time for multiple simulations runs to aid the MOO. A comparison of the SUMO model to the Aspen simulation is provided in Figure 2.

Table 1: Alstom GT26 combine cycle performance (Alstom, 2007)

Gas Turbine	
ISO rating (MW)	288
Exhaust Gas Flow (kg/s)	650
Exhaust Gas Temp (°C)	614
Steam Turbine	
Power Out (MW)	157
HP Pressure/Temp (bar/°C)	135.3/565
MP Pressure/Temp (bar/°C)	28/565
LP Pressure/Temp (bar/°C)	4.74/287

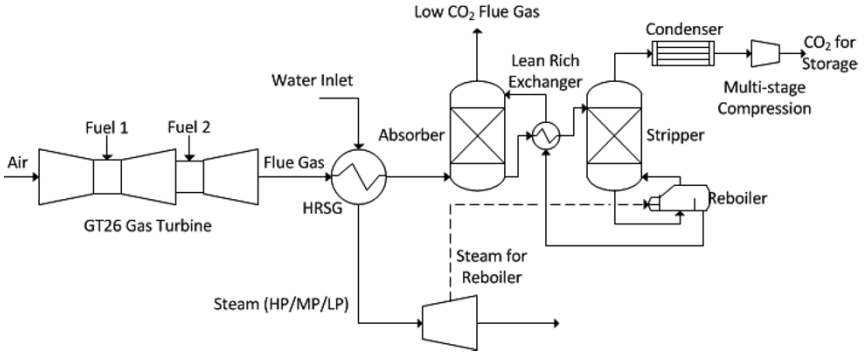

Figure 1. Simplified flow diagram for an Alstom GT26 with PCC.

The MOO is performed using the Genetic Algorithm code NSGA-II developed by Deb et al. (2002) and adapted for use in Microsoft Excel® by Sharma et al. (2012). MOO allows for the simultaneous optimisation of profitability, defined by Net Present Value (NPV) and the capture rate.

The economic framework first defined by Ho et al. (2009) is shown in Table 2. The economic output is given in 2011 Australian dollars ($AU). A new build NGCC power plant without capture would result in a NPV of $AU 255 million under these conditions. The electricity price data is the South Australian market price data (AEMO, 2014) for the 2013-14 financial year. During this period Australia had a carbon price of $AU 24.15 /t CO_{2e} and payment of this tax has been included in the economic analysis.

In the alternative scenarios, a time slice pseudo-steady-state modelling approach is used to integrate the performance of the plant over the full year. However, rather than optimise for each of the 8760 hours individually, a frequency distribution has been used to provide the integration of costs and revenue over the whole year on an hourly basis.
The simulations are optimised with respect to the maximum and minimum capture rates and cut off price. The maximum capture rate is used to set the size of the plant and hence the economic and power plant performance. The cut off price selects whether maximum or minimum capture is used at any given time based on the real electricity price data. When the real price exceeds the cut off price capture is reduced to the minimum capture rate and when the price falls below the cut off rate maximum capture is utilised. Hourly price fluctuations are shown in Figure 3a. Figure 3b shows the fit obtained using both a normal distribution and a log normal distribution, which is preferred. From this distribution it is possible to directly calculate the number of operational hours at both maximum and minimum capture rates. This is done by integrating below the cut off price for minimum capture rate and above the cut off price for maximum capture rate. The price probability is given by a log normal distribution:

$$p = \frac{1}{x\sqrt{2\pi}\sigma} e^{-\frac{\ln x - \mu}{2\sigma^2}} \quad (1)$$

Table 2: Economic parameters used

Discount Rate (%)	7	Load factor (%)	90
Project lifetime (y)	25	Natural gas price ($AU/GJ)	4
Build time (y)	2	Carbon Price (AU/tCO_{2e}$)	24.15
CO_2 storage cost (AU/tCO_2$)	6.03		

Table 3: Simulation case operating parameters. Turndown limit is 30 % (Peplinski, 2011)

Case	*Variable Capture*	*Rich and Lean Solvent Storage*	*Turndown Limitations*
Base	No	No	N/A
Option 1	Yes	No	No
Option 2	Yes	No	Yes (30 %)
Option 3	Yes	Yes - 2 h	No
Option 4	Yes	Yes – 2 h	Yes (30 %)

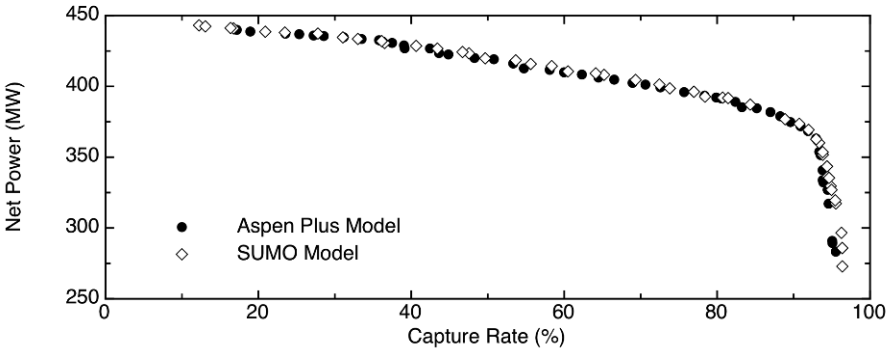

Figure 2. Comparison of the SUMO models to the detailed Aspen Plus® simulations.

The hours (h) of minimum capture can be calculated from the cumulative distribution function:

$$h_{min\,capture} = h_{total} \cdot \int_0^x p\,dx = h_{total} \cdot \left(\frac{1}{2} + \frac{1}{2}\mathrm{erf}\left(\frac{\ln x - \mu}{\sqrt{2}\sigma}\right)\right) \quad (2)$$

where x is the cut of price, μ is the location parameter and σ is the scale parameter and erf is the error function. The hours of maximum capture can also be calculated as the difference. This sets the total CO_2 captured. The SUMO model can then be used to calculate the total amount of power produced by the plant throughout the year. A constraint is imposed within the model to ensure that there is sufficient steam generated to satisfy the reboiler regeneration energy requirements.

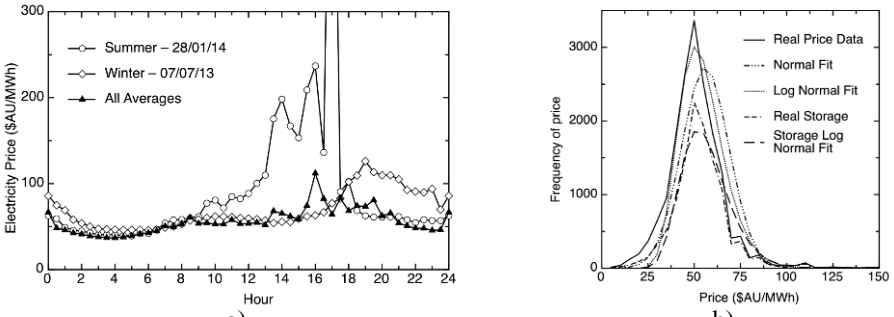

Figure 3. a) Electricity price data showing variability in the price across the most average summer and winter day (dates shown) and the total average. Storage is done during the total average highest 2 h period, from 4pm-6pm. The summer point at17:00 off the scale is 739.89 $/MWh. b) Electricity price histogram with real data and normal and log normal distribution. Log normal is used for this work. Storage peaks reduced due to lower hours total hours the system is free to vary in. Price mean is 56.01 $AU/MWh with a standard deviation of 18.12 $AU/MWh (μ = 3.96, σ = 0.32, R^2 = 0.957). With storage it becomes 58.02 $AU/MWh with a standard deviation of 19.46 $AU/MWh (μ = 4.01, σ = 0.33, R^2 = 0.959).

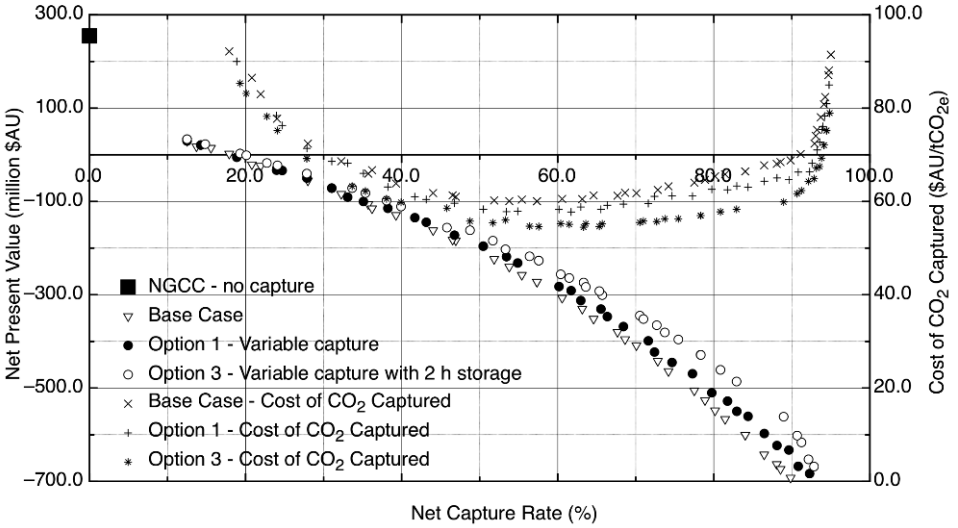

Figure 4. NPV for all cases as a function of capture rate. The cost of CO_2 captured is also shown. Cost of CO_2 capture calculated as $= \frac{\Delta NPV}{\sum discounted\ CO_2\ captured}$.

3. Results and Discussion

The net present value (NPV) for cases without turndown limits are shown in Figure 4. Table 3 shows the turndown NPV at selected capture rates. All cases show an improvement in NPV with dynamic optimisation. With turndown constraints imposed, the improvement compared with the base case is reduced.

The similarity between all cases at lower capture rates is expected as variable operation makes less difference to the plant performance as the difference between maximum and minimum capture rates is reduced. Higher capture rates provide more flexibility for the cases with variable operation and this results in better economic performance. The addition of turndown constraints into the results in reduced performance improvement. Limiting turndown reduces the possible variability and hence reduces the benefits of variable capture. The addition of solvent storage improves the economic performance of the power plant by transferring the energy cost from a time of expensive electricity prices to times with lower electricity prices.

4. Conclusions

A statistical approach was used in conjunction with MOO to allow the optimisation of a NGCC-CCS plant over a whole year. By fitting price data to a log normal distribution and setting a price point as an optimisation variable it was possible to optimise the plant with variable performance. Using this approach the plant could be optimised to achieve economic benefits for the same net plant performance.

Integration of Scheduling and Vessel Routing in Pipeless Plants

Munawar A. Shaik* and Pulkit Mathur

Department of Chemical Engineering, Indian Institute of Technology Delhi, India.

Abstract

A novel methodology for integrating scheduling and routing of moveable vessels for the optimal operation of pipeless plants is presented in this work. Herring-bone layout is assumed for processing stations. The proposed mathematical model is based on state-task-network process representation and unit-specific event based continuous-time formulation. Vessels are treated as states, the feasible routes for vessel transfer between different stations are considered as units and the movement of vessels on a route is considered as a routing task. The computational performance of the proposed formulation is illustrated through an example drawn from literature.

Keywords: Pipeless Plants, Scheduling, Routing, Vessels

1. Introduction

Pipeless plants offer an alternative flexible and responsive production route to traditional batch plants, where different transferable vessels keep moving between stationary processing stations for performing typical operations such as charging, mixing, heating, cooling, discharging, and cleaning. The vessels are carried on automated guided vehicles (AGVs) between processing stations. Unlike in traditional batch plants, cleaning between product changeovers in the same vessel can be done at another cleaning station without losing production time. Pipeless plants are expected to become a major trend in small to medium scale industries especially for processing of powders and slurries which are difficult to transport using pipelines.

In the operation of pipeless plants, decisions have to be made regarding scheduling of production processes, assignment of orders to stations and vessels, and routing of the AGVs. The efficiency of operation of pipeless plants depends on the optimality of the production schedules (Bok and Park, 1998). The optimal routing of AGVs must be determined for a safe and collision-free operation of transporting vessels from one station to another. Vessels are used for both processing and storage of materials in addition to transporting the batches from one station to another. Owing to this strongly interacting nature of the scheduling and vessel routing aspects for pipeless plants, they need to be addressed simultaneously using an integrating approach (Huang and Chung, 2005).

In this work a novel mathematical formulation is proposed for integrating scheduling and vessel routing in pipeless plants for an assumed fixed layout of processing stations. The proposed model is based on state-task-network (STN) process representation and unit-specific event-based continuous-time formulation adapted from the three-index model for batch plants by Vooradi and Shaik (2012). The development of the STN

depends on the number of vessels available, number of batches to be produced and their relationship. In the proposed novel STN, vessels have been treated as separate states (S^V) and the corresponding tasks have been converted into as many tasks as the number of vessels when the number of vessels available (N^V) is less than the total number of batches of all products (N^B) to be produced ($N^V<N^B$). Otherwise, when there are equal or more vessels available ($N^V \geq N^B$), then splitting of states of material and tasks has not been done. In addition to this, all tasks have been split based on the number of production sequences. The methodology used for handling vessel routing involves addition of vessel routing tasks and the corresponding routes as units. The different possibilities of feasible routes for different production sequences have been considered as separate units. The movement of an empty vessel or a vessel carrying material on a route has been considered to be a routing task. These routing tasks are product specific in order to maintain the identity of the production sequence. The movement of an empty vessel after the end of a particular production sequence to the first processing station has also been accounted for every batch of production. If a routing task repeats for a particular production sequence, it is considered to be different as it involves production and consumption of different states of material. The time of travel of vessels between different processing stations has been considered to be the processing time in the routing units.

This paper is organized as follows. The proposed mathematical formulation has been described in detail in section 2. The application to a benchmark problem from literature (Bok and Park, 1998) and the results for a case study have been discussed in section 3 followed by conclusions given in section 4.

2. Mathematical Model

The integrated scheduling and vessel routing problem addressed in this work can be stated as follows. Given: (i) scheduling horizon or demands for final products, (ii) the production recipe (i.e., the processing times for each task in suitable units, relation between tasks, states and units), (iii) the layout (determines the transfer time between stations) and the amount of available resources (amount of raw materials and number of moveable vessels), (iv) processing units and their capacity limits and (v) the number and type of vessels available and suitable tasks requiring these vessels. Determine: (i) the optimal sequence of tasks taking place in each unit, (ii) the start and end times of different tasks in each unit, (iii) the amount of material processed and stored at each time in each unit and (iv) vessel utilization and routing profiles. The objective considered is minimization of makespan or total production time for a specified horizon to produce specific demands of final products. The layout is fixed (say Herringbone layout) and the transfer times have been assumed on the basis of this type of layout.

The proposed mathematical formulation has been adapted from the three-index unit-specific event-based model for scheduling of batch plants by Vooradi and Shaik (2012) that has been customized for application to pipeless plants through addition of new constraints such as a single sequencing constraint for material flow replacing the two material balance equations in the model from literature, vessel balances to ensure appropriate vessel utilization and intermediate balances for all intermediate states except vessels replacing bounds on excess material to ensure proper material usage. The duration and tightening constraints have been modified to exclude transfer times as they

have been incorporated as processing times in route units. The variables involved have been reduced to a considerable extent by removal of batch sizes and excess material states for all materials since the primary considerations are optimal scheduling and routing which depend only on the number of batches of production of different products and their production sequences. The major constraints in the model are as follow.

2.1. Sequencing Constraints

$$\sum_{\substack{n'\in N\\ n'\le n}} \sum_{\substack{n''\in N\\ n'\le n''\le n'+\Delta n}} \sum_{i\in I_s^c} w(i,n',n'') \le \sum_{n'\in N} \sum_{\substack{n''\in N\\ n'\le n''\le n'+\Delta n\\ n''<n}} \sum_{i\in I_s^p} w(i,n',n'') \tag{1}$$

$$\forall n, s\in S^I, s\notin S^V$$

Eq.(1). ensures proper material flow sequencing as per the specified production recipe for all intermediate states so that production occurs before consumption.

2.2. Vessel Balances

$$ST(s,n) = ST_o(s) + \sum_{i\in I_s^c} \sum_{\substack{n'\in N\\ n\le n'\le n+\Delta n}} \rho_{is}\, w(i,n,n') \tag{2}$$

$$\forall n = 1, s\in S^V, N^V < N^B$$

$$ST(s,n) = ST(s,n-1) + \sum_{i\in I_s^p} \rho_{is} \sum_{\substack{n'\in N\\ n-1-\Delta n\le n'\le n-1}} w(i,n',n-1) + \sum_{i\in I_s^c} \rho_{is} \sum_{\substack{n'\in N\\ n\le n'\le n+\Delta n}} w(i,n,n') \tag{3}$$

$$\forall n > 1, s\in S^V, N^V < N^B$$

Eqs.(2) and (3) ensure appropriate recycle and reuse of vessels for the case when number of vessels are less than the total number of batches of production. For all other states the material balances are given in Eq.(4) and (5).

2.3. Intermediate State Balances

$$\sum_{i\in I_s^p} \rho_{is} \sum_{\substack{n'\in N\\ n-1-\Delta n\le n'\le n-1}} w(i,n',n-1) + \sum_{i\in I_s^c} \rho_{is} \sum_{\substack{n'\in N\\ n\le n'\le n+\Delta n}} w(i,n,n') = 0 \tag{4}$$

$$\forall s\in S^I, s\notin S^V, n\in N, n>1$$

$$\sum_{i\in I_s^c} \rho_{is} \sum_{\substack{n'\in N\\ n\le n'\le n+\Delta n}} w(i,n,n') = 0 \tag{5}$$

$$\forall s\in S^I, s\notin S^V, n\in N, n=1$$

No excess amount of intermediates is allowed to be stored in the vessels in Eq.(4) and (5).

2.4. Duration Constraints

$$T^f(i,n) = T^s(i,n) + \alpha_i\, w(i,n,n) \tag{6}$$

$$\forall i\in I, n\in N, \Delta n = 0$$

$$T^f(i,n') = T^s(i,n) + \alpha_i \; w(i,n,n') \tag{7}$$
$$\forall i \in I, n, n' \in N, n \le n' \le n + \Delta n, \Delta n > 0$$

$$T^f(i,n') = T^s(i,n) + \alpha_i \; w(i,n,n') + M(1 - w(i,n,n')) \tag{8}$$
$$\forall i \in I, n, n' \in N, n \le n' \le n + \Delta n, \Delta n > 0$$

The duration does not include transfer times or waiting times for units as they have been incorporated into the model as processing times through the modifications in the STN involving routing tasks in route units. Hence, the duration constraints in Eq. (6) – (8) are similar to the batch scheduling model of Vooradi and Shaik (2012).

2.5. Tightening Constraints

$$\sum_{i \in I_j} \sum_{n \in N} \sum_{\substack{n' \in N \\ n \le n' \le n + \Delta n}} \alpha_i \; w(i,n,n') \le MS \quad \forall j \in J \tag{9}$$

Since the transfer times have been incorporated in the duration constraints for routing tasks, the tightening constraint in Eq.(9) is written for all units including route units.

The other constraints such as allocation and sequencing and definition of objective function are similar to those in literature (Vooradi and Shaik, 2012).

3. Case Study and Results

The mathematical formulation described above has been implemented on a benchmark problem from literature (Bok and Park, 1998). The layout of processing stations is Herring-bone layout as shown in Figure 1 and the production sequence and processing times in all units for all products have been taken from Example 1 of Bok and Park (1998). The proposed STN is shown in Figure 2 where tasks are split into as many tasks as the number of products and vessels considered. The processing times are given in Table 1. The transfer times on vertical (V_0 to V_7) and horizontal routes (H_0 to H_2) have been assumed to be 0.05 h and 0.1 h respectively.

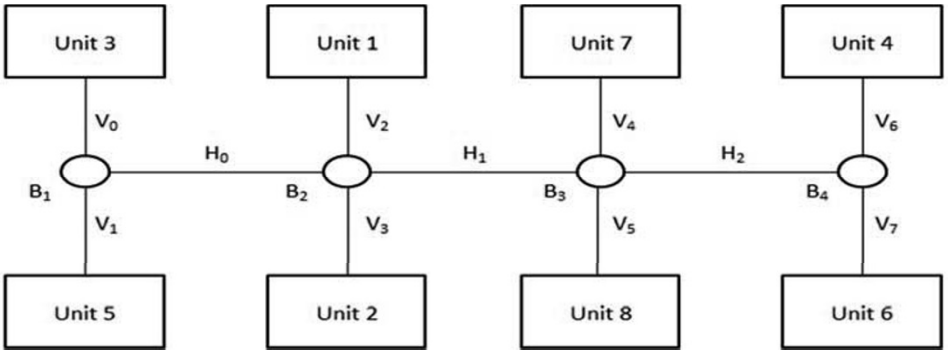

Figure 1. Herring-bone layout of processing stations.

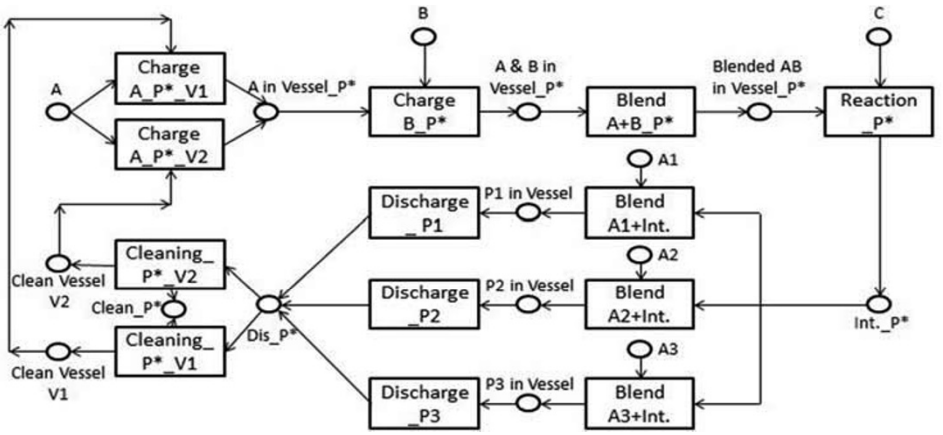

Figure 2. Proposed STN representation showing product and vessel based task splitting.

Table 1. Processing times in all units for all products.

Processing Times (h)	Unit 1 (U1)	Unit 2 (U2)	Unit 3 (U3)	Unit 4 (U4)	Unit 5 (U5)	Unit 6 (U6)	Unit 7 (U7)	Unit 8 (U8)
P1	0.6	0.5	0.5	0.85	0.85	0.6	0.5	0.5
P2	0.5	0.5	0.7	0.75	0.75	0.5	0.5	0.5
P3	0.5	0.6	0.5	0.65	0.65	0.6	0.5	0.5

The proposed mathematical formulation has been implemented on the above sample problem solved in GAMS 23.5 software using CPLEX 12.2 on a 3 GHz Intel Xeon processor with 32 GB RAM running on a Linux operating system. The computational results for this case study are summarized in Table 2.

Table 2. Computational results for the case study.

Number of Vessels	Number of Events	Number of Discrete Variables	Number of Continuous Variables	Number of Constraints	Makespan (h)	CPU time for Non Zero Gap (s)	CPU time for Zero Gap (s)
3	27	4371	9073	66202	6.25	589.8	41252.9
2	47	8286	17015	133601	9.90	240.5	878.8
1	72	12144	24697	195896	14.95	398.8	1869.2

It can be clearly inferred from the above table that the model size is least for the case of equal number of vessels and batches of production because vessels need not be modeled as separate states and there is no need of splitting tasks and states based on the number of vessels available for production. Also, the number of events and makespan increases with decrease in the number of available vessels since vessel reassignment can only take

place after completion of the production sequence. Lastly, there is an interplay of model size and complexity in determining the computational time required for solution. Therefore, computational time is the least for the two vessel case relative to the three vessel case, which is the most complex of the cases considered. A Gantt chart for the two vessel case illustrating both parallel and sequential processing over all units is shown in Figure 3. The gaps in time and event points between different processing tasks are due to the occurrence of routing tasks in route units, which are not explicitly shown.

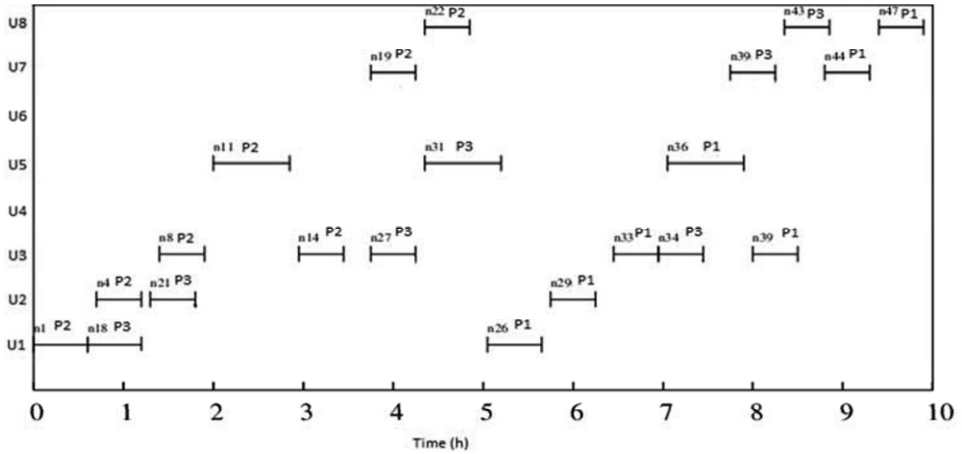

Figure 3. Gantt chart for the two vessel case.

4. Conclusion

A novel mathematical formulation has been proposed for integration of scheduling and vessel routing in pipeless plants for a fixed layout, based on adaptions from scheduling models for batch plants. Accordingly, STN representation has been modified to reflect different cases based on number of batches and number of vessels considered. The proposed formulation is feasible and effective in ensuring optimal scheduling and conflict-free routing of vessels. This approach can be further applied to other layouts of processing stations and more complex case studies to demonstrate its applicability and efficiency.

Abstract

Energy is becoming a critical resource for process industries as introduction of new policies drive changes in the energy supply systems. Energy availability and pricing is much more volatile. In this study, we propose a Mean Value Cross Decomposition approach to functionally separate production scheduling from energy-cost optimization. Such a decomposition makes it possible to exploit existing optimization solutions avoiding a need to create a new monolithic model. The proposed framework is applied to a continuous process of thermo-mechanical pulping using a discrete-time Resource-Task Network model. Example case study scenarios show that the approach gives optimal system-wide solutions while keeping the models separated.

Keywords: Scheduling, demand-side management, mean value cross decomposition.

1. Introduction

Today's electricity supply systems face new challenges due to introduction of new policies, volatility of energy availability and prices. One of the important technologies that support the transformation is demand-side response which on the operations level calls for energy-aware scheduling methods. Especially for large scale industrial energy users, energy-aware production scheduling can reduce the operating cost, as shown in case studies available in literature (Hadera et al., 2014). The traditional industrial approach for scheduling of energy intensive operations is to schedule the production first, satisfying all production specific rules, and to predict from that schedule the demand for energy. Next, energy purchase and sale optimization models can be used to find the best contracting strategy. This approach in general is suboptimal on the system level. There could be a schedule for the production that creates a demand with significantly lower total energy cost, out-weighting the sub-optimality of the schedule from the production point of view. The traditional strategy reported in literature is to combine all energy-related information into a single monolithic problem and to solve it. This ensures finding a system-wide optimal solution that satisfies both the scheduling constraints and energy-cost optimization constraints. However, from an industrial point of view, such a monolithic integration usually requires noticeable effort.

2. Problem statement

The goal of this work is to develop a decomposition framework for process scheduling and energy cost optimization while still ensuring a system-wide optimal solution.

The scheduler provides a feasible schedule, and the energy cost optimizer finds the best purchase and sales structure of contracts based on a fixed load curve. This framework helps to utilize already installed industrial solutions of energy contracts optimization. The joint optimization obviously requires an information exchange between the two optimizers. Under specific conditions the structure of the monolithic model can be exploited to develop a Mean Value Cross Decomposition (MVCD) scheme (Van Roy, 1983) – a variant of decomposition without a master problem (Holmberg, 1994). In the next section we show that the two optimizers can be modified such that one forms a part of the subproblem of the Benders' decomposition of the overall problem (energy-cost optimizer) and one forms a part of the subproblem of the Dantzig-Wolfe decomposition (energy-aware scheduler) after decomposing the monolithic model. It is important to note that it is not the goal of this work to develop the best possible scheduling model for the example process, but to develop and demonstrate the decomposition framework.

2.1. Industrial process description

We apply the decomposition approach on an energy-intense industrial process, Thermo-Mechanical Pulping (TMP). We formulate the scheduling model as a Mixed Integer Linear Program (MILP) using a discrete-time Resource-Task Network (RTN) representation (Castro et al., 2009). The model handles all production-specific constraints and includes information concerning the consumption of electricity. The scheduling model is expanded by a formulation for the minimization of deviation penalties which are accounted for when the process load deviates from the pre-agreed load curve (Hadera et al., 2014). Energy-cost optimization uses the Min-Cost Flow Network for the optimization of multiple time-sensitive electricity contracts including base load, time-of-use, day-ahead spot market and onsite power generation, and the opportunity to sell electricity back to the grid with revenues. The example process (Figure 1) consists of identical refiners which produce one type of pulp. The pulp flows to a storage tank and has to satisfy a deterministic demand curve. Additional flexibility is given by the option of buying pulp from an external source at a given cost.

3. Model formulation

In order to develop the decomposition approach we first develop a monolithic model of the problem. The model notation is shown in Table 1.

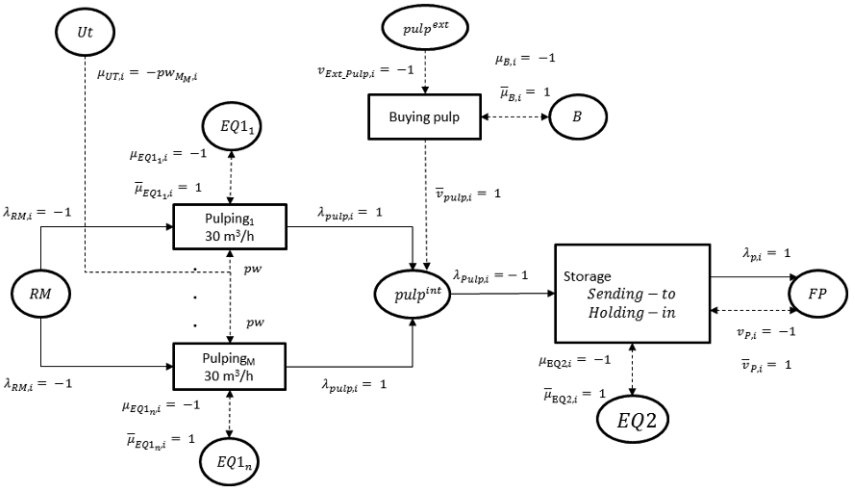

Figure 1. RTN superstructure for the thermo-mechanical pulping process

Table 1. Model notation

Sets: R– resources; I– tasks, T- time intervals, $EQ1/EQ2 \subseteq R$-refiners/storage tank, $EQ3 \subseteq R$-external buy, $RM \subseteq R$-raw material, $pulp^{int}/pulp^{ext} \subseteq R$-pulp from refiners/external source, $UT \subseteq R$-electricity, $CT \subseteq R$-cont. resources, $FP \subseteq R$-final product, I^c- continues tasks, I^B-buying task, I^S-storage task.
Parameters: l^{max}–maximum capacity volume of storage tank, l^{min}-minimum volume in storage, l^{init}-initial volume in storage, u-production rate of refiner in one time slot, u^{max}-maximum production by all refiners in one time slot, b^{max}-maximum pulp amount available to buy, c^{start}/c^{end}-refiner start-up/shut-down cost, $\prod_{r,t}^{in}/\prod_{r,t}^{out}$-resource input (electricity)/ output (final product) to/from the system in time t, c_t^{pulp}-external pulp price in slot t, p^{el}-electricity consumption of one refiner in one time slot.
Variables: $N_{i,t}$-binary, execution of task i in time t, $\xi_{i,t}/\xi_{i,t}^*$- cont. positive, amount handled /continuously send to storage, $R_{r,t}$- cont. positive, amount of r available at time t, $R_{r,t}^{end}$- cont. positive, amount of resource r available immediately before end of time t, $R_{r,t}^0$- cont. positive, amount of initial resource, n_t^{ref}-number of refiners, n_t^{end}/n_t^{start}- cont. positive, number of refiners shut-down/start-up, $pulp_t^{ext}/pulp_t^{int}$- cont. positive, pulp bought externally/produced by refiners, q_t- cont. positive, el. consumption, c^{el}-net electricity cost, c^{ref}-cost of start-up and shut-down of refiners, δ-penalties for load deviation

3.1. Monolithic model formulation

The objective function of the problem is to minimize the cost of energy and the production-specific costs as in Eq. (1). The core of the RTN formulation is the excess resource balance equation, shown in Eq. (2), and the handling of the continuous resources by Eq. (3). Proper balance of the $pulp^{int}$ and final product fp resource is ensured by Eq. (4). Using resource excess variable, we enforce the upper bound of all equipment resources and enforce no intermediate storage by Eq. (5). The storage capacities limits are enforced by Eq. (6). Another constraint restricts the amount handled by the hybrid task (Eq. 7) and continuous tasks (Eq. 8). Buying of pulp from the external source is limited by the desired level b^{max} as in Eq. (9). Some auxiliary variables are introduced in Eq. (10-11). Eq. (12) accounts for the electricity consumption in each time slot. We capture the number of refiners starting up or shutting down with the constraint in Eq. (13). Lastly, we account for the production costs in the objective function. The cost of the pulp bought (Eq. 14) and start-ups and shut-downs of refiners (Eq. 15) are accounted for.

$$min(e + \delta + c^{extpulp} + c^{ref}) \tag{1}$$

$$R_{r,t} = R_{r,t}^0|_{t=1} + R_{r,t-1}^{end}|_{r\in R^{RM}\cup R^{pulp^{int}}\cup R^{FP}} + R_{r,t-1}|_{r\in R^{EQ1}\cup R^{EQ2}\cup R^{EQ3}\cup R^{pulp^{ext}}} + \sum_{i\in I}(\mu_{r,i}N_{i,t} + v_{r,i}\xi_{i,t} + \overline{\mu}_{r,i}N_{i,t-1}) + \sum_{i\in I^S}(\overline{\mu}_{r,i}N_{i,t\,|t=1}) + \Pi_{r,t}^{in}\,|_{r\in R^{UT}} - \Pi_{r,t}^{out}\,|_{r\in R^{FP}} \quad \forall r \in R, t \in T \tag{2}$$

$$n_t^{ref} = n_{t-1}^{ref} + n_t^{start} - n_t^{end} \; \forall t \in T \tag{13}$$

$$c^{extpulp} = \sum_{t=1}^{T} c_t^{pulp} \cdot pulp_t^{ext} \tag{14}$$

$$c^{ref} = \sum_{t=1}^{T} \left(c^{start} \cdot n_t^{start} + c^{end} \cdot n_t^{end} \right) \tag{15}$$

We assume that for the considered production process the energy cost optimization problem has the same structure as the MILP formulation in Hadera et al. (2014). The plant has an option to choose from multiple contracts, onsite generation, and the possibility to sell electricity back to the grid. Therefore the monolithic problem is further extended by the same flow network as in Hadera et al. (2014), Eq. (13-22), and load deviation equations as in Eq. (30-32), which together represent all energy-related cost (net electricity cost e and load deviation penalties δ).

3.2. Functional decomposition approach using MVCD

The monolithic MILP problem can be simplified to the following general form:

$$min \; (C_1^T f + C_2^T y) \tag{16}$$

s.t.

$$A_1 f + D_1 x \leq b_1 \quad \text{[flow network constraints (energy purchase and sale)]} \tag{17}$$

$$A_2 q + D_2 y \leq b_2 \quad \text{[production scheduler constraints (optimize production cost)]} \tag{18}$$

$$q - A_3 f = 0 \quad \text{[complicating constraint]} \tag{19}$$

$$x \in X, \; y \in Y, \; q \geq 0, f \geq 0. \tag{20}$$

In the above equations let x and y represent the variables specific to the flow network and to the energy-aware scheduler, and let X and Y represent all variable bounds and types (continuous and integer requirements). Eq. (19) is a complicating constraint that links the two kinds of variables which are present in Eqs. (17-18). Note that the term $A_3 f$ represents the amount of electricity needed to be bought for the production process, i.e. the flow from the balancing node to the process demand node in any time slot. Any change in the values of any variable in Eq. (19) causes a change in the respective part of the monolithic model (Eq. 17 or 18), thus also in the value of the objective function components in Eq. (16), either the specific cost of the flow network $C_1^T f$ or the production specific cost $C_2^T y$. We consider the load deviation constraints to be integrated into the scheduling problem, i.e. the penalties are part of $C_2^T y$. The monolithic formulation can be decomposed using well known techniques of Benders' and Dantzig-Wolfe (D-W) decomposition. The sub-problems of these two decompositions , shown in Table 2, can be combined in a MVCD scheme (Holmberg, 1994). Note that both sub-problems will separate into two different problems; one related to the scheduling problem, and one related to the energy network. Further, the dual variable of Eq. (19) in the flow network part of Benders' sub-problem is equal to the Marginal Cost (MC) curve used in the D-W's sub-problem. Secondly, the schedule from the scheduler's part of the D-W's sub-problem is equal to the fixed schedule in Benders' sub-problem. Thus by iteratively solving these sub-problems and exchanging the information on production schedule and marginal cost curves (forward related to as the two signals) between them, a Cross Decomposition (CD) scheme can be constructed (Van Roy, 1983). Further, we can identify the flow network part of Benders' sub-problem as the energy cost minimization problem with a fixed production schedule.

Table 2. Decomposed models

Benders' sub-problem		Dantzig-Wolfe sub-problem	
scheduler $f^{EPS}(\bar{q}'_t)$	flow network $f^{MFN}(\bar{q}'_t)$	scheduler $f^{EPS}(\overline{MC}'_t)$	flow network $f^{MFN}(\overline{MC}'_t)$
$min(\delta + c^{extpulp} + c^{ref})$ (21)	$min(c^{el})$ (22)	$min(\delta + c^{extpulp} + c^{ref} + \sum_{t\in T} q_t \cdot \overline{MC}_t)$ (23)	$min(c^{el} - \sum_{t\in T} f_{i5,i7,t} \cdot \overline{MC}_t)$ (24)
subject to:			
Eq. (2-15) – production scheduling constraints	Eq. (13-22) from [3] – flow network constraints	Eq. (2-15) – production scheduling constraints	Eq. (13-22) from [3] – flow network constraints
Eq. (30-32) from [2] – load deviation penalties constraints	$f_{i5,i7,t} = \bar{q}_t \quad \forall t \in T$	Eq. (30-32) from [2] – load deviation penalties constraints	
$q_t = \bar{q}_t \quad \forall t \in T$			

Next, the scheduler part of D-W's sub-problem can be formulated as an energy-aware RTN scheduler with the MC curve as actual costs of energy that are penalized in the objective function. Thus we have identified the two problems which are currently being used in the industrial setting. However, a CD scheme requires the solution of additional complex master problems to guarantee convergence. An alternative is to adopt a MVCD which instead of using a master problem to guarantee convergence makes use of the mean values of the two signals (Holmberg, 1994). To solve the two partial sub-problems in Eq. (22-23) is enough to find a feasible solution of the monolithic problem - a schedule and the corresponding optimal purchasing and selling structure. However, to test the convergence, the value of the objective function of the complete sub-problems is needed (Eq. 21-24). The iterative algorithm (Fig. 2) is initialized by solving the production scheduling model using the day-ahead spot market price. There are a few reported variations of MVCD which differ on how to alter signals (q'_t and MC'_t in Fig. 3) in each iteration. We selected the following option:

- One-sided MVCD (OSWMVCD) – only one of the signals ($MC'_t = y$) is altered by calculating a weighted mean as in Eq. (25), the other (q') is used directly without any changes in order to overcome potential infeasibility problems:

$$y^i = \delta_i \tilde{y}^{i-1} + (1-\delta_i) y^{i-1}, \text{ where: } \delta_i = \frac{\beta+\gamma}{\beta i+\gamma}, \sum_{i=0}^{\infty} \delta_i = \infty, \beta = 1 \text{ and } \gamma = 3 \quad (25)$$

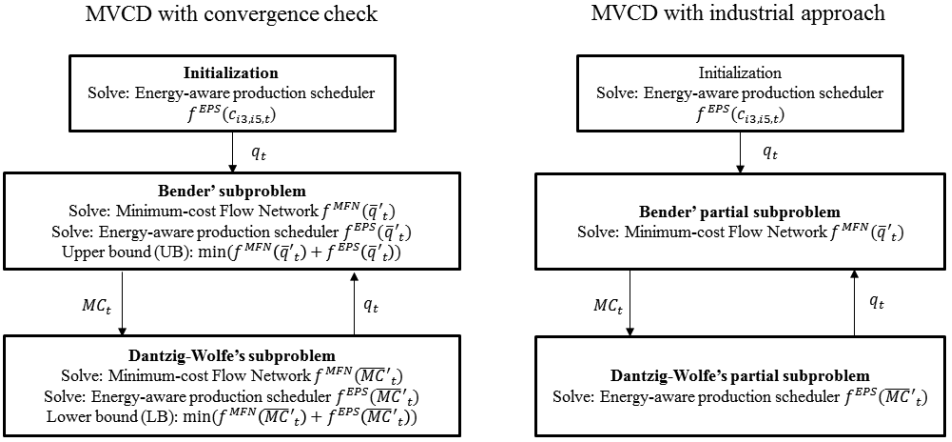

Figure 2. Generic framework for functional separation

4. Numerical case study

Three test instances were solved using GAMS/CPLEX 24.1.2 for the different solution approaches - monolithic model (RTN), convergence test with complete sub-problems (CRTN), and industrial approach (IOWMV), the two latter ones (Fig. 2) using OSWMCD and iterating MC_t only. With such a setup the load curve is always sent directly without mean value smoothing, which could cause infeasibility problems. For all non-monolithic approaches, a CPU limit of 180s is enforced. The results are reported in Table 3. Interestingly the decomposition resulted in higher CPU times than RTN.

Table 3. Numerical results for the case study

Model	Scenario	Best upper bound	Best lower bound	Algorithm iterations (best)	Total CPUs	Gap
RTN		219637,2	-	-	1,14	0%
CRTN*	1	219637,2	219637,2	13	24,60	0%
IOWMV*‡		219637,2	-	2	3,2	0%
RTN		-623600	-	-	1,09	0%
CRTN*	2	-623600	-623600	2	5,96	0%
IOWMV*‡		-623600	-	2	3,55	0%
RTN		122869,2	-	-	340,92	0%
CRTN*	3	123246,3	122681,78	30 (30)	776,84	0,31%
IOWMV*‡		123246,3	-	30 (15)	285,70	0,31%

* solved with max CPUs limit of 180s; ‡ solved with algorithm iterations limit of 30

5. Discussion and conclusion

The tests showed that for both variants of decomposition strategies optimal or close to optimal solutions are obtained for the considered TMP process. In general, the lack of optimality for the developed approach might be due to the duality gap between the objective function values of Benders' and Dantzig-Wolfe sub-problems. In addition, using IOWMV instead of mean values on both signals, there is no guarantee of convergence. Taking mean values on integer variables would produce infeasible solutions, but can be expected to converge to the Lagrangean relaxation (Holmberg, 1994). However, for industrial cases the presented framework allows simultaneously using existing models and solvers for the individual problems resulting in very good system-wide solutions. This re-use of existing solution also eases maintenance problems. Further work could focus on investigating other industrial processes such as steel-making. Another direction is to employ different combination of raw materials and resources as a subject of optimization, instead of energy considered in this work.

Abstract

This paper presents an optimization based modelling framework for the integration of maintenance and production in short-term scheduling of multipurpose process plants. An MILP formulation of the integrated approach for a State Task Network (STN) process representation is introduced. Targets and directions for further development of the proposed approach are discussed.

Keywords: maintenance, production, STN, short-term, scheduling

1. Introduction

According to the British Standards Institution (BS 3811:1993), maintenance can be defined as "the combination of all technical and administrative actions, including supervision actions, intended to retain an item in, or restore it to, a state in which it can perform a required function". Therefore, not only the disruptive activities performed in industrial plants every 5-10 years to update or renew the equipment should be accounted as maintenance. Cleaning operations, assets inspection, components lubrication or part-substitutions involving only a partial plant shutdown can also be accounted as maintenance.

In literature in the context of short-term scheduling, the interaction of maintenance and production scheduling has been widely explored. Dedopoulos at al. (1995) considered a set of maintenance tasks to be performed in the scheduling horizon with a penalty to be paid if any of them doesn't take place. Hazaras et al. (2012) account for different types of maintenance: fixed time maintenance intervals as well as a set of maintenance with flexible start time to be determined by the optimization. In summary, in the short-term scheduling context a maintenance task is mainly treated either as a fixed unavailability period of equipment; or as an additional "job" to be scheduled on the plant with some additional constraints which differentiate a maintenance from a production task. Therefore, the overall effect of maintenance activities on the production scheduling (Figure 1) can be summarized in a reduction of overall available time.

In this work, we want to make a step forward and explicitly take into account the effect that production has on maintenance requirements in order to "close the loop" between the two decision processes (Figure 1).

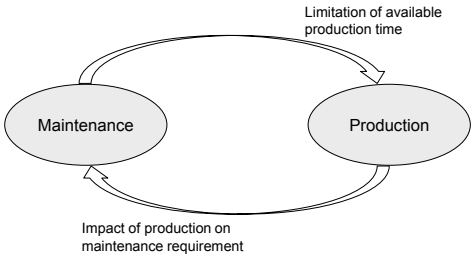

Figure 1 – Impact of maintenance on production schedule and vice versa: closing the loop

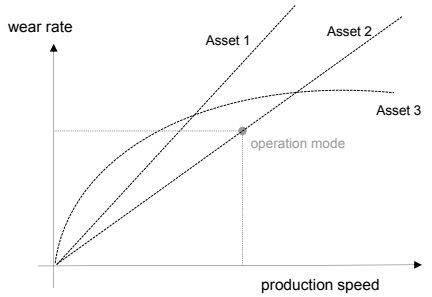

Figure 2 – Asset operation mode and relation between production speed and wear rate

The main objective of the paper is to describe a framework for the integration of maintenance and production in short-term scheduling of complex multipurpose batch process plants. We will highlight strengths and weaknesses of the proposed approach and describe challenges and opportunities for its further development.
The remainder of this paper is organized as follows. Section 2 discusses the concept of *operation mode*, the key element of the proposed integrated approach. In Section 3 we introduce all the other elements of the model which is then introduced and discussed in Section 4. Section 5 gives an insight on how the proposed model can be extended before providing some final conclusion in Section 6.

2. The key of integration: asset operation mode

The key element that we will consider in the following to strengthen the integration of maintenance and production scheduling is the assumption that each equipment of the plant (or at least most of them) has the possibility to work in different operation modes.
The impact of operation mode on the process and production is two-fold. On the one hand, we assume that by modifying the operation mode of an asset it's possible to adapt its production speed, i.e. the throughput for a continuous process or the processing time for a batch production. On the other hand, we assume that the operation mode impacts on the way/speed the equipment wears out. By modulating it, it is therefore possible to extend the *residual useful life* of the equipment, i.e. to prolong the time before the next maintenance (cleaning, lubrication…).
The relation between production speed and asset wear rate might be very process and equipment dependent. We will therefore assume that any equipment of the plant has its own characteristics in the speed/wear plane (Figure 2) which can be linear or nonlinear.

In this particular work we do not consider a specific application for the method we are proposing as our target is to develop a generic approach for the integration of maintenance and production scheduling. On the other hand, it is important to highlight that the concept of operation modes and the relation between production speed and asset wear rate is realistic and can be encountered in several applications, e.g. in the steel making process for stainless steel production (Harjunkoski et al., 2001). In the first production step (the electric arc furnace) steel scrap is molten by means of electric arcs generated by cathodes that are lowered into the metal bath. The length of the arcs (the production mode for this process) can be modified by operators with direct impact on the production time and on the wear of the equipment (in particular on the refractory material of the ladle).

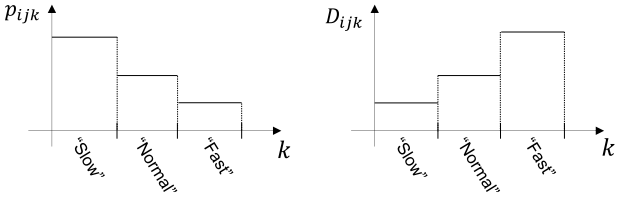

Figure 3 – Production time and wear of product *i* on unit *j* operating in mode *k*

3. Elements of the model

The reference modeling framework for our integrated approach is the State Task Network (STN) formulation as introduced by Shah et al. (1993). A simplified version of it is presented in Eq.(1.a-e) and will be used for our purpose. The key decision variables of the problem are: W_{ijt}(binary) if unit *j* starts processing task *i* at the beginning of time period *t*; B_{ijt} amount of material which starts undergoing task *i* in unit *j* at the beginning of time period *t*; S_{st} amount of material stored in state *s*, at the beginning of time period *t*. Constraint (1.a) ensures that no job can start before the previous one is finished; (1.c) is a material balance constraint for intermediate and final states (where ρ_{is} is the proportion of input of task *i* from state *s* and $\bar{\rho}_{is}$the proportion of output of task i to state *s*); (1.b) and (1.d) are respectively unit and storage capacity constraints. The objective of the optimization problem is assumed to be the maximization of the profit over a given time horizon.

$$\max \quad obj$$

$$\sum_{i\in I_j}\sum_{t'=t-p_i+1}^{t} W_{ijt'} \quad \le 1 \quad \forall j,t \tag{1.a}$$

$$V_{ij}^{min} W_{ijt} \le B_{ijt} \le V_{ij}^{max} W_{ijt} \quad \forall t,j,i\in I_j \tag{1.b}$$

$$S_{st} = S_{s,t-1} + \sum_{i\in \bar{T}_s} \bar{\rho}_{is} \sum_{j\in K_i} B_{ij,t-p_i} - \sum_{i\in T_s} \rho_{is} \sum_{j\in K_i} B_{ijt} \quad \forall s,t \tag{1.c}$$

$$0 \le S_{st} \le C_s \quad \forall s,t \tag{1.d}$$

$$W_{ijt} \in \{0,1\}, B_{ijt}, S_{st} \ge 0 \tag{1.e}$$

We will assume in the following that each unit *j* can work in a finite set of operation modes $k \in K_j$ and that the mode can be changed only if the unit is not active, i.e. only between consecutive jobs. With these assumptions, the relation between production speed and asset wear rate as we introduced it in Figure 2 can be simplified and any complex nonlinearity in the speed/wear dependency eliminated. For each product *i* and unit *j*, the production time p_{ijk} and the wear D_{ijk} will depend on the operation mode *k* as in Figure 3.

For the asset degradation and maintenance requirements, we will consider a model derived from Bock at al. (2012). We assume that each unit has a maximum residual useful life measured in "equivalent" running hours and that the usage of unit *j* for producing product *i* in mode *k* decreases the available residual life by D_{ijk}. When the lifetime of an asset reaches a critical threshold, it can be restored to its maximum level by mean of a maintenance activity which involves fixed costs and down time (τ_j).

4. An integrated model for production and maintenance scheduling

Having described all the elements of the integration model, assume the following variables:

W_{ijkt} equals 1 if unit *j* starts processing task *i* with operation mode *k* at the beginning of time period *t* (binary)

B_{ijkt} amount of material which starts undergoing task *i* in unit *j* with operation mode *k* at the beginning of time period *t*

S_{st} amount of material stored in state *s* at the beginning of time period *t*

R_{jt} remaining useful life of unit *j* at the beginning of time period *t*

M_{jt} equals 1 if maintenance of unit *j* starts at the beginning of time period *t* (binary)

Having defined this set of variables, it is possible to describe the integrated production scheduling problem as an MILP like in Eqs.(2.a-g). The constraints of the model can be interpreted as follows: Eq.(2.a) ensures that no contemporary production and maintenance activities are active on unit *j* at time *t*; Eq.(2.b) is a bound on the amount of product *i* that can be processed on unit *j*; Eq.(2.c) is, like in the original model, a material balance constraint for the intermediate and final states of the production. Eq.(2.d) is the key constraint of the proposed formulation as it takes care of updating the residual life of the units at each time period. In particular, the residual life if decreased by D_{ijk} if a production job starts to be processed in the current time period *t* and it's restored to its maximum value (R_j^{max}) if a maintenance activity is started. Eq.(2.e) is a bound on the amount of material that can be stored in state *s* at any time *t*. Eq.(2.f) is a bound on the residual life of unit *j* and defines the threshold (R_j^{min}) on R_{jt} triggering the start of a maintenance on unit *j* by mean of Eq.(2.d).

$$\max \quad obj$$

$$\sum_{k\in K_j}\sum_{i\in I_j}\sum_{t'=t-p_{ijk}+1}^{t} W_{ijkt'} + \sum_{t'=t-\tau_j+1}^{t} M_{jt'} \le 1 \quad \forall j,t \tag{2.a}$$

$$V_{ij}^{min} W_{ijkt} \le B_{ijkt} \le V_{ij}^{max} W_{ijkt} \quad \forall t, j, i \in I_j, k \in K_j \tag{2.b}$$

$$S_{st} = S_{s,t-1} + \sum_{i\in \overline{T}_s} \overline{\rho}_{is} \sum_{j\in K_i}\sum_{k\in K_j} B_{ijk,t-p_{ijk}} - \sum_{i\in T_s} \rho_{is} \sum_{j\in K_i}\sum_{k\in K_j} B_{ijkt} \quad \forall s,t \tag{2.c}$$

$$R_j^{max} M_{jt} \le R_{jt} \le R_{j,t-1} - \sum_{i\in I_j}\sum_{k\in K_j} D_{ijk} W_{ijkt} + U \cdot M_{jt} \quad \forall j,t \tag{2.d}$$

$$0 \le S_{st} \le C_s \quad \forall s,t \tag{2.e}$$

$$R_j^{min} \le R_{jt} \le R_j^{max} \quad \forall j,t \tag{2.f}$$

$$W_{ijkt}, M_{jt} \in \{0,1\}, B_{ijkt}, S_{st}, R_{jt} \ge 0 \tag{2.g}$$

The objective function of the MILP model can be chosen according to the use case Meaningful objective functions in this context are for example:

- Maximization of the profit on a given time horizon (value of final products minus production costs including maintenance costs)
- Maximization of the profit on a given time horizon with maintenance advance penalties (C. Varnier et al., 2012)
- Maximization of the profit on a given time horizon by assuming variable production costs for each production mode (e.g. due to an increase of electricity consumption)
- Minimization of production costs (e.g. including maintenance costs, variable production costs for each production modes,…) for a predefined demand profile over a given time horizon

We tested the proposed model on the STN process proposed by Kondili et al. (1993) with the objective of maximizing the profit over a time horizon of 50 time slots. For each unit (4), three distinct operation modes were introduced as well as production time and wear for each task (5), unit and mode like in Figure 3. The model was implemented in GAMS and resulted in a MILP with around 3500 equations, 1900 continuous variables and 1400 discrete variables (as reported by GAMS). By solving the model with CPLEX 12.6, the optimal solution was found in 50s but it took 1200s to verify the optimality criterion (0.1% gap).

5. Discussion and model extensions

The above model was shown to be able to describe the integration of the maintenance and production process in a short-term scheduling horizon. In this section, we want to discuss some of the weaknesses of the model in order to set the target for further development.

5.1. Time "dynamics"

One of the unwritten assumptions of the model is that the *dynamic* of the degradation process (and therefore the frequency of maintenance requirements) is fast enough to be captured within the production scheduling horizon. With reference to the model in Eqs.(2.a-g), this means that the average degradation D_{ijk} per time interval is not too small compared to R_j^{max}. Only with this assumption, i.e. only if maintenance requests for every unit appear more than once in any scheduling horizon, it make sense to compare production profits and maintenance costs in the objective function of the optimization problem as we described. Unfortunately, this assumption does frequently not hold in real industrial applications and if the different dynamics between maintenance and production are not explicitly taken into account, the model struggles to find a reasonable solution.

5.2. Asset degradation

In the proposed formulation, it is assumed that the performance of a unit is not changing along the unit life and that a unit is always able to perform any required production task notwithstanding its health. This may not always be the case; the asset degradation might impact the scheduling problem in different ways. For example, the maximum dimension of a batch that a unit can process might be a function of the unit health (e.g. due to quality reasons, physical reasons or health and safety reasons). Another way to account for unit degradation in the proposed modelling framework is to let the set of available operation modes K_j of unit j depend on the unit health, i.e. $K_j=f(R_{jt})$. Any operation mode might be used by the unit right after maintenance is performed (Figure 4), but only few of them might be available when the unit reaches the end of its useful life.

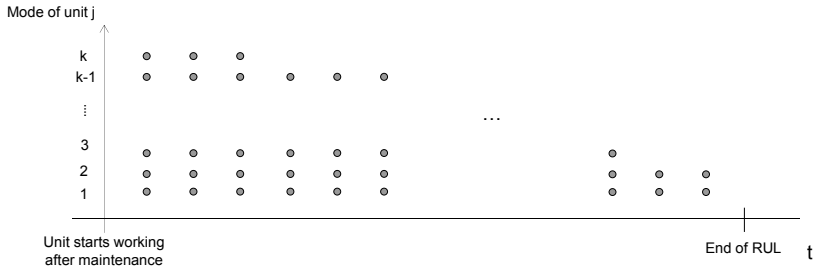

Figure 4 – Available operation mode throughout the useful life of a unit

6. Conclusions

In this paper we addressed the challenge of a tighter integration between production and maintenance scheduling. The key element for the integration of the two decision processes we introduced is the concept of operation mode of a production unit having impact on performance and wear rate. An MILP formulation to model and solve the integrated maintenance and production scheduling problem was proposed and discussed. Finally, further development directions of the model to account for time dynamic challenges and degradation were introduced.

Abstract
Scheduling and control have been long recognized as the two critical building blocks in many manufacturing execution systems. Operating at the interface between the supply chain and the process, the scheduler generates a detailed schedule that has to be executed by the process so as to meet the demands originating from the supply chain. Given the tight interactions between the two, there has been wide interest in integrating control and scheduling. A variety of methods ranging from monolithic integration into one large integrated problem, to hierarchical cooperative approaches have been proposed in literature. In this paper, we propose a novel approach to the integration problem.

Our key insight is that disturbances which occur post the generation of the original schedule, trigger a divergence between operational targets defined by the schedule and its execution. If left uncorrected, the disturbances will propagate between the process and the supply chain. A timely response could eliminate or minimize such effects. Recognizing this, we propose a novel framework for integrating scheduling and control that detects in real-time when a divergence occurs between the original schedule and its execution in the process, identifies the root-cause(s) of the divergence (i.e. the disturbance), and triggers a suitable response from the scheduler and the process so as to nullify or minimize its effect. In this paper, we will describe the proposed approach and illustrate it using an industrially motivated case study.

Keywords: Advanced control; reactive scheduling, abnormal situations

1. Introduction
A simple supply chain consists of raw material procurement, storage of raw materials, processing, storage of products and its dispatch to customers. In any production plant, customer orders are collected, demand is calculated and based on that a schedule is made which is then sent to the processing unit. The processing unit make products as per the schedule and then dispatch it to customers. After the products are delivered to the customers, the key performance indicators such as number of orders fulfilled, number of partial orders, number of cancelled orders, plant utilization, volume fulfilled, etc. are estimated.

Scheduling and control are very crucial in any production plant. Schedules are a set of tasks having information about the start time, duration, product id, quantity to be produced, equipment on which products ate to be made, grade of the products and set points of the controllers. Schedules are made typically for a time horizon of few days to weeks. Process control deals with real time execution of process. It controls the transformation of raw materials into products as per the set points specified by the schedule while rejecting disturbances. It makes sure that the product quality, production rate and equipment operating limits are within the desired range and evaluates constraints on capacity and quality. It operates typically in a time horizon of seconds or minutes. Even though scheduling and control works using different algorithms and for different users, they have some similarities. Both cope with uncertainties and both makes real time decisions taking into account new information. The uncertainty for scheduler includes rush orders, supplier problems, logistic difficulties, demand fluctuations and for controller includes equipment breakdown, manpower unavailability, low raw material inventory (Bansal et al., 2005). Scheduling interfaces with process control through production schedules, actual production information and production capability information (Harjunkoski et al., 2009).

Today's agile business climate is characterized by changing market trends, increasing competition, and environmental concerns. This has induced manufacturers to vie for faster, cheaper and more flexible production strategies in order to sustain their profitability. Companies have implemented various systems for planning (ERP), scheduling and advanced process control (MES/CPM) but these technologies operate at different spatial and temporal scales in the decision-making hierarchy. Integrated decision making between these levels, especially between production scheduling and advanced control is now considered to be absolutely essential and has received significant attention in the academic literature However, a number of key challenges have impeded the deployment of these techniques in industrial settings. Some challenges include modelling and solution of optimization algorithms, interaction of interface with users, human behavior and organization behavior. In this paper, we seek to develop and systematically evaluate a practicable approach for integrating scheduling and production control.

1.1. Literature Review

A variety of methods are used towards integration of scheduling and control (Harjunkoski and Engell, 2012). One set of method is on a monolithic approach in which scheduling and control are integrated in such a way that it is not possible to distinguish which decision belongs to scheduling and which one belongs to control. The benefit of this approach is that all the information required to make any decision will be available often but the challenge is to solve the mixed integer dynamic optimization problem which is nonlinear and non-convex. Another set of solution use hierarchical approach where three actions; scheduling, optimization and control exchange information with each other. The scheduling layer take decisions about batch sizes, assignment of resources and possible timings of production. Optimization layer computes the optimal batch trajectories and control layer implement these trajectories. Another approach is the classical hierarchical approach in which one scheduling system interacts with multiple control systems for different equipment. Scheduler gives the resource allocation and sequencing details to the optimization and control layers. Optimization layer set the trajectories, and decisions related to time are left for the controller. The problem with this approach is that at the time of uncertainty there will be

a mismatch between model and reality. There should be a repair mechanism that has to be implemented when there is a plant model mismatch to avoid sub optimal schedules. Since the start time decisions are taken by the controller, there will be no possibility that the plant will produce more than planned or before time. This can be removed by frequently giving schedules to the controller. There must be fast and frequent share of information between scheduling and control about the current status of production and availability of resources. Cooperative solution can also be an approach. In this, a schedule is made using a nominal model of system and then it is optimized. After optimization, original schedule is modified. This allows parallel computations.

There have been many advancements in scheduling techniques to handle the complexities introduced by the integration of scheduling with control. These includes use of more efficient mathematical solvers, considering inventory and resource constraints, developing expert systems, implementing neural network, multistage stochastic optimization and robust optimization procedures. Park et al. (2014) proposed an Internal coupling model (ICM) which is an explicit low order model that describes the closed loop input-output behavior of the process under supervisory control. Chu and You (2012) proposed an integration method which is formulated as a mixed integer dynamic optimization problem with discrete variables in scheduling problem and constraints of differential equation from the control problem. They provided an online closed loop solution with fast computational strategy that helps production system to quickly respond to uncertainties and disturbances. In this paper, we develop an alternate approach to the integration problem which focusses on real time performance of the process.

2. Proposed architecture

Our key insight is that the motivation for integration arises primarily when either (1) the process control system is unable to meet the goals set by the scheduler due to various disturbances originating at the process level, or (2) when the scheduler layer requires the process to operate differently at a short-notice due to some unforeseen event in the supply chain. Traditionally, the information exchange between the scheduler and process control layer is limited. The scheduler is ignorant about the process dynamics. It receives only the information about the task lengths, transition times and transition dynamics from the process. Similarly the process is ignorant about the information from supply chain. In general, the scheduling and control layers exchange information periodically (e.g.: weekly / fortnightly) with the scheduling layer transmitting the needs from the supply chain in the form of a periodic schedule and the control layer reporting on the actual performance of the process through a periodic production report. To account for the uncertainties, there is a need for precise and timely exchange of information between the scheduling and control layers which can be achieved by a tighter integration between them. This is accounted for in the proposed attaché framework.

In our framework, the primary purpose of integration is to ensure that any information available to one layer is made available to the other layer in a timely fashion so that it can exploit possible arbitrage opportunities for overall benefit. Consider a case where the process control system is unable to meet the goals set by the scheduler due to various disturbances originating at the process level. Another example is a case when the scheduler layer requires the process to operate differently at a short-notice due to

some unforeseen event in the supply chain. In such cases, disturbances, which occur post the generation of the original schedule, trigger a divergence between operational targets defined by the schedule and its execution. If left uncorrected, the disturbances will propagate between the process and the supply chain. A timely response based on timely information exchange could eliminate or minimize such effects through suitable arbitrage (e.g.: rescheduling). To achieve this in a practicable fashion, the attaché serves as an intermediary between scheduler and controller by serving as a feedback provider for scheduler, as shown in Figure 1. It provides a closer and more frequent interaction between the scheduler and the process by intervening the process at a higher frequency than the scheduler interacts with the process. It continuously observes the operating process as shown in Figure 1 and detects in real-time when a divergence occurs between the original schedule and its execution in the process by detecting the deviation in actual and predicted production. If the deviation is significant, it triggers a suitable response from the scheduler (i.e., rescheduling) so as to nullify or minimize the effect of the disturbance.

3. Case study

A simulation of Thermo Mechanical Pulping (TMP) process is considered as the case study. It consist of two stages (1) primary refiner that produces course pulp and (2) secondary refiner that reduces it to a quality that is suitable for paper making. A detailed description of the process is given by Bemporad et al. (2004). The manipulated variables are feed rate of chips (screw feeder rpm), dilution water flow to each of the refiners, set points to two regulatory controllers that control the gap between the rotating disks in each set of refiners; unmeasured disturbance inputs are fiber filling factor and fiber-water filling factor; measured outputs include primary and secondary refiner consistencies, primary and secondary refiner motor loads and vibration monitor measurements on the two refiners. The process produces three different grades of product each operating at a different throughput and setpoint. The process is controlled using a MPC controller. The parameter, feed RPM, is chosen as the disturbance variable and secondary consistency is the measured output considered. A disturbance generator produces three different cases of operation in the process, (1) plant operating at desired feed RPM, i.e., no disturbance case, (2) operating at a lower throughput, i.e., feed RPM reduces to a lower value, (3) complete shutdown, i.e., the feed RPM is 0.

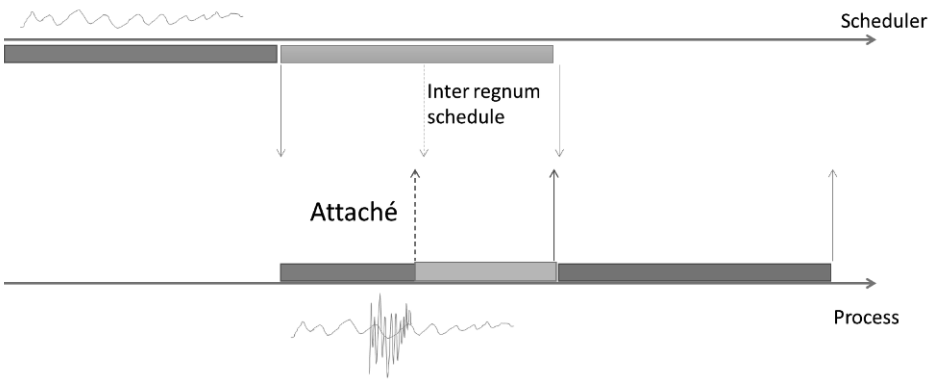

Figure 1: Schematic representation of the attaché framework

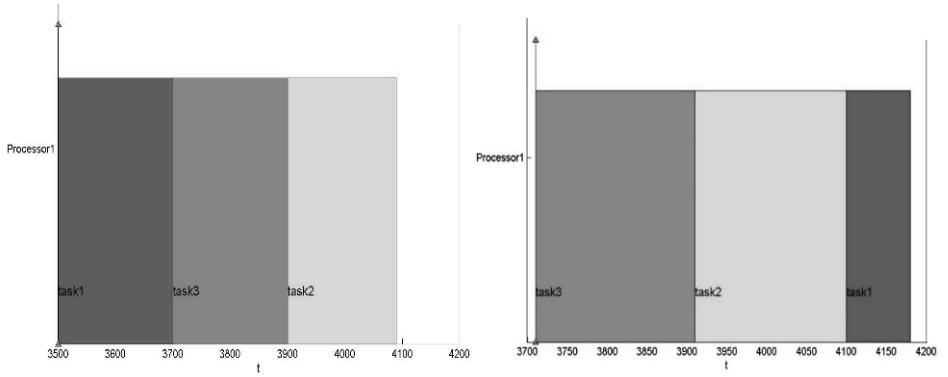


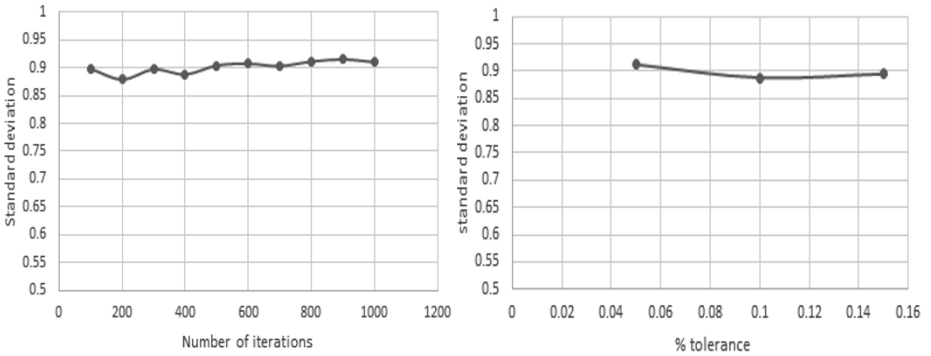
(a) (b)

Figure 2: Production schedule before (a) and after (b) rescheduling

The order type, quantity and due date are generated using random numbers with a maximum and minimum limit. The simulation horizon is of 52 weeks. Schedules are generated on a weekly basis based on the longest processing time strategy and sent to the process. After every intervention interval, attaché gets triggered and tries to detect any deviation in the actual production and the one predicted by the schedule. If the deviation detected is greater than a specified tolerance level, attaché escalates the problem to the scheduler. Rescheduling is done for the remaining time and quantity to be produced. The new schedule generated tries to compensate for the losses incurred during production due to disturbances, in the remaining time of the week. Once the simulation for a week is done, the quality of the products is checked. The qualified products are then used to fulfil the customer orders. No backlog of products are carried forward i.e. the demand of orders not fulfilled is cancelled.

To get an insight on attaché functioning, consider one simulation run. Zooming in to the 6^{th} week (where each week consist of 700 ticks), in Figure 2(a), which starts at 3500^{th} simulation tick, the process operates as per normal operation till 3600^{th} tick, but then due to an equipment problem, the throughput decreased till 3900^{th} tick where it resumes normal operation till the end of the scheduling horizon, i.e., 4200^{th} tick. The intervention frequency for attaché is set to be 100 ticks i.e., at every 100^{th} tick, attaché intervenes and compares the predicted production and actual production in that week for the time span of 100 ticks. Figure 2(a) shows the initial schedule made before the commencement of 6^{th} week. At 3600^{th} tick attaché intervenes and detects no deviation beyond the specified tolerance (10 %) and hence, no rescheduling is done. When attaché intervenes at 3700^{th} tick, it detects a deviation and rescheduling is done. Figure 2(b) shows the new schedule of the 6^{th} week after rescheduling. It can be clearly seen that the production has shifted in the time and the loss incurred in producing product grade 1 (task 1) is made up by shifting it to the end of the week.

A sensitivity study of the effect of the intervention interval and of tolerance level has been conducted. Our results as summarized in Figure 3 show that the performance improvement gained from attaché is relatively insensitive to the settings of these parameters.



(a) (b)

Figure 3. Standard deviation of percent improvement (a) in volume fulfilled with number of iterations (b) with % tolerance

4. Concluding remarks

In this paper, we proposed a novel framework for the integration of scheduling and control layers. In our method, the attaché observes the process, monitors the important decision variables periodically and detects if there is any significant divergence. When a significant divergence is detected, the problem is escalated to the scheduler, which can then reschedule the production and transfer it over to the process for implementation. To evaluate attaché, we have used the case study of thermo mechanical pulping process. The results show that attaché framework worked well in improving the volume of orders fulfilled during abnormal situations.

Abstract

Operational decisions in the day-to-day business of chemical production plants can have a significant impact on the resource efficiency, but this is usually not transparent to managers and operators because of complex interactions in the plants and the lack of real-time resource efficiency indicators (RTREI). As a first step towards real-time decision support to improve resource efficiency, this contribution presents principles for the definition of resource efficiency indicators that capture the performance of a plant on shorter time scales. Guided by these principles, individual RTREI for a specific plant can be chosen. To assess the indicators, an evaluation framework was developed that helps to identify which indicators are capable of reflecting the total resource efficiency best. To demonstrate the approach, indicators for an ethylene oxide production unit that is operated at INEOS in Cologne are presented and compared to the currently used energy efficiency indicator (EnPI), showing that the new indicators are better suited to capture the operational efficiency of the plant.

Keywords: Resource efficiency, energy efficiency, performance monitoring, environmental impact analysis

1. Introduction

Chemical processes are a major consumer of raw materials and energy. Increasing costs of raw material and energy as well as the need to minimize the environmental impact of chemical production processes call for the systematic monitoring and optimization of their resource efficiency. Optimization efforts in the operation of the plant usually focus on the economic optimality within the constraints posed by process limitations and environmental legislation and do not evaluate the resource efficiency during operations. Some companies report environmental KPI of the impact of their production processes on the environment, e.g. the global warming potential and carbon footprint according to the standard ISO/TS 14067 (2013). Such reporting is done in retrospect over long periods of time (usually a business year) and reflects the choice of raw materials, the plant technology used and the operational performance without separating between the different influences. As they are the result of integration over long periods of time and over many factors, they do not support the decision making processes in the daily operations. The European project MORE [www.more-nmp.eu] aims at developing solutions for real-time decision support to improve the resource efficiency of chemical

plants. The first step towards this goal is to define suitable RTREI that can be used for performance assessment over short periods of time (from minutes to days) and provide proper guidance to plant managers and operators. This contribution presents guidelines for the definition of RTREI that reflect the current technical performance of a production plant and can be used to steer the operation in real-time. Further an evaluation framework is described to assess the suitability of existing and proposed indicators. The methodology is applied to the case study of ethylene oxide production proving the relevance for industrial applications.

2. Principles for the definition of real-time resource efficiency indicators

2.1. Gate-to-gate approach

As the goal is to improve the operational performance, the entity of interest is a production site, a plant or a process unit and the boundary of the analysis that defines the inflows and outflows is the limit of the respective entity. The effect of the choice of raw materials or sources of energy and of distribution channels can be added to the effect of the production itself to compute e.g. a carbon footprint value, but in order to correctly assess the operational efficiency of a plant independent of business decisions on procurement and distribution, the scope is limited to the plant or process unit.

2.2. Material and energy flow analysis is the core

Resource efficiency means "more from less". The resource efficiency indicators are based on the physical flows and conversions of raw materials and energy to products and emissions to the environment. All relevant inflows, outflows and environmental impacts must be captured. The material and energy balances must be closed which poses significant challenges to the measurements of flows and concentrations. If the same input material can be either converted into the desired product or serve as a source of energy, an integrated energy and material flow analysis must be performed.

2.3. Resource and output specific

In the first step, the resource efficiency should be measured with a fine granularity, i.e. for all products and inputs of material and energy separately. Product specific RTREI are defined with respect to all resources used and products produced in a process as in Eq. (1).

$$RTREI_{RPS} = \frac{Product\ Output}{Resource\ Input} \tag{1}$$

Product here refers to a product with specific properties (purity, colour, etc.) and different product specifications will lead to a different consumption of energy and raw materials, e.g. because of the need of more intense purification steps. Similarly, the use of different raw materials (in particular if renewable feedstock is used) may lead to different efficiencies which must be reflected in specific indicators. In a second step, the indicators can be aggregated for reporting purposes, or averaged over similar products or different feedstock. This however reduces the potential to correctly assess the limitations and the potential for improvements.

2.4. Normalize to the best possible operation

The value of a resource and product specific RTREI by itself does not show whether the process is operated well. It should therefore be related to a baseline (cf. Eq. (2)), yielding the normalized resource efficiency, which indicates how close the current operation is to a best case. The best case can be obtained from a theoretical analysis (based on a model) or from the best demonstrated practice (based on historical data).

$$RTREI_{norm} = \frac{RTREI_{RPS}}{RTREI_{RPS,best\ case}} \quad (2)$$

2.5. RTREI are needed on different time-scales

In the definition of RTREI the choice of the temporal aggregation interval is crucial. The aggregation interval must be adapted to the decisions which are considered. E.g., for the choice of the operating parameters of an evaporator, its current performance, filtered over short intervals to remove stochastic influences should be used. For the choice of cleaning policies or for the setting of a reactor temperature, that increases the efficiency but reduces the life-time of the catalyst when set to higher values, longer horizons must be considered. Also the filling or depletion of internal storages must be taken into account.

2.6. Include the environmental impact

The impact on the environment must often be taken into account separately to measure the ecological performance. A full energy flow analysis (EFA) and material flow analysis (MFA) will include energy losses and pollutant streams; however the streams of pollutants may be so small that they hardly affect the overall resource efficiency. Therefore emissions to air, water and soil as well as the generation of solid waste should be measured by separate specific indicators. The amount of waste per amount of product manufactured may have to be differentiated according to its use (e.g. incinerated waste that generates or consumes energy, re-used waste or deposited waste). Moreover for reporting and assessment purposes, the RTREI concept can be extended to a Life Cycle Assessment (e.g. CO_2-footprint) by weighting the different streams with the upstream impacts.

2.7. Hierarchy of indicators

For the operation of a unit, the operators need local indicators that measure the performance of the unit, e.g. the amount of steam used by a distillation column. Such RTREI for an individual apparatus may however be misleading because resource utilization can be shifted to other units by different local operational policies. Therefore the primary resource efficiency indicators must be defined on a scale where the net effect of the operational policies on the resource efficiency is measured in a meaningful way (cf. Figure 1). Then secondary indicators can be introduced on the unit level but must be related to carefully chosen specifications of the performance (e.g. a certain purity of the stream leaving a column).

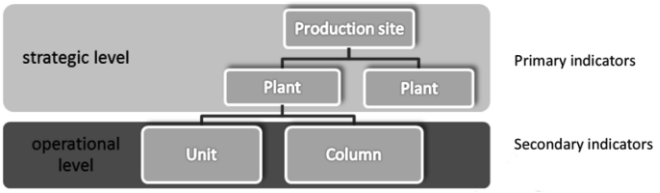

Figure 1: Hierarchy of Resource Efficiency Indicators

2.8. Focus on technical performance independent of external economic factors

The bottom line of a plant is its economic performance to which the resource efficiency contributes significantly. However, the economic figures are strongly influenced by external factors like prices for electricity, gas and oil or revenues from the different products. These economic factors vary independent from the operational performance and therefore the resource efficiency should in the first step be measured independent of e.g. energy prices. As trade-offs e.g. between low emissions or consumption of electric

power and economic performance may exist (sometimes due to pricing schemes or subsidies), resource efficiency and profitability should in the best case be represented as a multicriterial optimization problem.

3. MORE-RACER RTREI evaluation framework

In order to evaluate the real-time resource efficiency indicators, we use ideas from the RACER methodology (European Commission, 2009) and adapted it to the purpose considered here. In RACER, the main categories are Relevant, Accepted, Credible, Easy and Robust. The RTREI are evaluated with respect to the criteria listed under each category in Table 1. A grading system adopted from Lutter (2008) for the main criteria and sub-criteria presented is utilized which enables users to perform a rough screening of the proposed RTREI. The range is between 0 and 2 points, where 0 means "criterion not fulfilled", 1 point represents "partially fulfilled" and 2 point means "completely fulfilled". In the next step, the results for all indicators are visualized in a radar plot as average values per main category (cf. Figure 4).

Table 1: RACER sub-categories for the evaluation of RTREI.

Relevant	Accepted	Credible	Easy	Robust
• Goal related (resource efficiency) • Suitable for the time horizon considered • Influenced by operator actions • Transferability to other units	by • Stakeholders • Plant managers • Operators • Academia • Public	• Sound theoretical background • Consistent in direction and magnitude • Transparent • Clear documentation of assumptions and limitations	• Already in use • Data available in sufficient quality and frequency • Additional instrumentation affordable • Baseline can be provided	• Small influence of measurement errors • Reliable measurement and computation • No uncontrolled influences • No double accounting

4. Case study – ethylene oxide production plant

As an example, we discuss the use of different indicators for an ethylene oxide (EO) production plant. EO is a highly reactive substance used industrially to produce many chemicals and intermediates. The production on a commercial scale is performed by direct oxidation of ethylene on a fixed bed silver catalyst in parallel tubes. CO_2 and water are produced as undesired by-products in a parallel reaction. Both reactions are exothermal, and the full oxidation of ethylene to CO_2 and water has a larger reaction enthalpy than the main reaction. The ethylene oxide process is very interesting from an energy and resource efficiency point of view because the raw material can be converted to product or can be used as source of energy. It is important to obtain a high yield by means of a high selectivity for the main product with small purge streams and minimum external energy consumption. In present-day industrial processes, selectivity towards EO is high (>80%), however, with the ageing of the catalyst, the selectivity decreases, leading to a higher ethylene demand at a constant EO production rate. Consequently, the material efficiency in the sense of generated product mass per converted reactant is decreasing. Besides the selectivity, the process is currently evaluated by the energy performance indicator (EnPI), computed by Eq. (3).

$$EnPI = \frac{m_{EO}}{E_{el} + E_{Steam} + E_{FG}} \tag{3}$$

where m_{EO} denotes the EO product mass, E_{el} the electrical power consumption, E_{Steam} the energy content of the consumed steam and E_{FG} the energy content of the consumed

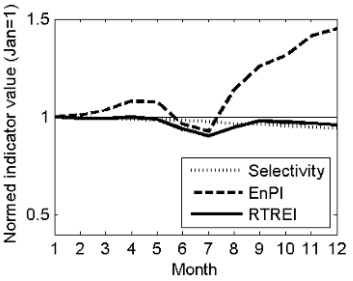

Figure 2: Evolution of selectivity, EnPI and RTREI over one year

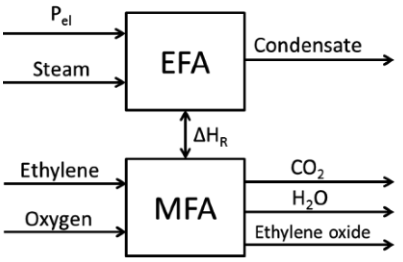

Figure 3: Integrated mass and energy flow analysis for the ethylene oxide plant

fuel gas. The trajectories of the presently used indicators over one year show a decrease in the selectivity (cf. Figure 2), whereas the energy efficiency of the process improves at the same time (increasing EnPI). The decreasing selectivity leads to a decreasing demand of steam but a higher consumption of ethylene per unit of ethylene oxide—more ethylene is used as a fuel. This is not desired because of the significantly higher economic value of ethylene compared to steam or fuel gas. After performing a combined energy and material efficiency analysis (cf. Figure 3), stated before as the second principle, a new indicator for the EO plant, the total energy consumption was introduced. Measurement data for the main in- and outgoing streams of material and energy is available at the plant.

The mass flow analysis is performed only for the ethylene feed under the assumptions:

- Total conversion of ethylene because of a total recycle,
- Only the above mentioned reactions and species are taken into account,
- Enthalpy of the species is only evaluated at standard conditions (standard enthalpy of formation), while temperature, pressure and mixing influences are neglected,
- Purge streams are neglected.

The total absolute energy consumption of this kind of processes is given by:

$$E_{tot} = E_{el} + E_{Steam} - \sum_{i=1}^{n_R} \Delta H_i^R = E_{el} + E_{Steam} - \sum_{j=1}^{n_C} h_{f,j}^0 \left(n_{out,j} - n_{in,j}\right) \quad (4)$$

Where E_{tot} denotes the total energy demand, n_R the number of reactions, ΔH_i^R the reaction enthalpy of reaction i, n_C the number of components, $h_{f,j}^0$ the specific enthalpy of formation of species j at standard conditions and n_j the molar amount of species j. Corresponding to the eighth principle, all sources of energy are weighted equally, irrespective of their financial value. As an alternative to the EnPI, the RTREI is computed as the desired output per used input in agreement with the third principle, shown in Eq. (5).

$$RTREI = \frac{m_{EO}}{E_{tot}}. \quad (5)$$

Figure 2 shows the evolution of the selectivity, the currently used energy performance indicator and the new RTREI for one year on a monthly basis, scaled to 1 at the beginning of the year regarding principle four. The EnPI is improving over time due to a decreasing selectivity of the catalyst whereas the RTREI deteriorates slightly. By evaluating the RTREI and the selectivity, the process performance in the sense of

energy and material efficiency is represented adequately. The results show the superiority of the integrated EFA/MFA based indicators over standard indicators that are currently used. However, for this complex process, the standalone resource efficiency indicators are not sufficient to optimize plant operation. Additional information is necessary which indicates the deviation from the best case scenario. Therefore, a meaningful baseline has to be generated.

5. RACER evaluation of the ethylene oxide plant indicators

The new combined material and energy RTREI was compared to the current energy related EnPI using the MORE-RACER methodology introduced above (cf. Figure 4).

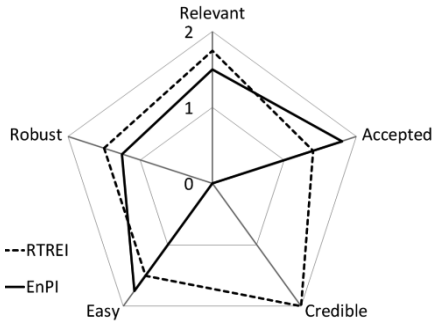

Figure 4: RACER evaluation results.

The EnPI is rated with 0 points for Credible since the indicator is ambiguous for the plant operators. However, compared to the RTREI, the EnPI is rated better in the categories Accepted and Easy. This is related to the higher effort necessary to calculate the RTREI and the less transparent computation since assumptions are necessary to obtain the results. In the categories Robust and Relevant, the results for both indicators differ slightly. The figure reveals the superiority of the RTREI over the EnPI.

6. Conclusions

While standard EnPI might be enough to describe the performance of a production process and its performance over long periods of time, the eight principles introduced enable the user to define RTREI that provide information on the current resource efficiency of the process. Primary and secondary indicators capture the global and local resource efficiency, without being biased by external economic effects. Furthermore, the MORE-RACER methodology was introduced to evaluate the real-time capability of the indicators for the purpose of monitoring resource efficiency in chemical production plants. The relevance for industrial production units was demonstrated for an ethylene oxide example provided by INEOS in Cologne.

A meta-multiparametric framework: Application to the operation of bio-based energy supply chains

Sergio Medina, Ahmed Shokry, Javier Silvente and Antonio Espuña

Chemical Engineering Department, ETSEIB, Universitat Politècnica de Catalunya, 647 Diagonal Avenue, 08028 Barcelona, Spain.

Abstract

This paper proposes a framework for the analysis of complex optimization problems under uncertainty. The usual multiparametric programing approach is skipped through the use of metamodels to mimic a set of already solved scenarios. Such framework has been applied to the operation of a bio-based energy supply chain, taking into account economic, environmental and social aspects: these objectives might be summarized in a single-objective formulation according to arbitrary economic criteria so, in order to assess the importance of the weighting factors used in the final decisions at different demand levels, a Kriging based metamodeling technique has been used to simplify the optimization procedures, leading to dramatic reductions in both the complexity of the methodology application and the required computational effort.

Keywords: metamodeling, kriging, uncertainty, multiparametric programming.

1. Introduction

The limited availability of fossil fuels and the concern related to the environmental impact associated to the use of these non-renewable resources have motivated the interest in the use of alternative technologies and biofuels for energy generation. One important practice is the use and exploitation of agroindustrial wastes (i.e. biomass) as a fuel for several power generation systems. The management of these situations generally faces to a challenging design and planning optimization problem which involves the capacities, cost and productions of the available energy generation units at each time instant (Silvente et al., 2013). Additionally, the network management is directly affected by several types of uncertainty in which we can highlight the demand uncertainty. Therefore, in order to ensure the reliability of the system, uncertainty must be considered due to the fact that the deterministic solution may become suboptimal or even infeasible (Kopanos and Pistikopoulos, 2013).

Different methods and tools have been proposed to consider uncertainty in the formulation of optimization models at different supply chain levels (demand, weather conditions, biomass supply, price variability across the time, etc). When this uncertainty affects not only the internal and external scenarios, but also the optimization parameters (like the importance of the different terms on the objective function), a way to analyze the effects of this uncertainty is the use of techniques referred as multiparametric programming. The main characteristic of multiparametric programming is its ability to obtain an optimal solution of the problem as a function of the uncertain/varying parameters and the region in the space of the parameters where these functions are valid (Sakizils et al., 2007).

In this work, a methodology based on the metamodeling is proposed in order to create a multimetaparametric framework which provides practical advantages over existing methodologies in terms of simplicity and computational effort, leading to significant decision making information.

2. Problem Statement

The planning of a bio-based energy production supply chain to satisfy highest profit under uncertainty parameters and objective reduction is considered. The basic optimization problem formulation is based on a linear programming framework which considers the production capacity, storage levels, equipment capacity and sales per market as main decision variables. This model takes into account the production of energy through biomass considering the possibility of resizing the equipments of the existing energy plants.

A multiobjective evaluation of production levels to be managed and energy sales to the main power grid have been also included in order to maximize the profit taking care about environmental and social impacts as additional objectives. The mathematical model includes not only the mass and energy balances constraints associated to the energy production, but also the constraints required to describe the technologies involved (Dryer, chipper, Gasifier and transport units).

A kriging metamodeling technique (Shokry and Espuña, 2014) has been applied as a way to manage uncertain parameters based on its properties and potential of accurately approximating complex problems. The next terms describe the problem under study:

2.1 Inputs

- *Process data*

- The set of materials $s \in S$, which includes raw, intermediates and final products.
- The tasks $i \in I$, which include on site treatments, pre-treatments and transportation.
- The set of economic criteria for environmental and social objectives.
- The set of locations (Fixed)$fc \in FC$, composed by suppliers (Biomass providers), intermediates (Pretreatment and treatment sites) and consumers (Markets).
- A time horizon $t \in T$, which represents the months of the year.
- A given expected energy demand profiles: for each short-term period and market, a different (uncertain) target value is considered.

- *Economic, Environmental and Social information*

- Product and consumable prices are considered
- Environmental impacts for raw material production, process and transportation systems are also considered. The importance of this assessment on the decision making procedure is considered uncertain.
- The social impact is considered as a function of the size of the different installed processes, although again, The importance of this assessment on the decision making procedure is considered uncertain.

An optimization model based on the State Task Network formulation allows summarizing the information about the activities from all the SC nodes through a single variable set. The main decisions to be made to maximize the profit are related to:

- Magnitude of the task $P_{i,j,fc,ffc,t}$. This is the most important variable in the model and represents the magnitude of a task *i* performed using technology *j* during period *t*, whose origin is location *fc* and destination is location *ffc*.
- Storage levels at each site and time.
- Size of installed equipment units.

The main equations of the mathematical formulation are now brief described. Storage levels of raw material in each site and at any time are specified in eq.1. Eq. 2 represents the energy balance in which the energy must respect the conservation law. the energy balance must be related to the amount of energy produced and consumed. Eq. 3 ensures that the production level and raw material processed in each facility will be greater or equal than a minimum utilization value defined by the decision maker and lower than the maximum capacity. Eq. 4 ensures that the raw material s purchased form site fc at time t is lower or equal than an upper limit which at the same time is the physical availability of raw material. Eq. 5 is just a constraint that represents the fact that the demand could be satisfied partially for the energy produce using biomass. It is important to notice that even if the solution is treated as an uncertain parameter on the model it must be consider as a deterministic value since each change of demand value implies an isolated optimization procedure.

$$S_{sft} - S_{sft-1} = \sum_{f'} \sum_{i \in \bar{T}_s} \sum_{j \in \left(J_i \cap \widetilde{J_{f'}}\right)} \alpha_{sij} P_{ijff't} - \sum_{f'} \sum_{i \in \bar{T}_s} \sum_{j \in \left(J_i \cap \widetilde{J_{f'}}\right)} \bar{\alpha}_{sij} P_{ijff't} \qquad \forall s, f, t \quad (1)$$

$$\sum_{s \in T_s} HV_s \alpha_{sij} P_{ijff't} = \sum_{s \in \bar{T}_s} HV_s \, \bar{\alpha}_{sij} P_{ijff't} \qquad \forall i \in \bar{I}, j, f, t \quad (2)$$

$$\beta_{jf} F_{jft-1} \leq \sum_{f'} \sum_{i \in I_j} \theta_{ijff'} P_{ijff't} \leq F_{jft-1} \qquad \forall f, j \in \tilde{J}_f, t \quad (3)$$

$$\sum_{f'} \sum_{i \in \bar{T}_s} \sum_{j \in J_i} P_{ijff't} \leq A_{sft} \qquad \forall s \in RM, f \in Sup, t \quad (4)$$

$$\sum_{f' \in M} Sales_{sf'ft} \leq Dem_{sft} \qquad \forall s \in FP, f \in Mkt, t \quad (5)$$

The expected profit of the entire supply chain is calculated considering incomes (Esales) and costs. The costs include fixed cost ($FCost_t$) related at the investment and the variable cost (EPurch) including the transportation, acquisition and production cost in eq. 6, subject to the previous constraints. Environmental impact is related to an LCA analysis. The main form of this analysis is in eq. 7. The social impact is calculated as the number of pretreatment and treatment sites installed as eq. 8 represents. In this equation the binary variable V_{jft} represents if a unit is installed or not. It is important to notice that in the proposed formulation the number of units installed will be the same for each of the parameters set since the superstructure is fixed, but it is considered in the model for comparison purposes.

$$Profit_t = Esales_t - \left(FCost_t + \sum_e EPurch_{et} \right) \qquad \forall t \quad (6)$$

$$Impact^{2002}_{overall} = \sum_f \sum_g \sum_t \sum_{a \in A_g} NormF_g \zeta_{ag} IC_{aft} \qquad \forall g, f, t \quad (7)$$

$$SoC = \sum_{j}\sum_{f}\sum_{t} V_{jft} \qquad \forall j,f,t \qquad (8)$$

For more details of the model and symbology readers are suggested to read (Pérez-Fortes et al., 2012).

The original formulation is a multiobjective one which contemplates the profit, environmental and social impact as objectives. In the presented work the new objective function, which is the one to be maximized, is calculating transforming the objectives environmental and social impacts into an economic one applying an arbitrary criterion (WeightSoc and WeghtEnv). The objective function calculation is described by eq. 9.

$$OF = \sum_{t} Profit_t + (SoC * WeightSoc) - (Impact_{overall}^{2002} * WeightEnv) \qquad \forall t \qquad (9)$$

Notice that if the arbitrary criterion change the optimal solution could be suboptimal since this value affects directly the OF value. For this reason an kriging metamodel will be created in order to facilitate further optimization once the values of the arbitrary criterion changes. The same occurs with the Demand value that in this case is treated as an uncertain parameter.

3. Methodology

The proposed framework could be summarized in a set of steps that must be done in order to ensure its functionality.

1. Identification of the uncertain parameters to be analysed; confirmation of the corresponding upper and lower bounds.
2. Generation of a well distributed (representative) design of experiments.
3. Generation of the set of optimum solutions.
4. Training of the metamodel. In this particular case, the selected technique was "kriging", but any other suitable process may be used (support vector machines, ANNs, etc.). One metamodel for each one of the problem DOFs have to be trained.
5. Validation of the obtained metamodel. According to the results on this step, it may be considered to go back to point 3 and to generate a larger training set of experiments.

4. Case study

The supply chain introduced by Pérez-Fortes et al. (2012) has been used as case-study. It contemplates the bio-based energy production in a small district in Ghana. The 9 most important communities there were taken into account as suppliers, potential production sites and/or market sites for a 3 months planning horizon. The optimal fixed superstructure obtained for this particular case study (Pérez-Fortes et al., 2012) has been considered and, for this superstructure, the objective of this study includes the analysis on how the changes in the uncertain parameters (electricity demand and decision making criterion) affect the planning decissions. In the original work, these parameters were fixed to 50 €/Env_unit, 1000 €/Soc_unit and 50000 kWh/month (WeightEnv, WeightSoc and Demand respectively); now these parameters are considered to vary in a range of 10-100 €/Env_unit, 100-10000€/Soc_unit, 49916-61009 kWh/month.

4.1. Results and discussion

Series of 25, 50, 75, 100, 125 and 150 experiments (combination of variables defining one single scenario) have been generated following Hammersly sampling technique and solved according to the proposed LP formulation using GAMS/CPLEX. Figure 1 shows the optimal objective values as a function of total demand and the environmental weight. The missing parameter under evaluation (Social weight) is not constant but even this it is worth noting that the response surface is clearly irregular, confirming that the parametric function may be nonlinear although the basic problem formulation is linear.

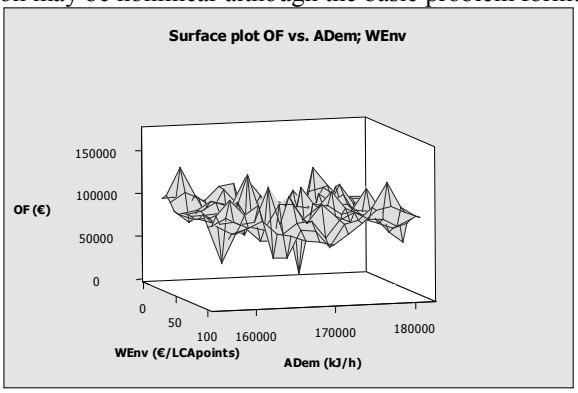

Figure 1. Behavior of the optimal objective function for different values in weightEnv and total demand parameters.

Figure 2 shows the kriging model cross-validation using sets of experiments of different sizes, and exhibits (a) the correlation between the estimated Objective Function obtained by a surrogate model trained using a reduced number of experiments, and the corresponding real optimum values (optimization of the original model), and (b) the quality of the metamodel as a function of the size of the training set. Although an obvious improvement in the quality of the fitting with the size of the training set is observed, the fitting is good enough to justify the use of the surrogate model, even in cases where the size of the training set is quite small. Similar plots are obtaining for the models fitted to reproduce the resulting values of the DOFs at their optimum values.

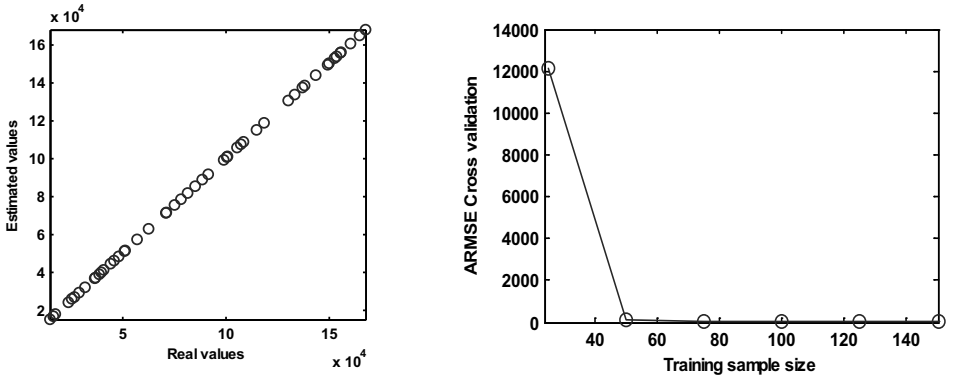

Figure 2. Cross-validation a) for a set of 50 experiments; b) as a function of the size of the training set.

Finally, Table 1 illustrates the reduction in the optimization time with the use of the metamodel. Although the solution of the 150 experiments requires a relatively high computational effort (this problem may become very important when a more complicated model is to be solved), once the surrogate model has been created the optimization time drops dramatically: for this example, the time to obtain the solution is reduced in more than 3 orders of magnitude (1/4,895), and of course higher reductions would be obtained for a more complex optimization problem.

Table 1. Computational effort required.

	Math. Programming (GAMS/CEPPLEX)	**Kriging metamodel**
Training effort (CPU s)	(model building)	(model building + 3300 s (150 experiments) + 70 s (training))
Optimization effort (CPU s)	22	0.00466

(*)HP-dc7900, Intel core 2-duo 3, 16 GHz, RAM 6GB.

5. Conclusions

In order to solve optimization problems under uncertainty, which usually requires programming, can be also successfully solved employing a framework based on Kriging metamodel. The resulting model behaves like a useful metamultiparametric framework. This has been proved in relatively simple case studies. More work is required to develop a robust framework to handle bigger and more complex problems (Highly nonlinear models, MIP problems, etc.).

Abstract

We propose a new continuous-time formulation for the short-term scheduling of single stage batch plants with parallel units that allows for direct heat integration between hot and cold streams linked to production tasks of different products. This is in essence a bi-objective optimization problem in which makespan and utility consumption are the conflicting objectives. Using industrial test problems from a vegetable oil refinery, we show that savings in utilities can already be obtained for the minimum makespan but that the optimal synchronization of hot and cold streams requires major production delays. In between, there are multiple Pareto optimal solutions to consider.

Keywords: Energy efficiency; Heat exchanger networks; Mathematical modeling.

1. Introduction

Increasing energy efficiency is an important goal of governments worldwide. The systems approach has been named process integration, involves pinch analysis or mathematical programming and can readily be applied to continuous plants (Fernández et al., 2012). In contrast, in batch plants, hot and cold streams are not always available and direct heat integration is only possible if the streams are synchronized. Indirect heat integration provides additional flexibility since the energy from the hot stream can be collected by a heat transfer medium and stored until the time it is required by the cold stream, but it is not the subject of this paper.

Vaklieva-Bancheva et al. (1996) and Adonyi et al. (2003) highlight that minimum utility consumption through direct integration leads to production delays. Halim and Srinivasan (2009) considered the bi-objective optimization problem through a two-stage decomposition approach but their best schedule featured minimum makespan as well as minimum utility usage. Seid and Majozi (2014) have proposed a general model for direct and indirect heat integration in multipurpose batch plants and found a better solution. However, and despite being suitable for the most complex plant topology, such model may not perform well in single stage batch plants. As an example, Castro et al. (2014b) have shown that a continuous-time formulation tailored for a simpler topology performs orders of magnitude better in a steam-sharing problem from a pulp plant. Computational importance gains relevance when solving multiple-criteria problems.

In this paper, we propose to rigorously tackle the bi-objective optimization problem involved in the simultaneous optimization of product sequencing, timing and heat integration decisions. From the latter point of view, the new formulation can be seen as an extension of the simultaneous targeting and design model of Yee et al. (1990) for

heat exchanger networks of continuous plants. An algorithm relying on the ϵ-constraint method is used for generating the Pareto optimal points.

2. Problem definition

Assume a multiproduct batch plant where the production recipe for product $i \in I$ involves multiple subtasks $k \in K_i$ with processing time $p_{i,k}$ to be executed inside a pre-assigned equipment unit $m \in M_i$. A subset of tasks requires heating or cooling defining respectively cold $c \in C$ and hot streams $h \in H$. Let such union represent a process stream $ps \in PS = C \cup H$ characterized by initial t_{ps}^{in}, final temperature t_{ps}^{out} (K) and heat capacity cp_{ps} (J/K). We assume that only direct heat integration is possible, thus excluding matches between hot and cold streams belonging to the same product. Heat integration between streams of different products is possible if the temperature difference is greater than the minimum approach temperature Δt (K) and the streams overlap in time (at least partially). The goal will be to find the optimal schedule that minimizes two conflicting objectives: (i) makespan; (ii) total utility consumption.

3. Mathematical model

We consider a continuous-time model for a single stage batch plant, similar to the one by Méndez et al. (2001). General precedence sequencing variables $X_{i,i'}$ identify if product i is completed before the start of product i'. Let $S_{i,k}$ and $E_{i,k}$ represent the starting and ending time of subtask k of product i, $|K_i|$ the last subtask of product i and hz an upper bound on the makespan. If product i precedes i' then $X_{i,i'} = 1$, Eq. (1) is enforced and Eq.(2) is relaxed, else it is the other way around. Eq. (3) states that the ending time is equal to the starting plus processing time. The starting time in stage $k+1$ is made equal to the ending time in k to avoid temperature degradation, Eq. (4). The latest ending time defines the makespan MS, Eq. (5).

$$E_{i,|K_i|} \leq S_{i',1} + hz(1 - X_{i,i'}) \; \forall i, i' > i, m \in M_i \cap M_{i'} \quad (1)$$

$$E_{i',|K_{i'}|} \leq S_{i,1} + hz \cdot X_{i,i'} \; \forall i, i' > i, m \in M_i \cap M_{i'} \quad (2)$$

$$E_{i,k} = S_{i,k} + p_{i,k} \; \forall i, k \in K_i \quad (3)$$

$$S_{i,k+1} = E_{i,k} \; \forall i, k \in K_i \backslash |K_i| \quad (4)$$

$$MK \geq E_{i,|K_i|} \; \forall i \quad (5)$$

The direct heat integration part of the model features starting and ending variables linked to process streams, Ts_{ps} and Te_{ps}. These can be linked to the tasks variables through Eqs. (6-7), where set $PS_{i,k}$ holds the single stream linked to task k of product i.

$$Ts_{ps} = \sum_i \sum_{k \in K_i \wedge ps \in PS_{i,k}} S_{i,k} \; \forall ps \quad (6)$$

$$Te_{ps} = \sum_i \sum_{k \in K_i \wedge ps \in PS_{i,k}} E_{i,k} \; \forall ps \quad (7)$$

We assume a superstructure where each hot/cold stream goes through a sequence of two stages from their initial to final temperature. In each stage, matches with different streams are possible but to avoid bilinear terms in the energy balances, isothermal mixing is assumed (Yee at al. 1990), leading to a parallel arrangement (see Figure 1).

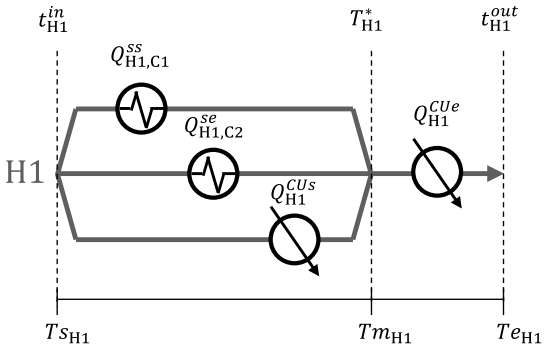

Figure 1. Cooling/heating of stream involves up to two stages, possibly with parallel matches.

Let T^*_{ps} be continuous variables representing the intermediate temperatures and Tm_{ps} the intermediate times. If a hot h and cold c stream exchange energy, four types of interaction are possible, identified through binary variables $Y^j_{h,c}, j \in \{ss, se, es, ee\}$. Taking type se as an example, the hot stream h starts its cooling by exchanging heat with cold stream c, which is in its second stage of heating having previously exchanged heat with another hot stream and/or heating utility. The two points for synchronization thus involve: (i) the starting time of h and the intermediate time of c; (ii) the intermediate time of h and the ending time of c. It should be noted that the complete set of synchronizing constraints given below was generated from a Generalized Disjunctive Programming model (Raman and Grossmann, 1994) using insights from the interaction of tasks with time periods of constant electricity pricing (Castro et al. 2014a).

$$Ts_c - hz(1 - Y^{ss}_{h,c}) \le Ts_h \le Ts_c + hz(1 - Y^{ss}_{h,c})\ \forall h, c \quad (8)$$

$$Tm_c - hz(1 - Y^{ss}_{h,c} - Y^{ee}_{h,c}) \le Tm_h \le Tm_c + hz(1 - Y^{ss}_{h,c} - Y^{ee}_{h,c})\ \forall h, c \quad (9)$$

$$Tm_c - hz(1 - Y^{se}_{h,c}) \le Ts_h \le Tm_c + hz(1 - Y^{se}_{h,c})\ \forall h, c \quad (10)$$

$$Te_c - hz(1 - Y^{se}_{h,c}) \le Tm_h \le Te_c + hz(1 - Y^{se}_{h,c})\ \forall h, c \quad (11)$$

$$Ts_c - hz(1 - Y^{es}_{h,c}) \le Tm_h \le Ts_c + hz(1 - Y^{es}_{h,c})\ \forall h, c \quad (12)$$

$$Tm_c - hz(1 - Y^{es}_{h,c}) \le Te_h \le Tm_c + hz(1 - Y^{es}_{h,c})\ \forall h, c \quad (13)$$

$$Te_c - hz(1 - Y^{ee}_{h,c}) \le Te_h \le Te_c + hz(1 - Y^{ee}_{h,c})\ \forall h, c \quad (14)$$

Eqs. (15)-(18) reflect the temperature driving force (TDF) constraints, where the big-M parameter is calculated through Eq. (19). Notice that no continuous variables appear in Eq. (18) since the minimum driving force Δt occurs between the two final temperatures. Note that TDF decreases throughout integration time, typically reaching Δt at the end.

$$T^*_h \ge T^*_c + \Delta t - bm_{h,c}(1 - Y^{ss}_{h,c})\ \forall h, c \quad (15)$$

$$T^*_h \ge t^{out}_c + \Delta t - bm_{h,c}(1 - Y^{se}_{h,c})\ \forall h, c \quad (16)$$

$$t^{out}_h \ge T^*_c + \Delta t - bm_{h,c}(1 - Y^{es}_{h,c})\ \forall h, c \quad (17)$$

$$Y^{ee}_{h,c}(t^{out}_h - t^{out}_c - \Delta t) \ge 0\ \forall h, c \quad (18)$$

$$bm_{h,c} = -t^{out}_h + t^{out}_c + \Delta t\ \forall h, c \quad (19)$$

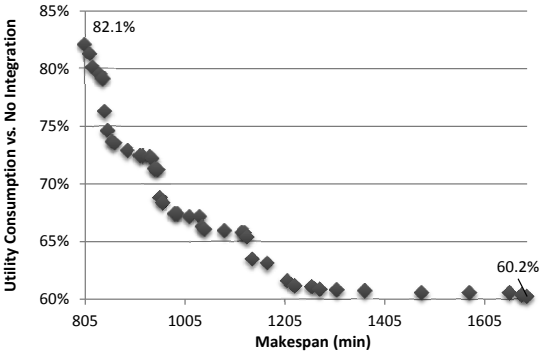

Figure 2. Pareto optimal solutions for a problem involving 33 process streams.

Two process streams are allowed to exchange energy only if the corresponding interaction type is selected, see Eq. (20). The upper bound $q_{h,c}$ is given by Eq. (21). Eq. (22) states that at most one type of interaction can be active.

$$Q_{h,c}^{j} \leq q_{h,c} Y_{h,c}^{j} \; \forall h, c, j \in \{ss, se, es, ee\} \tag{20}$$

$$q_{h,c} = min\left[cp_h\left(t_h^{in} - t_h^{out}\right), cp_c(t_c^{out} - t_c^{in})\right] \forall h, c \tag{21}$$

$$Y_{h,c}^{ss} + Y_{h,c}^{se} + Y_{h,c}^{es} + Y_{h,c}^{ee} \leq 1 \; \forall h, c \tag{22}$$

The remainder constraints deal with the stage energy balances. Let Q_h^{CUs}, Q_h^{CUe}, Q_c^{HUs} and Q_c^{HUe}, represent the energy removed/supplied by the cooling/heating utility (CU/HU) at the start and ending stages. The change in temperature of a stream is due to process streams and/or utilities. The total utility consumption is then given by Eq. (27).

$$cp_h\left(t_h^{in} - T_h^*\right) = \sum_c (Q_{h,c}^{ss} + Q_{h,c}^{se}) + Q_h^{CUs} \; \forall h \tag{23}$$

$$cp_h(T_h^* - t_h^{out}) = \sum_c (Q_{h,c}^{es} + Q_{h,c}^{ee}) + Q_h^{CUe} \; \forall h \tag{24}$$

$$cp_c(T_c^* - t_c^{in}) = \sum_h (Q_{h,c}^{ss} + Q_{h,c}^{es}) + Q_c^{HUs} \; \forall c \tag{25}$$

$$cp_c(t_c^{out} - T_c^*) = \sum_h (Q_{h,c}^{se} + Q_{h,c}^{ee}) + Q_c^{HUe} \; \forall c \tag{26}$$

$$UT = \sum_h (Q_h^{CUs} + Q_h^{CUe}) + \sum_c (Q_c^{HUs} + Q_c^{HUe}) \tag{27}$$

4. Pareto optimal solutions

The decision-making problem involves the minimization of two conflicting objectives, utility consumption and makespan: min (UT, MK). To generate the set of Pareto optimal points we choose the ϵ-constraint method, which involves solving multiple problems of the form (***P***), one for each value of auxiliary parameter ε. The domain of ε is found by solving the two single objective problems.

$$min \; UT$$

$$s.t. \; MK \leq \varepsilon \qquad \textbf{(P)}$$

$$Eqs.(1-27)$$

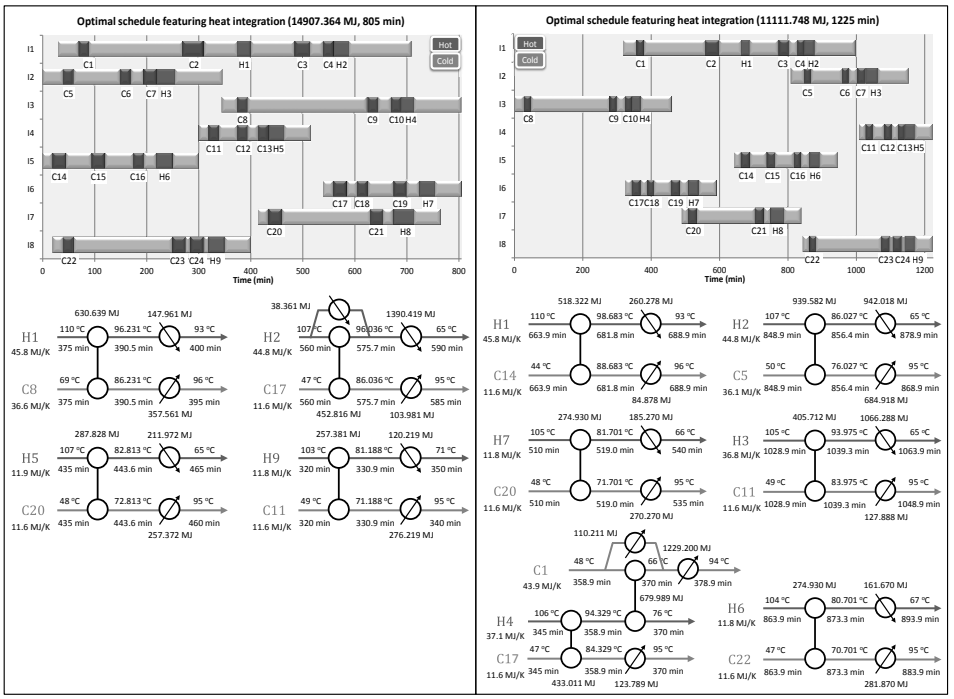

Figure 3. Two Pareto optimal schedules and corresponding matches for 33-stream problem.

Parameter $\varepsilon \in [805,1690]$ (min) for a 33-streams problem from a vegetable oil refinery. A total of 41 optimal solutions arise, ranging from the minimum makespan with 82.1% utility consumption compared to no integration, to the lowest value of 60.2%, for which the production time is more than doubled, see Figure 2. Perhaps the best solution is something in between. In particular, the right-most schedule in Figure 3 features 61.2% utilities and a makespan equal to 1225 min. It can be seen that lowering utility consumption requires additional matches between process streams (7 vs. 4), resulting in a more complex network. The start-start is by far the preferred type of interaction. The other interesting observation is that product sequencing has changed in all three equipment units with more than one product assigned, from (I2-I3, I5-I4-I6, I8-I7) to (I3-I2, I6-I5-I4, I7-I8). This is a clear indication of the importance of solving the scheduling and heat integration problems simultaneously (Seid and Majozi, 2014).

5. Computational studies

We consider four problems ranging from 18 to 46 streams. The general mixed-integer linear programming (MILP) formulation was implemented in GAMS and solved by CPLEX 12.6 running in parallel deterministic mode using up to 8 threads (relative optimality tolerance=10^{-6}). The hardware consisted of a desktop with an Intel i7-4790 CPU (3.6 GHz), 8 GB of RAM and running Windows 7.

Table 1 gives the results for the two extreme points of the Pareto set. The first three problems were generated so as to have the same minimum makespan. As the number of products and streams increases, so does the potential utility savings. The drawback is

that significant production delays may be needed to achieve the proper synchronization of tasks. The added complexity is reflected in the total computational time to generate the full Pareto set, with the 33-streams instance requiring roughly two days. In fact, the reported values in column 7 for 33 and 46 streams involve the solution of makespan-unconstrained problems, needed to find the upper bound on ε, and do not necessarily correspond to minimum utility consumption (large gap at termination). Adding the constraint $MK \leq 1740$ makes it possible to solve the 33-streams problem in less than 1 h. The last important aspect is that the mathematical formulation has a poor relaxation, equal to the difference between the energy requirements of hot and cold streams. Thus, the linear relaxation disregards timing and temperature driving force constraints.

Table 1. Main results from Pareto set generation

$\|I\|$	Streams	MK (min)	UT (MJ)	Savings	MK (min)	UT (MJ)	Savings	TCPUs
4	18	805	11569.5	15.6%	1140	9102.7	33.6%	29.5
6	26	805	13567.5	15.5%	1365	10007.0	37.7%	463
8	33	805	14907.4	17.9%	1740	10951.3[a,b]	39.7%	171971
11	46	1305	19823.2	26.5%	2330	15208.9[a,c]	43.6%	-

[a]Best possible solution up to 3600 CPUs, may be dominated ([b]Gap=19.5%; [c]Gap=52.9%).

6. Conclusions

This paper has addressed the simultaneous scheduling and heat integration problem in a multiproduct batch plant. Through the solution of four industrial cases studies from a vegetable oil refinery, it has been shown that energy efficiency can be improved substantially. There is a clear trade-off between production time and utility consumption, with larger utility savings typically associated to significantly longer production times. This can be interesting in plants operating well below their maximum capacity. Overall, there are a large number of Pareto optimal solutions to choose from.

Abstract

Improving the yield of batch-wise production is an increasingly important topic for the pharmaceutical industry; reasons for that include the rising public pressure on drug prices as well as a number of soon-expiring patents. This study defines a data-based, three-level approach for yield enhancements in batch-wise operations that is applied exemplary to the manufacturing of sterile drug products. The application on data of a yearly Parenterals production validated the presented approach by facilitating the identification of the main loss causes (e.g., quality control samples and scratched vials) and by supporting the development of improvements with the result of an increased production yield. As a case study, one loss cause (i.e., rubber stoppers with embedded particles) is discussed, where all three levels were applied and a process enhancement could be realised.

Keywords: Pharmaceutical Production, Industrial Application, Decision-making, Statistical Process Control, Multivariate Data Analysis.

1. Introduction

The growing public pressure on drug prices and the marketing of high-cost drug products renders efficiency of technical operations increasingly important to the success of pharmaceutical companies. Besides more strategically motivated efforts, for example improved scheduling algorithms or large scale supply chain optimisations, also operational improvements, including broadly applicable approaches for yield increases on the shop floor level, should be considered. The importance of research on the operational level is also supported by the fact that the increasing availability of production data provides the required database only since lately and corresponding methodologies are not yet established to the full extent.

Early efforts for yield improvements in pharmaceutical production have, for example, been reported by Nyfeler et al. (2004) with case studies about the production of sterile drug products. More recent industrial research on yield enhancements has considered the variability in raw material qualities and uses the composition of ingredients as decision variable for getting optimal drug product characteristics for all batches within a certain planning horizon (García-Muñoz et al., 2014; García-Muñoz, 2014). These efforts are supported by ongoing academic research on batch applications for model

predictive control (MPC), such as Laurí et al. (2014). The current state of process systems engineering tools tailored to the need of the pharmaceutical industry was reviewed and summarized by Troup and Georgakis (2013).

2. Methodology

This study, an expansion of Eberle et al. (2014), defines a hierarchical three-level approach for yield enhancements in batch-wise manufacturing, which is depicted in Fig. 1. For improving production yield, loss causes are prioritized on the first level (1) by their financial impact or active pharmaceutical ingredient (API) losses as the corresponding main cost driver in the biotechnology production area. The emergence patterns of prioritized loss causes are then characterised (2) by statistical analysis with process control charts and thereby screened for characteristics such as outliers, trends or shifts. Based on heuristics and the consultation of expert knowledge, this information is then considered for deriving improvement ideas. If the information available after the execution of the second level is sufficient for deriving favourable process enhancements, a deeper investigation is not necessary. However, if enhancements cannot be defined, an intra-process investigation (3) is performed. This third level is conducted by performing a fault tree analysis (FTA) first and then assigning measured parameters (e.g., gas pressure, temperatures) for as many branches of the FTA as possible. The branches of the FTA are then either starched or dropped based on statistical findings.

On the first level, processes are ranked by their loss impact L_P, which is calculated according to Eq. 1.

$$L_{\mathrm{p}} = \sum_{i=1}^{d} \sum_{k=1}^{n} Q_{k,i,p} \times F_{i,p} \tag{1}$$

L_{p} is determined for each process p as the sum of n batches and d drug products by multiplying quantity $Q_{k,i,p}$ [litres or units of drug product] and impact factor $F_{i,p}$, i.e., grams of API lost per unit for API losses [e.g., g/L or g/unit drug product] or costs of non-commercialized products [monetary units/L or monetary units/unit drug product]. The impact factor $F_{i,p}$ distinguishes the costs on a certain process stage for different products and accounts for the increasing associated costs during manufacturing. All these L_{p} are then graphed in the order of magnitude, as illustrated in Fig. 2 for the case study on embedded particles.

Then, on the second level, a statistical analysis of the loss emergence pattern is performed based on time-resolved loss data exclusively; production characteristics other than the chronological order and the lost quantities are not yet considered. The concept of this second level of the approach is to identify patterns that are supportive for identifying root causes of lost resources by screening the data for outliers, trends or shifts and assigning rationales.

If enhancements cannot be derived, the investigation is escalated to the third level of the proposed methodology, which starts with the creation of a fault tree analysis (FTA) for each loss cause of concern. An FTA facilitates the identification of influence factors for an observed loss phenomenon, for example moving belt velocities to the share of scratched vials. It is the goal of performing the FTA to first bring in all root causes and

then to list for each root cause as many measured parameters as possible for enabling a later reduction of FTA branches by identifying relevant factors or measured parameters. This is performed by cutting branches that were not supported by statistical findings and starching branches that are supported, indicating significant root causes more clearly and enabling the development of process enhancement opportunities.

3. Industrial Case Study

The presented approach was applied to a drug product facility of Roche in Switzerland, which is producing so-called Parenterals. Parenterals are drug products that reach the body by circumventing the gastrointestinal tract, including liquid drug products such as vials and pre-filled syringes. The process steps considered in this study include the compounding of the drug product solution, the filling into the primary product container and the visual inspection for defects.

The yearly production output of six biopharmaceutical Parenterals was investigated with the goal of increasing the production yield, considering some 111 loss causes that are occurring during the production of either pre-filled syringes, liquid vials or both product types. As can be seen in Fig. 2, which resulted from executing the first level of the presented approach, the five major loss causes trigger more than half of the costs for non-commercialised products, including samples and scratched vials. For these loss causes, improvement initiatives have been initiated or executed and will be discussed in a later publication. The focus of the work presented herein is on the loss cause ranked

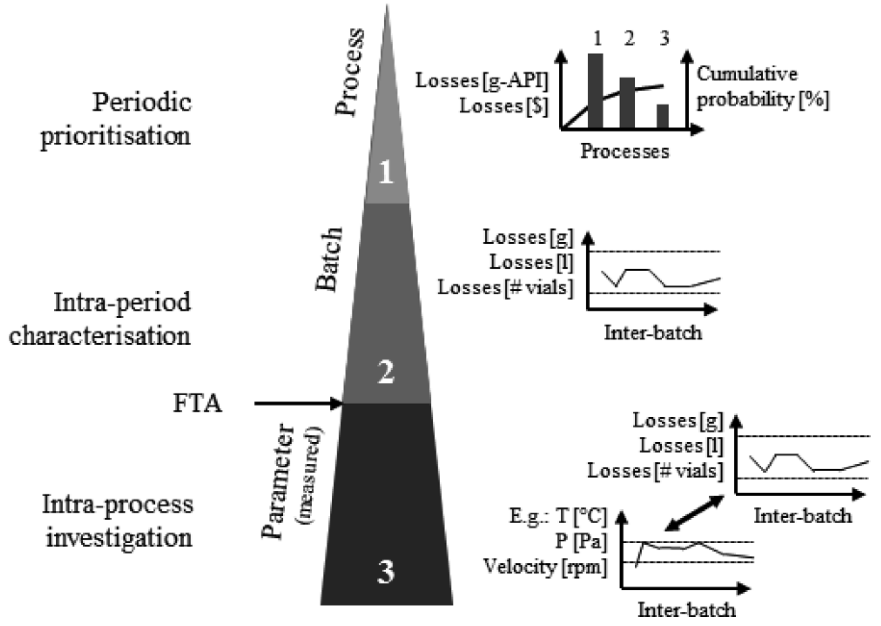

Figure 1: The presented approach is split into three hierarchical tiers that are prioritising (1), characterizing (2) and then investigating (3) loss causes.

sixth, i.e., embedded particles, which is marked in black in Fig. 2. Embedded particles

were selected as case study example in this publication, since the investigation of that loss cause required the application of all three levels of the presented methodology and therefore illustrates all the respective methodological elements to be considered.

The term embedded particles, as defined in this study, includes liquid drug products with impeccable quality that could be applied without a risk of harming a patient. However, the rubber stopper of such vials with embedded particles contains one or few very small areas with discolorations that are hardly visible to the naked eye. This kind of cosmetic defect still leads to the rejection of affected vials. As mentioned above, on the first level, embedded particles are ranked as the sixth most important loss cause in the sampled production period and cause nearly 10 % of costs for non-commercialized products.

On the second level, the emergence of embedded particles was investigated with the help of control charts. A trend or outliers was not detectable and, in more general terms, no solution for decreasing that kind of defect was derivable from available information on the second level. As a consequence of that, the decision was made to proceed to the third level of the presented approach, i.e., establishing an FTA, determining associated measured parameters for each FTA root cause and collecting data accordingly.

From all the vectors that potentially bring a cosmetic defect to the product (product solution, glass container, rubber stopper and isolator air), the rubber stopper was considered as the only relevant vector for embedded particles. A sample of untreated stoppers did not contain embedded particles, which led to the conclusion that the embedded particles must be generated during production processes and was not imported with the supply. Since stoppers are only exposed to conditions other than ambient conditions during their time in the cleaning and sterilisation unit, the focus was on these processes, indicated on the top of Fig. 3. Seven setting characteristics (i.e., batch size of drug product, batch size of stoppers in cleaning vessel, stopper cleaning

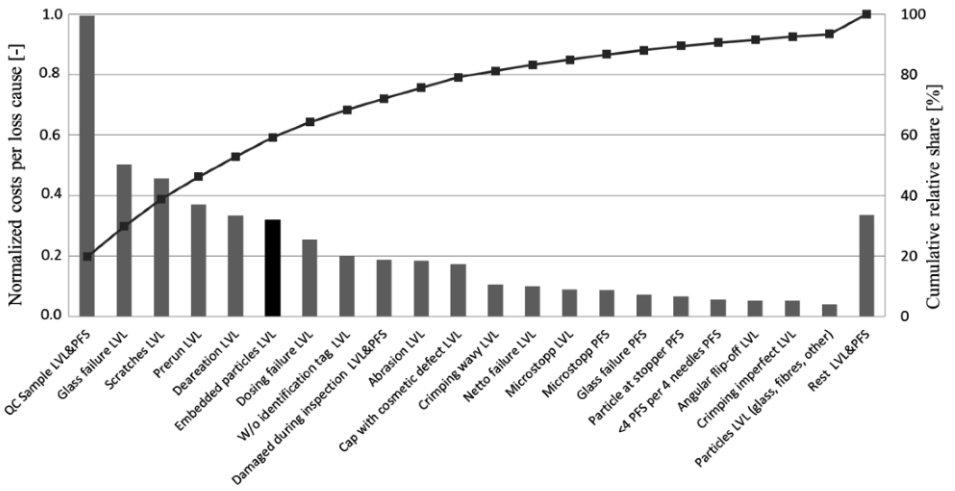

Figure 2: An overview chart for loss causes occurring during the production of Parenterals, indicating the causes on the abscissa in the order of magnitude and the associated absolute but normalized and cumulative relative costs on the left and right ordinate, respectively.

unit, stopper vessel, filled product, format of glass vial and filling period) and three process parameters (i.e., water temperature, water flow and air pressure) for the four process phases (i.e., rinsing, sterilising, drying and cooling) were investigated for all sampled stopper cleaning runs. Since the emergence of embedded particles was not normally distributed, a Kruskal-Wallis test (e.g., Glenberg and Andrzejewski, 2007) was performed and seven parameters that were identified as factors without quality impact could be removed from further analysis. However, the test revealed that the filling period, the batch size of the stoppers in the cleaning vessel as well as the minimal pressure during drying had a significant effect on the emergence of embedded particles, marked black in Fig. 3.

A Bonferroni corrected (Bonferroni, 1936) Mann-Whitney test revealed that embedded particles mostly emerge for the latest filling period, for the biggest stopper batch sizes and stopper cleaning runs with the highest minimal pressure during the drying process. Based on this information and with the support of expert knowledge it was concluded that a vacuum pump in the stopper cleaning unit was underperforming and exposing the stoppers to elevated humidity and temperatures. Hence, the pump was exchanged and the first yield data indicated that this correction measure was successful by reducing the loss by about 20 %.

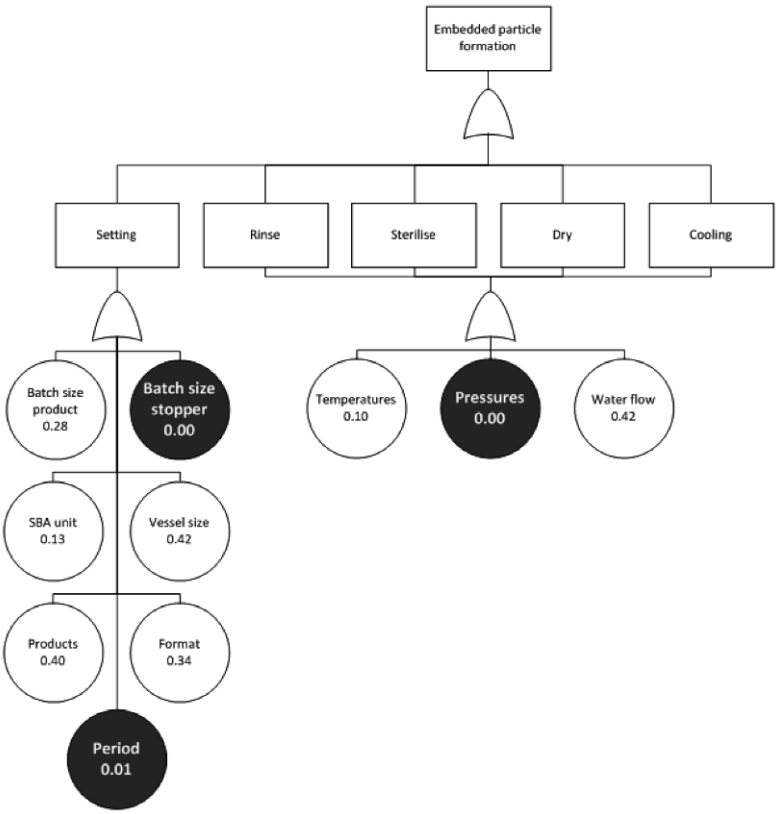

Figure 3: The FTA for embedded particles lists ten investigated parameters; the parameters represented by dark spots have a significant effect on embedded particles. The numbers listed for all parameters indicate the p-value of the Kruskal-Wallis test.

4. Conclusions

The presented approach structures data-based yield improvements in batch-wise productions, for example drug product manufacturing, by applying three hierarchical levels of statistical evaluation. Based on an initial process prioritisation on the first level, loss causes are characterised on the second level and investigated in more detail on the third level. The third level is only executed, if the information gained on the second level is not sufficient for deriving process enhancements. In summary, the developed tiered approach enables a structured use of production data and guides the effort of finding weak points that need improvement. Hence, the approach provides a generic framework for loss causes relevant on the long run but does not substitute process monitoring efforts on a more frequent basis.

Two advantages of the prioritisation as performed on the first level by considering Eq. 1 is that it enables the comparison of losses occurring in different measuring units and account for the increase in value during production processes. Applying the proposed approach to data of a yearly production of Parenterals facilitated the identification, quantification and prioritisation of the main loss causes during production, including QC samples or scratched vials. On the top of that, the information gained from applying the second and third level of the proposed approach allowed the development of enhancements with sustained effects on production yield.

5. Acknowledgement

The support of Sandra Schinzel for the investigation of the embedded particles as well as Markus Mattern and Philip Schneider for providing necessary resources is gratefully acknowledged.

Abstract

Due to changeable market price and flexible feed resources, the feed changeover for cracking furnace occurs frequently. The integration of scheduling and operation optimization is a promising way to further improve the performance of cracking furnaces system. Motivated by the above situations, a novel integrated cyclic scheduling and operation optimization for cracking furnaces system considering feed changeover is proposed to meet this challenge. This integrated problem is a Mixed-Integer Dynamic Optimization (MIDO) problem. Discretized by the Orthogonal Collocation on Finite Elements (OCFE), the MIDO problem is converted into a large scale Mixed Integer Non Linear Programming (MINLP) problem. A case study is used to demonstrate the efficacy of the developed integrated model.

Keywords: cyclic scheduling, operation optimization, cracking furnaces system, feed changeover, MIDO, MINLP.

1. Introduction

Ethylene cracking furnace is the main unit to produce the fundamental raw materials such as ethylene and propylene in petrochemical industry. For an ethylene plant, once it is set up, the number of ethylene cracking furnaces and their geometry configurations are fixed. Operation of the ethylene cracking furnaces system is the main engineering direction to improve the economic performance, and to meet technical and environmental requirements. With the development of economic and increase of global population, the demand for the petrochemical products such as ethylene and propylene is quite strong in the last several decades. Many ethylene plants nowadays have multiple cracking furnaces to process several different types of feeds. The scheduling and planning activities have been involved on the ethylene cracking furnaces system. Jain & Grossmann (1998) first proposed the cyclic scheduling of cracking furnaces system problem and formulated it as an MINLP problem using the exponential decaying function of ethylene yield. Then based on the exponential decaying functions of product yields, Zhao et al. (2011) proposed an MINLP for scheduling of ethylene cracking furnaces system, which can consider the secondary ethane cracking, no simultaneous cleanup constraints and dynamic scheduling. Wang et al. (2014) proposed a novel synchronized decision-supporting framework for the long term planning and scheduling problem of an ethylene plant. To consider the operation condition, Schulz et al. (2006) incorporated the furnaces models into the scheduling of ethylene cracking furnaces

system with the simplified models of distillation columns and raw material and product storage equations. Lim et al. (2009) incorporated a neural-network based on simulation data of rigorous models to consider the impact of feed processing rate on the product yield.

However, none of these above efforts have been made on the integration of scheduling and operation optimization for the ethylene cracking furnaces system. The integration of scheduling and operation optimization is a promising way to further improve the performance of cracking furnaces system, because it has been proven to make significant improvement for many chemical processes (Chu & You, 2014). Motivated by the above situations, a novel integrated cyclic scheduling and operation optimization for cracking furnaces system considering feed changeover is proposed to meet this challenge. The integrated model considering feed changeover is an MIDO problem. Discretized by the OCFE (Biegler, 2007) method, the MIDO problem is converted into a large scale MINLP problem. To demonstrate the efficacy of the developed integrated model considering feed changeover, the integrated model without allowing no-decoking feed changeover is used as the reference model.

2. Problems Statement

In the integrated cyclic scheduling and operation optimization of an ethylene cracking furnaces system with feed changeover, suppose there are *NJ* cracking furnaces, j=1,2,…,*NJ*. *NI* types of feeds are processed, i=1,2,…,*NI*. The considered products are the products, l=1,2,…,*NL*. The cyclic horizon *H* of each cracking furnace are divided into *NK* time-slots, k=1,2,…,*NK*. Two binary variables $WF_{i,j,k}$ and $WC_{j,k}$ are introduced to determine the feed time-slot matching and the changeover type between two consecutive time slots. The integrated cyclic scheduling and operation optimization of an ethylene cracking furnaces system with feed changeover is to determine scheduling activities: the feed-time slot matching and the changeover type between two consecutive time-slots and the operation activities of time slot utilized for cracking. The illustrated Gant chart of the integrated problem with feed changeover is shown in Figure 1.

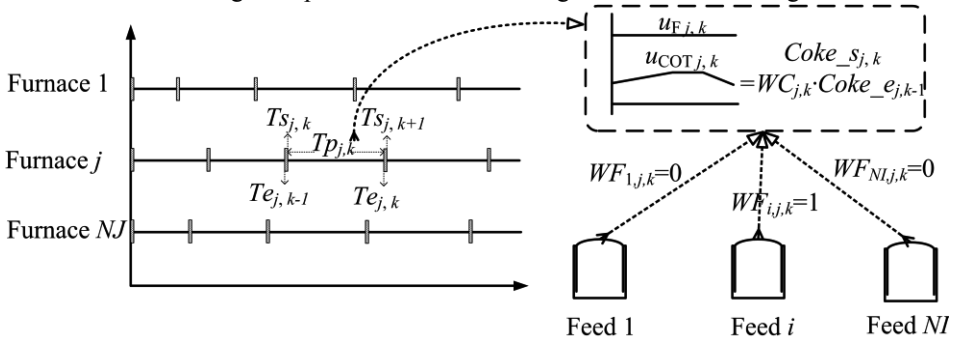

Figure 1 Integrated cyclic scheduling and operation optimization for cracking furnaces system considering feed changeover

3. Integrated Model and Solution Strategy

3.1. Objective Function

In the integrated problem, the maximization of the day mean profit is perused. The day mean profit is sale income of key product minus the clean and changeover cost divided by the cyclic scheduling horizon *H* as:

$$\max\ obj=\frac{\sum_{j=1}^{NJ}\sum_{k=1}^{NK}\left\{\sum_{l=1}^{NL}\left[\int_0^{Tp(j,k)} u_{\mathrm{F}j,k}(t)\cdot y_{j,k,l}(t)\cdot P_l dt\right]-Cc(j,k)\right\}}{H} \tag{1}$$

3.2. Dynamic Models considering Feed Changeover

The dynamic model is expressed as Eq.(2), where f_{FNN} and g_{FNN} mean the Feed-forward Neural Network model, which are obtained by is obtained using combination simulation of rigorous model Coilsim1D (Van Geem et al., 2007) and artificial neural network. Here the subscript l is the outputs of hydrogen (H_2), ethylene (C_2H_4), propylene (C_3H_6), 1,3-butadiene (C_4H_6), benzene (Benz). Here the dynamic models with several disjunctions are reformulated using big M method.

$$\begin{cases} \vee_{i=1,\cdots NI}\begin{bmatrix} WF(i,j,k) \\ \dot{x}_{\mathrm{coke}\,j,k}(t)=f_{\mathrm{FNN},i,j}(x_{\mathrm{coke}\,j,k}(t),u_{\mathrm{F}\,j,k}(t),u_{\mathrm{COT}\,j,k}(t)) \\ y_{j,k,l}(t)=g_{\mathrm{FNN},i,j,k,l}(x_{\mathrm{coke}\,j,k}(t),u_{\mathrm{F}\,j,k}(t),u_{\mathrm{COT}\,j,k}(t)) \\ T_{\mathrm{TMT}\,j,k}(t)=g_{\mathrm{FNN},i,j,TMT}(x_{\mathrm{coke}\,j,k}(t),u_{\mathrm{F}\,j,k}(t),u_{\mathrm{COT}\,j,k}(t)) \\ u_{\mathrm{F}\,j,k}(t)=(Dlo_{i,j}+Dup_{i,j})/2,\ COTlo_{i,j}\le u_{\mathrm{COT}\,j,k}(t)\le COTup_{i,j} \end{bmatrix} \\ T_{\mathrm{TMT}\,j,k}(t)\le 1090,\ Coke\_e_{j,k}=x_{\mathrm{coke}\,j,k}(Tp_{j,k}) \\ x_{\mathrm{coke}\,j,k}(t+1)=x_{\mathrm{coke}\,j,k}(t)+\dot{x}_{\mathrm{coke}j,k}(t)\cdot T_s(t),\ x_{\mathrm{coke}\,j,k}(0)=Coke\_s_{j,k} \\ \forall j,\forall k,\forall t\in[0,Tp_{j,k}] \end{cases} \tag{2}$$

3.3. Scheduling Constraints

3.3.1. Integrality Constraints

In the k time slot of j furnace, it can process no more than one feed at the same time. To express this logical constraint, a binary variable $WF_{i,j,k}$ is introduced. If feed i is processed in the k time slot of j furnace, it is one; otherwise, it is zero. The time slot number NK is a heuristic integer, which is set to a proper number. Thus some time slot may not be used for cracking. To reduce the solution searching space, some additional logical constraints are needed. During the cyclic horizon H, each feed and each ethylene cracking furnace should be utilized. These integrality constraints are expressed as:

$$\sum_{i=1}^{NI} WF_{i,j,k}\le 1,\ \ \sum_{j=1}^{NJ}\sum_{k=1}^{NK} WF_{i,j,k}\ge 1,\ \ \sum_{i=1}^{NI} WF_{i,j,1}=1,\ \ \forall i,\forall j,\forall k \tag{3}$$

$$\sum_{i=1}^{NI} WF_{i,j,k}\ge \sum_{i=1}^{NI} WF_{i,j,k+1},\ \ \forall j,\forall k\le NK-1 \tag{4}$$

3.3.2. Changeover Related Constraints

There are two types of changeovers in the ethylene cracking furnace. One is the decoking process which needs clean time (τ) and clean cost (Cs), and after which the coke is clean and the production efficiency of the ethylene cracking furnace is restored. The other one is the feed changeover without decoking, where a different feed is sent to the ethylene cracking furnace without coke clean process, but with a changeover cost (Co). To express the changeover, another binary variable is $WC_{j,k}$ introduced. $WC_{j,k}$=1

indicates the k time slot of j furnace is operated immediately following a feed changeover. $WC_{j,k}$=0 indicates the k time slot of j furnace is operated immediately following a decoking changeover. Thus the changeover cost ($Cc_{j,k}$) and initial coke thickness($Coke\_s_{j,k}$) can be expressed as Eqs.(5)-(10), where BM is big M parameter.

$$Cc_{j,k} \le \left[(1-WC_{j,k+1})\cdot Cs + WC_{j,k+1}\cdot Co\right] + BM\cdot(1-\sum_{i=1}^{NI} WF(i,j,k)), \forall j, \forall k \le NK-1 \quad (5)$$

$$Cc_{j,k} \ge \left[(1-WC_{j,k+1})\cdot Cs + WC_{j,k+1}\cdot Co\right] - BM\cdot(1-\sum_{i=1}^{NI} WF(i,j,k)), \forall j, \forall k \le NK-1 \quad (6)$$

$$Cc_{j,NK} \le \left[(1-WC_{j,1})\cdot Cs + WC_{j,1}\cdot Co\right] + BM\cdot(1-\sum_{i=1}^{NI} WF(i,j,NK)), \forall j \quad (7)$$

$$Cc_{j,NK} \ge \left[(1-WC_{j,1})\cdot Cs + WC_{j,1}\cdot Co\right] - BM\cdot(1-\sum_{i=1}^{NI} WF(i,j,NK)), \forall j \quad (8)$$

$$Cc_{j,k} \le BM\cdot\sum_{i=1}^{NI} WF(i,j,k),\ Cc_{j,k} \ge -BM\cdot\sum_{i=1}^{NI} WF(i,j,k)), \forall j, \forall k \quad (9)$$

$$Coke\_s_{j,k+1} = WC_{j,k+1}\cdot Coke\_e_{j,k},\ Coke\_s_{j,1} = WC_{j,1}\cdot Coke\_e_{j,NK}, \forall j, \forall k \le NK-1 \quad (10)$$

3.3.3. Timing Constraints

Due to the cyclic scheduling requirement of a round-table problem, the relation of starting time ($Ts_{j,k}$), ending time ($Te_{j,k}$) and feed processing time ($Tp_{j,k}$) can be expressed as Eqs.(11)-(15).

$$Ts_{1,1} = H,\ Ts_{j,1} \le H,\ \forall j \ge 2 \quad (11)$$

$$Ts_{j,1} = Te_{j,NK} + \tau\cdot(1-WC_{j,NK}), \forall j \quad (12)$$

$$Ts_{j,k} = Te_{j,k-1} + \tau\cdot(1-WC_{j,k}), \forall j, \forall k \ge 2 \quad (13)$$

$$Te_{j,1} = Ts_{j,1} + Tp_{j,1} - H, \forall j \quad (14)$$

$$Te_{j,k} = Ts_{j,k} + Tp_{j,k}, \forall j, \forall k \ge 2 \quad (15)$$

3.3.4. Material Balance

The feed arriving amount should be equal to the processed amount by the ethylene cracking furnaces system during the cyclic scheduling horizon H as:

$$F_i \cdot H = \sum_{j=1}^{NJ}\sum_{k=1}^{NK}\left[WF_{i,j,k}\int_0^{Tp_{j,k}} u_{Fj,k}(t)\right]dt,\ \forall i \quad (16)$$

3.4. Variables Bounds

The arriving rate of different feeds F_i, cyclic horizon H, slot starting time $Ts_{j,k}$, ending time $Te_{j,k}$ are bounded as:

$$\begin{aligned} &Flo_i \le F_i \le Fup_i,\ 60 \le H \le 360, 0 \le Ts(j,k) \le 360, \\ &0 \le Te(j,k) \le 360, 0 \le Tp(j,k) \le 360\ \forall i, \forall j, \forall k \end{aligned} \tag{17}$$

3.5. Solution Strategy

The integrated problem is a complex MIDO problem. Discretized by the Orthogonal Collocation on Finite Elements (OCFE) (Biegler, 2007), the MIDO problem is converted into a large scale MINLP problem. All of the models are modelled in the GAMS environment, and the resultant MINLP is solved using SBB as the MINLP solver with CONOPT as the nonlinear sub solver.

4. Case Study

A simple case study of one ethylene cracking furnace with multiple feeds is represented here. In the scope of our study, only an ethylene cracking furnace of GK-VI type is considered and it can process four different types of feeds: light naphtha (LNAP), naphtha (NAP), heavy vacuum gas oil (HVGO) and atmospheric gas oil (AGO). The prices of the high valued products and costs are supposed as in Table 1. The related parameters are supposed as in Table 2. Using the developed framework, the integrated cyclic scheduling and operation optimization of cracking furnaces system considering feed changeover (MIDO problem) is converted into an MINLP model, which is developed with GAMS version 24.1.2 and solved using SBB as the MINLP solver with CONOPT as the nonlinear sub solver. 5 finite elements for each processing time and 3 collocation points per finite element are used in the OFCE process. The resultant MINLP problem involves 77,171 equations, 7990 continuous variables and 25 discrete variables. The solving time with a PC with 64 bit Windows 7 Professional, Intel Core i3 CPU 2.1 GHz and 4 GB RAM is about six hours with a local integer solution. The optimal profiles of the coke thickness are shown in Figure 2(a), which gives a cyclic horizon of 84.9 days and a day mean profit of 2.591 Mil. RMB/day. For comparison purpose, the integrated problem without non decoking feed changeover is also solved as shown in Figure 2(b) of the optimal profiles of the coke thickness. The result gives a cyclic horizon of 253.2 days and a day mean profit of 2.544 Mil. RMB/day. It can be found that the integrated problem with feed changeover can bring more day mean profit, which is result from the more freedom of feed processing with feed changeover.

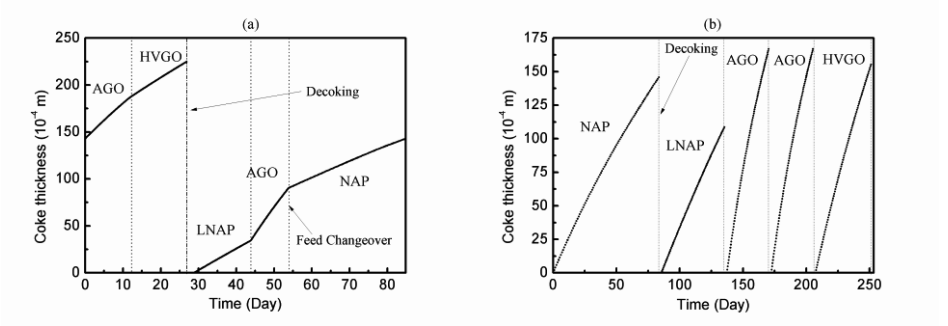

Figure 2 Results of integrated problem (a) with and (b) without non decoking feed changeover

Table 1 Economic indexes

Price of Key Product *l* [RMB/t]					Cost [RMB]		Decoking time [Day]
H_2	C_2H_4	C_3H_6	C_4H_6	Benz	*Cs*	*Co*	τ
14620	8,480	8,210	10,799	10,500	264,052.5	11,000	2

Table 2 Related parameters of the integrated model

Parameters	Feed *i*			
	1 (LNAP)	2 (NAP)	3 (HVGO)	4 (AGO)

5. Conclusions

The integration of scheduling and operation optimization is a promising way to further improve the performance of cracking furnaces system. In this paper, a novel integrated cyclic scheduling and operation optimization for cracking furnaces system considering feed changeover is proposed to meet this challenge. This integrated problem is a MIDO problem, which is discretized by the OCFE method and it is converted into a large scale MINLP problem. A case study is used to demonstrate the efficacy of the developed integrated model compared with the integrated strategy without allowing no-decoking feed changeover. Future work will be on the multi-furnaces multi-feeds, which needs more efforts to solve it.

Abstract

This work proposes a novel approach for the simultaneous synthesis of Heat Exchanger Networks (HEN) and Utility Systems. Given a set of hot and cold process streams and a set of available utility systems (e.g., gas turbine, steam cycle, boiler, etc), the method determines the optimal selection of utility systems, their arrangement and design (including steam generator), and the heat exchanger network (between process-process as well as process-utility and utility-utility streams) rigorously considering the trade-off between efficiency and capital costs. The mathematical model is formulated as a Mixed Integer NonLinear Program (MINLP) and it combines the SYNHEAT superstructure for HENs with ad hoc models/superstructures for utility systems. The challenging MINLP is solved with a two-level algorithm using at the upper level the Variable Neighbourhood Search (VNS) algorithm to optimize the integer variables, and at the lower level the SQP algorithm to optimize the real variables. The algorithm is tested on problems with up to 15 streams (corresponding to 465 binary variables).

Keywords: HEN synthesis, utility systems, MINLP, VNS, steam cycle

1. Introduction

The optimal design of energy systems and chemical processes involves also the synthesis of the Heat Exchanger Network (HEN) as well as of the utility systems necessary to provide thermal, refrigeration and electric power to the process units. To the best of our knowledge, all the available synthesis techniques tackle the two problems separately by limiting the set of integration options between the HEN and the set of utility streams. For instance, the well-known sequential approach proposed in the works of (Papoulias & Grossmann, 1983a), (Papoulias & Grossmann, 1983b) and (Floudas, Ciric, & Grossmann, 1986) has the following limitations.

1. HEN and utility systems (e.g., steam cycle) are designed sequentially.
2. As far as steam cycles are concerned, it is assumed that only evaporating/condensing steam can be integrated within the HEN to supply/remove heat from the process. For example, hot process streams cannot heat up boiler feedwater or superheat steam.
3. The matches of each utility stream can only be in parallel (it is considered one utility substream for each match which involves the given utility, as shown in Fig. 1A). This implies that the HEN superstructure excludes the series arrangement shown in Fig. 1B. Note that the parallel arrangement is possible only if the outlet temperature of cold/hot utility stream is lower/hotter than the inlet temperature of the hot/cold streams matched. This constraint does not allow to use cold utility streams with high outlet temperatures (e.g., feedwater of a steam cycle with outlet temperature of 300

°C) or hot utility streams with low outlet temperatures (e.g., flue gases with outlet temperature of 60 °C) excluding potentially advantageous utility systems.

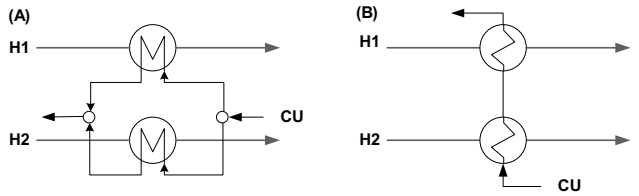

Figure 1. (A): cold utility stream with two matches in parallel (H1-CU and H2-CU). (B): cold utility stream with two matches in series.

Also simultaneous HEN synthesis techniques have limitations which make them not suitable for designing HENs optimally integrated with utility streams. For instance, the MINLP Synheat model of (Yee & Grossmann, 1990) has the following limitations:

1. utility superstructures/models are not included for selection and optimization,
2. the optimization of the utility stream mass flow rates is not tackled because it would lead to nonlinear nonconvex constraints,
3. utility streams are not included in the HEN superstructure but placed at the hot and cold ends of the superstructure (thus, matches of each utility stream can be only in parallel, as shown in Figure 1A).
4. matches between streams of different utilities (e.g., boiler – steam cycle) are not possible.

In utility synthesis techniques the optimization of the process HEN is not dealt with. The utility system is optimized to provide the thermal, electric and refrigeration power required by the process (for fixed process HEN). Synthesis techniques for HENS with multiple utilities, like the one proposed by (Na, Jung, Park, & Han, 2014), do not tackle the design problem of the utility systems (e.g., steam cycle and related boiler) and do not envisage the possibility for utility streams to have matches in series, as in Fig. 1B.

This work proposes a methodology and algorithm for the simultaneous synthesis of HENs and utility systems, which allows to (1) select among several available utility systems, (2) include complex superstructures of utility systems, (3) generate any possible match between process streams and utility streams, (4) optimize the design of the steam generator (arrangement and area of tube banks), (5) include design constraints on the HEN like “forbidden matches”, “restricted matches” and “no stream splitting”.

2. Superstructure, mathematical model, and two-level algorithm

The problem can be stated as below:

“Given a set of hot and cold process streams with given mass flow rates, inlet and outlet temperatures, and a set of available utility systems (e.g., cooling water, boiler, multiple-level steam cycle, refrigeration cycle, heat pump, etc) with given structure or superstructure of possible configurations, the method simultaneously determines the optimal selection of utility systems, their design (arrangement of the steam generator as well as of other heat exchangers of the utility systems, turbine size, mass flow rates of each utility stream, etc), and the heat exchanger network between process-process as well as process-utility and utility-utility streams.”

The proposed synthesis model combines the SYNHEAT temperature-stage HEN superstructure of (Yee & Grossmann, 1990) with models and superstructures of utility systems, as shown in Fig. 2. Utility systems are divided in two categories, U-HEN and

U-END. The streams of utilities in U-HEN can be fully integrated in the HEN, indeed they are dealt with as process streams (e.g., the gas turbine flue gases, the cooling air and the streams of the steam cycle in Fig. 2). Streams of utilities in U-END instead are not included in the HEN superstructure and they are placed at the hot/cold ends of the cold/hot streams (as done in (Yee & Grossmann, 1990)). As a result, utility streams in U-END have limited matching options with other streams. However, they require a much lower number of binary and real variables compared to utility streams in U-HEN. A utility is included in U-END only if its streams have very hot/cold inlet and outlet temperatures compared to those of the cold/hot streams. In such a case, the optimal matching is likely to be at the hot/cold ends of the HEN superstructure. If this condition is not verified, it is advisable to include the utility in U-HEN so as not to exclude better matching options. It is worth noting that the set U-END may be empty if no utility can be reasonably classified as "hot/cold-end" utility, or a stream may not need a "hot/cold-end" utility because its target temperature is variable (e.g., flue gases).
The optimization problems involves the following variables, objective function and constraints.

- Binary optimization variables: activation of utility system (U-END and U-HEN), activation of utility system options (only for utility with superstructure), activation of heat exchangers in the HEN (for process-process and process-utility streams in U-HEN and utility-utility streams both in U-HEN), activation of end utility (in U-END) for each process stream as well as utility stream in U-HEN.

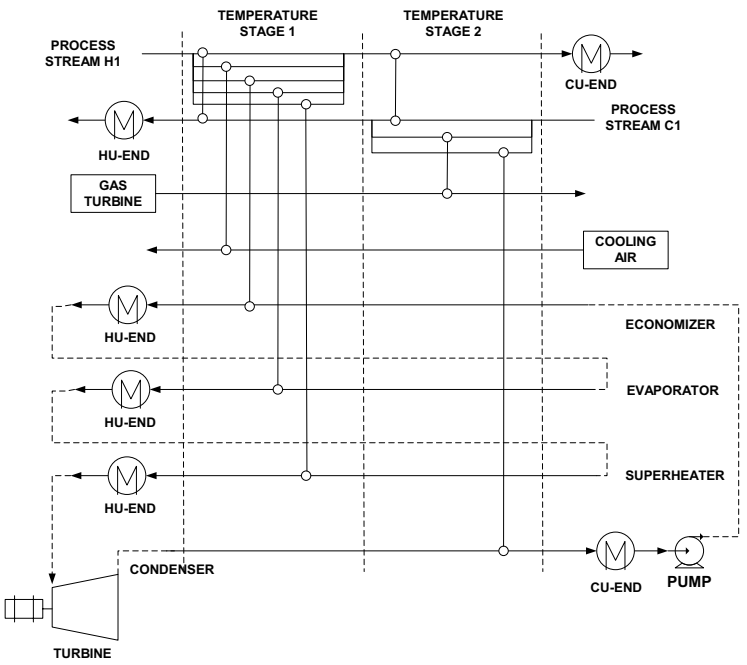

Figure 2. Superstructure of HEN and utility systems. CU-END and HU-END denote respectively "cold/hot-end" utilities.

- Real optimization variables: mass flow rates of utility streams, thermal power exchanged in each heat exchanger, stream temperatures at the inlet/exit of each heat exchanger.

- Objective function: minimum total annual cost, sum of the utility capital cost (fixed activation cost + size depending cost), heat exchanger costs (fixed activation cost + area depending cost) and utility operating cost (energy consumption + other operating costs).
- Constraints: logical constraints to activate/deactivate utility systems and heat exchangers, energy balance equation of each stream, energy balance equation of each stream at each temperature stage, feasibility of stream temperatures in each match, model equations of each complex utility system (e.g., steam cycle), upper and lower bounds on each continuous variable.

It is worth noting that the energy balance equations contain bilinear terms (nonconvex), the products of flow rates and inlet/outlet temperatures of streams in U-HEN.
The challenging MINLP is tackled with a two-level algorithm: at the upper level the Variable Neighborhood Search (VNS) algorithm of (Egea et al., 2014) optimizes the binary variables (dealing with a balck-box integer problem), while at the lower level the SNOPT SQP algorithm optimizes the real variables. In order to minimize the variables and constraints of the lower-level NonLinear Program (NLP), the adaptive reformulation strategy of (Chen et al., 2008) is used. Given the combination of binary variables set by the VNS algorithm, it removes variables and constraints of the NLP.

3. Test case

The algorithm has been tested on several test cases including literature HEN synthesis problems (without utility optimization) and ad hoc problems comprising utility systems. Here we report the computational results for a test problem representative of integrated power plants (e.g., Integrated Gasification Combined Cycles) where the heat recovery steam generator (HRSG) must recover heat from multiple hot streams. Stream data are reported in Table 1. The heat exchangers have an activation cost of 3000 \$/y and area cost of 150 \$/m^{2}y. The boiler has an activation cost (C_A) of 40000 \$/y and energy + size-related cost (C_P) of 200 \$/kWy. For cooling water C_A = 4000 \$/y and C_B = 20 \$/kWy, while for the steam cycle C_A = 1000000 \$/y and C_B = -600000 \$/kWy. A scale factor equal to 0.75 is considered for the area cost of the heat exchangers.

Table 1. Stream data of the test problem.

Stream	F [kW/K]	Tin [°C]	Tout [°C]	h [kW/Km^2]
H1 (process)	200	600	>= 60	0.06
H2 (process)	40	900	250	0.04
H3 (process)	50	350	200	0.04
C1 (process)	20	100	250	0.5
C2 (process)	30	15	150	1.5
BOILER (HU-END)	var	1000	300	0.5
COOLING WATER (CU-END)	var	15	25	1.5
ECONOMIZER (CU-HEN)	var	30	275	1
EVAPORATOR (CU-HEN)	var	275	275	10
SUPERHEATER (CU-HEN)	var	275	565	0.6
CONDENSER (HU-HEN)	var	30	30	2

The optimization has been repeated for ten times with 60000 function evaluations of the VNS algorithm. The best solution is shown in Fig. 3 and its objective function value (total annual cost of the plant) is equal to -19.4587 M\$/y (being a negative value, it is a

revenue). The average objective function of the solutions returned by the algorithm is equal to -19.45259 M$/y, which, being quite close to the best solution value, indicates a good reliability of the VNS algorithm. The CPU computational time of a run is about 800 seconds.

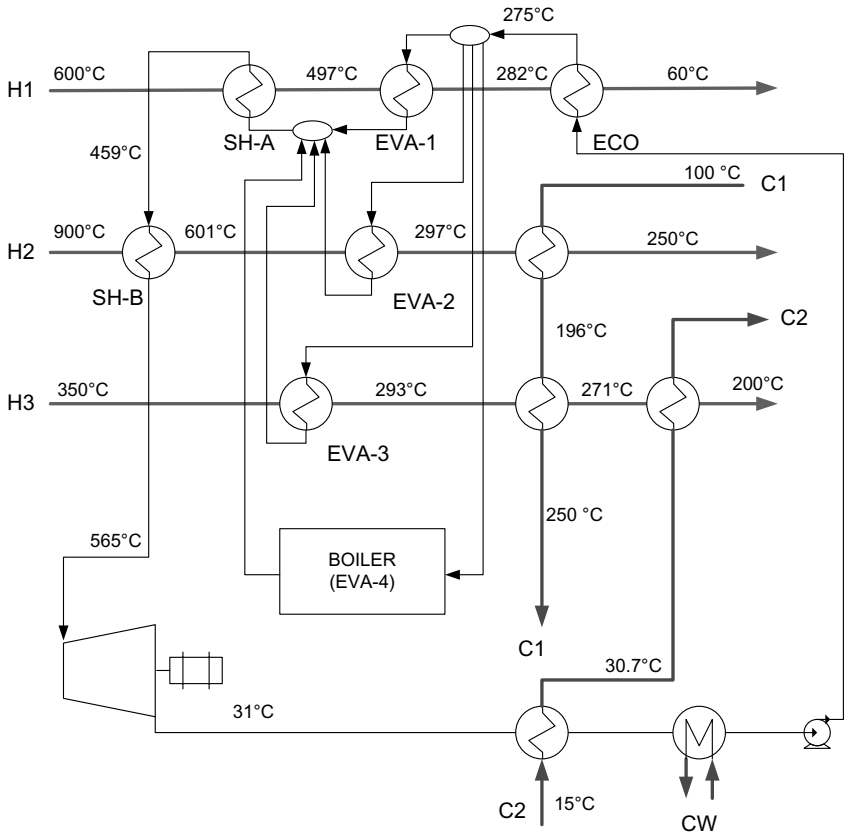

Figure 3. Best solution found by the two-stage algorithm

It is worth noting that the algorithm identifies a solution in which:

- heat exchangers of stream H1 are arranged as a conventional HRSG,
- steam superheating is split into two heat exchangers which are placed in series,
- steam evaporation is split into four heat exchangers (H1, H2, H3, boiler) connected in parallel.
- the steam cycle has been automatically arranged so as to perform cogeneration of power and heat, a particularly efficient thermodynamic solution, as it is heating up the cold stream C2 by means of the heat rejected by the condenser (at turbine outlet).

Such a solution with a so deep integration between the steam cycle and the process HEN cannot be found by other synthesis techniques. Also the layout of the HEN is really interesting as it combines energy efficiency and arrangement simplicity.

The algorithm has been tested also on literature problems with a larger number of streams, up to 15, and up to 465 integer variables. Computational results indicate that the number of function evaluations of the VNS algorithm required to reach close-to-optimal solutions increases considerably. For instance, with 465 integer variables, 300000 function evaluations (corresponding to 10000 s CPU time) are not sufficient to

find the optimal solution. However the returned solution has an objective function value only 3% suboptimal compared to the best-known solutions for the literature problem.

4. Conclusions

Compared to classic HEN synthesis methods, the proposed methodology returns improved HENs and utility system designs in which utility streams are fully integrated within the HEN and advantageous thermodynamic expedients, such as cogeneration, are exploited. The SQP algorithm is extremely efficient and, most important, finds the global optimum also for the problem formulations with variable utility flows (with nonlinear nonconvex constraints). The computational time and convergence rate (in terms of decrease rate of the objective function) of VNS strongly depends on the number of integer variables. However close-to-optimal solutions can be obtained also for problems with a large number of streams within a reasonable computational time (10000 s CPU time), and parallel-computing environment optimized for SQP algorithms, like that proposed by (Kang, Liu, Ren, & Tang, 2014), may significantly decrease the computational time. Future works are aimed at including more complex utility superstructures and testing other optimization algorithms (e.g., branch-bound gradient-based MINLP methods).

Process Simulations Supporting a Techno-Economic Framework to Optimize Biorefinery Supply Chains

Sumesh Sukumara, Kwabena Darkwah and Jeffrey R. Seay*

Department of Chemical and Materials Engineering, University of Kentucky, 177 F Paul Anderson Tower, Lexington 40508, USA
jeffrey.seay@uky.edu

Abstract

With recent innovations in the field of renewable energy, several promising biorefining techniques have been discovered. While many of these innovations have demonstrated promising outcomes in a small scale, laboratory settings, validation of these for their practical viability must be substantiated. While several contributions exist that captures the economic performance and inherent uncertainties of biorefinery supply chains, further emphasis must be directed towards coupling the models with basic sciences. One of the major voids in this existing body of knowledge is the ability to embody experimental outcomes while identifying the optimum supply chain logistics. This contribution illustrates a novel methodology for capturing the experimental details and coupling it with a techno-economic framework. In order to develop the process simulations, various tools from the Aspen Engineering Suite (Aspen Tech®) are explored extensively and tailored in a unique manner to share critical data for further analyses. This attribute of the proposed approach enables successful linking of the basic sciences with the broader biomass supply chain, guiding the decision making process. The resulting comprehensive framework will provide insight in channelling resources appropriately and acting as a decision support tool for investors, policy makers and related stakeholders.

Keywords: Decision Support Tool, Biofuels, Fermentation, User-Defined Functions, Biomass.

1. Introduction and Motivation

The production transportation fuel, energy and chemicals from renewable resources has increasingly gained attention in the past decade. Researchers around the world are aspiring to discover various bio-based pathways to create fuels and chemicals with biomass as a primary feedstock. While several feedstocks exist, due to the increased availability and choice (Naik *et al.* 2010), second generation (lignocellulosic) biomass is considered to be a promising source in meeting the progressively rising energy demands (U.S. Energy Information 2013). In addition to dedicated energy crops, several second generation processes have the capability to include waste agricultural and forest residues, making this extremely attractive for the production of biofuels. However, recent studies demonstrate that the economic viability of second generation biofuels are subject to higher uncertainties, mainly due to the costs associated with agriculture, upstream and downstream conversion processes (Van Eijck, Batidzirai, and Faaij 2014). Therefore, it is imperative to account for various contributors which are involved in the overall supply chain of converting biomass into biofuels and bio-chemicals. Sukumara *et al.* 2013, have demonstrated a framework that links conversion and transportation

models to evaluate the optimum biorefinery configuration (Sukumara *et al*. 2014). This model is intended towards capturing the broader scope of the supply chain while simultaneously evaluating viability of the operational configurations for second generation biorefineries. However, in the framework presented, details pertaining to the addition of fundamental scientific innovations are limited as the process models are based on generic conversion yields and reaction stoichiometry. In order to make the model accessible to fundamental scientific outcomes, this contribution exhibits a supplementary method that can be applied towards embodying the experimental details to the developed framework. This linking enables researchers involved in the development of novel biomass conversion and biofuel separation processes, a route to evaluate and validate the operational viability of their innovations.

2. Background

The development of sustainable biofuel production systems are challenged by the complex nature of the voluminous decisions that policy makers, stakeholders and producers have to make (Seay and Badurdeen 2014). The production of biofuels and biochemicals from biomass involves complex processes and processing steps. The biochemical conversion of biomass into biofuels, for instance, involves pre-treating, hydrolysis to produce fermentable sugars, fermentation to produce products and concentration and purification of products. The complexity and interdependency of the processing systems, coupled with the numerous assumptions that are made to scale-up such processes to commercial level introduces trade-offs that must be included in assessing the economic viability of such process (Geraili, Sharma, and Romagnoli 2014). Additionally, bio-butanol production using biochemical conversion route and fermentation is crippled by low conversions, yields and final product concentrations due to substrate and product inhibition on the microorganism used in the fermentation step (Abdehagh, Tezel, and Thibault 2014). Given these challenges, the process profitability is sensitive to marginal changes in the processing inputs, process yields and cost estimation of the process inputs and products. These inputs are generally modelled with estimated fixed process parameters, such as, yields, reactions and production rates (Geraili, Sharma, and Romagnoli 2014). Simulation as a major tool in process engineering allows for the scaling up of experimental data and prediction on the performance of processes based on process parameters. Experiments have inherent errors due to measurements sensitivity and subjective biases. Thus, simulation and modeling processes that rely on literature data to be used for profitability assessment of a project could be misleading. Simulation packages, such as Aspen Engineering Suite (Aspen Tech®) have thermodynamics packages and other models that can predict reliable trends of processes with credible inputs. Most simulation processes in the literature rely on simplified models, equations and linear models that give overall estimates of large integrated biorefineries. In order to develop a robust and comprehensive framework that depicts actual trends in conversion technologies and processing (which are inherently non-linear in a biorefinery), policy makers, stake holders and manufacturers rely on the use of a decision support tool that addresses the mentioned shortcomings. Furthermore, such a robust framework can be used to determine the possible sources of experimental errors, eliminating infeasible options and thus saving time to ensure the use of accurate economic measures to assess the profitability of a biorefinery (Geraili, Sharma, and Romagnoli 2014).

Based on the examination of current literature, a major void in the existing state of knowledge is determined as the lack of capacity of the decision support tools to contain novel discoveries (Seay and Badurdeen 2014). Thus, this contribution will illustrate a methodology to incorporate fundamental results into the process simulations which categorically links to the multidisciplinary biorefinery assessment framework.

3. Decision Support Tool

As a characteristic of emerging chemical technologies, the supply chain for the production of biofuels have several pivotal stages and cumulative impacts which determines its practical application in any given locale. In a unique contribution (Sukumara *et al*. 2014), a framework is demonstrated that encompasses major models to capture the impacts pertaining to the conversion and transportation operations. Figure 1, shows a schematic of an extended contribution based on the principal framework (Sukumara et al. 2014), highlighting the current domain of focus for this research. The following sections describe the existing state of knowledge and novel contributions made to enhance the accessibility of the multidisciplinary decision support tool.

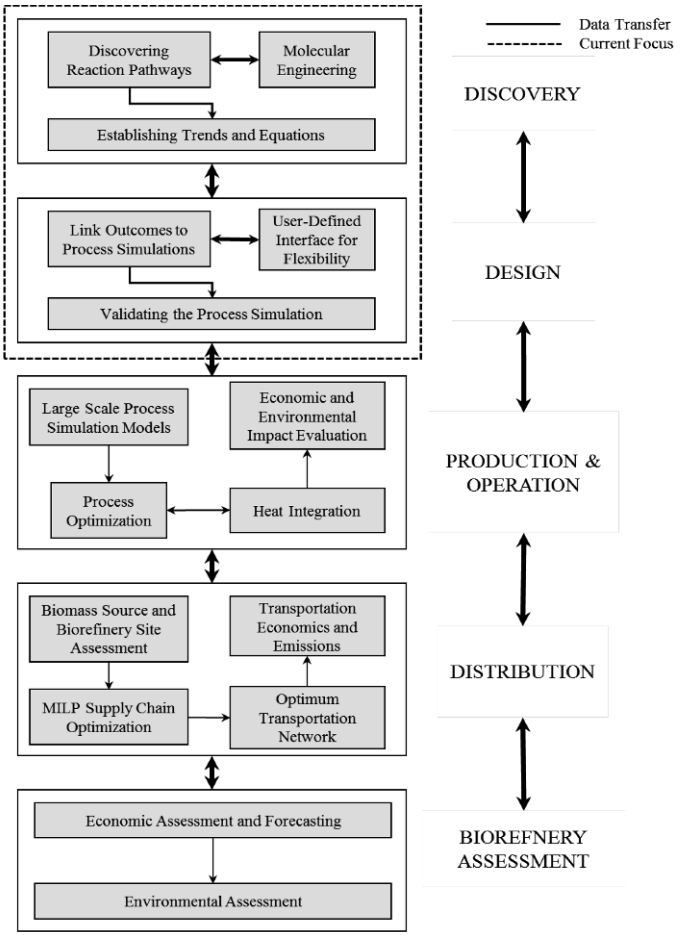

Figure 1. Realms of the decision support framework incorporating experimental outcomes for assessing viability of future biorefinery configurations

3. 1 Overview

Sukumara *et al.*, 2013 illustrated a novel framework that linked gaps in the current state of knowledge by coupling process simulations to the supply chain optimization (Faulkner 2012) and discrete event simulation models (Amundson 2013). The research used Aspen Plus® as a tool to develop process simulations which is further linked to the Mixed Integer Liner Programming (MILP) optimization model.

3.2 Creating and Linking Process Simulations

The deterministic decision support tool is run iteratively, initiated by simulating the conversion models for biorefining processes. In a previous research (Sukumara 2014), simulations are developed for biochemical conversion process, such as, fermentation of corn stover to ethanol. Amongst many, the three major processing challenges for the biological process (mainly from agricultural residue and dedicated energy crops) are determined to be hydrolysis of cellulose, fermentation and finally product purification. Hence, various potential schemes, tolerant micro-organisms and several processing configurations are being investigated to improve the conversion yield of the end products. Therefore, while performing runs, it is necessary to simultaneously import the research outcomes to a broader techno-economic framework to determine the corresponding practical consequences. With the objective of including fundamental details to the framework, the venues to introduce the user-defined data are explored in this contribution.

3.3 Inclusion of Novel Research Outcomes

Aspen Engineering Suite (Aspen Tech®), a versatile process simulation tool which allows for the integration of higher level of details into process models while being able to access the broader economic and operational performances. The simulation has several avenues to incorporate user-defined commands, major ones being: Microsoft Excel®, calculator blocks (Aspen Plus® Built-in model) and dynamically linked FORTRAN subroutine. A common practice is to use the built-in ports available in the simulation; however, biochemical processes have relatively complex conversion mechanisms. Therefore, options towards exploring custom modelling must be considered to incorporate such non-conventional mechanisms. While each of the interfaces could be used in various competencies, the current work demonstrates a procedure to dynamically link user-defined functions to brace the techno-economic framework. In order to illustrate the working of the model, a case study is framed with a decoupled unit operation to explore the capability of the model to adopt data from experimental outcomes.

4. Case Study, Results and Discussions

The objective of this proof-of-concept is to simulate a batch reactor to convert corn stover into glucose using a biological pathway. The data and reaction schemes used for this operation are adopted from a previous contribution (Kadam, Rydholm, and McMillan 2004). Hence, the exploratory goal is to recreate a profile that can portray the original experimental outcome from the literature. A major segment of the process simulation (cellulose hydrolysis) is run to establish the compatibility of this integration. The conversion of cellulose and production of glucose is tracked with respect to the operation time (7 days).

The results from the simulation are plotted to compare with the findings in the literature (Kadam, Rydholm, and McMillan 2004). It is observed that the variations in the

reproduced data are minimal and the accumulation of glucose in the reactor is consistent with the original data. In the perspective of the overall outlook, this is a preliminary success. Nevertheless, this outcome translates into a greater contribution, as it justifies an interconnection and a potential avenue for researchers to validate and assess the viability of their innovations. Figure 2 shows the generated concentration profiles followed by the potential economic results that can be achieved by such implementation.

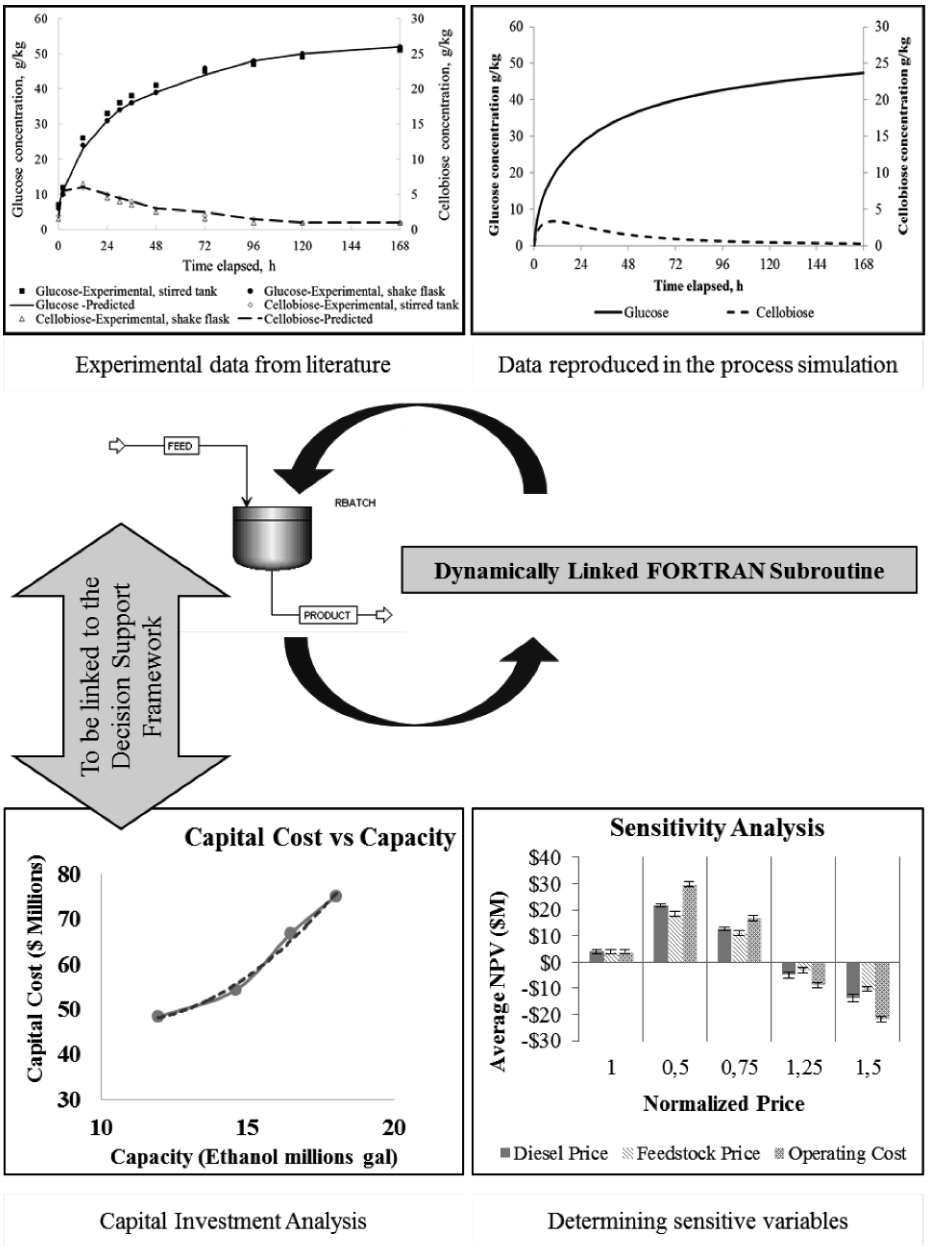

Figure 2. Results on the experimental work from the literature

Note: The top left plot shows the data and predicted trends from the literature (Kadam, Rydholm, and McMillan 2004). The top right plot is the recreated work using the Aspen Plus® user-defined (FORTRAN) function. Bottom plots elaborate on the nature of results that can be determined using this unique integration.

5. Conclusions and Future Work

In conclusion, this contribution demonstrates one of the promising integrations that can be established with the decision support tool to enhance the resolution of the input which in-turn will translate into a practical and bolstered assessment scheme. The contribution paves one pathway to link the fundamental research with an indicator that can answer a range of questions pertaining to the economic viability of a process in a region. This is one of the several potential approaches which captures and couples the discrete domains of basic science and engineering. Similarly, several other user-defined models for processes, such as, fermentation and product purification can be coupled to the framework making it an ideal test venue. In the future, several other novel discovery schemes could be justified to evaluate the feasibility, operability and sustainability of discovered pathways from biomass to biofuels, energy and chemicals.

Abstract

The scheduling problem of a large-scale seawater reverse osmosis (SWRO) desalination plant is considered as a mixed-integer nonlinear programming problem (MINLP) over the time horizon. It is hard to find out the exact solution directly, especially when the working environment is changing. So, when the variables are changed, it is needed to find out a new scheduling plan quickly to meet the changes. In this paper, a rescheduling model of operational optimization of a large-scale SWRO is built, which is a bi-objective optimization with criterions of efficiency and stability. A rolling horizon approach (RHA) is used to make the solution meet the requirements of accuracy and rapidity. The framework of RHS is structured and a two-stage differential evolution (TSDE) algorithm is used to compute the solution. A simulation based on a real case with fluctuations in freshwater demand in Liuheng Seawater Desalination Plant in Zhejiang province was made, and the results show that the performance of the proposed algorithm is satisfied.

Keywords: reactive scheduling, reserve osmosis, rolling horizon approach, optimization

1. Introduction

There are many uncertainties in the seawater reverse osmosis (SWRO) desalination process (Sassi, 2013). When the uncertainty occurs, the scheduling made based on the steady states will not work well any more. A reschedule problem of SWRO desalination plant under uncertain freshwater demand is studied in this paper. The objective function of this optimization problem contemplates the dual combination of two performances: the optimization performance (OP) and the stability performance (SP). The OP is the total cost of plant, and the SP refers to the degree of deviation between the rescheduling and the original schedule. The rolling horizon approach (RHA) is an excellent method to speed the computation of scheduling problem (Suresh, 1997; Wang, 2005), so it is used to satisfy the requirement of quickly calculation in rescheduling. A case study shows the satisfied performances of the proposed approach.

2. Mathematical formulation

A large-scale SWRO desalination plant is usually structured with a number of independent RO units in parallel, as shown in Figure 1. Each RO unit has different permeate rate $Q_i(k)$. The water product flows into the storage tanks and is supplied to

users after pH adjusting and minerals adding. In this paper, we assume that the capacity of storage tank is large enough for freshwater supply to simplify the scheduling problem.

The operational optimization of SWRO desalination process is carried out by making a schedule to determine how the RO units work in a time horizon, *K*. In the schedule, the on/off state of each RO unit is determined, and if the RO unit is on, the optimal amount of produced fresh water of RO unit is proposed too. A hybrid scheduling approach is proposed to deal with the uncertain freshwater demand, which consists of two parts: a predictive schedule with redundant freshwater to fit the low amplitude uncertainties and a reactive schedule with RHA to deal with high amplitude uncertainties.

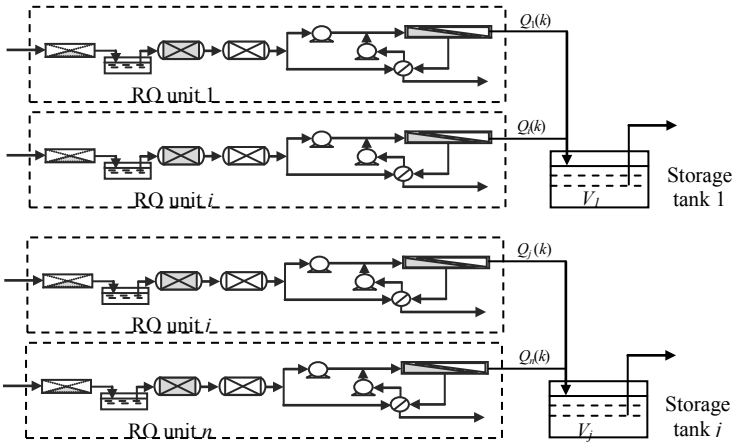

Figure 1: Schematic diagram of a large-scale SWRO desalination plant

2.1. Objective function

The objective function of this rescheduling problem includes two terms: optimization performance and stability performance. The purpose of the operational optimization is to minimize the objective function, which is presented as Eq.(1).

$$\textbf{min} \quad Obj = \alpha \cdot OP + \beta \cdot SP \tag{1}$$

Here, α and β are the weights of OP and SP respectively.

2.1.1. Optimization performance, OP

The OP of this problem is the total cost of plant, which consists of three main parts: the operational cost (OC), the energy cost (EC), and the default fine (DF), shown in Eq.(2).

$$OP = OC + EC + DF \tag{2}$$

The OC includes the maintenance expense when the machine runs and the cleaning & repairing expense when the machine stops. It is presented as Eq.(3).

$$OC = \sum_{k=1}^{K} \sum_{i=1}^{n} \left(\alpha_i(k) \times c_1 \times Q_i(k) + \left(1 - \alpha_i(k)\right) \times C_2 \right) \tag{3}$$

Where, K is the period of scheduling, n is the number of RO units. we consider that the maintenace expense is proportional to freshwater output $Q_i(k)$, and c_1 is the coefficient. The cleaning & repairing expense is a constant C_2. $\alpha_i(k)$ is the on/off status of Unit i at time k, $\alpha_i(k)$=1 when the Unit i is running; $\alpha_i(k)$=0 when it stops.

The EC is the consumption of electrical energy, which is presented as Eq.(4).

$$EC = \sum_{k=1}^{K}\left(P_e(k)\cdot \sum_{i=1}^{n}\left(\alpha_i(k)\times c_3 \times Q_i(k)\right)\right) \tag{4}$$

Where, $P_e(k)$ is electrical price at time k, and c_3 is the coefficient.

The DF is an additional compensation to the shortage of freshwater, which is presented as Eq.(5). Here, $\omega_{DF}(k)$ is the coefficient of default fine.

$$DF = \sum_{k=1}^{K}\omega_{DF}(k)\cdot\left(\left(D(k)+\xi\right) - \sum_{j=1}^{m} S_j(k), \right) \tag{5}$$

Where, ξ is the uncertainty of fresh water demand.

2.1.2. Stability performance, SP

The stability performance refers to the degree of deviation between the rescheduling and the original schedule (here is the predictive schedule), which is shown as Eq.(6).
