Preface

It is our great pleasure to present this volume of Computer-Aided Chemical Engineering for the joint event of the 12th International Symposium on Process Systems Engineering (PSE) and the 25th European Symposium on Computer Aided Process Engineering (ESCAPE) in Copenhagen, Denmark. Through this conference we would like to highlight the contributions of the process systems engineering community to the sustainability of the modern society. Through contributions from academia and industry, we aim to establish the core products of PSE/CAPE, to point out the new and changing scope of our achievements, and to define the future challenges we face. We also would like to celebrate the 25th anniversary of the ESCAPE-series, the 12th PSE conference and the 39th year of the Computers and Chemical Engineering journal.

The PSE series is a triennial conference which has been held since 1982, organized on behalf of the international PSE Executive Committee with representations from countries from the Asia-Pacific, Europe and the Americas. The annual ESCAPE series started in Elsinore, Denmark in 1992 and is organized on behalf of the CAPE working party of the European Federation of Chemical Engineering. In 2006 these two events were also combined in Garmisch-Partenkirchen, Germany.

Both symposia serve as a forum for engineers, scientists, researchers, managers and students from academia and industry to report on progress that has been made in PSE/CAPE, to discuss the current challenges that need to be addressed, and, to highlight new developments in the applications of methods, algorithms, tools to solve a wide range of problems. The PSE-2015/ESCAPE-25 joint event includes a large number of keynote lecturers from industry and academia as well as four plenary lectures covering topics on globalization, energy, environment and health from well-known experts from all over the world. In addition close to 525 papers will be presented covering the following topics: modelling, numerical analysis and simulation; mathematical programming (optimization); cyber-infrastructure, informatics and intelligent systems; process and product synthesis/design; process dynamics, control and monitoring; abnormal events management and process safety; plant operations, integration, planning/scheduling and supply chain; enterprise-wide management and technology-driven policy making. As well as the following domain applications: molecular, biological, pharmaceutical, food, energy, and environmental systems engineering.

More than 1200 abstracts were submitted and the final technical program includes around 520 presentations out of which, 425 manuscripts are included in this proceedings volume. These manuscripts have been peer-reviewed and we thank the scientific committee members for their timely and thorough reviews. We would also like to thank our volunteers (Stefano Cignitti, Seyed S. Mansouri, Amata Anantpinijwatna, Maria-Ona Bertran, Rebecca Frauzem, Thomas Bisgaard and Xavi Flores-Alsina), without whose help this proceedings volume would not have been ready on time. Finally, we thank all the authors for their high quality manuscripts and for submitting them on time. We do hope the contents of this volume will serve as valuable reference to the scientific community and practitioners of systems engineering and a permanent record of the joint PSE-2015/ESCAPE-25 conference.

Recent Advances in Mathematical Programming Techniques for the Optimization of Process Systems under Uncertainty

Ignacio E. Grossmann, Robert M. Apap, Bruno A. Calfa, Pablo Garcia-Herreros, Qi Zhang

Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, U.S.A.

Abstract

Optimization under uncertainty has been an active area of research for many years. However, its application in Process Synthesis has faced a number of important barriers that have prevented its effective application. Barriers include availability of information on the uncertainty of the data (ad-hoc or historical), determination of the nature of the uncertainties (exogenous vs. endogenous), selection of an appropriate strategy for hedging against uncertainty (robust optimization vs. stochastic programming), large computational expense (often orders of magnitude larger than deterministic models), and difficulty in the interpretation of the results by non-expert users. In this paper, we describe recent advances that have addressed some of these barriers.

Keywords: decision rule, robust optimization, stochastic programming, exogenous uncertainty, endogenous uncertainty, scenario generation.

1. Introduction

Optimization under uncertainty has been an active area of research in Process Systems Engineering (Sahinidis, 2004; Li and Ierapetritou, 2008; Grossmann et al., 2014). This area has been motivated by the fact that parameters involved in optimization models for synthesis, design, planning, scheduling and supply chain are often uncertain. Typical parameters include product demands, prices of chemicals, product yields, oil reservoir sizes, and technical parameters like kinetic constants or transfer coefficients. Yet, despite the importance of accounting for uncertainties, the impact of techniques for optimization under uncertainty at the level of applications has been limited. This has been due to a number of modeling and computational barriers. In this paper, we first provide a brief overview of the area and then describe some recent advances that are facilitating the wider deployment and application of optimization under uncertainty.

A major modeling decision in optimization under uncertainty is whether one should rely on robust optimization (Ben-Tal et al., 2009; Lin et al., 2004; Li and Ierapetritou, 2008b), or whether one should use stochastic programming (Ierapetritou and Pistikopoulos, 1994; Subrahmanyam et al., 1994; Iyer and Grossmann, 1998; Schultz, 2003; Ahmed and Garcia, 2003; Li and Ierapetritou, 2012). The basic idea in the robust optimization approach is to guarantee feasibility over a specified uncertainty set, while in stochastic programming a subset of decisions are made by anticipating that recourse actions can be taken once the uncertainties are revealed over a pre-specified scenario tree with discrete probabilities of the uncertainties. On the one hand, the robust

optimization approach tends to be more appropriate for short-term scheduling problems in which feasibility over a specified set of uncertain parameters is a major concern, and when there is not much scope for recourse decisions. The stochastic programming approach, on the other hand, tends to be more appropriate for long-term production planning and strategic design decisions, since it does not fix all the decisions at the initial point of the planning horizon as it allows recourse decisions in future times to adapt in response to how the uncertainties are revealed. It should also be noted that chance constrained optimization can be regarded as a generalization of robust optimization in which distribution functions are specified for the uncertainties with which a level of probability for meeting the constraints is specified (Li et al., 2008).

Computationally, stochastic programming problems tend to be very expensive to solve. This is particularly true if one has to deal with both exogenous and endogenous parameters, where the realization of the latter depends on the decisions taken (e.g., oilfield size), while the former are independent of decisions (e.g., demands) (Jonsbråten, 1998). Chance constrained programming is also computationally challenging, especially when the level of probability is specified for the joint constraints. Robust optimization tends to be the least computationally expensive, especially for linear problems. In all cases, however, it is of great importance to have as a basis a computationally efficient deterministic model since adding uncertainty unavoidably adds complexity to the computations. Aside from the computational issues, there is also the question of how to specify the uncertainties (e.g., an intuitive guess or through statistical analysis of historical data) and how to interpret the results that are predicted from the various models.

In this paper, we address the following specific challenges in optimization under uncertainty: (a) how to account for recourse in robust optimization, (b) how to effectively solve two- or multi-stage stochastic optimization problems, (c) how to effectively handle both exogenous and endogenous uncertainties in multi-stage stochastic programming, and (d) how to incorporate historical data in the generation of scenarios. As will be shown, significant progress has been made to address these issues.

2. Decision Rule Approach for Modeling Recourse in Robust Optimization

Robust optimization (Ben-Tal et al., 2009) is one approach for incorporating uncertainty in optimization models. The uncertainty is specified in terms of an uncertainty set in which any point is a possible realization of the uncertainty. The goal is to find a solution that is feasible for all possible realizations of the uncertainty while minimizing (or maximizing) the objective function. Since the worst case scenario is one of the possible realizations, a robust optimization model returns a solution that is optimal for this particular scenario. However, considering the worst case is often overly conservative. One can reduce the level of conservatism by appropriately adjusting the size of the uncertainty set. Bertsimas and Sim (2004) propose such an approach in which a pre-specified "budget" parameter limits the number of uncertain parameters that can change at the same time. The general formulation for linear models is as follows:

$$\min_{x}\{c^T x: A(u)x \leq b \quad \forall\, u \in U\} \tag{1}$$

where the parameter u is uncertain and defined over the corresponding uncertainty set U in which we assume the uncertainty budget is included. Eq. (1) corresponds to a semi-

infinite programming problem, but can be simplified by considering the dual of each row in the matrix A (robust counterpart), which yields a finite dimensional optimization problem. A drawback with this approach is that specifying the uncertainty set U is not trivial, not only because the uncertainty set might not be well known, but also because the user has to specify the uncertainty "budget," ranging from very conservative (all parameters vary independently) to less risk averse (e.g., limiting the number of independent variations). Another reason for over-conservatism in traditional robust optimization is the disregard of recourse (i.e., reactive actions after the realization of the uncertainty), which is a very unrealistic assumption in many cases, such as in problems involving investment and long-term contract decisions. In this section, we present a recent development in robust optimization that allows recourse to a certain extent, and demonstrate the effectiveness of this method by applying it to an industrial case study.

2.1. The Affine Decision Rule Approach

Consider the following multi-stage (T stages) optimization problem under uncertainty,

$$\min_{x}\left\{ c^T x_1 : A_1(u)x_1 + \sum_{t=2}^{T} A_t x_t(u) \le b \quad \forall\, u \in U \right\} \tag{2}$$

where x_t is the vector of the t-th-stage variables. For simplicity, we assume that the objective function only depends on x_1 and that only matrix A_1 is uncertain. While x_1 does not depend on u, x_t for $t \ge 2$ are recourse variables and depend on the realization of the uncertainty. Note that x_t only depends on the u that are realized up to stage t.

The problem given in Eq. (2) cannot be solved as such since the set of possible functions for $x_t(u)$ is infinitely large. The idea in the Decision Rule approach (Kuhn et al., 2011), also referred to as Adjustable Robust Optimization (Ben-Tal et al., 2009), is to restrict oneself to a certain type of functions for $x_t(u)$, in particular to the set of affine functions. Hence, we set $x_t(u) = \alpha_t + \mathrm{B}_t u$, and we obtain the following robust formulation by constraint-wise construction:

$$\min_{x_1,\alpha,B}\left\{ c^T x_1 : \max_{u\in U}\left\{ a_{1,i}^T(u)x_1 + \sum_{t=2}^{T} a_{ti}^T(\alpha_t + \mathrm{B}_t u)\right\} \le b_i \quad \forall\, i \right\} \tag{3}$$

which can be reformulated into a single-level problem for certain types of uncertainty sets by using techniques applying strong duality. This results in a robust counterpart formulation in which the decision variables are x_1 as well as the parameters for the affine decision rules, α and B. By applying the Decision Rule approach, the multi-stage problem is transformed into a single-stage problem to which the classic robust optimization reformulation is applied. Obviously, it is quite restrictive to only consider affine functions; however, this allows us to retain computational tractability and still account for recourse to a certain extent (for rigorous treatment of recourse see Grossmann et al. (2014)).

2.2. Industrial Case Study

In this case study, we consider the scheduling of an air separation unit (ASU) with added cryogenic energy storage (CES) capability. In an integrated ASU-CES system,

electricity recovered from the CES can be used internally to power the ASU, to sell power back to the grid during higher-price periods, or to provide operating reserve capacity which can be dispatched in case of emergency. The uncertainty lies in the reserve demand since we do not know in advance when and how much of the provided reserve capacity will be requested. However, since noncompliance results in very high penalties, reserve providers have to operate in a way such that dispatch of the committed reserve capacities can be guaranteed. For the discrete-time MILP model on which this work is based, we refer to Zhang et al. (2015). The data for this case study are provided by Praxair. In the proposed model, the first-stage decisions are the ones related to the base operation of the plant as well as how much reserve capacity to provide. The recourse variables are the amounts of liquid produced in addition to the base production after a reserve dispatch occurs. This additional liquid is then fed into the CES tank to make sure that there is sufficient inventory to also guarantee the next potential dispatch. The affine decision rules are constructed such that the recourse variables depend on the realization of the uncertainty prior to the corresponding time period. Furthermore, in order to reduce the degree of conservatism, we apply an uncertainty set which sets a limit to the number of time periods in which maximum reserve dispatch can occur.

Applying the proposed model, the scheduling problem is solved for a one-week time horizon, obtaining a 5% cost reduction compared to the worst-case solution. Figure 1 shows the flows into and out of the CES tank as well as the CES inventory profile in the particular scenario in which no reserve power is dispatched. The budget parameter is chosen such that maximum reserve dispatch can only happen once during the entire scheduling horizon. Note that the final inventory level is nonzero, and not as high as the maximum reserve capacity that is provided, which is due to the recourse actions. We should note that the resulting MILP model with approximately 53,000 constraints, 55,000 continuous variables, and 2,500 binary variables was solved in about 10 minutes to 1 % optimality gap using CPLEX 12.6.

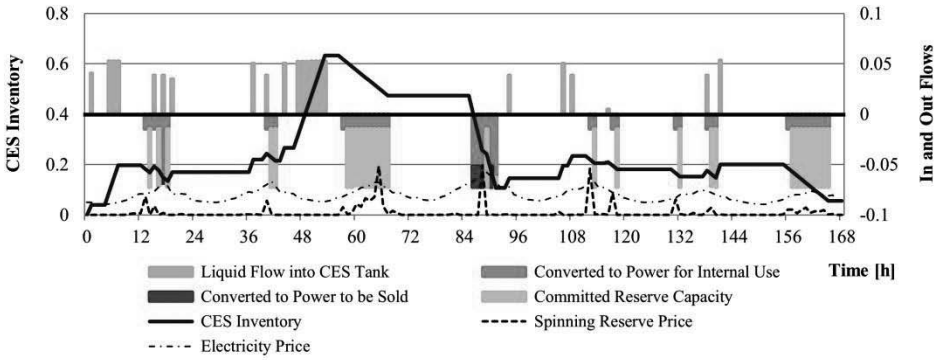

Figure 1. The CES inventory is shown for the scenario in which no reserve power is dispatched, resulting in a nonzero final CES inventory level.

3. Two-Stage and Multistage Stochastic Programming

Stochastic programming is the framework that models mathematical programs with uncertainty by optimizing the expected value over the possible realizations. In general, the expected value is computed by integrating over the set of uncertain parameters,

which might be a challenging task. In the case of discrete uncertainty sets with finite support, the realizations can be characterized with a finite number of scenarios, simplifying the calculation of the expected value. Accordingly, stochastic programming is often regarded as a scenario-based approach for optimization under uncertainty (Birge and Louveaux, 2011). The formulations can accommodate decision making at different stages according to the sequence in which uncertainty reveals. The stages imply a discrete time representation of the problem and establish the information of the uncertain parameters available at that time. The potential paths in which discrete uncertain parameters might evolve are represented in a scenario tree as shown in Figure 2. In these trees, each node is a decision-making instance with known realization of the uncertain parameters up to the current state; potential future realizations are represented with branches from the given node.

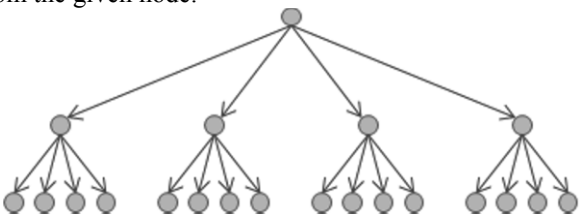

Figure 2. Tree representation of scenarios in a stochastic program with three stages.

The simplest stochastic programming formulation considers decisions that are made before uncertainty reveals. It is called single-stage stochastic programming or stochastic programming without recourse. Among the stochastic programs that consider recourse, the most widely used formulation is the Mixed-Integer Linear Program (MILP) with continuous recourse in a second stage. The two-stage stochastic programming formulation divides the decisions into two sets: here-and-now decisions that are made before uncertainty reveals, and wait-and-see decisions that are independent for each scenario. The typical formulation of a linear stochastic programming problem is presented in Eq. (4),

$$\begin{aligned} \min_{x \in X} \quad & c^T x + \mathbb{E}[Q(x,s)] \\ \text{s.t.} \quad & Q(x,s) = \min_{y_s \in Y} \; d_s^T y_s \\ & \qquad \text{s.t.} \;\; W y_s \le h_s - T_s x \end{aligned} \tag{4}$$

where x is the vector of first-stage decisions in mixed-integer polyhedral set X, y_s is the vector of second-stage (recourse) decisions in polyhedral set Y, and s is the index for scenarios. An important property of the formulation presented in Eq. (4) is that the feasible region for the first-stage variables x is a convex polyhedron (Birge and Louveaux, 2011). Based on this property and assuming that the second-stage problems ($Q(x,s)$) are bounded, an MILP reformulation that explicitly calculates the expected value can be derived by including all second-stage problems. This reformulation, the deterministic equivalent of the stochastic programming problem that is presented in Eq. (5), may lead to very large problem sizes if the number of scenarios is large.

$$\begin{aligned} \min \quad & c^T x + \sum_{s \in S} p_s (d_s^T y_s) \\ \text{s.t.} \quad & W y_s \le h_s - T_s x \qquad \forall\, s \in S \end{aligned} \tag{5}$$

$$x \in X;\ \ y_s \in Y$$

The benefits of using a stochastic programming model can be quantified by the Value of the Stochastic Solution (VSS). The VSS is the difference between the expected value of the objective functions obtained from the stochastic formulation and a deterministic formulation that substitutes the uncertain parameters with their expectation. The expected value of the deterministic formulation is calculated by solving the problem, implementing the first-stage solution, and evaluating the scenarios with their optimal recourse. The model in Eq. (4) can also be extended to a multistage stochastic programming model. The tree corresponding to a three-stage problem has the same structure as the one shown in Figure 2. The solution of multistage stochastic programming problems is considerably harder, and special care must be taken to avoid anticipating the uncertain parameters that have not been revealed. The general formulation of a three-stage stochastic programming problem is presented in Eq. (6),

$$\begin{aligned} &\min_{x\in X} \quad c^T x + \mathbb{E}[Q_2(x,s)] \\ &\text{s.t.} \quad Q_2(x,s) = \min_{y_s\in Y} \ d_s^T y_s + \mathbb{E}[Q_3(x,y_s,s)] \\ &\qquad\qquad \text{s.t.}\ W y_s \le h_s - T_s x \\ &\qquad\qquad\quad Q_3(x,y_s,s) = \min_{z_s\in Z} \ f_s^T z_s \\ &\qquad\qquad\qquad\qquad \text{s.t.} \quad V z_s \le g_s - U_s x - W y_s \end{aligned} \tag{6}$$

One way of transforming the formulation in Eq. (6) into its deterministic equivalent is to generate a set of copied variables for each path from the root node to the branches, and introduce non-anticipativity constraints (Ruszczyński, 1997). This reformulation has the advantage of being relatively easy to implement. The solution of large-scale stochastic programming problems is a challenging area of research due to the very large number of scenarios needed to model industrial problems and the rapid growth of scenarios in multistage stochastic programming. Methods frequently used to solve large stochastic programming problems leverage the scenario structure of the problems. The L-shaped method is the implementation of Benders decomposition to two-stage stochastic programming problems (Van Slyke & Wets, 1969). The method considers the first-stage variables as complicating and iterates between a relaxed master problem and subproblems that are solved by scenario. Lagrangean relaxation is also used in decomposition strategies for two-stage and multistage stochastic programming problems. The most common implementation generates sets of copied variables for each scenario and their corresponding non-anticipativity constraints. A Lagrangean relaxation of the problem is obtained by dualizing the non-anticipativity constraints, which makes the problem amenable to scenario decomposition. Other decomposition strategies are Progressive Hedging and Nested Decomposition procedures.

3.1. Example of Two-Stage Stochastic Programming

The design of a resilient supply chain with risk of disruptions is presented by Garcia-Herreros et al. (2014). The problem is formulated as a two-stage stochastic program. In the first stage, distribution centers (DCs) are selected from a set of candidate locations and their capacities are established. In the second stage, the demand assignment decisions are made according to the selected DCs and random disruptions in each scenario. The example includes: 1 production plant, 9 candidate locations for DCs, and

30 customers with demands for 2 commodities. The parameters of the instance were generated randomly. The candidate DCs have disruption probabilities between 2% and 10%. The number of scenarios in the full-space problem is $2^9 = 512$. The design is based on a time-horizon (N) of 365 days; on this time-scale, investment cost can be interpreted as annualized cost. The instance is used to illustrate the use of Benders decomposition, the benefits of strengthening the master problem, and the impact of solving a reduced subset of relevant scenarios. The selected relevant subset of scenarios includes scenarios with up to 4 simultaneous disruptions, for a total of 256 scenarios with probability equal to 99.99%. The full-space model yields a total cost of $7,225,447, while the reduced model yields a similar cost of $7,224,591. Both solutions predict the same design decisions and therefore the same investment cost. The largest difference in the results is in the expected cost of penalties. Both problems were solved to 0% optimality tolerance using the special Benders decomposition algorithm described in Garcia-Herreros et al. (2014). Both formulations involve 9 binary variables; the full-space model has 318,479 constraints and 309,263 continuous variables, while the reduced-space model has 159,247 and 154,639, respectively. The Multi-cut Benders solution times were 281 s and 151 s, respectively, while the Strengthened multi-cut Benders solution times were 176 s and 89 s, respectively. As can be seen in Figure 3, the use of the strengthened multi-cut master problem reduces the solution time because it requires fewer iterations. The solution times for the full-space and the reduced instances without any decomposition strategy, using GUROBI 5.5.0, were 3,349 s and 1,684 s, respectively. The much smaller solution times with the decomposition algorithms demonstrate that the proposed methodology is effective to solve large-scale instances of high computational complexity.

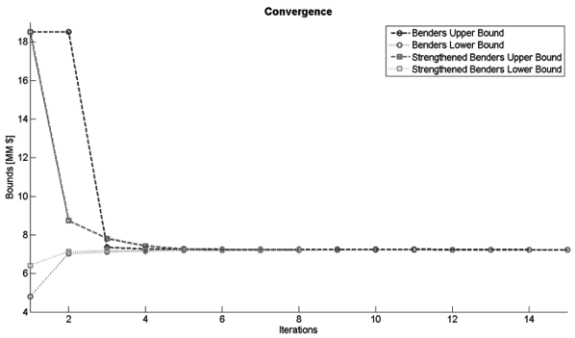

Figure 3. Convergence of Benders algorithms for the full-space instance of the large-scale example.

4. Multistage Stochastic Programming under Endogenous and Exogenous Uncertainties

Uncertain parameters can be classified into two categories depending upon the way the uncertainty is resolved: exogenous, where realizations occur independently of the decisions; and endogenous, where the realizations are affected by the decisions. In the endogenous case, the decisions may affect the timing of the realizations or their underlying probability distribution (Jonsbråten, 1998). In this section, we consider the first class of endogenous uncertainty where decisions affect the timing of realizations. In the context of process systems engineering, exogenous uncertainties often correspond to market uncertainties, such as oil prices. Endogenous uncertainties are technical

uncertainties, such as oilfield size, that are only resolved after a decision is made at a given point in time (e.g., to drill a particular oilfield). Surprisingly, although many problems contain both types of uncertainties, optimization under both types has been largely unexplored in the literature.

In the case where the uncertainty is purely exogenous, the shape of the scenario tree is known in advance, since exogenous realizations occur automatically in each time period. This is shown in Figure 4 with the standard form of the tree, as well as its alternative representation which gives each scenario a unique set of nodes.

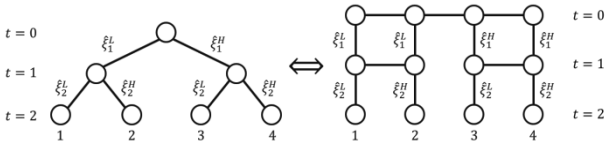

Figure 4. An exogenous scenario tree and its alternative representation.

In the case of endogenous uncertainty, however, the shape of the scenario tree is conditional, since the timing of realizations depends on the process decisions. As shown in Figure 5, we use a superstructure form of the alternative tree in order to capture all possible outcomes (Apap and Grossmann, 2015).

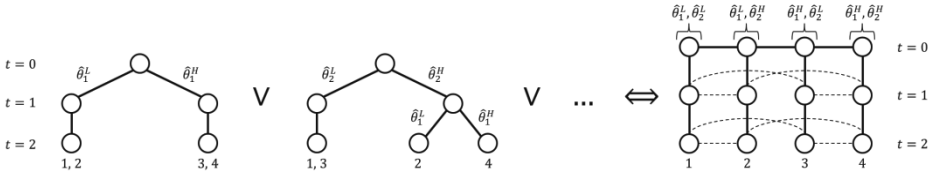

Figure 5. A superstructure representation for endogenous scenario trees.

For simplicity, we assume that the scenarios correspond to all possible combinations of realizations of the uncertain parameters. In other words, the set of scenarios in the exogenous scenario tree corresponds to a Cartesian product over the sets of realizations for the exogenous parameters (denoted by $\mathcal{R}_X$), and, similarly, the set of scenarios in the endogenous scenario tree corresponds to a Cartesian product over the sets of realizations for the endogenous parameters (denoted by $\mathcal{R}_N$). For the case of both endogenous and exogenous parameters, we generate the set of scenarios by simply taking the Cartesian product of all possible combinations of realizations of the endogenous parameters and all possible combinations of realizations of the exogenous parameters, $\mathcal{R}_N \times \mathcal{R}_X$. This is equivalent to copying the exogenous scenario tree for each possible combination of realizations of the endogenous parameters. We then link these exogenous trees by adding first-period and endogenous non-anticipativity constraints, thereby producing what we refer to as a 'composite' scenario tree as shown in Figure 6.

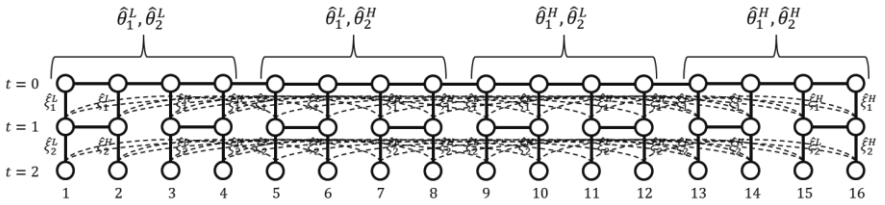

Figure 6. A 'composite' scenario tree for endogenous and exogenous realizations.

The general model for this class of problems, originally proposed by Goel and Grossmann (2006), is a mixed-integer linear disjunctive program. A simplified, compact form of the updated model (Apap and Grossmann, 2015) is given in Eq. (7)-(15).

$$\min_{x} \phi = \sum_{s \in \mathcal{S}} p^s \sum_{t \in \mathcal{T}} c_t^s x_t^s \tag{7}$$

$$\text{s.t.} \quad \sum_{\tau=1}^{t} A_{\tau,t}^s x_\tau^s \leq a_t^s \qquad \forall\, t \in \mathcal{T},\ s \in \mathcal{S} \tag{8}$$

$$x_1^s = x_1^{s'} \qquad \forall\, (s, s') \in \mathcal{SP}_F \tag{9}$$

$$x_{t+1}^s = x_{t+1}^{s'} \qquad \forall\, (t, s, s') \in \mathcal{SP}_X \tag{10}$$

$$\begin{bmatrix} Z_t^{s,s'} \\ x_{t+1}^s = x_{t+1}^{s'},\ t < T \end{bmatrix} \vee \left[\neg Z_t^{s,s'}\right] \qquad \forall\, (t, s, s') \in \mathcal{SP}_N \tag{11}$$

$$Z_t^{s,s'} \Leftrightarrow F(x_1^s, x_2^s, \ldots, x_t^s) \qquad \forall\, (t, s, s') \in \mathcal{SP}_N \tag{12}$$

$$x_{k,t}^s \in \{0,1\} \qquad \forall\, t \in \mathcal{T},\ s \in \mathcal{S},\ k \in \mathcal{K}' \tag{13}$$

$$x_{k,t}^s \in \mathbb{R} \qquad \forall\, t \in \mathcal{T},\ s \in \mathcal{S},\ k \in \mathcal{K} \backslash \mathcal{K}' \tag{14}$$

$$Z_t^{s,s'} \in \{True, False\} \qquad \forall\, (t, s, s') \in \mathcal{SP}_N \tag{15}$$

The objective function, Eq. (7), minimizes the total expected cost associated with decisions x_t^s, weighted by the probability of each scenario, p^s. Eq. (8) represents constraints that govern decisions x_t^s and link decisions across time periods. First-period non-anticipativity constraints (NACs) are given by Eq. (9), exogenous NACs are given by Eq. (10), and disjunctive constraint (11) conditionally enforces endogenous NACs based on the value of Boolean variable $Z_t^{s,s'}$. The value of $Z_t^{s,s'}$ is determined by an uncertainty resolution rule in Eq. (12).

Because the number of NACs grows exponentially as the number of time periods, uncertain parameters, or realizations increases, most problems of practical interest are too large to be solved directly with commercial MILP solvers. In order to eliminate redundant NACs, a number of theoretical properties have been proposed by Goel and Grossmann (2006), Gupta and Grossmann (2011), and Apap and Grossmann (2015) based on the concepts of symmetry, adjacency, transitivity, and scenario grouping. These properties drastically reduce the number of constraints; however, the resulting model is often still intractable, and special solution approaches are required.

One effective approach is Lagrangean decomposition (LD), in which the complicating non-anticipativity constraints are dualized in order to decompose the problem into independent scenario subproblems that can be solved in parallel. More recently, a

sequential scenario decomposition heuristic (SSD) has been proposed that involves sequentially solving endogenous MILP subproblems to determine the integer decisions, fixing these decisions to satisfy the first-period and exogenous NACs, and then solving the original problem as an LP (Apap and Grossmann, 2015).

4.1. Oilfield Planning Example

We consider a modified form of the MILP described in Gupta and Grossmann (2014) (see Case (i)) for maximizing the total expected NPV in the development planning of an offshore oilfield. There are 3 oilfields, 3 potential FPSOs, and 9 possible field-FPSO connections. A total of 30 wells can be drilled over a 5-year planning horizon. Fields 2 and 3 have a known recoverable oil volume; however, the size of field 1 has two possible realizations with equal probabilities. The oil and gas prices are also uncertain, with two possible realizations with equal probabilities in each time period. (The oil and gas prices are assumed to be correlated.) This gives rise to a total of 64 scenarios with equal probabilities. This instance of the modified oilfield problem (Apap and Grossmann, 2015) is an MILP with 333,249 constraints, 70,465 continuous variables, and 7,360 binary variables. After applying the theoretical reduction properties, there are 124,980 constraints (a 62% reduction), 70,465 continuous variables, and 7,000 binary variables. The problem was modeled in GAMS 24.3.3 and solved with CPLEX 12.6.0.1.

In the case of solving the reduced model directly, the optimality gap cannot be improved past 50% after more than 11 hours. In contrast, the sequential scenario decomposition heuristic (SSD) finds a high-quality feasible solution in only 41 seconds, and the Lagrangean decomposition (LD) algorithm finds a high-quality upper bound in only 14 seconds. This is an optimality gap of only 0.20%, obtained in under one minute. Table 1 summarizes the results for the example problem.

Table 1. Numerical results for the oilfield development planning example.

Problem Type	Total Expected NPV ($\$10^9$)		Optimality Gap	Solution Time (s)
	Lower Bound	Upper Bound		
Reduced Model	6.968	10.495	50.61%	40,562
LD	-	7.180	0.20%	14
SSD	7.166	-		41

5. Data-Driven Approaches to Scenario Generation

Before solving a robust or stochastic optimization model in practice, one has to choose a proper model of the uncertainty. This is motivated by the fact that the quality of such model directly impacts the quality of the solution of the optimization problem. In this section, we discuss methods for uncertainty modeling that use historical and forecast data for scenario-based optimization frameworks (e.g., stochastic programming).

Scenario trees are discrete representations of the probable outcomes of uncertain parameters, which are continuous random variables in most applications in process systems engineering. Also, a scenario tree is an input to a stochastic programming model. Therefore, systematically generating scenario trees that more accurately capture

the true, but generally unknown structure of the uncertainty improves the quality of the solution to the original stochastic problem (see Chapter 4 in King and Wallace, 2012). Given an initial structure of the tree (number of stages and number of branches from each node), data-driven scenario tree generation methods directly use available data to specify the probabilities of the branches and values of the outcomes.

In this section, we discuss the property-matching method of Høyland and Wallace (2001) and an extension that addresses the potential under-determination of such method. The property-matching method aims at generating scenario trees by matching statistical properties (e.g., moments and co-moments) calculated from the tree to the respective properties estimated from actual data (historical or forecast). Specifically, generating a scenario tree requires solving an optimization problem in which the objective function is an error measure (deviation of properties from the tree and data), and the decision variables are branch probabilities and node values. Consider the case of a two-stage scenario tree with N scenarios that is used to model a single uncertain parameter (see Figure 7). The scenario probabilities and node values are represented by the vectors p and x, respectively.

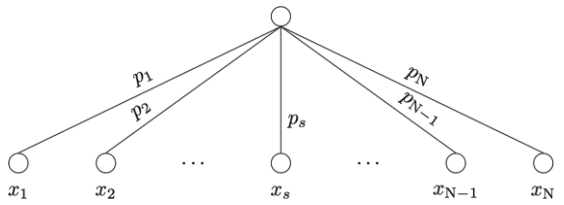

Figure 7. Two-stage scenario tree for one uncertain parameter.

The property-matching optimization model is given in Eq. (16). The set of statistical properties to be matched is denoted by J, and the target value for property j is given by Sval_j. Also, $f_j(\cdot,\cdot)$ is the mathematical expression of statistical property j calculated from the tree, and w_j is a weight vector.

$$\begin{aligned} &\min_{x,p} \sum_{j\in J} \text{w}_j \cdot \left(f_j(x,p) - \text{Sval}_j\right)^2 \\ &\text{s.t.} \quad \sum_{s=1}^{\text{N}} p_s = 1 \\ &\qquad p_s \in [0,1] \qquad\qquad \forall\, s = 1,\ldots,\text{N} \end{aligned} \tag{16}$$

The optimization model in (16) may be over- or under-determined depending on the number of branches, targets, and uncertain parameters. For instance, for one uncertain parameter and four moments as targets (Calfa et al., 2014), it can be calculated that we can only have a tree with $\text{N} = 2$ scenarios for a well-posed model. If we were to increase N to three or more, then this would result in an under-specified model. To overcome this under-specification issue and to allow more scenarios to be considered, a distribution-matching approach has been proposed and is briefly described as follows.

In addition to matching (co-)moments, points of the (empirical or estimated) marginal cumulative distribution function (CDF) are also matched, thus increasing the number of

target values and balancing the difference between the number of variables and data points. Specifically, let $j = \text{CDF}$ denote the marginal CDF property to be matched. Following the notation in Eq. (16), the functional form used in the distribution matching problem is given by Eq. (17).

$$f_{\text{CDF}}(x,p) = \widehat{CDF}(x_s) - \sum_{s'=1}^{s} p_{s'} \qquad \forall\, s = 1, \ldots, \text{N} \tag{17}$$

where $\widehat{CDF}(\cdot)$ denotes the empirical or estimated marginal CDF of random variable x. Note that we must ensure that the node values are ordered due to the cumulative information being matched, e.g., $x_s \leq x_{s+1}$, $\forall\, s = 1, \ldots, \text{N} - 1$. The approach described above can be extended for the case of multiple uncertain parameters as well as autocorrelated uncertainties (stochastic processes), such as product demand and price. In the latter case, scenario tree generation is aided by time series forecasting (see Calfa et al. (2014) and references therein).

5.1. Two-Stage Scenario Tree Generation Example

A network of three chemical plants is described in Calfa et al. (2014) (see Example 1). The yield of plant P1 is the uncertain parameter and the distribution of its historical data is given in Figure 8. The empirical CDF was obtained and approximated by a smooth function (generalized logistic function), i.e., $\widehat{CDF}(\cdot)$ in Eq. (17). In this example, $\text{N} = 5$ scenarios were considered, and the targets include the first four moments and CDF information. The scenario generation problem is a nonlinear program with 10 variables and 14 constraints. It was modeled in AIMMS 3.13 and solved with IPOPT 3.10.1 using AIMMS' multi-start module in less than one second. Figure 9 shows the profile of optimized scenario probabilities as well as node values of the generated scenario tree. Note that the profile captures the shape of the distribution of the original data, including tail effects.

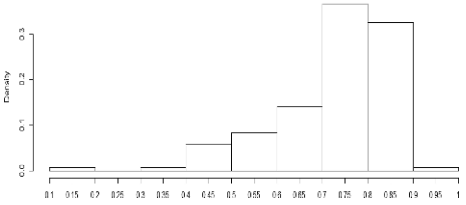

Figure 8. Distribution of the historical data for the production yield of plant P1.

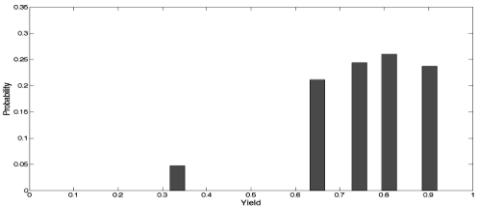

Figure 9. Profile of scenario probabilities obtained with the distribution-matching approach.

6. Conclusions

In this paper, we have addressed several major challenges in optimization under uncertainty. We have shown that recourse can be accounted for in robust optimization with linear decision rules, which has the effect of producing less conservative solutions, as was shown in the example on cryogenic energy storage. To effectively solve two-stage stochastic optimization problems, we have shown the importance of developing tailored solution strategies; e.g., by reducing the number of scenarios, tightening the MILP formulation, and applying decomposition schemes like Benders with multiple cuts. This was illustrated in the case of supply chains under disruptions. We have also

shown that both exogenous and endogenous uncertainties can be effectively handled in multi-stage stochastic programming by relying on theoretical properties to reduce the number of non-anticipativity constraints, and applying Lagrangean decomposition coupled with fast heuristics. This was illustrated in an oilfield planning problem. Finally, we have shown that to avoid assigning arbitrary probabilities and outcomes in scenario trees, historical data can be incorporated to generate these scenarios by using moment matching supplemented by matching cumulative distribution function values. This was illustrated with a production planning problem.

All of the examples in this paper have demonstrated the progress that has been made in this area, although the models have been restricted to MILP models. It is clear that major challenges remain in this area that we have not addressed in this paper. One of these challenges is the effective solution of stochastic MINLP problems (Li et al., 2011; Tarhan et al., 2013). Another one is the interpretation of results from these models, which can be aided by the addition of risk measures in the objective function and/or by the use of simulation (Applequist et al., 2000; Barbaro and Bagajewicz, 2004; You et al., 2009).

A Multidisciplinary Hierarchical Framework for the Design of Consumer Centered Chemical Products

Ka M. Ng

Department of Chemical and Biomolecular Engineering, The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong
kekmng@ust.hk

Abstract

New consumer products such as personal care products, mobile phones, smart windows, LED lamps, EV batteries, thin film solar cells, printed electronics, air purifiers, and medical devices, are being introduced to the market at an increasingly rapid pace. This is driven partly by consumer demands and partly by the emergence of new molecules, nanomaterials, advanced materials, and innovative processing technologies. This presentation describes a framework for the design of chemical products in which the chemical engineer drives the product design project in collaboration with personnel in marketing, finance, business development, chemistry, physics, mechanical engineering, electronic engineering, and so on. In this framework, the many product design and development tasks are classified into management, business and marketing, research and design, manufacturing, and finance and economics. These are performed in three phases – product conceptualization, product design and prototyping, and product manufacturing and launch. The framework includes rule-based methods such as Quality Function Deployment and *RAT*^{2}*IO*, and model-based methods such as computer-aided molecular design, and transport models. It also includes databases for chemicals and equipment, and computer-aided tools for property prediction, process simulation, computational fluid dynamics, etc. Experiments are used whenever model predictions are impossible or not sufficiently accurate. This framework is illustrated with two examples – a sunscreen cream and a die attach adhesive for LED lamps.

Keywords: Multidisciplinary, hierarchical, chemical products, design.

1. Introduction

The importance of chemical product design to the development of the chemical engineering profession has long been established (Stephanopoulos, 2003; Cussler and Wei, 2003; Hill, 2004; Gani, 2004a,b, Seider and Widagdo, 2012). Many texts have appeared (Bröckel, 2007, 2013; Ng *et al*., 2007, Wesselingh *et al*., 2007; Wei, 2007; Cussler and Moggridge, 2011) which help define the scope and approach for chemical product design. Different methods of relevance to consumer centered chemical product design have also been developed in the last decade (Wibowo and Ng, 2001; Bagajewicz, 2007; Cheng *et al.*, 2009; Whitnack *et al.*, 2009; Conte *et al.*, 2011, 2012; Mettie *et al.*, 2014; Bernardo and Saraiva, 2014; among others).

There are four broad questions in product design:

- What (product) to make?
- How to make (the desired product)?
- Do we want to make the identified product (among other alternative products)?

- If the above is affirmative, how do we come up with such a product from conceptualization to product launch efficiently and profitably?

The first two questions are answered by the 4-step product design procedure proposed by Cussler and Moggridge – needs, ideas, selection and manufacture, and the many methods and tools developed in the literature. Answering the last two questions requires a broader perspective.

2. Multidisciplinary Hierarchical Framework

To this end, a multidisciplinary hierarchical framework for the design of chemical products has been developed. It is consumer centered ensuring that the consumers' wants and needs are met. It is hierarchical covering the design activities level by level with additional details at ever finer scales while keeping the overall product design project in mind. It is multidisciplinary in that skills and knowledge from various disciplines such as basic sciences, material science, chemical engineering, electronic engineering, marketing and finance are considered. It does not mean that the chemical engineers will become marketing personnel or tax lawyers. Rather, this chemical engineering centered framework call for a thorough understanding of what is offered by other disciplines so that the chemical engineer can manage a product development project effectively. We believe, because of the collaborative nature of product design, the proposed approach can enhance the chemical engineers' contribution to chemical product design in industry and to promote the teaching of product design in academia.

Figure 1 shows such an approach which covers all the tasks for product design from conceptualization to product launch. The design activities span three phases in time – product conceptualization (Phase I), detail design and prototyping (Phase II), and product manufacturing and launch (Phase III) – and can be classified by job function in terms of management, business and marketing, research and design, manufacturing, and finance and economics. The activities can also be grouped into various tasks (such as project management, market study, product design, prototyping, etc.), which may last over more than one development phase (Cheng *et al.*, 2009). For example, economic analysis includes activities in both Phase II and Phase III, and involves manufacturing as well as finance and economics. Of particular interest are those activities, italicized in Figure 1, that require the input of a chemical engineer. The rest of the issues, non-italicized, such as product launch, are normally handled by personnel from other disciplines. The personnel from different disciplines work together to come up with the final product. For example, product specifications cannot be fixed without the input from the business team on customers' preference. It is hard for the project team to evaluate the return on investment without considering the tax issues. With the rapid pace of introducing new products to the market, effective project management is crucial to launch the product on time.

While Figure 1 shows the workflow with timeline, a product design model as well as the accompanying methods, tools, databases and experiments is still needed to execute a product design project. This is discussed in the next section.

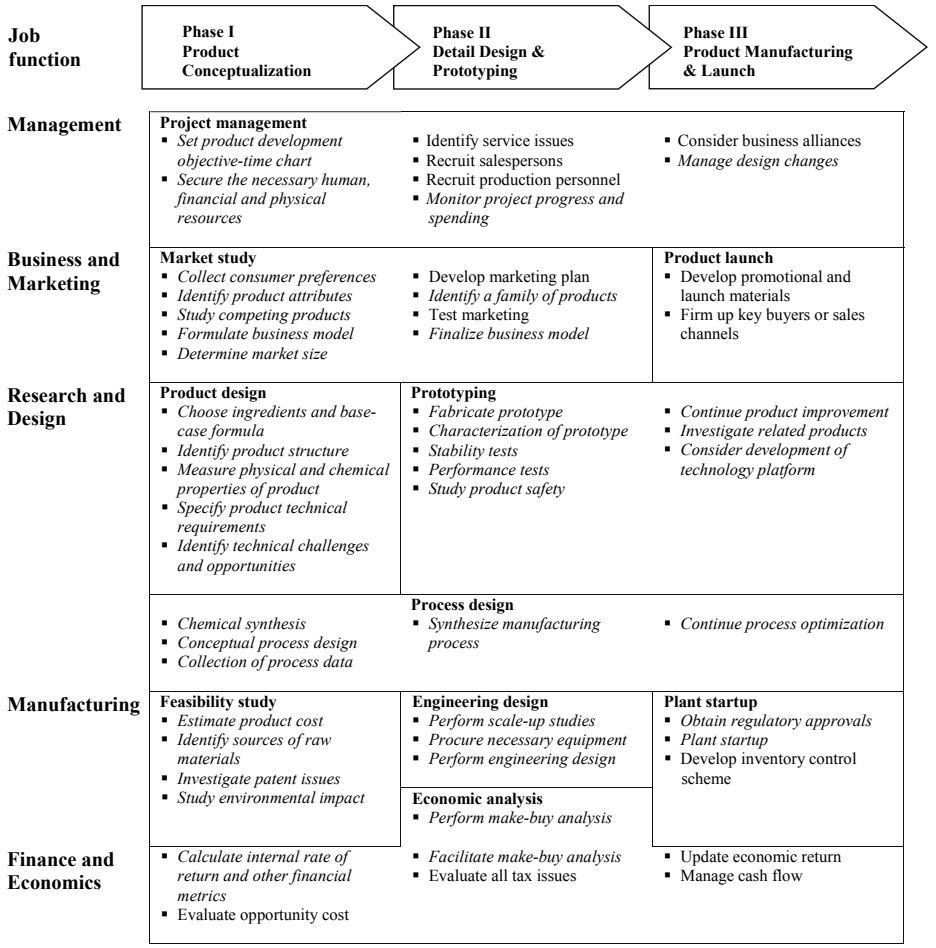

Figure 1. The phases and job functions in a multidisciplinary framework for product design.

3. Grand Product Design Model

Figure 2 captures the most important tasks in Figure 1 that are central to Chemical Engineering. Let us go down the figure from the top. The **product structure** ($\underline{s}$), either a microstructure such as the phase volume fraction or emulsion particle size of an emulsion or a macro structure such as the structure of an air purifier, depends on the **ingredients** ($\underline{x}$), and **process design** ($\underline{pd}$), which can be further broken down into process flowsheet ($\underline{pd}_{fs}$) and **operating conditions** ($\underline{pd}_{op}$). The **product structure** is obtained by the process model $\underline{s} \leftarrow T_S(\underline{x},\underline{pd})$.

The transformation symbol signifies the fact that the 'model' might involve computations, heuristics and experiments. For example, there is a wealth of qualitative information on the selection of emulsification equipment ranging from stirred tanks to colloid mills. Equations are available for calculating the viscosity of emulsions, and for calculating the emulsion droplet size as a function of the continuous phase viscosity, the applied pressure

and equipment specifications of a homogenizer. Criteria for the selection of emulsification units based on capacity and energy consumption are also available (Wibowo and Ng, 2002). However, there are no reliable equations for predicting the emulsion particle size under sonication and experiment data are required. In fact, since so much is not known or is not known as exactly as desired, it is often necessary to iterate between modeling and experiments in product design and process synthesis. Of course, if only equations are used for predicting the product structure, the transformation simply becomes a mathematical function $\underline{s}=T_s(\underline{x},\underline{pd})$.

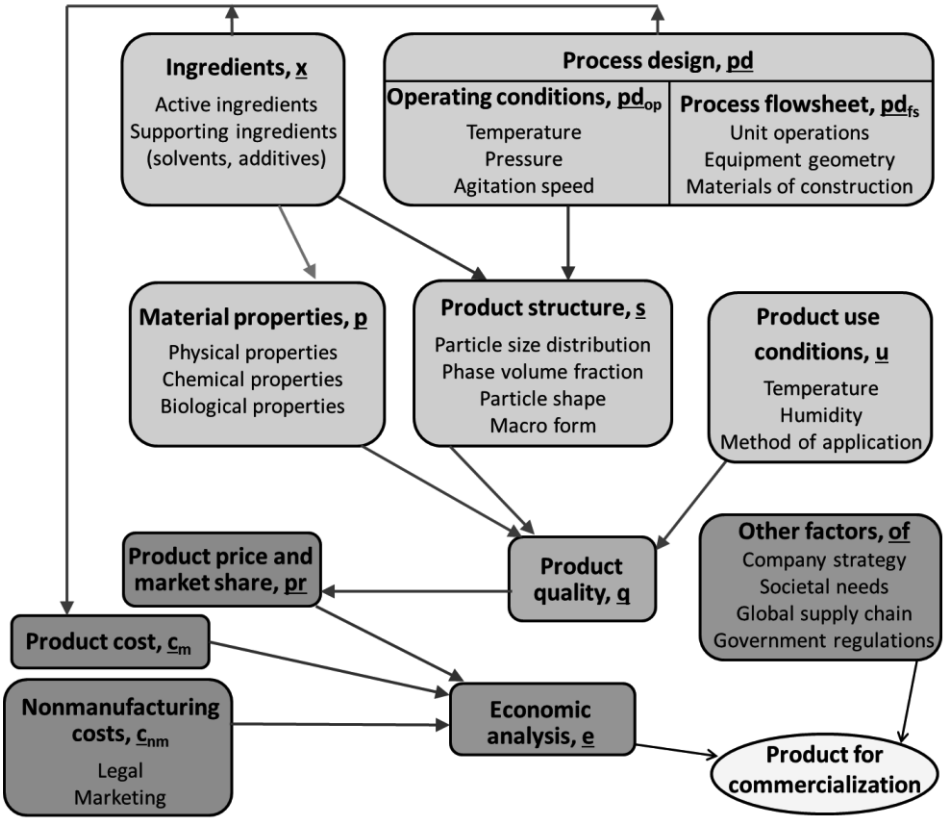

Figure 2. The Grand Product Design Model.

Material properties depend on the type of active ingredients, additives and their composition, $\underline{p}\leftarrow T_p(\underline{x})$. Software such as ICAS developed at the Technical University of Denmark can be used for property predictions. The product structure and material properties in turn determine the **product quality** ($\underline{q}$). Note that the product quality also depends on the **product use conditions** under which the product is used. Thus, we have $\underline{q}\leftarrow T_q(\underline{p},\underline{s},\underline{u})$. For example, a water-based moisturizing sun lotion is not expected to fare well at the beach although it may be an excellent day cream. The qualitative product qualities are customarily distinguished from the more quantitative product performance although they are often lumped into product quality. Setting the **product price** and the desired **market share** ($\underline{pms}$) using a suitable pricing model $\underline{P}_{pms}\leftarrow T_{pms}(\underline{q};\underline{M})$ is an

important exercise because the market size determines the amount of production and the necessary investment. The pricing model accounts for the quality, price, and market share of the competing products (as represented by $\underline{M}$). The manufacturing component of the **product cost** ($\underline{c}_m$) is determined by the materials used in the product and the production process, $\underline{c}_m \leftarrow T_{cm}(\underline{x},\underline{pd})$. The cost model should reflect the amount of production in order to account for the economies of scale. Other **non-manufacturing costs**, $\underline{c}_{nm}$, such as those related to legal issues and marketing need to be included in the total product cost. The parameters $\underline{c}_m$, $\underline{c}_{nm}$ and $\underline{P}_{pms}$ constitute the input information to the economic model $\underline{e} \leftarrow T_e(\underline{c}_m, \underline{w}_{nm}, \underline{P}_{pms})$. If $\underline{e}$ includes only financial metrics such as NPV, present value and ROI, the economic model basically represents a capital budgeting process. If other factors such as environmental considerations, sustainability issues, government policies, etc. are considered alongside the profitability analysis, the model has to be solved as a **multiobjective optimization** problem to determine the product for commercialization, $\underline{Pc}$. Here, $\underline{Pc}$, the product alternatives, are related to $\underline{x}$ and $\underline{s}$. Thus, we have the *Grand Product Design Model*:

Max [$\underline{\text{Pc}}$, $\underline{\text{of}}$]

subject to

$\underline{p} \leftarrow T_p(\underline{x})$	(Property model)
$\underline{s} \leftarrow T_s(\underline{x},\underline{pd})$	(Process model)
$\underline{q} \leftarrow T_q(\underline{p},\underline{s},\underline{u})$	(Quality model)
$\underline{P}_{pms} \leftarrow T_{pms}(\underline{q};\underline{M})$	(Pricing model)
$\underline{c}_m \leftarrow T_{cm}(\underline{x}, \underline{pd})$	(Cost model)
$\underline{e} \leftarrow T_e(\underline{c}_m, \underline{c}_{nm}, \underline{P}_{pms})$	(Economic model)
$\underline{f}(\underline{e}, \underline{of}, \underline{c}_m, \underline{c}_{nm}, \underline{P}_{pms}, \underline{x}, \underline{pd}, \underline{q}, \underline{p}, \underline{s}, \underline{u}; \underline{Y}) \le 0$	(Model parameter constraints)

There are four challenges in solving this model. One is the fact that we have to deal with an inverse problem. As can be seen in Figure 1, product design begins with a concept (i.e. a vision of the final product), which leads to product specifications. Thus, we have to work "backwards" in Figure 2 to identify the material properties and product structure. Most of the existing equations and design procedures are formulated in the "forward" direction. Another challenge is the fact that not all the transformation relations are cast in equation form. The solution method or strategy has to be sufficiently flexible to accommodate information in the form of heuristics, graphs, and output from other computer programs. Third, domain knowledge of specific market segments or classes of products is required for the product designer to be effective. For example, a designer familiar with home appliances such as air purifiers or water filters may not be as effective in designing creams and pastes. Often, experience accumulated over time may not be in written form. Fourth, there are unresolved scientific problems that have to be handled by experiments. A case in point is the process model $\underline{s} \leftarrow T_s(\underline{x},\underline{pd})$. While the emulsion droplet size in a simple emulsion can be predicted, there is no theory or model for predicting the more complex lamellar microstructures. In fact, the missing knowledge gaps identified in product design are research opportunities in chemical engineering sciences.

Currently, the grand product design model is executed by and large sequentially and iteratively in industry without taking full advantage of the advances in computations. A thorough understanding of the interplay of the different elements of the grand product design model is expected to minimize the time for product design and maximize the value of the product for market launch. To expedite the execution of the Grand Product Design

Model from a chemical engineer's perspective requires the methods, databases, tools and experiments to be discussed next.

4. Methods, Databases, Tools and Experiments

Because of the diversity of chemical product types, a wide variety of methods, databases, tools and experiments are needed to execute the *Grand Product Design Model*. They can be classified as follows:

- Methods
  - Rule-based (Objective-time chart, quality function deployment, house of quality, root cause analysis, fishbone diagram, innovation map, RAT^2IO, table of heuristics, business model canvas, etc.)
  - Model-based (*CAMD*, transport processes, experimental correlations, etc.)
  - Hybrid (Design procedures, etc.)
- Databases (Thermodynamic database, equipment database, etc.)
- Tools (*ICAS*, *CFD*, *GAMS*, etc.)
- Experiments (*VLE*, *SLE*, reaction kinetics, etc.)

Various generic methods and tools have already been developed for product design. For example, the use of the consumer preference function is a powerful technique for identifying a desirable product (Whitnack *et al.*, 2009). An objective-time chart can be used to set the objectives and sub-objectives that have to be met within a given time horizon. Resources are important to achieve an objective or sub-objective. RAT^2IO, a mnemonic acronym that stands for resources, activities, time, tools, input/output, information, and objective, can be used to help identify what is needed for the various activities in a product development project. House of quality in quality function deployment can be used to relate the desired product attributes to quantitative and measurable metrics.

While the methods, databases, tools, and experiments can be defined at a higher level, it is expected that the details would differ considerably at a lower level where specific classes of products are considered. The development of these methods, databases and tools and the formulation of the strategy to use them to solve the Grand Product Design Model will require substantial research effort. Perhaps, the best way to proceed is to perform case studies to fill in the details for the Grand Product Design Model.

5. Case Studies

Two case studies focusing on different facets of the grand product design model are discussed next. One is concerned with the development of a sunscreen cream (Cheng *et al.*, 2009). It illustrates a design procedure that uses some modelling, but primarily depends on experience and experiments. The other is concerned with a die attach adhesive for *LED* lamps, emphasizing the use of models in product design.

5.1. Sunscreen Cream

A sunscreen cream is an emulsion with many ingredients including sunblock agents, emollients, emulsifiers, stabilizers, neutralizers, humectants, film formers, thickeners, fragrances, etc. It should rub-in quickly, feel smooth, not oily or greasy, and flow well when poured from the bottle, but not appear runny. These qualitative product attributes

are translated into a shear-thinning product with a viscosity of around 0.025Pa.s when applied to the skin at a shear rate of around 1,000 s^{-1} and a viscosity of around 500Pa.s at a shear rate of 0.01s^{-1}. The selection of ingredients $\underline{x}$ is often based on a hybrid method. Natural or synthetic chemical compounds as well as their concentrations are chosen based on in-house or literature information (Table 1) while the emulsifiers are selected using the HLB method.

Table 1. A Database of Ingredients and Their Selection Criteria.

Ingredients	Examples	Suggested concentration (wt%)
Emollient [HLB value]	Synthetic oils: Caprylic/Capric triglyceride [5], C_{12}-C_{15} alkyl benzoate [13]; Natural oils: Sunflower oil [7], sweet almond oil [7], coconut oil [8]; Silicone oils: Cyclomethicone [5], dimethicone [5]	10-40
Humectant	Glycerol, propylene glycol, butylene glycol, sorbitol	1-5
Thickener	Carbomers, xanthan gum, carboxymethyl cellulose	0.1-0.5
Emulsifier [HLB value]	Steareth-2 [4.9], oleth-20 [15], glyceryl stearate [3.8], PEG-100 stearate [16], Polysorbate 20 [16.7]	1-6
Film former	PVP/ dimethylaminoethyl-methacrylate copolymer, PVP/ hexadecene copolymer, aloe vera	0.1-2.5
Stabilizer	Sodium chloride, EDTA disodium salt dihydrate	0.01-0.2
Neutralizer	Triethanolamine, citric acid	0.01-0.5
Preservative	Tocopheryl, diazolidinyl urea, iodopropynyl butylcarbamate, methylparaben, propylparaben	0.01-0.5

After fixing the composition of the cream, rheological models such as the Herschel-Bulkley model and the Oldroyd model can be used to adjust the thickener concentration. To calculate the energy intensity required to obtain the desired emulsion droplet size of 100 μm in a stirred tank (a pre-emulsification unit), mechanistic models for coalescence and breakage can be used. Figure 3 shows the region at the upper right-hand corner where breakage is feasible. For an emulsion droplet size of 100 μm, the maximum energy required for the stirred tank is around 25W/kg. Typical flowsheets for the manufacture of creams and pastes are available. In a typical flowsheet, the stirred tank is followed by a homogenizer or colloid mill to further breakup the emulsion particles to 5 μm. Design equations with adjustable parameters for these equipment units are also available.

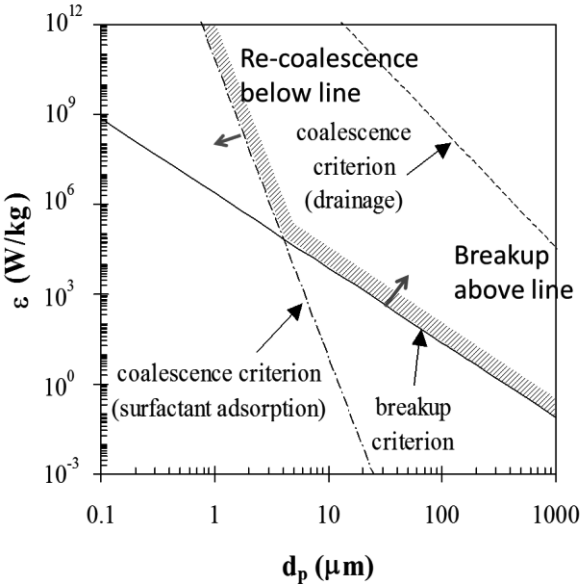

Figure 3. Depiction of coalescence and breakup criteria.

5.2. Die Attach Adhesive

The key component of an *LED* lamp is the *LED* chip, which is attached to a substrate such as alumina by a die attach adhesive (*DAA*). Despite its relatively high efficiency in converting energy to light, typically over half of the power to an *LED* is still dissipated as heat, which shortens the *LED* chip life. Hence, it is crucial that the heat generated by the chip be removed as fast as possible (a qualitative product attribute), which requires a *DAA* with high thermal conductivity (25-40 W/mK) (a quantitative technical specification). A conventional *DAA* consists of micron-sized silver particles embedded in a polymer matrix. A new product concept involves the addition of silver nanorods or silver nanoparticles in the matrix to connect the micron-sized particles. With improved connectivity, it is expected that the thermal conductivity of the *DAA* can be increased while keeping the total amount of silver at a fixed level.

The objective of product design was to maximize the economic return (NPV) in producing a die attach adhesive with the desired thermal conductivity. After an investigation of the competing products on the market, the thermal conductivity of DAA was set at 40 W/mK. For the property model $\underline{p} \leftarrow T_p(\underline{x})$, a simple model can be used to relate the thermal conductivity of a composite to the volume fraction and thermal conductivity of polymer, silver microparticles and nanoparticles.

$$\lambda_e = (\lambda_1^{0.5}\phi_1 + \lambda_2^{0.5}\phi_2 + \lambda_3^{0.5}\phi_3)^2 \quad (1)$$

Here, λ_e is the thermal conductivity of the composite, λ_1, λ_2, λ_3 (ϕ_1, ϕ_2, ϕ_3) are the thermal conductivities (volume fractions) of the polymer, silver microparticles, and silver

nanoparticles, respectively. The thermal conductivity of the polymer (λ_1) can be estimated from a database or using a *CAMD* tool,

$$\lambda_1 = f(T_c, M_w, T_b, T) \tag{2}$$

where T_c is critical temperature, M_w molecular weight, T_b boiling point, and T temperature. λ_2 is the thermal conductivity of the silver microparticle fillers; it equals 429 W/mK. λ_3 is the thermal conductivity of the silver nanoparticle fillers which is size-dependent and has to be measured. For the process model $\underline{s} \leftarrow T_s(\underline{x},\underline{pd})$, a proper mixing procedure is crucial to produce a composite with nanoparticles dispersed evenly among the microparticles. However, a basic understanding of the process let alone a model is available. In the current study, the mixing conditions were fixed after experimental optimization. For the quality model $\underline{q} \leftarrow T_q(\underline{p},\underline{s},\underline{u})$, in addition to thermal conductivity, the storage temperature, curing temperature and time, and the *DAA* viscosity prior to curing are important product attributes as well. For the pricing model $\underline{P}_{pms} \leftarrow T_{pms}(\underline{q};\underline{M})$, the following model proposed by Bagajewicz (2007) can be used to relate the product price (p_n) and sales volume (d_n) to those of the competition's.

$$p_n d_n = \left(\frac{\alpha}{\beta}\right)^{\rho} p_c \left(\frac{Y - p_n d_n}{p_c}\right)^{1-\rho} d_n^{\rho} \tag{3}$$

$$Y \geq p_n d_n + p_c d_c \tag{4}$$

Here, Y is the total market size, ρ is an adjustable parameter, α measures how much the consumer knows about the new product, and β relates the appeal of the new product in comparison to the competing product. The following equation can be used for the manufacturing product cost:

$$c_m = (w_2 c_2 + w_3 c_3) d_n + process\ cost \tag{5}$$

Here w_2, w_3 (c_2, c_3) are the weight fractions (costs) of silver microparticles and nanoparticles, respectively. The IRR can be obtained by setting NPV to be zero:

$$NPV = \sum_{j=-n}^{m} \frac{(Project\ Cash\ Flow)_j}{(1+R)^j} = 0 \tag{6}$$

Here, R is the internal rate of return. A base-case product formulation has been established (Table 2) which can be further optimized using the models above.

Table 2. Composition and component cost of the DAA product.

Ingredient	Composition (wt%)	Component Cost ($/kg DAA)
Silver flakes	79	1,185
Silver nanoparticles	10	200
Epoxy resin	5	0.25
Curing agent	5	0.15
Dispersing agent	1	0.02
Solvent	NA	0.06
Syringe dispenser (10mL)	NA	0.05
Total	100	1,385.53

6. Conclusions

Considerable research effort over the past decade has taken consumer-centered chemical product design to a point where a chemical engineer has a clearer perspective and some of the necessary methods and tools to champion the development of a superior product rapidly, efficiently and effectively. This multidisciplinary hierarchical framework is an attempt to capture what we have learned and identify what else needs to be developed. The demand for new consumer products in a rapidly changing global marketplace would help propel the research on product design forward.

Abstract

A model-based methodology is proposed which derives process design decisions at different levels of the process hierarchy under consideration of various process intensification options. The approach integrates process analysis, model identification, and process synthesis. The methodology is exemplified by designing a process for the production of a long-chain aldehyde via homogeneously catalyzed hydroformylation of 1-dodecene.

Keywords: Process Design, Multi-scale Systems, Reaction Networks, Dynamic Optimization, Chemicals Production.

1. Introduction

Optimal design of sustainable chemical process systems is of paramount importance for best utilization of raw materials and realization of energetically efficient conversion chains. A process system can be decomposed into a multi-scale structure (Freund and Sundmacher, 2011) with four hierarchical levels (Fig. 1): molecular level, phase level, process unit level, and plant level. Every scale is characterized by individual phenomena and events. Process analysis breaks a process down to convey inputs, outputs and transfer behavioral functions in order to gain a detailed understanding of the internal processes and identify accessible decision variables. Process synthesis is a bottom-up aggregation procedure that makes use of this information to derive an optimal system configuration. The final optimum depends strongly on the applied objective function (e.g., minimal costs, maximal productivity) and additional constraints the process has to fulfill (e.g., product quality, safety, operability).

The molecular level deals with all process design decisions which are linked to the structure of individual molecules, namely the choice of suitable molecular reactants to generate the desired product and the selection of auxiliary substances, in particular catalysts and solvents. E.g., Norskov et al. (2009) use quantum chemical methods to support the “in silico” design of catalysts based on molecular descriptors. Recently, Zhou et al. (2014) developed a method for the selection of reaction solvents based on the surface charge distribution of molecules.

On the phase level, one is interested in analysing and designing thermodynamic and transport properties as function of intensive state variables. Besides classical fluid property models (EoS, G^E-models), recently molecular models became an emerging tool in chemical engineering that allows the prediction of pure component and mixture properties based on molecular information (Guevara-Carrion et al., 2012).

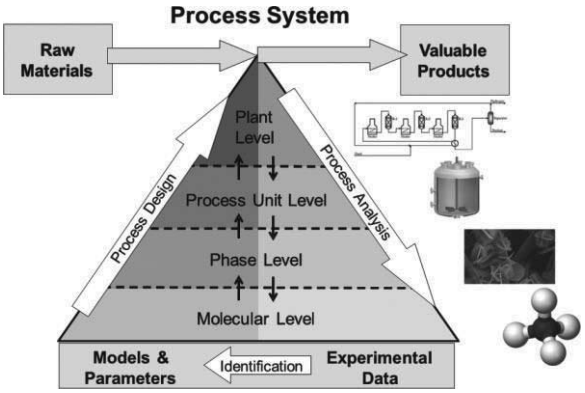

Figure 1: Efficient design of process systems requires integration of process analysis, identification and synthesis on all levels of the process hierarchy.

Process units realize the generation, contacting and separation of phases and organize the transport of mass, heat, and momentum between them. On the process unit level, models of different complexity are used for analysis and design. Short-cut models can be used to identify attainable regions in the composition space, while rigorous models are the basis for detailed optimization under consideration of decision variables such as the geometrical parameters, dosing points of reactants, extraction points of products, and heating/cooling mechanisms (Peschel et al., 2011).
Finally, the interconnection of many process units to constitute the whole process is investigated on the plant level. Variations of the topology of the process unit network can lead to dramatic performance improvements of the overall production process. While in many cases heuristic rules are still used to optimize the structure of chemical production plants (Dimian and Bildea, 2008), applied mathematics provides powerful mixed integer nonlinear programming (MINLP) algorithms for systematic optimization based on superstructures (Yeomans and Grossmann, 1999, Adjiman et al., 2000; Floudas and Lin, 2004; Gangadwala et al., 2008; Mitsos and Barton, 2009; Trespalacios and Grossmann, 2014).
In this contribution, a process design approach is proposed that tries to link the four levels of the process hierarchy, i.e., from the molecular level up to the plant level. The approach is briefly exemplified with the design of a process example, namely the synthesis of the linear aldehyde tridecanal via hydroformylation using a transition metal-organic complex as homogeneous catalyst. Tridecanal is a biodegradable chemical used as flavour compound, surfactant and plasticiser.

2. Molecular level

On the molecular level, all decisions linked to the structure of individual molecules involved in the production process are to be considered: the selection of suitable molecular reactants A and B to generate the target product molecule C, and the selection of auxiliary substances, in particular suitable catalysts and solvents.

2.1. Selection of reactants

For the choice of the main reactant A, atomic efficiency, transformation efficiency, and feedstock are key parameters to be accounted for. To achieve high atomic efficiency, one should avoid excess atoms of A not being part of the product molecule C, because such atoms yield a coupled by-product D. Single-product stoichiometry is always

preferred in the main reaction, unless the coupled by-product has an added value which improves the economic potential of the overall process. The underlying reaction mechanism should feature high transformation efficiency, i.e. the number of intermediate reaction steps at the catalyst should be as small as possible. Moreover, the feedstock for A needs to be selected under consideration of availability, price, storage capability, and sustainability. If A can be converted to C via alternative reaction schemes with different partner reactants B, one should select B such that the achievable equilibrium conversion of A is maximized, and the properties of B and C are very different to ensure simple separation and recovery of B. Of course, in selecting B not only the stoichiometry of the main reaction is important, but also the appearance of undesired by-products. Their formation is strongly controlled by the catalyst selected and – in case of liquid phase syntheses – also by the type and composition of the solvents used.

2.2. Selection of catalysts

Even if thermodynamically feasible, chemical reactions are often kinetically hindered. Hence, suitable catalysts must be selected to activate reactants, in order to enhance the rates of desired reactions and suppress undesired side reactions. Regarding catalyst selection, one has to account for catalyst activity, selectivity, stability, price, and separation from the reaction products. With regard to the last criterion, heterogeneous catalysts are advantageous. But modern homogeneous catalysts, such as metal-organic ligand systems, often offer higher selectivity. Moreover, their properties can be tuned by optimal design of the molecular catalyst structure. Screening of possible catalytic compounds today can be efficiently performed in high throughput devices (e.g. Senkan, 2001). In addition, computer-aided catalyst design receives increasing interest. In particular coupled cluster theory and density functional theory is used for the investigation of reaction pathways and/or for the estimation of rate constants of individual reaction steps (e.g. Metcalfe et al., 2010).

2.3. Selection of solvents

Another important class of auxiliary agents in chemical processes are solvents. They increase the solubility of reactants and catalysts in the liquid phase, avoid hazardous operation conditions, and support product isolation and/or catalyst recovery. Due to the fact that a solvent influences reaction rates and may deactivate the catalyst, normally solvent and catalyst should be selected simultaneously. Key criteria for the selection of reaction solvents are: separation from reaction products, low price, high stability, and non-hazardousness. Computer Aided Molecular Design (CAMD) has become a key approach for the rational derivation of optimal molecular structures of solvents (e.g. Struebing et al., 2013; Zhou et al., 2014). The design of solvents can be supported using molecular modelling/quantum chemical calculations (MM/QC), group contribution methods (GC), or data-driven approaches based on existing data banks and high-throughput screening.

2.4. Example: Molecular level decisions for tridecanal synthesis

We consider the synthesis of the target molecule C, the biodegradable linear aldehyde tridecanal (TDC), via hydroformylation. The olefin 1-dodecene is acting as the main reactant A. It can be obtained in sustainable manner via dehydration of bioethanol followed by the Shell Higher Olefin Process (SHOP) (Cornils and Herrmann, 1997). Alternatively, 1-dodecene could be produced from 1-dodecane via dehydrogenation, a route which features low carbon footprint if it is performed photocatalytically instead of thermocatalytically (Franke and Julis, 2014). The syngas components CO and H_2 are the partner reactant(s) B. No coupled by-product D is formed. The hydroformylation reaction is catalyzed by homogeneous transition metal-ligand catalyst. The transition

metal of choice is Rhodium due to its very high activity (see Figure 2). The chemo- and regio-selectivity of the catalyst is controlled by the chelating ligands. Ligand design decisions still are mainly based on heuristics, but computer-aided catalyst design is expected to become an important approach in the next years. For the hydroformylation of 1-dodecene, Schäfer et al. (2012) found in systematic batch reactor experiments that Rh-Biphephos is a highly active as well as highly selective catalyst.

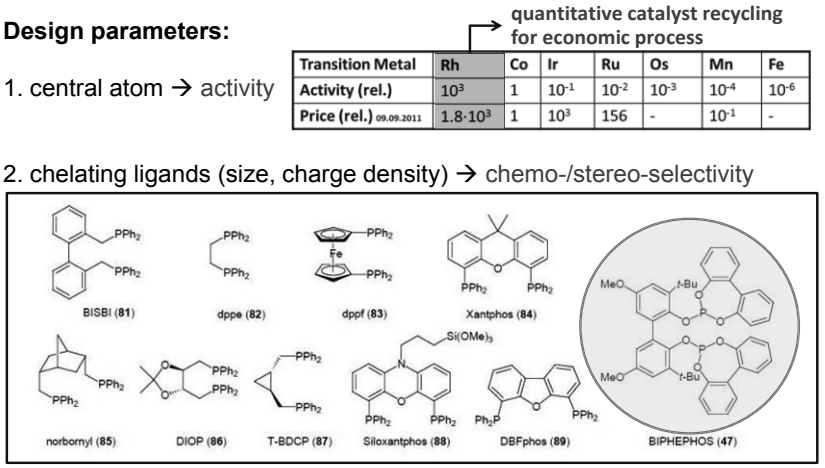

Figure 2: The hydroformylation catalyst can be designed from central atoms and ligands such that high activity, high chemo- and high stereo-selectivity are achievable.

The synthesis of tridecanal via hydroformylation of 1-dodecene features excellent atomic efficiency and transformation efficiency, and it uses a well accessible feedstock. Furthermore, a very high equilibrium conversion of A (1-dodecene) is achievable, and the pair B/C (syngas/tridecanal) can be easily separated due to their different size and physicochemical properties. The stability of Rh-Biphephos catalyst is also sufficient.

But the very high prices of both Rhodium and the ligand (Figure 2) require efficient recovery of the catalyst, i.e. separation from the product mixture. Economic input/ output calculations of the overall process show that the rest concentration of Rhodium in the product mixture must not exceed 1 ppm. For efficient catalyst recycling, Subramaniam (2010) proposed a polymer-supported ligand. The catalyst solubility can be tuned by control of the polymer molecular weight such that catalyst recycling can be achieved via precipitation followed by filtration or by membrane nanofiltration. This is a very good example how a separation function can be directly integrated into the molecular structure of a homogeneous catalyst.
Alternatively, unmodified Rh-Biphephos can be separated via liquid-liquid phase splitting inducible by suitable mass separating agents which can be selected and optimized via CAMD. By means of quantum chemical calculations (COSMO-RS), McBride and Sundmacher (2015) found dimethylformamide/n-decane as best solvent mixture to separate the Rh-Biphephos from the reaction product tridecanal at room temperature, while the same solvents form a single-phase mixture with the reactants at reaction temperature (ca. 100 °C).

3. Phase level

3.1. Determination of optimal process route

Once the main species involved in a chemical conversion process are identified on the molecular level, the optimal process route must be determined. For this purpose, the core of the conversion process, namely the underlying chemical reaction network must be inspected in detail. This requires knowledge about the reaction mechanism, based on which a thorough kinetic-thermodynamic analysis can be performed. The essential quantitative information can be harvested from optimally designed (OED) perturbation experiments in a semi-batch reactor, using suitable Process Analytical Tools (PAT) such as GC, HPLC, IR and Raman spectroscopy. Statistical analysis of perturbation experiments yields useful information from which a reaction kinetic model can be extracted. Ideally, the kinetic model should comprise thermodynamically consistent rate expressions of all essential reaction steps involved in the network. Of course, the level of detail depends on the availability of experimental data and on the constraints under which perturbation experiments are performed. In addition to experiments, today theoretical data from quantum chemical models can be very helpful for deriving suitable kinetic expressions (Karst et al., 2014).

A valid reaction kinetic model is the essential input information for the determination of the optimal process route. For this purpose, we do not consider any pre-defined reaction device, but an arbitrary well-mixed matter element moving in the thermodynamic state space (Figure 3). It is characterized by the time-dependent state vector $x(t)$, containing temperature T, pressure P, chemical composition y, and linear velocity v as observable variables. Depending on the physico-chemical situation, the state vector can be extended to describe additional states of interest, e.g. the size distribution of a particle population existing within the matter element. The state of a matter element evolves during processing time due to the action of internal and external fluxes j, namely the vector of species mass fluxes m_A, the vector of chemical reactions fluxes r_V, the heat flux q_A, the work flux w, surface forces f_A, and body forces f_V.

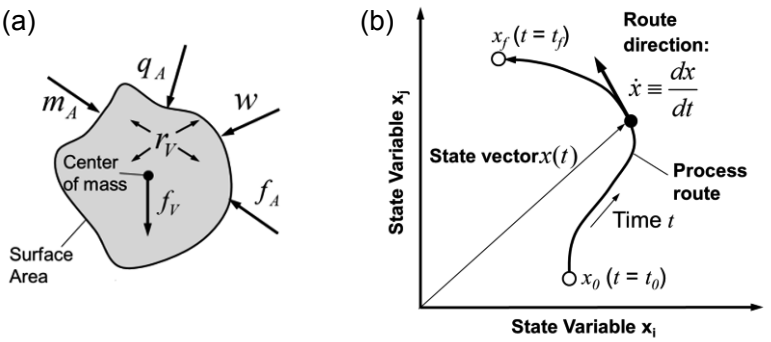

Figure 3: (a) Matter element with acting fluxes; (b) process route in state space.

In each process the state of the matter elements, $x^T = (T, P, y, v)$, is transformed from the initial point x_0 to a final point x_f (see Fig. 3). Each trajectory in state space which connects the initial and final point is called a feasible "process route". The best process route can be determined by solving the following dynamic optimization problem:

$$\min_{j(t),p}\left\{\int_{t_0}^{t_f} E(x(t),j(t),p)dt + E_0(x_0) + E_f(x_f)\right\}$$

s.t.

$C\frac{dx(t)}{dt} = Fj(t) + Nr_V$	balance equations of matter element	(1)
$r_V = r_V\big(x(t)\big)$	reaction rate expressions	
$C = C\big(x(t)\big)$	capacity matrix (from thermodyn. eqs. of state)	
$F = F(p)$	matrix of flux-weighting factors	
$x(t_0) = x_0;\ \ x\big(t_f\big) = x_f$	initial state and final state	
$h(x(t),p) \le 0$	inequality constraints	

According to Eq. (1), a generalized cost function (process cost + initial cost + final cost) is minimized via manipulation of the time-dependent fluxes $j^T = (m_A, q_A, w, f_A, f_V)$ and time-independent parameters *p*. The dynamic equality constraints are the mass, energy and momentum balance equations of the matter element. The capacity matrix *C* contains the thermodynamic system properties, e.g. density, heat capacity etc., obtainable from equations of state. *F* represents the matrix of flux-weighting factors, and *N* is the stoichiometry matrix. Eq. (1) is a generally valid formulation for matter elements in batch processes as well as in continuous processes. In the latter case *t* represents the residence time. To identify the ideal process route, i.e. the full performance potential of the reaction system, it is advisable to solve Eq. (1) for unlimited fluxes *j*. However, to obtain technically meaningful results, some inequality constraints (*h* in Eq.(2)) are to be included such as non-negativity of temperature and concentrations, as well as constraints concerning the validity range of the rate expressions and equations of state. When solving Eq.(1), we have to take into account that the initial and final state are often coupled due to recycling of unconverted reactants and products. Eq.(1) is a DAE-constrained optimization problem which the treated discretizing the control and state variables simultaneously (Biegler, 2007). The resulting NLP problem can be solved e.g. with the solver CONOPT (Drud, 1985). The optimal flux profiles $j_{opt}(t)$ represent the ideal process route which can be used for benchmarking any possible technical approximation on the next design level, namely the process unit level.

3.2. Example: Phase level decisions for tridecanal synthesis

The reaction network of the homogeneously catalyzed synthesis of tridecanal was investigated in detail by Kiedorf et al. (2014) using experimental perturbation techniques. The authors proposed a reduced model consisting of 6 reaction steps (Fig. 4b). Hentschel et al. (2014) used this network and corresponding rate expressions to determine the optimal process route of matter elements via dynamic optimization, according to Eq.(1). Thereby, the initial and final states were coupled by an ideal separation sub-system which allows recycling of any species in the network at arbitrarily high purity (Fig.4a). The chemo-selectivity w.r.t. the tridecanal (nC13al) was maximized. The results show that recycling of iso-dodecene (iC12en) is essential for achieving high chemo-selectivity (Fig.4c). This is due to the fact that iC12en can be isomerized back to 1-dodecene (n-C12en) via reaction step r_2 and converted into the desired product nC13al via step r_1 (Fig.4b). For 95 % conversion of 1-dodecene the optimal concentration profiles (Fig.4d), the corresponding mass and heat flux profiles (Fig.4e), and the resulting temperature and gas pressure profiles (Fig.4f) are shown below. The temperature profile reflects the fact that the reverse isomerisation of iC12en to nC12en is favored at higher temperature. Lower partial pressure of H_2 in the first time period (Fig.4f) suppresses the undesired hydrogenation steps r_3 and r_4. In summary, the selectivity-optimal process route requires distributed dosing of the reactants H_2, CO and

nC12en, distributed cooling due to the exothermic hydroformylation, and selective recycling of isomer iC12en, catalyst Rh-Biphephos, and solvents (n-decane/DMF).

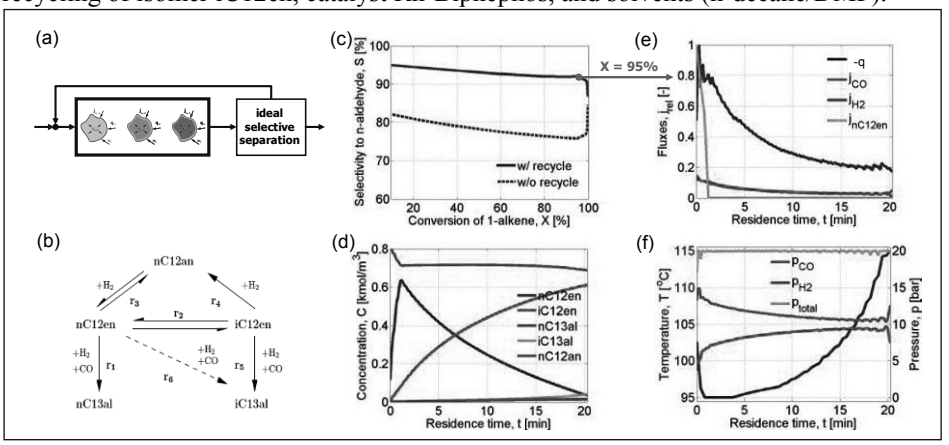

Figure 4: a) reaction-separation recycle system, b) reaction network of TDC synthesis, c) optimal selectivity-conversion curves with/without recycle, d) concentration profiles at X = 95 %, e) optimal flux profiles, f) optimal temperature and pressure profiles.

These findings set the conditions to be met by the separation system. As first separation steps after the reaction, a flash for syngas recovery and a decanter for catalyst recovery via LL-phase splitting are the methods of choice (Dimian and Bildea, 2008). The decantation yields a DMF-rich phase containing the Rh-Biphephos catalyst which is recycled to the reaction's initial state, and a n-decane-rich phase containing some unconverted reactant and all products showsn in Fig.4b. The conceptual design of the separation sequence for the n-decane phase can be derived from conventional Residue Curve Map analysis (RCM; Doherty and Malone, 2003), a methodology closely related to the process route analysis proposed in section 3.1 since both approaches essentially investigate trajectories of matter elements in the thermodynamic state space.

4. Process unit level

4.1. Technical realization of optimal process route

On the process unit level, the optimal process route is approximated by means of suitable existing or novel devices. Thereby, additional physical and technical constraints regarding the fluxes have to be accounted for. While the matter element on the phase level is optimally controlled over the time coordinate, on the unit level one has to decide whether the optimal route should be realized in a continuously operated, spatially distributed device or in a semi-batch operated, temporally distributed device. Secondly, one has to check if the interesting fluxes are directly controllable in practice or must be replaced by other variables, and if simultaneous action of fluxes is realizable. According to irreversible thermodynamics, the fluxes are driven by conjugated forces which are related to the difference between the actual state and the equilibrium state ($x - x_{eq}$). For small deviation from the equilibrium state, a quasi-linear transport law can be used:

$$j = K(x)\left(x - x_{eq}\right) \tag{2}$$

where $K(x)$ stands for the matrix of transport coefficients. According to Eq. (2), instead of the fluxes j, one can use the corresponding equilibrium states x_{eq} as control variables. This requires specification of the transport mechanisms to be applied. The choice of

mechanisms, the feasible windows of transport coefficients and geometrical parameters (volume-related surface areas, $a=A/V$) determine the technically realizable extensive fluxes, the type of devices to be selected and the size of equipment. When optimizing technically feasible process routes, one must integrate additional constraints: a) the transport laws, Eq. (2), and b) bounds of transport coefficients as well as geometrical parameters. Since these bounds often become active constraints, one should perform systematic sensitivity analysis of the optimal solution. Even if properly designed, each type of equipment will only approximate, but not directly match the ideal process route. In particular, matter elements in reality are neither perfectly mixed, nor is the residence time of matter elements traveling through a process unit uniformly distributed. Hence, we must also investigate the robustness of the obtained optimal solution with respect to non-ideal micro- and macro-mixing of matter elements.

4.2. Example: Process unit level decisions for tridecanal synthesis

From systematic dynamic optimization studies, we found that a segmented flow reactor with discrete dosing of syngas and alkene is the best technical approximation of the cost-optimal process route in a continuously operated system (Peschel et al., 2012). The gas-liquid mass transfer coefficient was identified as critical parameter for the achievable chemo-selectivity at given alkene conversion (Fig.5a). Thus, the reactor should be equipped e.g. with static mixtures in order to enhance gas-liquid mass transfer in a sufficient manner (Fig.5b).

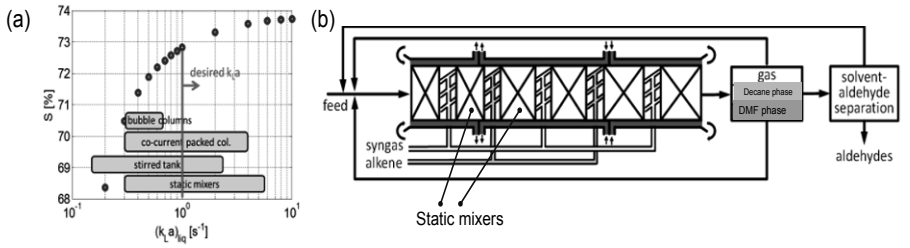

Figure 5: (a) Selectivity vs. GL-mass transfer coefficient; (b) segmented flow reactor.

5. Plant level

5.1. Process integration and operability analysis

Process design decisions on the plant level are mainly focused on material and energy integration as well as on operability aspects. As a versatile tool for evaluating many integration possibilities, superstructure based optimization is a widely used technique. Regarding energy integration, pinch analysis is a classical but still important method for determination of the best heat exchanger network (HEN). Once the optimal plant topology is identified one should investigate its operability, i.e. the controllability of steady states as well as also the start-up behavior. In order to ensure long-term stability of catalysts, experiments on the miniplant scale are an indispensable element of operability analysis on the plant scale (Zagajewski et al., 2014).

5.2. Example: Plant level decisions for tridecanal synthesis

The cost-optimal flowsheet for the production of tridecanal is sketched in Fig.6a. There, a tubular reactor featuring optimal dosing of H_2 and CO and optimal cooling along the flow direction is embedded into the process. This reactor provides 2.8 % cost savings compared to a standard stirred tank reactor (CSTR, Fig.6b). By application of selectors (Dimian and Bildea, 2008), it was decided to apply distillation for material integration, i.e. for separation of the solvent n-Decane and non-converted n/iso-C12-alkenes. For final nC13al separation, vacuum distillation must be applied to avoid thermal aldehyde

decomposition. Micovic et al. (2013) found that combining distillation with melt crystallization further reduces the energy demand for C13-isomers separation.

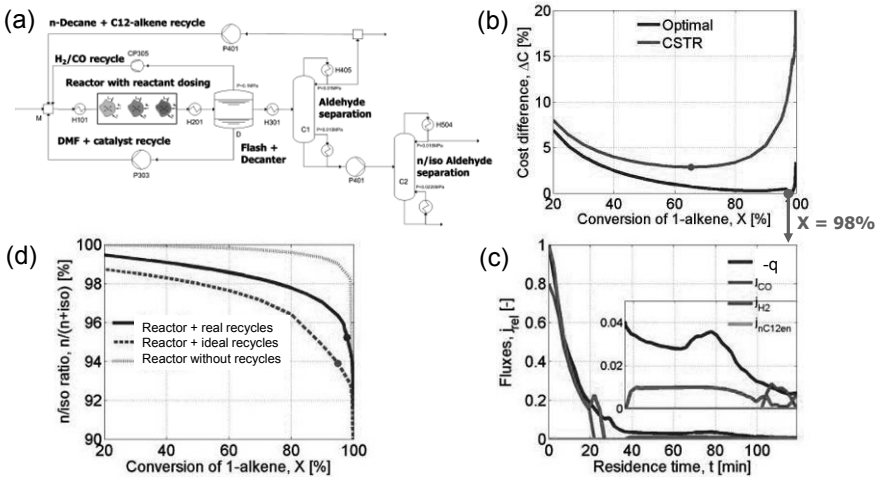

Figure 6: a) Flowsheet for n-aldehyde production using the solvent pair n-decane/DMF for catalyst separation, b) total cost vs. conversion of 1-alkene, c) optimal flux profiles at 98 % conversion, d) n/iso ratio of aldehydes vs. conversion of 1-alkene.

6. Conclusion

The presented multi-level process design approach was successfully applied to several examples of chemicals production and energy conversion (Karst et al., 2014; El Sibai et al., 2015). The core element is the detailed kinetic analysis of the underlying reaction network based on which the optimal processing route of matter elements is identified. The proposed flux-oriented methodology allows systematic comparison of various process intensification options during the design of process units.

PSE Tools for Process Intensification

Philip Lutze

Technical University Dortmund, Dep. of Biochemical & Chemical Engineering, Laboratory of Fluid Separations, Emil-Figge-Strasse 70, D-44277 Dortmund, Germany.

Abstract

Process intensification is considered to be one important tool to meet the requirements for more efficient and sustainable processing. Even though many different intensified technologies have been developed, only some of them have been implemented in industry yet. One of the reasons is that process synthesis and design of intensified processes, benchmarking between different intensified technologies or targeted intensification beyond currently existing solution is complex and challenging. Addressing such complexity and offering systematic solution procedures is the strength of process systems engineering. Therefore, an overview of some of the recently developed methods and tools for process design and synthesis to achieve process intensification acting at different scales of the process is given.

Keywords: Conceptual process design; Optimization. Process synthesis;

1. Introduction

In recent years, Process Intensification (PI) has attracted much interest to meet the increasing demands for highly efficient and more sustainable processing. Many different definitions on scope, principle and target of PI exist. However, one particularly practical definition of PI is that PI is a tool for the targeted enhancement of involved phenomena at different scales which overcome occurring bottlenecks and limitations of the performance to achieve a targeted benefit based on a set of performance criteria (Lutze et al., 2010). The four scales are i) process & plant; ii) equipment & operation; iii) phase & transport; and iv) fundamental & molecular; (Freund and Sundmacher, 2011; Lutze et al., 2012). Examples for PI ranges from vapour recompression in distillation to reactive distillation, micro reactors all the way down to apply new kind of solvents or new kind of energy sources for the operation. Process systems engineering (PSE) offers a broad set of methods and tools for efficient problem solving for different domains. That includes modelling; product design; simulation, synthesis, design, optimization, dynamics, and control of processes; safety, knowledge management etc.
The symbiosis of PSE and PI has been stressed earlier in some of those domains (Moulijn et al., 2008). However, since then, more intensified equipment has been developed which potentially creates a large number of options to improve a process. However, to date only a limited number have achieved implementation in industry (Harmsen, 2010). A reason for this is that the identification of the best PI option is neither simple nor systematic. Until now, most PI has been selected based on case-based trial-and-error procedures, not comparing different PI options on a quantitative basis. Hence, it is believed that tools from PSE are keys to enable the implementation of PI in industry (Lutze et al., 2010). Therefore, some of the recent contributions in this area are addressed within this paper.

2. PSE tools for process synthesis/design incorporating PI

PI has always been used as a solution technique at different scales to improve process performance limiting phenomena. Hence, different PSE methods/tools on how to systematically address the identification and benchmarking of PI solutions at different scales have been developed (see Figure 1). Those include methods for process synthesis for improved integration of conventional unit operations, synthesis/design methods incorporating PI equipment but also synthesis/design methods which work apart from existing PI solutions in order to come up with predictive solutions. Additionally, solvent or reaction selection is important tools to enable PI. Within chapters 3-6, some of the recent contributions of PSE tools to achieve PI are addressed.

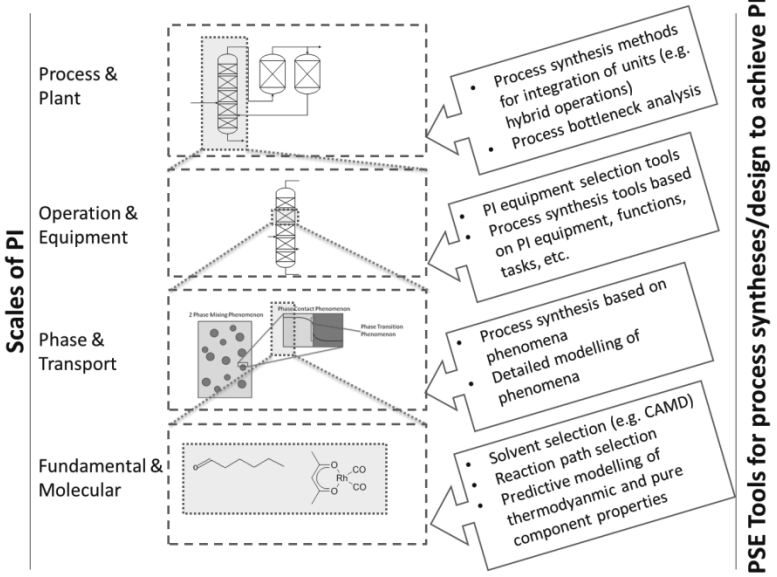

Figure 1: Illustration of PSE tools for process syntheses/design to achieve PI at different scales.

3. PSE tools at Process & Plant level

A process or a plant is producing one or more products from one or more raw materials in a desired quality and quantity. A process consists of a set of unit operations which are connected to each other in a specific way. Improved connection between or an external integration of these unit operations can be performed to intensify the process. Examples are the external integration of reactor and separator or the external integration of two different unit operations to fulfil one separation, also known as hybrid separation (Lutze and Gorak, 2013; see Fig. 2). Heat exchanger networks are not PI. But the integration of vapour recompression units to increase the energy utilization is considered to be PI at the process/plant level because the flowsheet structure itself is not changed.

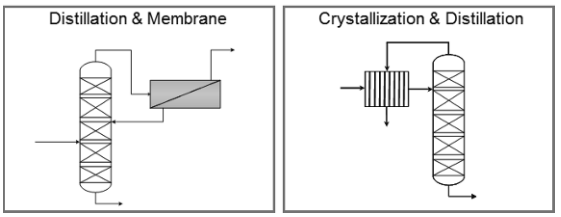

Figure 2: Exemplified scheme of two different hybrid separations.

Recently developed PSE tools for synthesis/design of hybrid separations have been summarized in an excellent review by Skiborowski et al. (2013). Recker et al. (2014) proposed a systematic and optimization-based approach to design integrated reaction-separation Processes exploiting shortcut methods to screen a set of alternative processes and rigorous optimization of the entire to identify the best. An important discussion on targeting PI at the process level is a proper selection of criteria and a sophisticated method for bottleneck analysis. Even though PI is often linked with a volume reduction due to efficiency increase, more proper criteria to benchmark PI should include intrinsic PI performance measures including costs (Criscuoli and Drioli, 2007; Lutze et al., 2010), sustainability (Carvalho et al., 2008) as well as Life-cycle-assessment (Babi et al. 2014). For bottleneck analysis systematic methods to source bottlenecks such as method of Carvalho et al. (2008) have been proposed. Their method decomposes the process into a set of process graphs. For each of these process graphs, mass and energy indicators such as material-value-added or energy and waste costs are calculated needing information about costs/prices of input and output mass/energy. Based on these indicators limitations/bottlenecks are identified for improving the sustainability of the process. Hildebrandt and Fox (2014) proposed to exploit mass, energy and entropy balances because those give not only big insights in the process in terms of a proper bottleneck analysis but also they can be directly targeted for improved process design.

4. PSE tools at Operation & Equipment level

Each process is a connection of tasks. A task can be defined as a purpose which it fulfils in the process such as conversion, separation, mixing and energy supply tasks. A task can be realized by one or multiple equipment and/or multiple tasks can be realized in single equipment. At this level, the task of the equipment is not changed by PI but rather the process space within the equipment/operation. Examples for PI at this scale are structuring or miniaturization of the apparatuses in order to support the involved phenomena without changing the task of this process step or without necessarily changing the involved transport phenomena. For example, a micro heat exchanger improves the heat addition/removal by offering a better surface area to volume ratio.

Besides, specific design methods for single PI equipment, different tools for the selection of suitable PI technologies have been developed. Kiss et al. (2012) developed a framework for the selection of energy efficient distillation technologies based on systems information. Commenge and Falk (2014) developed a methodological framework for the selection of intensified equipment and development of innovative technologies. Based on the identification of the bottleneck of the process a set of intensification strategies are selected through a connection matrix including structuring, altering operating conditions, etc.. Following, through an additional matrix, the PI equipment can be selected. Lutze et al. (2012) proposed a systematic synthesis/design method incorporating more than 100 PI equipment stored in a database. This method employs a decomposition-based solution approach in which based on an identification of the bottlenecks of an existing process, a set of intensified solutions are generated which are afterwards subsequently screened by a stepwise procedure. Even though the number of process options generated for complex case studies are large, the decomposition approach is a suitable solution strategy which reduces the number of options in case the constraints are properly selected (see Figure 3). Holtbruegge et al. (2014) developed a tool in Matlab© for the automatized generation of (reaction-) separation processes including reactive and hybrid separations based on exploiting

thermodynamic knowledge on the system. The highlighted their tool for the separation of a fermentation supernatant as well as the production of ethyl lactate.

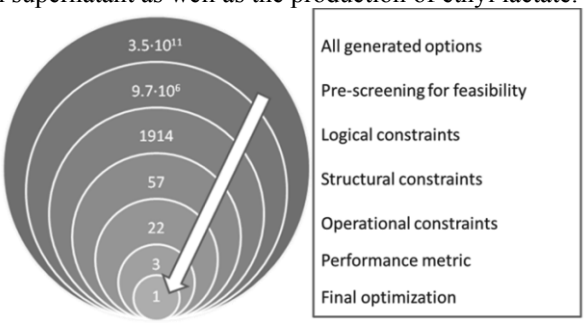

Figure 3: Generation and reduction of PI options for the production of n-acetyl-neuraminic acid by decomposition approach (Lutze et al. (2012).

A synthesis/design method going beyond existing PI solutions are the development of novel reactor networks based on elementary process functions using a three-level approach (Peschel et al., 2010). Firstly, the optimal route in the state space is identified. In the second level operational constraints based on detailed transport calculations are integrated. In the third level, different set and combinations of equipment are identified and filled with technical constraints which form the basis of the optimization of a detailed model leading to the identification of the best technical solution. The method has been illustrated for an SO_2 oxidation reactor (Peschel et al., 2010) and the production of ethylene oxide (Peschel et al., 2012). Another design/synthesis framework is proposed by Babi et al. (2014) in which the bottlenecks of a process are connected to tasks which are subsequently improved at the task level through recombination or integration with other tasks or which are directly targeted by improving the involved thermodynamic phenomena of equipment. They have tested their method on the production of methyl acetate. Their method allowed the systematic built-up a number of different conventional and intensified processes. Their best options in terms of LCA and costs were reactive distillation and integrated membrane-assisted distillation process.

5. PSE tools at Phase & Transport level

Within an equipment one or multiple phases occur in which a set of components form a phase. Within each phase mass, energy and momentum are transferred. Basic PI concepts at this scale are the integration of multiple actions in one phase or the addition of multiple phases. For example, the integration of a vapour phase and a liquid phase in which a reaction takes place will enable reactive flash or in case of countercurrent connection of many of those into a reactive distillation.

The synthesis concept from Rong et al. (2008) is based on process phenomena such as chemical reaction, materials phases, transport phenomena, phase behaviour and separation phenomena etc. Each phenomenon is influenced by materials, operating modes, flow pattern, facility medium, structure, energy sources as well as key variables, components and phases. If a key phenomenon including key variables is identified to be limiting the process, trial-and-error variations are used to enhance them which may lead to PI solutions. The concept has been briefly illustrated for the production of peracetic acid (Rong et al., 2008). Lutze et al. (2013) developed a systematic synthesis/design methodology based on elementary phenomena. Elementary phenomena include transport phenomena - which are mass transfer, energy transfer and fluid dynamics or

momentum transfer - , thermodynamics including reactions and kinetics. Transport phenomena are grounded on the conservation laws within the system and subject to driving forces based on thermodynamics as well as subject to boundaries including equipment and material-bound characteristics. Their method is capable to stepwise generate a set of phenomena-based options as well as stepwise reduce the number of options through a decomposition approach. Furthermore, their model-based method gives fully predictive solutions. They have explained each step of their method in detail for the production of isopropyl acetate in which they have generated more than 200.000 feasible solutions which they reduced stepwise to 22 by refinement of the solution. Their obtained best option was an integrated membrane-heat-exchanger flow reactor (Fig. 4)which outcompete reactive distillation as well as a conventional process.

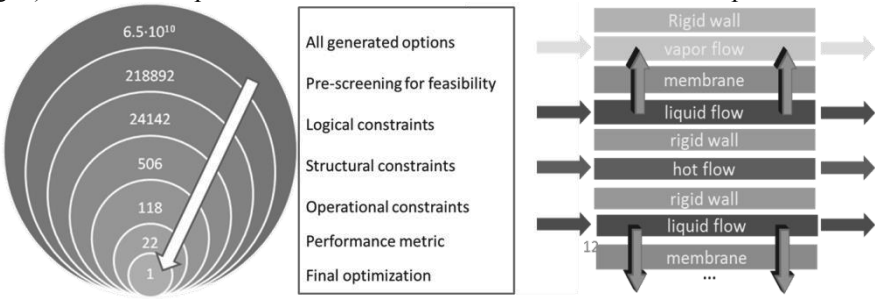

Figure 4: Generation and reduction of PI options for the production of isopropyl acetate (left) and integrated membrane-heat-exchanger flow reactor (right) (Lutze et al. (2013).

6. PSE tools at Fundamental & Molecular level

At the fundamental and molecular level the basis of the performance of molecules in pure or mixture state are set involving thermodynamics and kinetics of reactions. Here PI aims at the targeted tuning of solvents for separation systems incorporating the development of ionic liquids as tuneable solvents, reactive solvents, or the targeted enhancement of kinetics by catalyst development.

Any PSE tools at this level, either for example focussing on improved reaction pathways or identifying better solvents, for example by CAMD approaches enable more efficient processing and the potential use of PI technologies. An example is given by Roughton et al. (2011). They presented an integrated method incorporating the design of the solvent in terms of an ionic liquid and the design of the associated extractive distillation processes breaking azeotropes. Voll and Marquardt (2012) presented an approach for optimization-based evaluation of reaction pathways for biorenewables processing based on reaction network flux analysis.

7. Conclusions

Different PSE methods/tools on how to systematically address the identification and benchmarking of PI solutions at different scales have been developed (see Figure 1) and are between ready-to-be–applied and promising. Each of those has its advantages and disadvantages. Process synthesis tools at higher levels allow the potentially quick identification of a set of suitable PI equipment to improve the process but are limited to the initial search space of PI solutions. Here development of common or open databases will help to further push those developments. Process synthesis tools for PI at lower levels may allow the generation of truly predictive and innovative PI solutions but the problem to be solved is much more complex. It is believed that future development in

mathematical approaches as well as database management will increase the applicability of these concepts. Furthermore, integration of methods/tools from the fundamental/molecular level will increase further the degree of freedoms in process synthesis/design for PI, however, also the complexity of the solution identification. Finally, the development within PSE and PI separately and also together are promising to push implementation of more efficient technologies into industrial processes.

Abstract

The integration of design and control, control and scheduling and design, control and scheduling, all have been core PSE challenges. While significant progress has been achieved over the years, it is fair to say that at the moment there is not a generally accepted methodology and/or "protocol" for such an integration - it is also interesting to note that currently, there is not a commercially available software [or even in a prototype form] system to fully support such an activity.

Here, we present the foundations for such an integrated framework and especially a software platform that enables such integration based on research developments over the last twenty -five years. In articular, we describe PAROC, a prototype software system which allows for the representation, modelling and solution of integrated design, scheduling and control problems. Its main features include: (i) a high-fidelity dynamic model representation, also involving global sensitivity analysis, parameter estimation and mixed integer dynamic optimisation capabilities; (ii) a suite/toolbox of model approximation methods; (iii) a host of multi-parametric programming solvers for mixed continuous/integer problems; (iv) a state-space modelling representation capability for scheduling and control problems; and (v) an advanced toolkit for multi-parametric/explicit Model Predictive Control and moving horizon reactive scheduling problems. Algorithms that enable the integration capabilities of the systems for design, scheduling and control are presented on a case of a series of cogeneration units.

Keywords: multi-parametric receding horizon policies, control, design optimisation, optimal scheduling, integration

1. Introduction and Overview

Designing economically profitable plants and improving their operational performance has been a core research field in Process Systems Engineering. The need to optimise the performance of a plant includes (i) long-term decisions, (ii) mid-term decisions and (iii) short-term decisions as well as (iv) their interactions. Therefore, a variety of computational tools has been developed for advanced model development (e.g. ASPEN Plus®, gPROMS®), – including global sensitivity analysis, parameter estimation, and mixed-integer dynamic optimisation capabilities – as well as algorithms for operational scheduling procedures and advanced control methodologies.

It is generally accepted that the decisions regarding the plant design affect its operation in a most determinative manner, since they are the less likely to change while a possible change usually requires not only a considerable investment but also the permanent cease of operation; an action

that affects production profit. Operational scheduling optimises the plant performance in the mid-term while taking into account uncertainty that originates from raw material shortages, fluctuation in pricing, demand changes, equipment failure and the like. Most commonly, the operational scheduling optimisation procedures are based on the assumption that the design of the plant is given and remains fixed for the entire operational horizon and that the regulatory and supervisory control of the system work flawlessly. The control strategies of a process constitute the short-term decisions in terms of operation. A variety of procedures are implemented with regulatory (P, PI, PID) control and model predictive control to be the most notable. The main burden of the controller is to reject measured and unmeasured disturbances while trying to maintain certain operation set-points imposed by the mid-term operational optimisation. Table 1 presents a list of the most notable contributions on model predictive control.

The focus of the operational performance optimisation has shifted from addressing the design, scheduling and control aspects individually into a combined, integrated approach. The common factor in these approaches is the effect of short-term decision-making into mid- or long-term decisions. Therefore, numerous works have appeared in the literature throughout the past years regarding (i) the interactions of design and control and (ii) the integrated approach to scheduling and control. An indicative list of the different techniques employed to target the design and control problem is presented in Table 2. Superstructures, MIDO formulations and combinations of online optimisation techniques with embedded model predictive control are worth noting.

On the other hand, recent contributions (from 2002 onwards) have opened the road to the integration of operational mid-term scheduling and control via a variety of methods. Among them, the MIDO approaches as well as the state-space scheduling problem representation with integrated online or offline model predictive control strategies are the most notable. Table 3 indicates the major contributions.

While significant progress has been achieved over the years in integrating design with control and control with scheduling, it is fair to say that at the moment there is not a generally accepted methodology and/or "protocol" for the integration of all three aspects - it is also interesting to note

that currently, there is not a commercially available software [or even in a prototype form] system to fully support such an activity. In this work we present the foundations for such an integration, based on 25 years of research. We present PAROC, a prototype software system which allows for the representation, modelling and solution of integrated design, scheduling and control problems.

2. The PAROC Framework

The PAROC (PARametric Optimisation and Control) framework (depicted in Figure 1) is the cornerstone for the development and testing of receding horizon optimisation policies for process systems. Starting with a "high-fidelity" dynamic model of the process at hand, PAROC provides the theoretical, technical and software basis for the development of multi-parametric model predictive controllers, multi-parametric moving horizon estimators, multi-parametric rolling horizon process schedules, and the like, with embedded dynamic optimisation capabilities as well as model validation techniques. A brief step-by-step description follows.

"High-fidelity" model analysis and dynamic optimisation. The "high-fidelity" model of the process at hand, implemented in gPROMS®, is the framework basis. Ranging from simple, ordinary differential equations to complex, partial differential equations and non-linear algebraic relations it provides the platform upon which analysis such as parameter estimation and global sensitivity analysis is performed. Most commonly, a "first principle" approach is followed to capture the dynamic behaviour of the process.

Model Approximation. The modelling techniques employed for the derivation of a "high-fidelity" model usually result in highly complex systems which are too computationally expensive to be handled by the standard multi-parametric optimisation programming approach. Therefore, an intermediate step that simplifies the model interpretation of the process into a linear, discrete ODE system is needed. For the model approximation, (i) the linearization capabilities of gPROMS®, (ii) the System Identification Toolbox of MATLAB® or (ii) the model reduction techniques presented in Narciso and Pistikopoulos (2008); Rivotti et al. (2012); Lambert et al. (2013) (and ref-

erences therein) are utilised. The resulting state-space representation is adequately simple to be treated in a multi-parametric receding horizon basis, yet it is focused on compromising the original model accuracy as little as possible[1].

Multi-parametric programming, receding horizon policies and mpMHE. In this step, the approximate state-space model is treated in a receding horizon policy that results into the formulation of a linear or quadratic program with continuous or continuous and binary decision variables (i.e. LP, QP, MILP, MIQP problems). The optimisation problem is subjected to constraints that result from the state-space representation (equality constraints) as well as box constraints for the state variables, the input and output variables and the input rate (inequality constraints). In the most

[1]The state-space model accuracy is determined as the mismatch between the original "high-fidelity" model and the approximate model via simulation results under the same inputs and initial conditions.

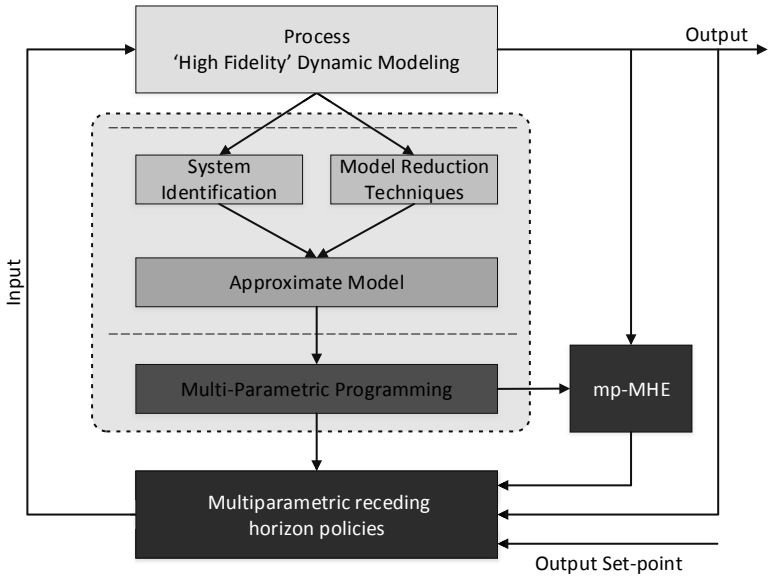

Figure 1: The PAROC Framework. Actions in the gray area happen once and offline.

generic case, treating the states as uncertain but bounded parameters and reformulating the problem statement accordingly results into multi-parametric programming problem which, based on the initial formulation, is classifed as an mpLP, mpQP, mpMILP or mpMIQP. The solution of such problems is provided once and offline by the software package POP®, thereby eliminating the need of an online optimiser to handle the receding horizon problem whether this is model predictive controller, a scheduler or a moving horizon estimator. The online solution of the receding horizon policy is therefore reduced into a piecewise affine evaluation.

Closed-Loop validation and software implementation. The closed loop validation of the receding horizon policies takes place against the original "high-fidelity" model and is enabled by the interactions between the modeling software and the solution of the multi-parametric programming problem. There are currently two approaches regarding this. The first is based on the inteconnectivity between the gPROMS® platform and MATLAB® via the use of gO:MATLAB® while the second relies on the development of a dynamic link library, which contains the solution to the receding horizon optimisation problem and is called by the simulator at every simulation step.

The next section discusses the interactions of process design and operations for a series of heat and power cogeneration (CHP) units for domestic/residential use.

3. Towards the integration of design and operational optimisation

In this section, an example for the integration of design and operational optimisation is presented. A series of CHP units based on Diangelakis et al. (2014b) is considered for domestic/residential use. The objective is to acquire the optimal operation policy, the optimal model based controller and the optimal design of the series through a single optimisation formulation, utilising the PAROC software platform. The process design aspect of this example consists mainly of the size of the prime movers, hence the ability of power and heat production of the system is affected. Fur-

thermore, an insulated tank for hot water storage is considered, the size of which is subjected to optimisation. The choice between a single or multiple units is also considered, therefore the scheduled operation and control of the units is also a matter of optimisation.

Following the principles described in section 2, a "high-fidelity" model of a CHP unit is considered, similar to the procedure described in Diangelakis et al. (2014a). In this case though, an integrated approach is followed where the model approximation procedure also takes into account the design variables of the high fidelity model, in this case the engine displacement volume as well as the volume of an insulated hot water buffer tank. After the approximation the electrical power output of the internal combustion engine is the output of a state-space model the inputs of which are the position of the butterfly in the throttle valve and the displacement volume of the internal combustion engine. Similarly the optimal action of the heat recovery subsystem is a subject to the size of the insulated tank. For the design of the mp-MPC the design variables are treated as measured uncertain parameters. The resulting control scheme, is exported in the dynamic link library format of a gPROMS® ModelBuilder foreign object as described formerly.

The scheduling problem formulation in the form of Kopanos and Pistikopoulos (2014) is taken into consideration, enhanced by dynamic control decision and dynamics feedback in a bottom-up approach as described in Baldea and Harjunkoski (2014). The use of the design-dependent mp-MPC scheme presented above coupled with a design-dependent scheduling formulation, forms the core of the operational strategies. A conceptual schematic representation of the system and the configuration is presented in Figure 2.

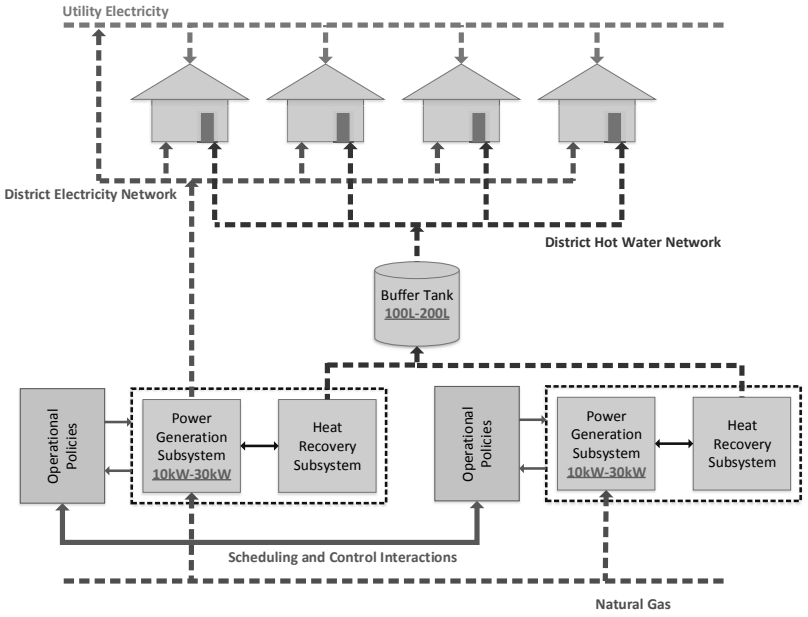

Figure 2: Simultaneous design and operational optimisation via design dependent mp-MPC. An indicative range for the design variables is denoted in red.

The realisation of the design uncertainty is subject to optimisation. More specifically, the design dependent multi-parametric controller as well as the design-dependent optimal scheduling[2] are

[2]The optimal scheduling is addressed as a receding horizon multi-parametric programming problem.

inserted in gPROMS®. Using the dynamic optimisation capabilities of the latter, the model is optimised using single vector shooting techniques. The value for the design variables as a result of the optimisation procedure acts as an uncertainty realisation for both the controller and the scheduler, therefore achieving simultaneous design and operational optimisation. This novel approach manages to determine (i) the mid-term operational strategy (ii) the short-term optimal control actions and (iii) the design of the system as a result of a single dynamic optimisation procedure. Consequently, the dependence among the control strategy, the operational policy and the design of the system is examined.

4. Concluding Remarks

In this paper we have presented the PAROC framework and the software platform for the development of receding horizon policies via multi-parametric programming. Furthermore, we showed how the framework and its software components enable the simultaneous design and operational optimisation of process systems using research conducted in the last 25 years. The example of the series of CHP units for domestic/residential use helps us demonstrate the concept of design and operational optimisation.

Industrially Applied PSE for Problem Solving Excellence

Antoon J.B. ten Kate

AkzoNobel, Zutphenseweg 10, 7418 AJ Deventer, the Netherlands
antoon.tenkate@akzonobel.com

Abstract

PSE, process systems engineering, is about the development and application of systematic methods for process studies by the chemical engineer. By means of software tools, the application of these methods is facilitated. Over the last about half a century, CAPE (computer aided process engineering) tools have found their way into process engineering. E.g. nowadays it is unthinkable to design a plant without a simulation in a flow sheet package. But there are many more applications of PSE in industry.

With this paper we aim to provide a taste of the meaning of PSE in our industrial R&D environment. We do not intend our overview to being complete, but we hope to give a flavour of what we perceive as the benefits of PSE during process development in our industry, and in which aspects we believe the PSE arena should be extended to render further benefits.

Keywords: PSE, CAPE, PI, industrial process & product development

1. Introduction

Traditionally PSE is concerned with the understanding and development of systematic procedures that assists the chemical engineer to design, operate and control the chemical production facilities (Gani et al., 2007). The typical engineering work stream for the chemical engineer comprises the development of (conceptual) process design, mass and energy balances, equipment selection and sizing, control strategies, techno-economic evaluations and so on. CAPE tools are applied in all of these work streams.

These are typical activities for any kind of chemical engineer, either working at the plant, in an engineering unit or in process R&D. Yet, obviously the focus in R&D is more on the ‘unknown’ than it is at the plant or in engineering, where the focus is more on debottlenecking and troubleshooting or designing a plant based on existing knowledge.

PSE offers both the methodological approach to unravelling the unknown, as well as the software tools needed in that approach. In the following sections, we will first discuss software tools, and subsequently, outline a structured approach in process R&D.

2. Providing Software to Exploration

When applying CAPE tools, our objective is to provide a (semi-)quantitative description of at least a part of the process or product of concern. A variety of CAPE modelling tools is available for R&D purposes, for different scales in dimensions and time:

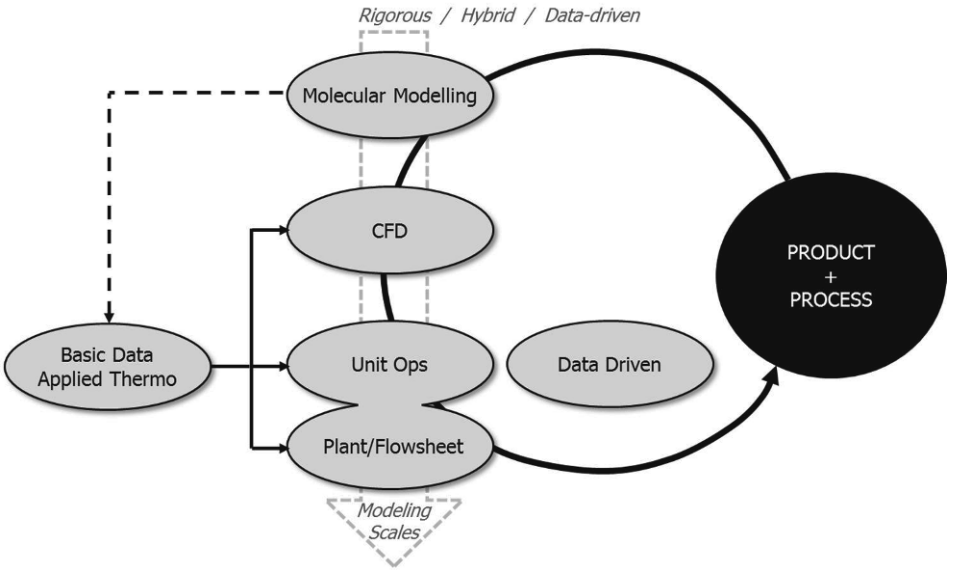

Figure 1. Chemical engineering modelling platforms at the various scales

- At the smallest scale molecular modelling tools are available. They provide an alternative approach to experiments for gaining insight into reaction mechanism, crystallization behavior, emulsion stability and so on.
- At a somewhat larger scale, CFD (computational fluid dynamics) provides insight into flow characteristics in systems that otherwise are hard to investigate, e.g. at high temperature or harsh corrosive conditions. CFD has long outgrown its infancy state of 'colors for directors' as e.g. it is capable to describe multi-phase reactive systems.
- The heart of process engineering modeling remains the simulation of single and integrated unit operations up to the entire plant. Aspen Engineering Suite, ChemCAD, Hysis, Pro/II, ProSim and gProms are software platforms that offer flow sheeting capabilities for steady state and dynamic simulation.

Larger scale models are typically more of use for manufacturing, like manufacturing execution system (MES) and enterprise resource planning (ERP). The related CAPE tools are less applicable in the R&D environment.

Basic data, comprising chemical and physical properties, are crucial for plant and unit operation models and CFD models. In general the basic data models used in unit operation and plant modeling are more sophisticated than those in CFD applications.

The time and effort for building the model is typically larger than for running the model and the interpretation of the simulation results. Likewise it takes more time and effort to set up an experiment than performing the experiment and interpreting the results:

- model: computation time << interpretation time << model synthesis time
- experiment: interpretation time << experimental time << preparation time

It typically takes a much shorter time to simulate the effect of a certain event than to perform an experiment, if the model is available. However, if not available, the model needs to first be developed and just doing an experiment may be much more efficient.

On top of that, the experiment may reveal certain aspects not covered by the model, e.g. unforeseen side reactions. A balanced choice between modelling and experimentation should be made.

The previous remarks should not be interpreted as a plea to strive for 'universal models', i.e. models that include everything. The strength of models lie in the fact that they are an abstraction of reality. The model should be fit for its purpose. In that sense, the purpose affects the shape of the model. E.g. the vapour pressure does not have to be included in the kinetic model of a liquid phase reaction. Vice versa, the user should not expect this model to represent the vapour pressure of the reaction mixture.

Hence, a pragmatic choice should be made between models and experiments or the combination of those. In our practice, we strive for the latter: where models serve as quantitative input for the hypothesis based research and where experiments serve as quantitative input for building and validating the models. This will be further exemplified in the section 4.

3. Providing Structure to Exploration

PSE provides a structured approach to problem solving. Methodologies have been and are being developed to provide this structure for (conceptual) process and product design. There are numerous methodologies: some of them make use of superstructures, others of heuristic and rule-based systems, again others of expert systems, and so on.

However, all of these methodologies have to start from somewhere, and it is our impression that typically a database forms the starting point. After the targets for the conceptual design are set, the tools start searching their database, retrieving information about the heuristic rules or parameters for the predictive evaluation. If the information is not available, the user is required to put in the specific information. We believe an open structure would be more useful allowing the user to selectively use those parts of the methodology that are of specific interest. Moreover, we believe the use of semi-predictive models would be beneficial.

Semi-predictive models require only a few data points for parameterization of the system of concern. As a physical property example, NRTL-SAC (Chen et al., 2006) and HSP (Abbott et al., 2013) require polymer solubility data in a few solvents to enable representation of the solubility of that polymer in a wide domain of solvents and solvent mixtures. It shows the strength of the intimate alignment of experiments and modelling, delivering an accurate representation with a small experimental and modelling effort.

We believe the power of the semi-predictive modelling approach is underestimated, not only for physical properties but in general. We would like to see more of these semi-predictive models. We believe these kinds of models have a better chance of providing representation at the required quality level, than extending the fully predictive methods with a higher order correction and extending their database. We believe semi-predictive models can be very powerful instrument in industrial R&D as they generate a high-precision representation but only need a few dedicated data points for parameterization. These data points should be obtained through well-designed experiments, the design of which could be based on the model.

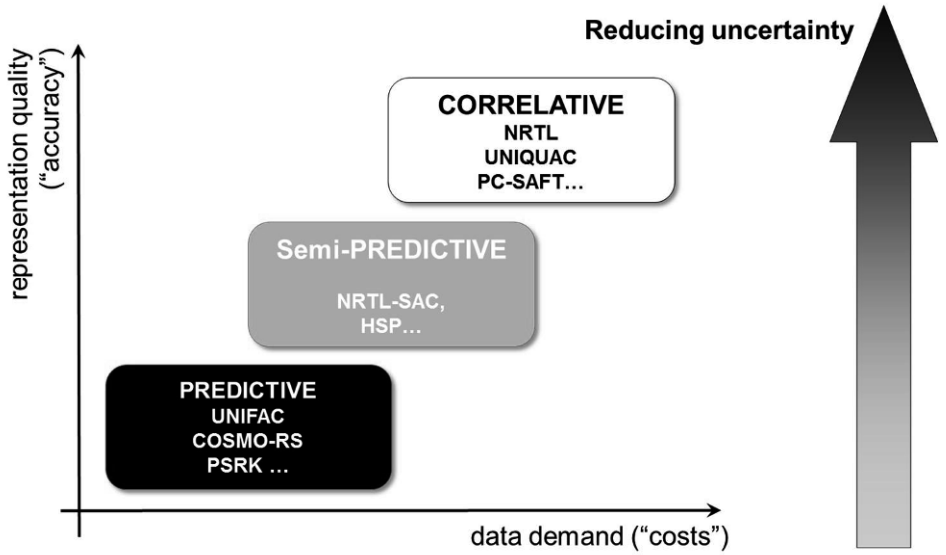

Figure 2. Different types of physical property models

Another intriguing trend in PSE is its application in product design. CAPE tools are finding their use in product design, which are derived from existing and proven methods in process design. The methods are typically based on reverse modelling: whereas in process design the properties of a mixture are calculated from the mixture composition, in product design the search is towards identifying constituents and compositions that match a desired property set (Gani et al., 2006). More and more use is made of PSE in product design and some even call it the third paradigm in process engineering (Hill, 2009). It is a very welcome trend that has the potential at least to enhance the typical trial-and-error approach in this area.

Another application area of PSE is related to PI (process intensification). It requires a different kind of approach than the methodologies based on unit operation modeling. It is encouraging to notice that methods are becoming available for this, like the function-based approach (Freund et al., 2008) that, in essence, is based on driving force analysis. Though the methods provide an excellent basis, in many cases they require very detailed and quantitative information of the process, e.g. a high precision kinetic model. However, in industrial reality the information is frequently not available at the necessary quality level, making the methods less applicable for an industrial environment. Nonetheless, the structured approach is still very interesting as it offers an excellent way for developing a PI assessment of a chemical process. In industry, we would appreciate a more open structure that does not require the very detailed information, but that can build on qualitative descriptions and reasoning.

4. Problem Solving Excellence

PSE can be applied industrially for problem solving excellence. PSE offers methods to deal with challenges like a malfunctioning process or poor control of quality, and to seize opportunities like a novel, lower cost and more environmentally friendly process for an existing product.

In process development projects we generally adopt a staged-wise approach, as schematically shown in Figure 3. In all stages, PSE methods and CAPE models play a crucial role. The integral process model is the technology backbone, giving directions to the type of experiments and integrating all information in a single place.

- In the first phase, preliminary investigations are conducted to obtain a first semi-quantitative impression of the technology. The derived preliminary techno-economic assessment provides data for the business case. As a result, already at a very early stage a picture is available of the potential benefits plus the technological challenges ahead. This translates into a time, resources and cost picture.
- The second stage deals with filling in the gaps. Experiments are conducted to collect the relevant data on which the model parameters are regressed. The operation and conditions of the experiments may be chosen differently than those of the targeted process system, aiming at simplifying the experimentation, easier interpretation of the results or a higher quality level of information. The model enables the translation from the experimental operation and conditions to those of the targeted process system. At the same time, the model provides a structure for designing the experiments. As example, reaction kinetics and vapor-liquid equilibria typically are measured separately and brought together in a process model, e.g. to evaluate the concept of reactive distillation.
- In the third stage, the developed model is validated against data from a pilot plant. It is the first time the targeted process is performed, e.g. the reactive distillation. The model serves as basis for the pilot plant design and the experimental plan. Based on the experimental outcome the model is validated.
- If needed, an additional stage is included. This might be the case if the fate of contaminants is unclear and the effect of closing the loops needs to be investigated. An alternative reason might be customer sample preparation. Quite often demo and pilot stages are combined.
- Finally, in the last stage, typically considered beyond the scope of the R&D project itself, the plant is designed, constructed, commissioned and started-up.

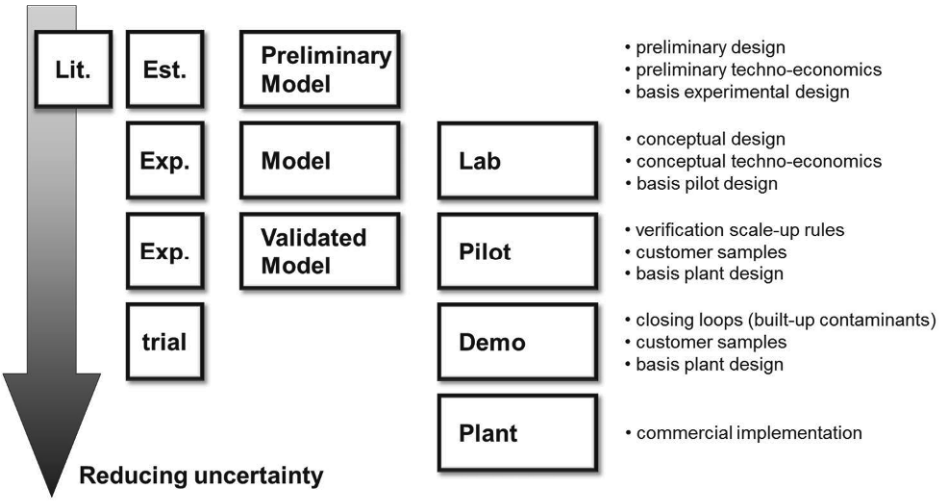

Figure 3. staged-wise approach in process development projects

In the practice of industrial R&D, there is tension between the business objectives posing constraints on time and budget, and the time and effort required for acquiring in-depth knowledge and developing quantitative models. Shortest time to market, or preferably shortest time to profit, and maximum financial benefits are key factors in the business context. So, how uncertain are we about the technology? And how does that uncertainty relate to acceptable risks and the health of the business case?

PSE offers a systematic platform assisting us in reducing the uncertainty of the technology. As a consequence it also helps us to better evaluate the business case, as it depends on the technology among others. From that point of view, our interest is not only about reducing the uncertainty but also we would like to know the level of uncertainty and its effect on the depending business risk. With respect to the latter, we would appreciate CAPE models that provide information about the reliability of the simulation outcome, preferably in a quantitative manner. Although a lot of effort is directed towards improving the chemical engineering models and process conceptual design, this area of uncertainty seems to be an area attracting less attention.

5. Conclusions

It is particularly useful to applying the basic principle of PSE in process development work. In process R&D the systematic engineering approach of PSE guides the laboratory experiments, it helps in interpreting the experimental observations and it assists in translating the results to other process configurations and conditions.

From a perspective of industrial R&D, we would like to suggest the following recommendations to the PSE community:

- extension of PSE methods in the area of PI,
- extension of PSE methods in the area of (conceptual) product design,
- development and application of semi-predictive methods,
- more attention to the subject of uncertainty in the PSE community.

PSE is more than just CAPE by offering a systematic and structured framework. Using principles of PSE, we strive for the best of both worlds integrating experimental or plant observations, and computer simulations. In this way, PSE enhances our problem solving excellence.

Sustainable Production of Liquid Fuels

Jonathan P. Raftery and M. N. Karim*

Texas A&M University, College Station, TX 77843, USA
nazkarim@che.tamu.edu

Abstract

Sustainable energy is the key to long term, global energy stability, which includes the need for a sustainable liquid transportation fuel. Ethanol and butanol are options to fill this energy need if they can be produced in an economical and sustainable fashion. This paper looks at various processes designed for the continuous production of ethanol and butanol via the biochemical conversion of lignocellulosic biomass. Processes designed for ethanol production include conventional separate hydrolysis and fermentation (SHF) as well as consolidated bioprocessing (CBP) with options for various biomass feedstocks and corresponding pretreatment technologies are optimized to determine the minimum breakeven selling price of the ethanol produced. The production of butanol via acetone-butanol-ethanol (ABE) fermentation and a gas stripping recovery process is also analyzed. It is found that both SHF and CBP processes give favourable economic outlooks, with SHF being favoured without energy generation and CBP being favoured when the waste is used for energy production. In addition, it has been shown that using continuous ABE fermentation with gas stripping is capable of producing a product stream with

Keywords: bioethanol, biobutanol, sustainability, consolidated bioprocessing, acetone-butanol-ethanol fermentation

1. Introduction

Though currently in the midst of the shale gas boom, the global, long term energy outlook will depend on the development of sustainable energy sources to displace the current petroleum-based energy sources. For this, many possible sustainable energy sources can be implemented, including wind, solar, geothermal and hydroelectric. While these forms of sustainable energy can displace much of the need of petroleum products, current energy needs also include liquid transportation fuels which the previously mentioned sustainable technologies cannot directly provide. However, sustainable liquid transportation fuels can be sustainably produced through the use of thermochemical or biochemical biomass conversion methods in the form of ethanol or butanol. Of these two conversion technologies, the biochemical production of ethanol from cellulosic materials produces the lowest amount of carbon dioxide emissions with the highest net energy yield and similar petroleum input (Farrell et al., 2006). A further analysis of these processes can be critical to ensuring a complete, sustainable energy future after petroleum.

Many different processes have been considered for the production of ethanol from lignocellulosic biomass. Traditional ethanol processes, termed separate hydrolysis and fermentation or SHF, involve the pretreatment of the biomass to degrade the crystalline

lignin structure, the use of enzymes to break down the cellulose and hemicellulose polymers to simple 5-carbon and 6-carbon sugars, then the fermentation of those simple sugars to ethanol (Humbird et al., 2011). Other process designs try to eliminate the use of enzymes through the use of genetically modified organisms with saccharolytic and ethanologenic capabilites, a process known as consolidated bioprocessing or CBP (Argyros et al., 2011; Ryu and Karim, 2011). Butanol is primarily produced as the main product of acetone-ethanol-butanol (ABE) fermentation using *Clostridium acetobutylicum* (Jones and Woods, 1986). These processes, while promising, are mostly batch processes that have not been implemented at the large scale, leaving doubts in their commercial feasibility.

This work examines continuous methods of ethanol and butanol production through biochemical means to determine the viability of continuous, sustainable processes to produce of liquid fuels. Focus is placed on the economic feasibility of ethanol production from both the SHF and CBP process designs. Energy generation through the use of the lignin waste products is also considered for both ethanol processes to reduce the external energy requirements of the processes. A novel process design for the biochemical production of butanol using ABE fermentation and gas stripping is also examined for overall feasibility of butanol production.

2. Methodology and Modelling

2.1. Ethanol Production

Separate hydrolysis and fermentation and consolidated processing are considered for the production of ethanol from lignocellulosic biomass. The process was designed to run for 350 days over a 10 year period, with a 5% interest added to the capital investment over that period. Each process is first considered with the use of external energy, and then the use of biological waste for energy production is considered as a way to reduce the utility and waste treatment costs of the plant. Biomass options for both processes were focused on those available in the state of Texas, USA, including sugarcane bagasse (SB), sorghum (SOR), hybrid poplar (HP), switchgrass (SW) and corn stover (CS) (State Energy Conservation Office). The total combined biomass flowrate to the process was constrained to be within 2,000 and 3,500 U.S. tons per day. Each biomass type considered has at least two pretreatment options available, based on available literature data, and include sodium hydroxide (NaOH), liquid hot water (LHW), dilute sulfuric acid (DSA) and ammonia fiber explosion (AFEX). Table 1 shows the pretreatment options considered for each biomass option and the source from which the data was taken. Due to consolidated bioprocessing only being applicable for cellulose fermentation, a separate fermentation path was required for the fermentation of the solubilized 5-carbon sugars. Ethanol recovery was done using a flash tank, distillation column and molecular sieve. Figure 1 shows the simplified process superstructure of both the SHF and CBP processes.

Mass balance, energy balance and cost models were constructed around each process unit. The objective is to minimize the selling price of the produced ethanol necessary to overcome the annualized capital, operating and labor costs of the plant. Global optima for each of the four mixed-integer nonlinear programs are found using the Couenne solver available in the GAMS modeling environment.

Table 1. Biomass and corresponding pretreatment options for the proposed bioethanol plant design.

Biomass Type	Pretreatment Available	Source
Sugarcane Bagasse	Sodium Hydroxide	Yu et al, 2013

2.2. Butanol Production

The production of butanol via ABE fermentation of a 60 grams/L glucose solution was analyzed using Aspen Plus. The process, shown in Figure 2, consisted of an immobilized cell bioreactor utilizing *Clostridium acetobutylicum*. The flowrate of the reactor feed is 1,000 L/hr with a reactor volume of 1,000 L, a dilution rate in the reactor of 1 hr^{-1}. Reactor yields of each product were determined based on the stoichiometry of the ABE reaction, as shown in Eq. 1 (Gottschalk 1979).

$$100\ \text{Glucose} \rightarrow 22\ \text{Acetone} + 56\ \text{Butanol} + 7\ \text{Ethanol} + 14\ \text{Acetate} + 4\ \text{Butyrate} + 211\ CO_2 + 135\ H_2 + \text{Biomass} \quad (1)$$

The effluent of this reactor is sent to a gas stripping processes consisting of two consecutive absorption columns that use a continuously cycling mixture of carbon dioxide and hydrogen as a stripping agent, chosen due to their production during fermentation. The outlet gas of each absorption column is condensed for recovery of the acetone, ethanol, and butanol products. A gas purge is used to prevent byproducts of the ABE fermentation from building up in the recycled stripping gas. Operation conditions in the absorption columns and condensers and the inlet composition and flowrate of the stripping gas was allowed to vary to determine the optimal mass fraction of butanol in the product stream subject to a recovery of 90% of the produced butanol during fermentation.

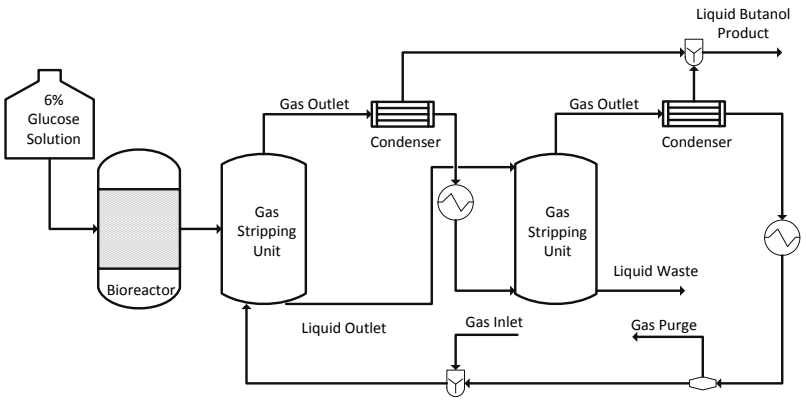

Figure 2. Butanol production through the use of ABE fermentation and gas stripping.

3. Results

3.1. Ethanol Production

Table 2 shows the optimal results for the four ethanol production facilities. Sugarcane bagasse, the cheapest of the five biomass options at $13.60 per ton, is chosen for separate hydrolysis and fermentation and is combined with a sodium hydroxide pretreatment option that provides the highest conversion its cellulose and hemicellulose to simple sugars at 96% and 86%, respectively. Consolidated bioprocessing is done most economically with a mixture of bagasse, sorghum and hybrid poplar pretreated with sodium hydroxide, dilute sulfuric acid and liquid hot water, respectively. While

sorghum with sodium hydroxide remains the primary biomass and pretreatment, the addition of sorghum with dilute sulfuric acid and hybrid poplar with liquid hot water reduced the xylan composition in the process, thereby reducing the size of reactor necessary for its processing.

From the economic results in Table 2 it can be seen that separate hydrolysis and fermentation is a more economical option for ethanol production in the absence of energy generation, due to the decreased ethanol production of the CBP process. When internal energy generation is considered, CBP becomes the a slightly more economically attractive production method due to the difference of $42 million in operating costs, attributed to the decrease in the organism, including enzymes and fermentation organisms, and utilities costs. Energy generation is based on the lignin content of the process waste, so its inclusion leads to an increase in the total biomass flowrate of the process, which also results in an increase of the amount of ethanol produced from each process.

Table 2. Optimal results for the separate hydrolysis and fermentation and consolidated bioprocessing process designs with external energy use only (SHF; CBP) and energy generation from biological waste (SHF-Energy; CBP-Energy).

	CBP	**SHF**	**SHF-Energy**	**CBP-Energy**
Ethanol Cost	$3.17	$2.97	$2.44	$2.42
Ethanol Produced (MM gal)	53.6	73.5	76.2	55.7
Biomass Flowrate (U.S. tons/day)	3,210	3,377	3,500	3,491
Sugarcane Bagasse	83%	100%	100%	81%
Sorghum	14%	-	-	15%
Hybrid Poplar	3%	-	-	4%
Pretreatment Type				
Sugarcane Bagasse	NaOH	NaOH	NaOH	NaOH
Sorghum	DSA	-	-	DSA
Hybrid Poplar	LHW	-	-	LHW
Process Costs				
Capital Cost (MM$/yr)	10.4	9.4	10.7	12.0
Operating Cost (MM$/yr)	138.0	170.8	135.1	93.6
Organism Cost	3.5	25.6	26.6	3.5
Utilities Cost	80.0	96.6	72.0	52.6
Waste Cost	20.7	21.1	8.1	0.0
Labor Cost (MM$/yr)	29.2	38.4	39.8	29.0

3.2. Butanol Production

Results for the optimized ABE recovery system are shown in Table 2. Small discrepancies in the mass balance can be attributed to minor adjustments made to the stoichiometry made in the Aspen simulation to allow for fermentation without the need for biological components. These results show that 90.3% of the butanol produced by ABE fermentation reaction can be recovered using a 2:1 ratio of carbon dioxide to hydrogen in the gas feed of the process, fed at a flowrate of 35.5 kg/hr. The recovered butanol exits the process at a flowrate of 13.5 kg/hr which consists of 13.28% of the total product stream. In addition, ethanol and acetone were also recovered with a flowrate of 1.16 kg/hr and 4.6 kg/hr, a yield of 85.14% and 75.16% respectively, and bringing the total ABE recovery to 86.6% overall. The optimal operating conditions for the process unit operations to achieve this butanol output are shown in Table 3.

Table 3. Process feed and outlet stream data for the proposed butanol recovery system using gas stripping with hydrogen and carbon dioxide.

Component	Feed Streams (kg/hr)		Outlet Streams (kg/hr)		
	Reactor Feed	Gas Feed	Gas Purge	Liquid Waste	Product Stream
Glucose	60.00	0.00	0.00	0.00	0.00
Water	956.00	0.00	2.67	875.40	78.40
Carbon Dioxide	0.00	23.50	51.74	2.29	4.65
Hydrogen	0.00	12.02	13.14	0.00	0.00
Acetone	0.00	0.00	0.27	0.87	3.46
Butanol	0.00	0.00	0.06	1.38	13.50
Ethanol	0.00	0.00	0.00	0.18	0.98
Acetate	0.00	0.00	0.02	2.47	0.54
Butyrate	0.00	0.00	0.00	1.17	0.10
Total Mass		1051.66			1053.28

Table 4. Optimal operating conditions for the various process units used for butanol stripping and recovery.

Process Unit	Manipulated Variable	Optimal Value
Stripper 1	Stage 1 Pressure	1.00 bar
Stripper 2	Stage 1 Pressure	1.00 bar
Condenser 1	Temperature	0.00 ℃
	Pressure	9.82 bar
Condenser 2	Temperature	17.97 ℃
	Pressure	0.11 bar
Heater 1	Temperature	37.00 ℃
	Pressure	2.00 bar
Heater 2	Temperature	37.00 ℃
	Pressure	1.00 bar

4. Conclusions

One of the major steps toward overcoming petroleum dependence in the area of energy is the production of a liquid transportation fuel that can be produced at commercial levels and is competitive with the economics of current gasoline and diesel production

processes. This work has shown that the continuous production of biofuels, both ethanol and butanol, is achievable. Two different biological processing platforms for the production of ethanol, separate hydrolysis and fermentation and consolidated bioprocessing, were analysed for their technoeconomic feasibility. It was shown that SHF performs better in the absence of internal energy generation, while CBP is a more viable option when energy generation is considered. In addition, the production and recovery of butanol through fermentative means was explored. By using a gas stripping process composed of two absorbers and a cycling hydrogen-carbon dioxide stripping agent it was possible to achieve a butanol recovery of 90.3% and an ABE recovery of 86.6% overall. These results are important steps toward the commercialization of biochemically based biofuels production as an alternative to petroleum-based options.

Industrial perspectives on the deployment of scheduling solutions

Iiro Harjunkoski

ABB Corporate Research, Wallstadter Str. 59, 68526 Ladenburg, Germany
iiro.harjunkoski@de.abb.com

Abstract

A scheduling optimization solution is in many ways still a complex and "exotic" function that seldomly finds its way into the daily practice of the industrial plant floor. Scheduling is too often seen as something decoupled and theoretical that requires high-level experts for using and maintaining it. In this paper we discuss some of the hurdles for deploying scheduling solutions. Some needs for improvements are identified both in academia and industry and by addressing the main pain points it can be seen that with a common mindset the complexity of scheduling can be lowered significantly.

Keywords: scheduling deployment, communication, integration, ISA-95.

1. Introduction

Despite many significant achievements in the development of scheduling methods and solutions, one important still unresolved technical challenge and hurdle is their deployment in an industrial context. Today the most typical and successful approach to bring a theoretical solution "live" is that plant experts directly collaborate with the university experts to locally build a solution that is tailored to their needs. This often results in strongly tailored implementations that are normally not reusable, which limits a wider distribution of novel approaches. Also, as a difference to hardware solutions (e.g. sensors), the life cycle of the locally developed scheduling solution heavily depends on the availability of the key implementers and the long-term strategic interest and commitment of the company management to maintain and further enhance the tools. Many scheduling companies successfully extend their businesses mainly building on already established technologies. This means that in times where cost- and process efficiency or throughput is valued higher than ever, it is not evident how novel optimization strategies that are today developed in academia can reach their end users. In the following we discuss challenges, lessons learned and ongoing trends affecting the scheduling. The cost and time aspects of deployment are key issues to be resolved.

2. An academic challenge

In general, the industrial need for new optimization schemes is growing and this has also been addressed by earlier PSE-events (Henning, 2009; Harjunkoski, 2012), highlighting some arising challenges. New communication technologies make it possible to collect and exchange information, which creates many opportunities for including a wider scope of aspects related to production. With the ever increasing availability of data and higher level of automation and electrification, production scheduling cannot anymore be seen as an autonomous solution. Concepts such as Internet-of-Things, Smart Grids, Smart Manufacturing, Big Data, Industry 4.0 and enlarged scope on Enterprise-wide Optimization topics (EWO, Grossmann, 2012)

increase the pressure to connect and interact with neighboring solutions and systems. To define what actually makes sense, what brings additional value and is technically feasible is also a clear academic challenge. Examples of this are the increasing research on industrial demand-side management taking advantage of the fluctuating price information of electricity (e.g. Mitra et al., 2014), as well as on integration of scheduling and control. A generic overview of the latter can be found in Engell and Harjunkoski (2012) and Baldea and Harjunkoski (2014), some concrete approaches are proposed e.g. in Subramanian et al. (2012). In a similar fashion, integration to the supply chain level (e.g. Maravelias and Sung, 2009) is important in order to receive up-to-date commercial order information, including their priorities. All of the above areas of research ensure, among others, that the provided schedule is aware of the surrounding environment as well as the underlying process. Figure 1 illustrates the required flexibility and dynamics of a modern scheduling solution.

Some of the main hurdles are identified in modeling and solution of the resulting problems. Modeling is a challenge when combining different optimization domains: how to express the main decisions and limitations in a compact and balanced way such that different targets are simultaneously met? One fairly common approach is bi-level or Lagrangean decomposition if enabled by the underlying problem structure. Especially in scheduling, the represention of time is very important and for instance in industrial demand-side management the process itself may need to be planned on a minute-level, whereas the electricity consumption only needs to be accounted for every 15 or 60 minutes. To solve the resulting models is mathematically challenging: Many of the complex requirements are non-linear and non-convex, which poses a main challenge to the solution algorithms. Also, by combining or expanding the models to cover more problem aspects, the number of decisions to be optimized often increases significantly, for instance through a larger number of binary variables. To make problems solvable, smarter modeling strategies are needed besides more efficient solution algorithms.

To summarize, even if this paper mainly focuses on the industrial aspects, the collaboration and inventive contribution from the academia is crucial to tackle the practical challenges faced by the industry – today and tomorrow.

3. Industrial realities

The principal question in the industry is where should a scheduling solution in the first place be located. In most industrial environments, a scheduling solution cannot live as an “island” but must be closely connected to the production environment – for instance to a distributed control system (DCS), manufacturing execution system (MES) or collaborative production management (CPM) system – in order to be able to automatically obtain all the production and process data that is important for scheduling.

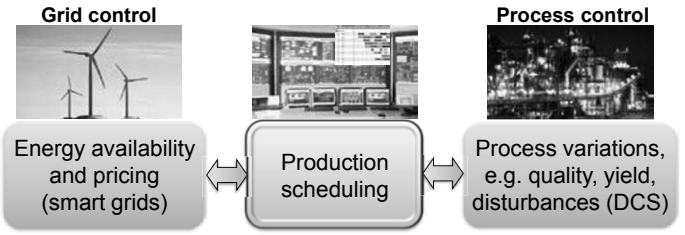

Figure 1. Scheduling dynamics – balancing between control systems

A connection to the enterprise resource planning (ERP) is also a must since the whole production is triggered by customer orders mostly entering via an ERP interface. ERP systems are further also used for procurement to ensure that all material and resources are available when needed according to the production plan. The connectivity issues is in fact one of the main differences between the academic and industrial focuses.

Another, even a more important aspect, is the cost and return of investment (ROI). For any company, an investment without clear and provable ROI is normally not approved. For this, typically the net present value (NPV) is used to account for future revenues and costs, c_n, using a discount rate, r. See Eq. (1), where N is the number of years considered. NPV however only gives a rough idea of how an investment compares to other alternatives and here the well known "garbage in – garbage out" law applies.

$$NPV = \sum_{n=0}^{N} \frac{c_n}{(1+r)^n} \quad (1)$$

Nevertheless, NPV is widely used as it is one of the few comparable metrics that can be calculated for each investment alternative. Here, a key challenge is how to reliably prove how much the improvement of deploying a new scheduling solution actually is. This is necessary also for defining the revenues (price tag), since few companies allow more than a couple of months to a year payback time on software investments. Two issues make it especially difficult to come up with hard facts or clear figures:

- A scheduling solution is a plan for the future production for which no exact reference exists – how to compare reality with a theoretical option?
- Real production is dynamic, it is often difficult to exactly follow a given schedule due to disturbances, uncertainties in processing times or involved manual decision steps

The common approach to evaluate the potential is to take a historical production schedule, extract the production orders and make a reschedule with a more "optimal" methodology to compare and prove a positive difference. This mainly works only in fully predictable environments as a future schedule cannot react to changes that are unknown by the time of the scheduling. Even if the potential improvement is significant, it is very important to be able to itemize each improvement factor in detail. Most of the current scheduling approaches do not directly support this. Both industry and academia must be involved in enabling a more reliable value proposition: Industry to provide some clear metrics to evaluate the goodness and information of the most common uncertainties and academia to build methologies that can also take these into account in the generation of production schedules, e.g. by serving multiple objectives.

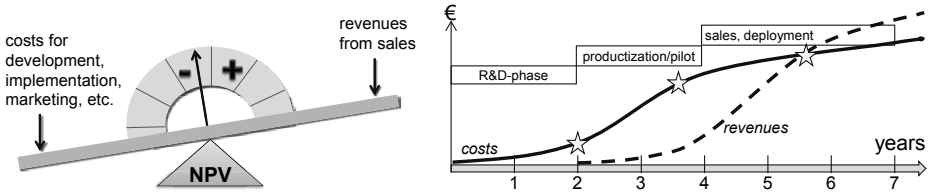

Figure 2. NVP should be positive for an investment decision, example costs/revenues on the right

In Figure 2, the NPV is simplified. On the right hand side typical cumulative costs (solid line) and revenues (dashed line) of a productization of scheduling are displayed.

A couple of remarks: The R&D phase constitutes to only a fraction of the total costs, as making a model into a maintainable product is a significant effort. Most products also imply a responsibility to deliver to promise with some responsibilities. In Figure 2, the R&D phase is assumed to be finished by year 2, productization including first pilot(s) starts at that point (leftmost star) and the market introduction of the product happens sometimes between year 3 and 4 (second star). Sales material, training, and direct deployment costs are also not to be neglected by advanced solutions such as scheduling. The revenues ramp up after the market introduction and first references but may slow down in some years as either competition has launched its products or an advanced function becomes a commodity. Therefore, in this theoretical example the payback time is around 5,5 years. This issue should nevertheless not be neglected as it may be one of the biggest hurdles for productization – how long a payback time can a company afford? Another observation is that in case a vendor wants to be profitable with a scheduling solution he needs most likely to sell more than 20 installations before reaching a profit. It is thus very important to shorten the productization time without losing the quality.

4. Communication challenge

As discussed above, new developments do not only challenge the solution algorithm developers, which are commonly from the academia when it comes to novel methods. In order to achieve faster solution response times, to tackle the modeling challenges when combining various domains into one concept and meet the expectations on solution quality, the deployment efficiency in the industries must be also significantly improved (Harjunkoski et al., 2014). Here one the key challenges is to create more modular and flexible systems that enable seamless data communication and even can combine earlier separated business models. This ensures that new opportunities can be exploited. Standards such as ISA-95 (ANSI/ISA-95.00.03-2005) can be helpful in paving the way for some of these tasks.

5. Lessons learned

It is important to acknowledge best practices and things to avoid from earlier deployment projects in order to ensure good quality and eliminate unnecessary costs. Framinan and Ruiz (2012) provide well-covered guidelines taking into account a multitude of deployment aspects. A thorough discussion on the lessons learned from practical implementations is given in Harjunkoski et al. (2014). Here we can only highlight a few facts. As already stated above, the success depends on resolving many practical issues, such as change management, deployability, ease of use, application development and maintenance. The following list highlights some of the major aspects:

- The production scheduler is finally responsible for the schedule and must also take some manual decisions, especially when there are conflicting goals between related organizations. His targets are safety, meeting customer orders and inventory targets, lower the manufacturing, inventory and logistics costs. He must feel supported by the scheduling tool in his everyday job having all critical information available to him. Also, the scheduling tool must be flexible enough to allow him to handle the disruptions in the production.
- The business opportunity in improved scheduling must be well recognized to ensure a full organizational support. This implies tracking certain metrics that depend on the quality of production scheduling, such as customer service level, sales volume, asset utilization, manufacturing costs, inventory costs, to name a few. The main challenge

here is to accurately estimate the impact of improved scheduling for establishing alignment of all stakeholders.

- Quick proof-of-concept study. At the beginning of any deployment project the following must be demonstrated: expected value of the improved scheduling process, ability to solve the problem, availability of data needed, how to integrate to existing scheduling process and information system. This should be accomplished within a few weeks.
- Effective system integration is a must since the scheduling model is only a small piece of an overall scheduling application. The software infrastructure must be capable of communicating with the ERP system as well as with spreadsheets and databases. Also, the generated schedule must be available to the scheduler in a flexible user interface.
- Effective user control also requires good graphical user interfaces (GUI). The scheduler must be able to response to dynamic changes in the production scheduling environment. Since it is practically impossible to incorporate all business considerations into a scheduling model the production scheduler must be able to manually modify some input data and adjust the resulting schedule to address unsolved business issues. Here, interactive Gantt charts and trend curves are enablers to more efficient use of the scheduling tool.
- The automated scheduling must be robust, i.e. the scheduling should always return a feasible schedule, even when the optimization would fail. The solution should also be scalable, i.e. able to solve the whole range of problem sizes in the daily business.

6. The implementation

The multitude of aspects that are discussed above require a systematic approach for the deployment. It is evident that all aspects may not apply everywhere, nor may it be difficult to fulfill all requirements and recommendations. Nevertheless, there are standards to support the integration by offering a uniform data structure. The ISA-95 standard (ANSI/ISA-95.00.03-2005) defines most of the required data fields and offers an XML-based integration that is very useful in a SW-context as it contains supporting functions such as XML-schemas. Many programming languages have built-in functions to enable easy handling of XML data. The XML implementation of the ISA-95 standard is called B2MML (business to manufacturing markup language) and a basic introduction with a simple example on how to use it for scheduling can be found in Harjunkoski and Bauer (2014). Using a standard avoids some problems in agreeing on the data design and also makes it easier to communicate between unrelated systems.

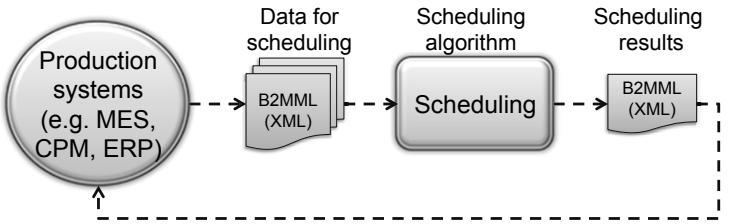

Figure 3. Scheduling as a part of a larger system

An example of the information flow between a production system and the scheduling algorithm is shown in Figure 3. Note that in Figure 3 we refer to the actual solution engine (main academic scope) – there can be a number of user interfaces including Gantt charts, planning sheets and order management embedded into the MES but those

imply mainly software programming and require normally no extensive optimization skills. The benefit of connecting to the scheduling algorithm via XML is that this makes it easy to plug it into an existing system and also enables the use of web services, i.e. where the algorithm is running on a remote server with powerful computing resources.

Another aspect is that ISA-95 is becoming the industrial standard between ERP and the manufacturing layer and there are an increasing number of trained professionals. Therefore, maintaining more generic data for instance in an ISA-95 database is much easier than collecting data that is specifically aimed for a certain scheduling model, the meaning of which is not clear to non-scheduling experts. Ideally, the B2MML data can be even used for modeling the scheduling problem in a more operator-friendly way using terminology that is closer to the operations. The most common B2MML-elements within the context of scheduling are listed in Table 1.

Table 1. B2MML-elements relevant for scheduling

Element	Description	Function
Equipment	Equipment resources to for planning	input
Material	Material relevant for scheduling	input
Personnel	Personnel required for planning purposes	input
ProcessSegment	Process structure (stages, steps)	input
OperationsDefinition	Production recipes for making a product	input
OperationsSchedule	Input: production orders, Output: schedule	input/output
OperationsCapability	Availability of resources, e.g. for shifts	input
OperationsPerformance	Feedback from the process, e.g. from MES	input

A small example of B2MML is given in Figure 4, where the beginning of scheduled order is shown. It shows the references to the recipe and resource decisions.

Figure 4. B2MML example on OperationsSchedule

Regardless of the use of standards, the path from an idea to a product contains several hurdles and requires commitment throughout the project as well as a wide pool of competences. Figure 5 summarizes the main steps. Unfortunately, each of the steps cannot be discussed within the context of this paper.

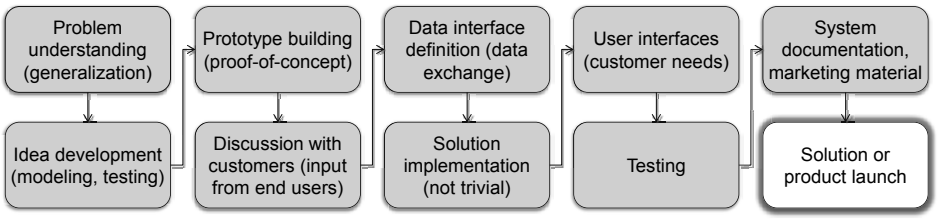

Figure 5. Generic development steps for any deployment project

7. Trends affecting scheduling

As everything else, scheduling is affected by changes in the environment and this section focuses on a few of them. The so called hypes or trends may not all be long-lived but they certainly also affect the expectations of the end users. Also, at least for researchers it is always desired to challenge the current state-of-the-art and investigate the true potential of emerging technologies. Below some of the relevant trends for scheduling are discussed.

- Internet of Things: This is the enabler for cyber-physical systems, which is the core of for instance Industrie 4.0 (Germany) and Smart Manufacturing (US) activities. What it basically means is that any device can be connected to the internet allowing both way communication across- or between plants. This makes new data available also to scheduling and supports more horizontal applications with decentralized decision making. Can scheduling benefit from this collaboration potential?
- Automation Cloud enables software applications be installed not physically in the plant but anywhere through either intra- or internet connection. This enables the use of much more powerful computing resources (e.g. parallel computing) and remote administration. Technically, it is possible to solve larger scheduling problems but there are still few algorithms fully taking advantage of this.
- Big Data technologies aim at analyzing large sets of non-structured data. This can enable new knowledge about the production identifying problems early or creating more accurate data-based models. The scheduling function can become more aware and knowledgeable about the underlying and surrounding processes.
- Smart Grids and Renewable Energy. These energy-related topics have increased the importance of energy for scheduling. It has already opened a bi-directional information flow making it possible for scheduling to adapt to changing energy availability and pricing (industrial demand-side management). Also, new processes related to energy may become part of the production planning.
- Mobility, Unmanned Sites and Remote Operations all contribute to more automated scheduling. The main idea is to increase the safety of operations, reduce costs and be able to monitor and interact with the process from anywhere at any time. Not having operators at hand puts more responsibility on the automated scheduling. This raises the global perspective possibly leading to larger problem instances.
- Service, for instance software as a service, provides a large number of opportunities, where basically the imagination is the limit. Can this be a way to make scheduling

easier deployable or provide a performance-based solution where the end-customer pays related to the quality of the resulting schedule or the computational efforts?

It is evident that fulfilling all of these aspects requires one or two decades of further developments. What it in any case shows is that the function of scheduling will have a central role also in a more automated and integrated industrial landscape.

8. Conclusions

This paper has summarized some of the main aspects and challenges of deploying scheduling solution into an industrial product, also including some ongoing and emerging trends. As scheduling is worthless as an "island" solution it is important to take the hosting environment into consideration. The natural "home" of a scheduling solution is within an operations management system. Moreover, the economic impact of scheduling should be stronger highlighted, where both academia and industry should collaborate closely. Often the deployment costs are so significant that this alone may hinder deployment projects. Thus one should be able to prove the actual value of a scheduling solution to the end customers. In order to partly reduce the implementation costs and to increase re-usability, standards should be applied.

Abstract

The smart factory in petrochemical industry is operational excellence as the goal, through the operational management of the whole process, with a high degree of automation, digitization, visualization, modeling and integrated refining chemical factory, which is the future development direction of the petrochemical enterprises. This paper discusses the development process of petrochemical industry smart factory, describes its architecture and key technologies. Then based on industry background, the paper gives a smart factory model definition. It puts forward thesis in production control, equipment management, HSE management, energy management, supply chain management and decision support six business domain as the focus, information technology and standardization to support the petrochemical smart factory "6+2" model framework. Finally, the paper points out the future development trend of smart factory and further research directions.

Keywords: process system engineering; petrochemical industry; smart factory

1. Introduction

The industry of petrochemical has become the large modern industrial system after decades of development, and it has made great contributions to the development of world economy and the improvement of people's lives. In recent years, the size of the petrochemical industry has been enlarged and industrial patterns have also changed considerably (Kadambur and Kotecha, 2015), which made regions play increasing role in the petrochemical industry, like North America, the Middle East and Asia-Pacific. The whole related industry has quickened the adjustment of the industrial structure, and began to transform from the stage of scale-economy to that of quality-effectiveness-economy. Product structure is reforming remarkably, and output of highly-performed, high value-added, specific chemical increase day by day (Industrie 4.0 Working Group, 2013). The development of petrochemical industry has been more and more limited by the resources and protection of environment. Driven by the Technology Revolution, the petrochemical industry will develop rapidly with the help of the technical innovation (Khosravi et al., 2015; Ramteke and Srinivasan, 2011). And the combination of new information technology, operation technology and manufacturing technology will bring great changes in the production patterns of petrochemical industry (Sa'idi et al., 2014).

In such background, traditional industry of petrochemical has not adapted to the requirement of the customer, market and the technology development. A new production pattern needs to adjust to the new changes of shorter product life cycle (Industrie 4.0

Working Group, 2013), to cope with the rapid upgrading of many types of products in small scales, to ameliorate the effectiveness resource optimization and energy utilization, to satisfy the need of global manufacturing and sustainable development of enterprises. Therefore, smart factory seems to be the best choice.

2. The emergence and development of smart factory

In recent years, Smart factory has been widely mentioned in the business and academic circles (Lucke et al., 2008; Radziwon et al., 2014). In some papers, Yoon et al.(2011) used Ubiquitous Factory (U-Factory), Zkule (2011) used Factory- of- Things (FoT) to explain the concept of smart factory. In addition, the key factor of Smart Process Manufacturing and German Industry 4.0 (Industrie 4.0 Working Group, 2013) is also smart factory.

2.1. Ubiquitous Factory

The PARC in Xerox put forward the concept of ubiquitous computing, which allows the small, low-cost, networked devices to distribute in various places in our lives (Weiser, 1991; Zuehlke, 2010). In the model of U-computing, people can acquire and process the desired information by any method, anytime, anywhere. As the development of sensor net, RFID etc., the U-Computing has many specific forms, such as U-home (Lai et al., 2013) etc.. Yoon (2012) came with up the concept of Ubiquitous Factory. He pointed out that the frame of the U-Factory should integrate the information technology, advanced manufacturing technology and automatically complete the whole industrial process through the data acquisition and exchange of workers, resources, products and systems. The frame mainly consists of four parts: U-human, U-Resources, U-Product, and U-MES.

2.2. Factory-of-Things

MIT founded the Auto-ID Center, and Ashton (2009) put forward the concept of the Internet-of-Things (IoT), which means that all items are connected through the RFID and the Internet, can realize the intelligent identification and management. The IoT requires that items automatically acquire and process data, exchange information with other items (Maass and Varshney, 2012). The IoT is more like an uncertain and open network, in which the intelligent devices and pseudo entities are endowed enough capacities to complete the required operation independently according to the goal and circumstance (Lucke, et al., 2008). Based on the IoT, Zuehlke (2010) held the opinion that the future factory should be the Factory-of-Things (FoT). In this mode, intelligent devices interact with each other on the basis of semantic services. Devices inside of the factory can achieve specific goals through self-organization. Zuehlke (2010) explained the concept with four dimensions: technology, framework, security and human.

2.3. Smart Process Manufacturing

The research on the Smart Process Manufacturing (SPM, 2010) has been conducted by the Engineering Virtual Organization (EVO). The EVO developed the roadmap of Smart Process Manufacturing and defined the SPM as: an integrated, knowledge-enabled, model-rich enterprise in which all operating actions are determined and executed proactively applying the best possible information and a wide range of performance metrics.

2.4. Industry 4.0

Industry 4.0 is based on the Cyber Physical Systems (CPS), and realized the novel manufacturing method (Industrie 4.0 Working Group, 2013). The CPS is that the devices are connected to the Internet, which makes them have the ability of computing, communication, accurate control, remote coordination and autonomy (Håkansson and Hartung, 2014). Therefore, the CPS realized the fusion between the virtual cyber world and the real world. The core of the Industry 4.0 is that a highly flexible, personalized, digital smart manufacturing pattern which was established by the real-time web and effective communications among people, equipment and products. In this mode, the production process becomes more distributed, and scale effect is no longer the key factor of industrial production; the product becomes more specific, and the future product will be produced in the custom-made pattern; and the users will participate in the production throughout the whole process.

3. Research progress in smart factory of petrochemical industry

3.1. Modeling and Simulation

The modeling and simulation of enterprises is a very important way to research on these entities, and it can also provide strategies for the enterprises' operation and management. Since the manufacturing process of petrochemical is usually very complicated, many key technological parameters cannot be obtained directly, the producing systems are also multi-scale in time. It is an indispensable method to have a better understanding of the whole production process with the development of models and simulation systems. In the early period of the research of smart factory, Pei and Rong (2005) came up with a smart factory simulation platform based on Matlab, which is the prototype of the smart factory. Zhang and Rong (2005) put forward an enterprise logistics balance layered modeling theory according to the ISA-95 standard, which was also used to develop the decision support system of smart factory. Zhu et al. (2013)conducted the research about the information integration of smart factory and put forward an information integration solution in the multi-scale perspective. Qi et al.(2013) came up with a four-storey framework for modeling and simulation. This method was used to construct the multi-layered and modular simulation systems.

3.2. Intelligent Control

Intelligent control is derived from conventional control, which is used to deal with the complex processes that cannot be controlled by traditional methods. The intelligent control systems mainly have the following characters: learning function, adaptive function and organizing function (Sun, 2007).

Bhuvaneswari et al. (2012) used the artificial neural network to maintain the pipelines and make fault diagnosis of them. Monedero et al. (2012) developed a decision-making system based on data mining technology and kernel of neural networks, which is used to make predictions for future optimization. The test results showed that this decision system can help reduce about 7 % energy consumption. The system will be piloted in the petrochemical industry. Sa'idi et al. (2014) built a Risk-based maintenance model through fuzzy logic method, and used this model to conduct the risk assessment of failures in Abadan oil refinery, Iran. Yüzgeç et al. (2010) optimize the control operation of the short-term plan of the petroleum refining using the Model Predictive Control method.

3.3. Intelligent Optimization Algorithms

The research of optimization for petrochemical engineering is quite significant, which mainly includes global optimization methods and heuristic methods. These methods are intriguing interest for researchers at current time, especially applicable for the complicated that cannot be dealt with by tradition approaches (Yu, 2007).

Kadambur and Kotecha (2015) optimized the production plan of petrochemical industry based on Teaching-Learning-Based-Optimization algorithm. Compared with traditional methods, this approach can increase the profit about 8.16 %. Zhou et al. (2015) optimized heated oil pipeline based on Particle Swarm Optimization-Differential Evolution method, which can save 17.59 % of energy cost in the application of 2640 m^3/h oil transfer. Lavric et al. (2005) used Genetic Algorithm to optimize the conversion rate of hydrogenated waste to hydrogen. By using this algorithm, an oil refinery factory in Iran can increase 22.6 % hydrogen products and save about 1.9 million every year. Ramteke and Srinivasan (2011) solved the refinery crude oil scheduling problem by combining the Genetic Algorithm and Graph-based Representation method. Khosravi et al. (2015) optimized the parameters of shell and tube heat exchangers to maximize the thermal efficiency by using three methods: Genetic Algorithm, Firefly Algorithm, and Cuckoo Algorithm.

4. The definition and framework of smart factory in petrochemical industry

On the basis of the above study, in the context of the petrochemical industry, we believe that smart factory in petrochemical industry is operational excellence as the goal, through the operational management of the whole process, with a high degree of automation, digitization, visualization, modeling and integrated refining chemical factory, which is the direction of future development of the petrochemical enterprises. Through the revolution of technology and business, the enterprises could have the outstanding capabilities of perception, prediction, interoperability, analysis and optimization. The smart factory mainly contains six core business, four capabilities, and two supporting systems. The framework of smart factory in petrochemical industry can be shown in Figure 1.

Moreover, the factors of smart factory in petrochemical industry consist of characteristics, capabilities, key business areas, intelligent application fields and key technologies. The details are presented in Table 1.

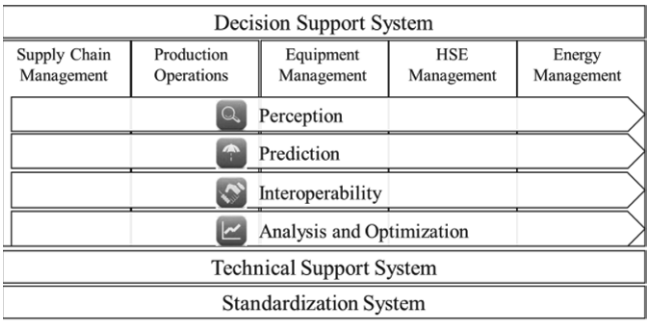

Figure 1. The framework of smart factory in petrochemical industry.

Table 1. Factors of the smart factory in petrochemical industry.

Factors	Descriptions
Characteristics	Digitization, Visualization, Modeling , Integration , Automation
Capabilities	Perception, Prediction, interoperability, Analysis and Optimization
Business Areas	Production Operations, Equipment Management, Energy Management, HSE Management, Supply Chain Management, Decision Support
Intelligent Application Fields	Business Intelligence, Manufacture Intelligence, Control Intelligence
Key Technologies	Optimization Technology, Artificial Intelligence, Control Technology, Information Technology, Petrochemical Technology

5. Conclusions and future researches

Establishing the smart factory is the important measure to handle the shortage of the gas and oil resources, the update of the oil quality, the optimization of industrial structure, the fierce competition in the global market, energy conservation and emission reduction, and environmental protection. The prospects of the smart factory are listed as below:

For equipment, traditional manufacturing units will be gradually changed to be the smart manufacturing units which have capacity of state acquisition, perception and can make intelligent predictions, optimizations and decisions; the smart control systems can optimize multi-devices, conduct self-study and -organize; the industrial robots are also used in the harsh conditions of the petrochemical production processes.

For technology, the knowledge based on analysis of the big data will be developed, which can help realize the combination of the massive information of heterogeneous perception; the technology of the combination of virtual reality and visualization will be widely applied in the petrochemical field; the modeling technology of complex systems, collaborative optimization technology etc. will make great progresses; the molecular technologies and ‘green’ system engineering will be spread in this industry.

For business, the construction of the smart factories in petrochemical industry can be divided into three process domains: production operations, petrochemical supply chain and whole lifecycle management.

Abstract

Pharmacokinetic modeling allows predicting the drug concentration reached in the blood as a consequence of a specific administration. When such models are based on mammalian anatomy and physiology it is possible to theoretically evaluate the drug concentration in every organ and tissue of the body. This is the case of the so-called physiologically based pharmacokinetic (PBPK) models. This paper proposes and validates a procedure to deploy PBPK models based on a simplified, although highly consistent with human anatomy and physiology, approach. The article aims at reducing the pharmacokinetic variations among subjects due to inter-individual variability, by applying a strategy to individualize some model parameters. The simulation results are validated respect to experimental data on remifentanil.

Keywords: Pharmacokinetics; Physiologically-Based modeling; Complexity reduction; Lumping; Personalization; Remifentanil.

1. Introduction

The knowledge of drug concentration reached in blood and tissues is fundamental information in the medical field. In fact, it allows understanding the drug bio-distribution extent and the related pharmacological effects. The purpose of pharmacokinetics (PK) is to evaluate how the drug administered to a patient is affected by the body activity in terms of absorption, distribution, metabolism, and excretion (*i.e.* the so-called ADME elements). Ordinary PK studies are characterized by an empirical source and require sampling of blood at various time intervals to determine a concentration-time profile. When organ and tissue concentrations are also required, this activity becomes even more critical, as the sampling of tissues is a highly invasive practice in particular in case of human patients.

PK models were originally conceived as tools to evaluate the drug concentration-time curves in blood with the target of limiting/reducing the experimental activity. Those models were formulated by defining simple mass balances for the drug respect to few controlled volumes, which resembled the schematization of continuous stirred tank reactors (CSTRs) as the ones commonly solved in chemical engineering problems. A detailed description of such models is available in Wagner (1993), while a modern application of compartmental models is reported in Laínez-Aguirre *et al.* (2014). These

models have the limitation to asses only the drug concentration in blood. More sophisticated models, designed to study drug distribution in the whole organism, are based on human/mammal anatomy and physiology.

By considering a rather high number of compartments, it is possible to reproduce a simplified mockup of the mammalian organism. This can be achieved by assigning to every compartment a correspondence to a given organ or tissue. These are the so-called physiologically based pharmacokinetic (PBPK) models, which are obtained by interconnecting the compartments according to a faithful similarity respect to mammal anatomy. Himmelstein and Lutz (1979) published an extended review of these models. A whole-body PBPK model, commonly taken as reference, is the one proposed by Jain *et al.* (1981). In that study the rat body is partitioned into 21 compartments that are mathematically described by a system of 38 ordinary differential equations (ODEs) and 98 adaptive parameters. Some of these parameters may be estimated from either experimental or literature information, but 37 require to be fitted by means of a nonlinear regression procedure. When the number of regressed parameters is so high the mathematical procedure (*i.e.* nonlinear regression) becomes risky and inaccurate, despite the detailed description of the PK in the different organs. In addition, the amount of experimental data necessary to carry out the nonlinear regression is so high and complex that the model itself becomes almost useless and too much specialized to the specific mammalian body respect to which the experimental data are measured.

Drugs can be administered via several routes (*e.g.*, enteral, parenteral, inhalation, topical). In particular, as far as the parenteral route is concerned, the body absorption is considered complete and practically instantaneous, so that the entire dose is readily available for distribution in the organism. Conversely, in case of oral (*i.e.* enteral) administration, the drug bioavailability is a function of gastrointestinal absorption. This point introduces a significant and challenging complexity in the model. Specific intestinal absorption model for drugs available in the literature feature quite complex formulations and nevertheless do not usually take into account the amount of drug released in the intestinal lumen prior to absorption. The most well-known model of this category is the compartmental absorption and transit (*i.e.* CAT) model proposed by Yu *et al.*(1996a,b), and afterwards slightly modified and finally commercialized as ACAT model (Agoram *et al.*, 2001). Recently, Pavurala and Achenie (2012, 2013) proposed a model that couples the CAT model with a drug dissolution one. By doing so, they analyzed the entire process of oral absorption. Del Cont *et al.* (2014) published a model considering the physical processes determining drugs release from an ensemble of poly-dispersed, swelling, and not eroding polymeric particles. Mošat' *et al.* (2013) implemented a PBPK model for the rat based on a program that can automatically generate an ODEs system, featuring a vascular network structure. They identified also the optimal set of parameters that describe the cyclosporin PK.

Some drugs are characterized by a peculiar phenomenon occurring as a consequence of bile recirculation during digestion that is named enterohepatic circulation (EHC). This is due to the fact that a drug fraction in the liver is excreted with the bile, which accumulates and concentrates in the gall bladder, and is finally reintroduced into the intestine. This causes a double intestinal absorption for a certain fraction of the dose, and produces the characteristic *double peak* in the PK concentration-time curves. This aspect is often neglected because of the modeling complexity introduced, but it is important as the EHC extends the drug permanence in the organism. Jain *et al.* (2011) proposed a simple PK model accounting for this feature.

Several authors focused on reducing the complexity introduced when a large number of compartments are accounted for and proposed to lump the organs and tissues that show

a similar behavior respect to drug distribution. On one hand, this practice can reduce the model complexity but on the other hand preserves the physiological consistency (*e.g.*, Gueorguieva *et al.* (2006); Nestorov *et al.* (1998)). Reduced complexity PBPK models are rather common. For instance, Di Muria *et al.* (2010) devised a simplified model based on just seven compartments, which lump together organs and tissues as a function of affinity to blood perfusion. Indeed, they assumed that a higher blood perfusion is related to a faster drug distribution. Consequently, the poorly perfused organs and tissues are lumped into a single compartment called Tissues, while the highly perfused ones are considered with the blood in the Plasma compartment. That model is characterized by a system of 7 ODEs and 22 adaptive parameters, which can be either determined from the literature or by a nonlinear regression respect to experimental data. Abbiati *et al.*(2014) adopted a similar approach but they moved the anatomical and physiological consistency a step forward by proposing a personalization of some parameters that took to the so called patient-individualized PBPK definition. This PK modeling has to face some challenging issues, first of all the inter-individual variability among patients. In fact, the PK profile is affected by a large number of aspects (*e.g.*, sex, body mass, age, health status, race) that cause the concentration to vary in a rather wide interval. To address this problem, this paper proposes a strategy to individualize the PBPK model respect to some given characteristic of the patient (*e.g.,* body mass (BM), body surface area (BSA), sex). An interesting potential of PBPK models is that they can be applied also to small/medium size mammals (*e.g.*, mice, rat, monkeys) and scaled up to humans, even if this practice is quite challenging and somehow risky in terms of consistency (Kenyon, 2012). Another field where PBPK models can play an important role is the cancer-fight, since antitumor drugs have often negative side effects that limit clinical trials. A further possible action to improve the predictive feature of PBPK models consists in supporting the pharmacokinetics with the pharmacodynamics. This coupling makes viable the evaluation of the pharmacological effect induced by the drug concentration on the action site (Meibohm and Dorendorf, 1997).

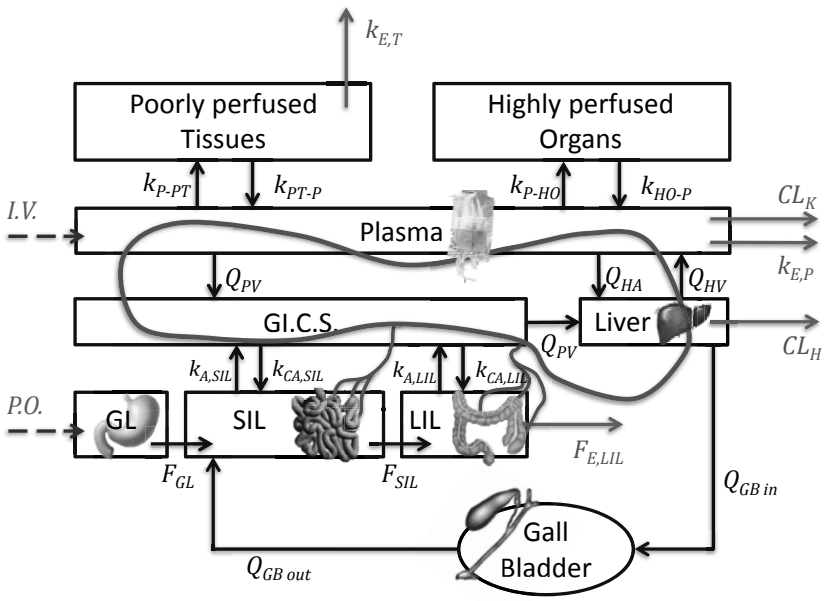

Figure 1: PBPK model structure.

2. Methods

The PBPK model proposed in in this paper draws inspiration from the work of Di Muria *et al.* (2010) but implements a new formulation of the compartmental structure and the related equations (see also Abbiati *et al.*, 2014). The model goal is to be consistent with the absorption, distribution, metabolism, and excretion (ADME) processes which characterize the presence of drug in the body. Section 2.1 analyses in depth the model, while Section 2.2 discusses how some of the model parameters can be personalized.

2.1. Model structure

Figure 1 shows how the proposed PBPK model is structurally organized. In the following, we provide a description of the model centered on its anatomical and physiological consistency. For the sake of conciseness, some details are not fully commented but can be found in Abbiati *et al.* (2014).

The model is based on nine compartments. The gastrointestinal tract features the gastric (GL), the small intestinal (SIL), and the large intestinal (LIL) lumina. If the drug is administered as an oral bolus ($P.O.$) it passes through the stomach and intestinal tracts with a fraction being finally eliminated with the faeces ($F_{E,LIL}$). The absorption from the intestine into the blood circulation system is a complex phenomenon, which is treated in a simplified fashion. We assume that the SIL is responsible for most of the absorption/diffusion into the $GI.C.S.$, as those blood vessels receive the drug from the intestine and bring it to the liver. Because of its morphology, the SIL should be considered as a longitudinal duct, *i.e.* similar to a plug flow reactor (PFR) in terms of modeling conceptualization. To avoid the solution of partial differential equations (PDE) originated by the axial and time variables, the PFR can be spatially discretized into a series of continuously stirred reactors (*i.e.* CSTRs). By doing so, the PDE is reduced to a set of ODEs, which are numerically simpler to solve. A specific mass transfer coefficient ($k_{A,SIL}$) quantifies the body absorption. However, it is worth considering also a dual phenomenon based on the so-called active expulsion mechanism that is induced by glycoprotein P. That mechanism sends back to the intestinal lumen a fraction of the absorbed drug and allows introducing in the numerical model a counterdiffusion mass transfer coefficient ($k_{CA,SIL}$) along with the typical PSE terminology. These two coefficients are different because the wall of the intestinal lumen is not isotropic and therefore diffusion and counterdiffusion phenomena are not equimolar. Finally, a similar modeling approach is adopted for the LIL, which is considered as a single compartment as its contribution to drug absorption respect to the SIL is much reduced if not minimal.

Once the drug reaches the blood circulation, it moves to the liver, which is an important metabolic site. Here a fraction of drug molecules reacts to give metabolites, the related term being the hepatic clearance (CL_H), while another fraction is excreted into the bile. Here the EHC takes place; the drug conveyed to the gall bladder is then delivered to the SIL. Again, according to the PSE terminology, the drug is recycled to the SIL compartment. The drug portion that remains unmodified in the liver reaches the systemic circulation. Here it can be either distributed in every organ and tissue of the organism or eliminated (see terms $k_{E,P}$ and CL_K). The extended PBPK structure shown in Figure 1 can be treated in a simplified version in case of endovenous administration as the gastrointestinal tract can be neglected. This takes to a reduced five-compartment model, whose numerical model is reported in Equations (1-5).

$$\frac{dC_P(t)}{dt} = -C_P(t)\cdot\left(\frac{k_{P-PT}}{R}+\frac{k_{P-HO}}{R}+\frac{Q_{HA}}{V_P}+\frac{Q_{PV}}{V_P}\right)+C_{PT}(t)\cdot k_{PT-P}\cdot\frac{V_{PT}}{V_P}+C_L(t)\cdot\frac{Q_{HV}}{V_P}+ C_{HO}(t)\cdot k_{HO-P}\cdot\frac{V_{HO}}{V_P}-C_P(t)\cdot\frac{k_{E,P}}{R}-C_P(t)\cdot\frac{CL_K}{V_P}+\frac{IV(t)}{V_P} \quad (1)$$

$$\frac{dC_{GICS}(t)}{dt} = -C_{GICS}(t) \cdot \left(\frac{Q_{PV}}{V_{GICS}} + \frac{k_{CA,SIL}}{R} + \frac{k_{CA,LIL}}{R}\right) + C_{SIL}(t) \cdot k_{A,SIL} \cdot \frac{V_{SIL}}{V_{GICS}} + C_{LIL}(t) \cdot k_{A,LIL} \cdot \frac{V_{LIL}}{V_{GICS}} + C_P(t) \cdot \frac{Q_{PV}}{V_{GICS}} \quad (2)$$

$$\frac{dC_L(t)}{dt} = -C_L(t) \cdot \left(\frac{Q_{HV}}{V_L} + \frac{CL_H}{V_L}\right) + C_P(t) \cdot \frac{Q_{HA}}{V_L} + C_{GICS}(t) \cdot \frac{Q_{PV}}{V_L} \quad (3)$$

$$\frac{dC_{PT}(t)}{dt} = -C_{PT}(t) \cdot \left(k_{PT-P} + k_{E,T}\right) + \frac{C_P(t)}{R} \cdot k_{P-PT} \cdot \frac{V_P}{V_{PT}} \quad (4)$$

$$\frac{dC_{HO}(t)}{dt} = -C_{HO}(t) \cdot k_{HO-P} + C_P(t) \cdot \frac{k_{P-HO}}{R} \cdot \frac{V_P}{V_{HO}} \quad (5)$$

2.2. Model identification

One of the challenging activities of PK modeling is the difficulty to deal with patients' variability, which depends on a number of factors as discussed in the Introduction. To account for this variability, the adaptive parameters of Equations (1-5) are subdivided into three main categories: (i) individualized, (ii) assigned, and (iii) degrees of freedom (DoF).

2.2.1. Individualized parameters

Whenever experimental or literature data about the dependency of anatomical and physiological values from patient features are available, it is possible to exploit their characteristics to evaluate the adaptive parameters. For instance, the volumes of organs and cardiac stroke volume are assessed as a function of patient's sex and body mass.

If the body surface area value is available, Cowles *et al.* (1971) propose for the human cardiac stroke volume (CO) the following formula:

$$CO = 3.5 \cdot BSA \quad (6)$$

Conversely, if the body mass value is known, Lindstedt and Schaeffer (2002) propose:

$$CO = 0.084 \cdot BM \quad (7)$$

To assess how the cardiac stroke volume is conveyed to a specific organ, Williams and Leggett (1989) list a set of coefficients that depend on the patient's sex. Similar information, but related to the volume of organs can be found in Brown *et al.* (1997).

2.2.2. Assigned parameters

Some parameters cannot be individualized, however they are available in literature as experimental data. In this case the value is assumed constant for every patient.

2.2.3. Degrees of freedom

Because of its simplified nature, the PBPK model accounts for some parameters that cannot be determined from either literature or experimental data because they do not have a real physiological meaning. For instance, this is the case of the mass transfer coefficient of the lumped organs compartment. It is then advisable to implement a fitting procedure to identify the adaptive parameters based on available PK experimental values. A nonlinear regression routine minimizes the objective function that measures the distance between the experimental concentrations and the model predicted values by modifying the adaptive parameters that play the role of DoF.

3. Model validation

Both identification and validation of Equation (1-5) model were performed by considering the PK of an analgesic drug, *i.e.* remifentanil based on two available literature studies. The former PK study (Egan *et al.*, 1993) was used to identify the DoF as discussed in Section 2.2.3; the latter PK study (Westmoreland *et al.*, 1993) was used to validate the model predictions respect to the experimental data.

For what concerns the DoF evaluation, a bounded optimization process allows identifying the optimal DoF within a suitable feasibility region. Table 1 lists the optimal DoF values and assigned bounds. Once identified, the DoF values are assumed as

known and constant for any future application of the model that was tuned for that specific drug (*i.e.* remifentanil).

Table 1: Optimal values of the DoF in the PBPK model of Equations (1-5).

Parameters	Value	Unit of measure	Lower Bounds	Upper Bounds
Eff_H	0.144	-	0.1	0.3
Eff_K	0.394	-	0.1	0.7
$k_{E,P}$	1.732	min^{-1}	0	3
$k_{E,T}$	0.063	min^{-1}	0	3
k_{HO-P}	0.044	min^{-1}	0	2
k_{P-HO}	0.662	min^{-1}	0	2
k_{P-PT}	0.479	min^{-1}	0	1
k_{PT-P}	0.279	min^{-1}	0	1

Westmoreland *et al.* (1993) studied the PK of remifentanil administered through an endovenous injection of four doses (2, 5, 15, 30 µg/kg) to an equivalent number of mixed groups of patients. Every group (composed by 6 patients) was treated as a hypothetical individual with averaged body characteristics. The knowledge of the BM of single patients allowed the personalization of some parameters, while the remaining ones were either assigned from literature values or calculated by a nonlinear regression respect to the Egan *et al.* (1993) work. Figure 2 shows a comparison between experimental values and PBPK model predictions.

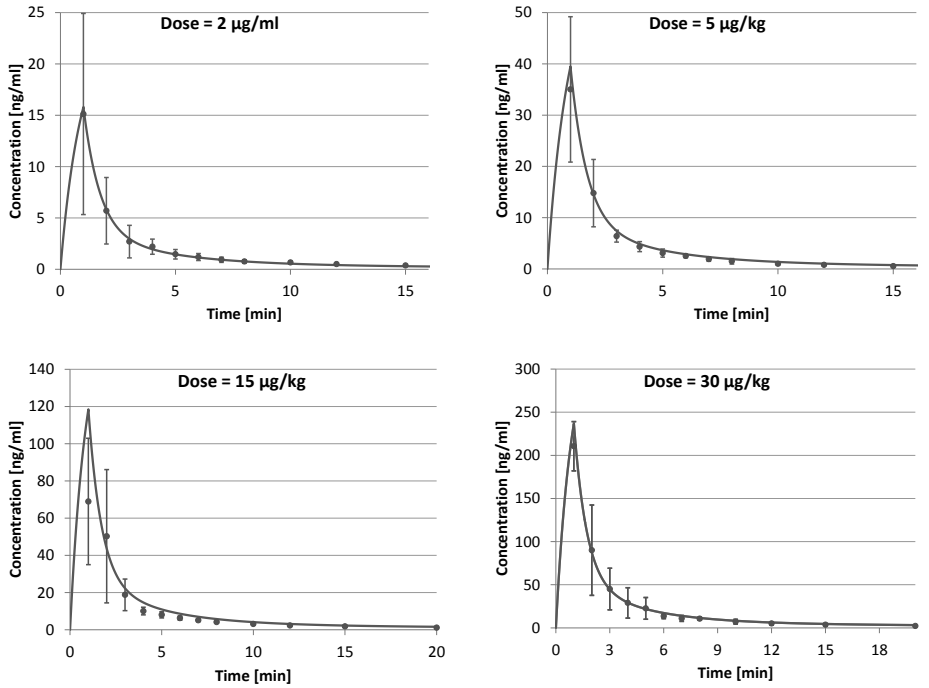

Figure 2: Comparison between model prediction (line) and experimental data (points with standard deviation) from the Westmoreland *et al.* (1993) study.

The model predictions are analyzed in terms of proximity to experimental values (see Table 2) by considering two important PK indicators (*i.e.* the area under the curve, AUC, and the blood peak concentration, C_{MAX}).

Table 2: AUC and C_{MAX} percentage distance between experimental data and model predictions.

	Group 1 [2 µg/kg]	Group 2 [5 µg/kg]	Group 3 [15 µg/kg]	Group 4 [30 µg/kg]
$\Delta\ AUC$ %	9.3	7.5	30.4	5.9
$\Delta\ C_{MAX}$ %	4.5	12.8	71.7	12.9

To assess the usability of mathematical tools in PK studies, one can refer to the specifications issued by FDA (1997) about the level-A IVIVC thresholds that recommend a percent Prediction Error, %PE = 100·[(observed value – predicted value)/observed value] lower than 10% for both C_{MAX} and AUC. Indeed, the predictions reported in Table 2 are lower than or pretty close to the 10% thresholds with the exception of Group 3. However, such values are not only badly described by the PBPK model but they are also scarcely consistent with the experimental data observed in the other groups (*i.e.* #1, #2, and #4). For instance, Figure 2 shows how the trends of peak values measured for Groups 1, 2, and 4 are much higher than the Group 3 one.

4. Conclusions

The capability to asses in a reliable and reproducible way the PK profiles of specific patients administered with different active principles is one of the main objectives of pharmaceutical researchers. This paper proposed and discussed a PSE approach to PBPK modeling. The human body was described as a system of interconnected compartments, whose mathematical behavior is assumed similar to interconnected CSTRs. The mathematical formulation of the PBPK model was tailored to the specific human subject by applying as far as possible correlations, available in literature, for the determination of the adaptive parameters (either general or individualized). The remaining unknown parameters were estimated by a nonlinear regression procedure. Simulations results are encouraging as the blood concentration-time curves, obtained with the individualized parameter set, show a rather good consistency. The AUC, which is the reference PK parameter in pharmaceutical studies, is close to the experimental one for at least three out of four predictions. In addition the single experimental data points are pretty well forecast by the model, which is not just within the standard deviation window but also close to the central value of the distribution. A possible improvement of the model would consist in further enhancing its personalization capability by having more detailed information related to single patients.

Abstract

The increased availability of software tools for solids-based process modeling has created opportunities to enhance pharmaceutical development through the use of models. In particular, recent work in the area of integrated process modeling has demonstrated the potential of these simulations to complement experimental studies during process development. Once developed, these models also facilitate the use of other mathematical tools like process feasibility analysis and optimization. This work will emphasize recent developments in the area of flowsheet modeling for pharmaceutical processes. Methods for feasibility analysis and optimization of these complex process models will also be discussed. These tools can play an important role in pharmaceutical process development.
Keywords: flowsheet modelling, feasibility analysis, surrogate-based optimization

1. Introduction

The use of continuous processes for pharmaceutical manufacturing has been increasingly discussed as a strategy for reducing manufacturing costs and enhancing product quality. Despite the potential to realize economic and quality advantages through continuous manufacturing, adoption of this technology within the pharmaceutical industry has been slow (Plumb, 2005). This may be due in part to the new and unique challenges associated with process development for continuous, solids-based systems. Among these is the need to develop accurate and computationally efficient predictive models for particulate processes that can be used for simulation and optimization. These models can supplement experimental work during process development and suggest optimal operating conditions for product manufacturing (Gernaey et al., 2012). In addition, process models can be used to explore design space and optimize process performance (Boukouvala & Ierapetritou, 2013). This work will focus on the development of integrated process models for continuous tablet manufacturing processes and the use of these models for process design and optimization applications. The use of reduced-order modeling as a tool for flowsheet improvement and surrogate-based optimization will also be discussed.

2. Integrated flowsheet modeling

Modeling solids-based processes is challenging due to the nature of granular flows. The behavior of bulk granular materials is influenced by particle-level phenomena, which makes it difficult to develop continuum equations describing powder flows (Muir Wood, 2008). Although these particle-level phenomena can be described using discrete element method (DEM) simulations (Ketterhagen et al., 2009), the computational

expense associated with DEM renders it prohibitive for flowsheet modeling and optimization applications. Therefore it is necessary to develop lower-order, semi-empirical and empirical models for pharmaceutically relevant unit operations. This has been accomplished for a variety of processes including continuous powder blending (Boukouvala, Dubey, et al., 2012), roller compaction(Hsu et al., 2010) and wet granulation(Marshall et al., 2013). In recent years, flowsheet models that integrate these various unit operations have been developed using gPROMS^{TM} ModelBuilder. These can be used to simulate continuous tablet manufacturing processes via methods including wet granulation (Boukouvala, Chaudhury, et al., 2013), dry granulation and direct compaction (Boukouvala, Niotis, et al., 2012).

2.1. Integration of reduced-order models

While detailed process models are preferred for process simulation, these models are not always available. In these cases, reduced-order or data-based models can be implemented (Boukouvala et al., 2011). Reduced-order models can be used to bridge the gap between experimental knowledge or high-fidelity (e.g. DEM) simulations and equation-oriented process models. For instance, PCA-based reduced-order models have been shown to facilitate efficient and accurate representation of distributed parameter information from DEM simulations (Boukouvala, Gao, et al., 2013; Rogers & Ierapetritou, 2014). These reduced-order models evaluate in a matter of cpu-seconds (as compared with hours or even days for DEM) and are therefore much better suited to flowsheet modeling applications. Figure 1shows an example of a flowsheet model that incorporates particle velocity information from a discrete-element reduced-order model (DE-ROM). The flowsheet model represents a continuous feeding and blending process that consists of three loss-in-weight feeders and a single continuous blender. A reduced-order model is used to predict distributed axial velocity information within the blender as function of the agitator rotation rate. This information can be used to model the residence time distribution within the blender. The flowsheet model has been used to simulate the dynamic response of the continuous blending system to a disturbance introduced by refill of one of the loss-in-weight feeders, Feeder A. The results of this dynamic simulation are shown in the chart in Figure 1, where the black line indicates the concentration of component A entering the blender and the red line indicates the concentration of component A exiting the blender. The feeder refill occurs at t=100 seconds and immediately thereafter the concentration of component A entering the blender increases sharply. This increase in concentration is dampened due to the residence time distribution in the blender, as indicated by the broader concentration profile at the blender exit. Through the use of a reduced-order model it is thus possible to simulate the dynamic response of the continuous blending process to a transient disturbance.

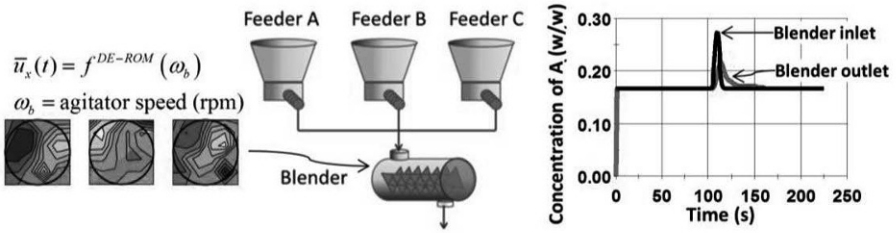

Figure 1: Flowsheet simulation for a continuous feeding and blending process. A discrete-element reduced-order model is used to obtain distributed axial velocity information in the blender.

3. Pharmaceutical process optimization

In the previous section it has been shown that flowsheet models can be developed to simulate solids-based pharmaceutical processes. While these models are useful for scenario analysis, they may not be well suited to applications requiring a large number of model evaluations. Integrated process models can incorporate tens of thousands of equations, making them difficult for deterministic optimization solvers to handle efficiently (Jones et al., 1998). In addition, the use of reduced-order models within flowsheet simulations can make it difficult to obtain gradient information. For both of the aforementioned reasons, surrogate-based optimization strategies may be needed to optimize processes that are described by integrated flowsheet models (Boukouvala & Ierapetritou, 2013).

Surrogate-based optimization, also referred to as black-box or response-surface optimization, describes the use of input-output mappings to approximate a complex process model followed by the use of this response surface for optimization purposes (Jones, 2001; Jones et al., 1998). The response surface is more computationally efficient to evaluate than the original flowsheet model and may also have other desirable properties such as smoothness. Surrogate-based strategies can be used to optimize objectives related to cost or profit for continuous pharmaceutical manufacturing processes. For instance, Boukouvala and Ierapetritou (Boukouvala & Ierapetritou, 2013) have demonstrated the use of a kriging response surface to minimize the cost of a continuous direct compression process for tablet manufacturing. Surrogate-based methods can be extended to constrained optimization problems by incorporating a black-box feasibility stage (Banerjee & Ierapetritou, 2002). In the context of pharmaceutical manufacturing, constraints can be placed on product quality and the feasibility test problem can be solved in order to identify boundaries of the process design space. Establishing design space is a particularly important aspect of process development given the current focus on quality by design (QbD) in the pharmaceutical industry(Yu, 2008).

Important considerations when implementing a surrogate-based optimization algorithm are:

- Selection of a reduced-order modeling method for surrogate development
- Balancing sample requirements with computational cost during model development
- Assurance of convergence to a global optimum

Surrogate models can be developed using a variety of methods including, but certainly not limited to, quadratic response surfaces, radial basis functions, artificial neural

networks and kriging interpolators (Jones, 2001). In the current work we will present surrogate-based strategies that employ kriging response surfaces. Kriging is selected for its ability to model highly nonlinear and dynamic processes, and due to the demonstrated efficacy of kriging in pharmaceutical process modeling (Boukouvala et al., 2010, 2011; Jia et al., 2009). In order to balance sampling requirements for surrogate-model development with the computational expense associated with large numbers model evaluations, many surrogate-based optimization algorithms include an iterative model improvement phase. The selection of additional samples during the model improvement phase can be guided by an expected improvement function, which seeks to identify samples that are likely to improve the current best value of the objective function given the accuracy, or lack thereof, of the surrogate model (Jones et al., 1998). Kriging response surfaces are well-suited to the use of an expected improvement function, as the variance of the kriging predictor can be estimated at each point on the response surface (Kleijnen, 2009). In the context of surrogate-based feasibility analysis, the modified expected improvement function introduced by Boukouvala and Ierapetritou (F. Boukouvala & M. G. Ierapetritou, 2012) can be implemented. This function guides sampling towards the boundaries of the feasible region in order to provide an accurate representation of black-box constraints with a limited number of model evaluations. Demonstrating convergence to a global solution is an ongoing challenge in the area of surrogate-based optimization. Several authors (Agarwal & Biegler, 2013; F. Boukouvala & M. Ierapetritou, 2012) have recommended the use of a surrogate-based global search coupled with a local trust-region search in the area surrounding the optimum to ensure global convergence. These methods can be applied to constrained global optimization problems, so they are appropriate for pharmaceutical applications which often involve strict constraints on product quality.

3.1. Surrogate-based feasibility analysis

For pharmaceutical applications, surrogate-based feasibility analysis is of particular interest, as it can be used to inform the selection of process design space. Feasibility analysis can be used to identify the limits within which acceptable product quality can be achieved. In general it is recommended for the design space to be well within those limits in order to ensure process robustness.(Chatterjee, 2012) Given the importance of selecting a design space conservatively relative to the boundaries of the feasible region, it may be desirable to explicitly account for surrogate model prediction error in pharmaceutical applications. When a surrogate model based on kriging is used, it is straightforward to account for model inaccuracy through the variance of the kriging predictor. This can be accomplished as shown in Figure 2, which depicts the feasible region for a roller compaction process with respect to the bulk density of the entering powder (ρin) and the inlet angle (θin), an estimated model parameter. The formulation of the feasibility test problem for this process has previously been described in the literature (F. Boukouvala & M. G. Ierapetritou, 2012; Hsu et al., 2010). In this case, the variance of the kriging predictor can be explicitly added to the feasibility function in order to ensure that the surrogate model is conservative relative to the original process model. This is shown in Figure 2, where the black line indicates the boundary of the feasible region obtained from the original process model and the boundary of the surrogate-based feasible region is shown in blue. Although the surrogate model is quite accurate, it is still possible for an infeasible point to be classified as feasible approximately 1 percent of the time, as established over a validation set of 10,000 samples. In order to avoid operating outside of the feasible region, the conservative

approximation of the feasible region is shown in red can be used. This approximation takes into account the variance of the kriging predictor and is always conservative relative to the original process model.

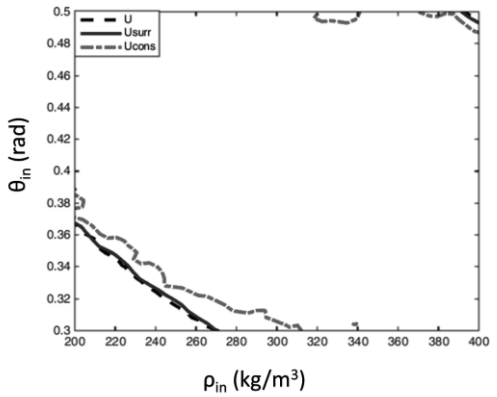

Figure 2: Surrogate-based feasibility analysis for a roller compaction process. The feasible region obtained from the original process model (U) is shown in black. The surrogate-based feasible region (Usurr) is given in blue. The conservative approximation of the feasible region (Ucons) is shown in red.

4. Conclusions and future perspectives

Recent advances in solids-based process modeling have made it possible to develop integrated process models for pharmaceutical applications. The use of reduced-order models can help to enhance the accuracy of these flowsheet simulations for pharmaceutical applications, as demonstrated by the case study in Figure 1. Flowsheet simulations have many potential industrial applications for pharmaceutical process development. Among these is the use of process models to guide design space selection. This requires the use of surrogate-based optimization methods, which can be applied to complex and computationally expensive process models.

The developments discussed in this work indicate the exciting potential for the implementation of modeling and optimization tools within the pharmaceutical industry. However there is still much work to be done in the area of pharmaceutical process modeling. For instance, models that can explicitly account for the effect of bulk material properties on the performance of solids-handling unit operations would improve the accuracy of pharmaceutical process models. Also, models that can better capture the dynamics of continuous processes, such as residence time distribution approaches, would improve the ability to model the response of continuous systems to transient disturbances. Within the area of surrogate-based optimization, there exist many ongoing challenges related to surrogate-model development and global algorithm convergence. Ongoing work to address these challenges can help to improve the solution speed and accuracy of optimization problems involving pharmaceutical flowsheet simulations.

Abstract

New technologies are developed at a high rate in many areas like in process industries. Basis for new technologies are inventions and innovations generating intellectual property rights. By licensing, permission is granted to others to use these rights under controlled circumstances. Technology licensing often includes not only patents but for example also know-how, design and trademarks.

Drivers for in- or out-licensing of process technologies are manifold. Some very important drivers include, reducing own development risks, speeding up commercialization, earning royalties or partnering with other companies, all of which are business reasons. Engineering know-how of the in-licensing party is necessary to assess the technology, the own development options, the fit within the companies' value chain, and foremost, to calculate the cost benefit using a new process technology. Relevant engineering know-how of the out-licensing party is in offering and selling the technology: engineers need to describe the advantages for licensees, design and optimize the process, or calculate potential license fees by analyzing the benefits of the technology for the licensee.

The licensing business requires continuous development of the licensed technology. Processes need to be analyzed and continuously improved. Specific and optimized designs for licensees are required based on the licensee's design or optimization targets and constraints. Examples from ongoing business will be used to describe the engineering-business-interface.

Keywords: Commercialization, Intellectual Property, optimization, process.

1. Introduction

Licensing is known to almost everyone from software licenses or from patent licensing. It is an important basis of different businesses and has become more popular and relevant within the last years: for example, royalties from patent licensing have increased in the US from US$15 billion in 1990 to more than $110 billion in 2000 (Poltorak and Lerner (2004)). Many petrochemical, chemical or pharmaceutical companies are active in the licensing business. Most universities are spending money for a technology transfer department trying to commercialize results of their employees, like chemical engineers, in different stages of technology development. Licensing as a business model is an interesting option to commercialize technologies especially if inventions are involved.

Commercialization of technology products, e.g. by licensing, is mainly relevant to engineers in Business-to-Business (B2B) relationships, where sellers and buyers are often engineers or other scientists, who mostly perceive marketing as a discipline of minor importance. But, due to the organizational realities, as well as market, technological and competitive uncertainties, the marketing concept and a modification and adaption of standard tools like the Marketing Mix are of high importance (Mohr et al (2005)), and marketing of technology products in B2B markets is a distinct discipline (Taylor (2013)). The characteristics of B2B markets are described for example by Hutt and Speh (2007), Homburg et al (2013) and Kotler and Keller (2009).
In Technology Licensing, engineers in business and technology development are working closely together forming the interface across which all relevant information is passed to achieve a successful commercialization with advantages for suppliers and customers. Characteristics of licensing and examples from the chemical industry are described.

2. What is Licensing?

A useful description is: "A license is, simply stated, permission to do something the granting party (the licensor) has the right to otherwise prohibit". (Poltorak and Lerner, 2004). In the case of intellectual property (IP), licensing is an agreement between the owner of IP and another party (the licensee) to use the licensed rights in exchange for compensation.
According to the World Intellectual Property Organisation WIPO, "Intellectual property (IP) refers to creations of the mind, such as inventions; literary and artistic works; designs; and symbols, names and images used in commerce. IP is protected in law by, for example, patents, copyright and trademarks, which enable people to earn recognition or financial benefit from what they invent or create. By striking the right balance between the interests of innovators and the wider public interest, the IP system aims to foster an environment in which creativity and innovation can flourish." (WIPO 2015)
Therefore, different forms of licensing are present in different markets, like

- Character and entertainment licensing,
- Corporate trademark and brand licensing,
- Fashion licensing - Designer fashion, names and brands,
- Sports licensing - Major sport leagues,
- Art licensing - Literary and artistic works, performances, broadcasts,
- Science & Industry - Scientific works, discoveries and any inventions in all fields of human endeavour.

The most relevant types of licensing are depicted in Figure 1: Cross-licensing – each party allows others to use its IP; Exclusive licensing – licensor provides the right to use IP only to one licensee exclusively; Non-exclusive licensing – licensor provides the right to use the same scope of IP to several licensees; Sub-licensing – is an agreement given by a licensee to a third party, under the rights of the licensee originally granted by the owner of IP to licensee.

3. Technology Licensing

Technology Licensing is a special form of IP licensing. "Technology can be defined broadly as "know-how," more specifically (with respect to a firm), as the information required to produce and/or sell a product or service." (Capon and Glazer (1987)). Often, know-how is patentable and patents can be licensed. Also, and important to technology

licensing, Know-How itself can be licensed requiring a confidentiality agreement between the supplier of know-how and the user. Technology licensing often includes a license to execute patents, use know-how received under confidentiality and use a registered trademark to sell the products.

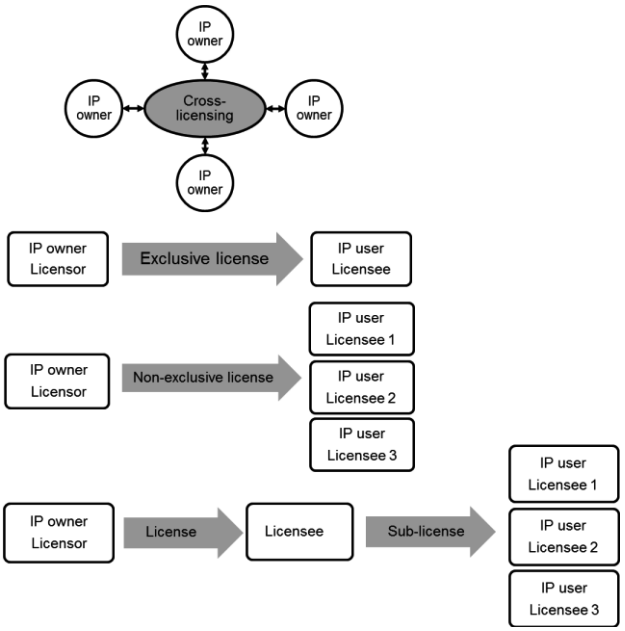

Figure 1: Types of licensing

Technology licensing is different depending on the status of technology development. Based on Megantz (1996), four stages of technology development can be described:

• **The basic-research results stage** – The technology is an early development by R&D specialists. Commercial implications are difficult to estimate.

• **The prototype-development stage** – Prototype units are generally available, but documentation is still preliminary. Market viability and manufacturability are to be proved.

• **The pilot production stage** –Technology has been proved in terms of functionality and manufacturability, but not in the market. There are sample units built and documentation is finished.

• **The industrial stage** – Last stage of the technology development, at which the technology has been successfully marketed. Several plants have been purchased and built. The economic viability and utility are proved.

In general, the more advanced the stage of technology development is, the easier it is to market it. Usually, the first stage at which a company can try to market the technology is prototype stage. However, the risk for customers is very high and not many of them decide to license technology which is only in the second stage of the development. Moreover, the more advanced technology is and the more often its performance has been proved, the higher value it has.

In the chemical industry, technology licensing has a long tradition. At the beginning of the 20th century, cross-licensing agreements between few dominating chemical companies have been used to increase market entry hurdles into the chemical market.

Technology licensing in this industry became popular after World War II, in order to make a profit from innovations. Since then the market for chemical technologies started to grow rapidly (Fosfuri (2006), Arora (1997)). Many petrochemical, chemical, pharmaceutical and engineering companies are active in licensing, some of which even with a focus on licensing. Even search engines for licensed technologies by chemical companies exist on the internet.
An overview of advantages and disadvantages of technology licensing is given Table 1.

Table 1: Advantages and disadvantages of technology licensing

	Advantages	Disadvantages
For Licensor	• Partnering/shared resources • Financial revenues from IP • No production investment • No production risk • Access to new markets • Some control of innovation and technology development	• Specialized personnel with technology and commercial skills • Less revenue than by own production • Potential competition by licensee • Commercial success depends on licensee
For Licensee	• Partnering/shared resources • Lower risk • Faster access to market • Access to new technologies for further development	• Technology not ready for commercial use • License fee as additional cost • Dependence on licensed technology

4. Examples from BASF

4.1. Hydrogen separation based on CELTEC®

BASF has a broad portfolio of research projects that ideally get transferred to prototype-development and pilot production before becoming an industrial product and solution. Due to technical and commercial challenges, only a fraction of research projects reach the pilot phase.
For more than 10 years, BASF had developed the CELTEC technology, a membrane electrode assembly (MEA) for high temperature polymer electrolyte membrane fuel cells based on a sol-gel-process for the membrane production (Seel et al (2009), Schmidt and Baurmeister (2007)). The MEA comprises of several components, namely a proton conducting membrane and two gas diffusion electrodes (Figure 2 left).
CELTEC can also be used for hydrogen separation. Hydrogen is catalytically activated at the anode and protons are transported through the membrane. The technology can increase the yield of chemical processes or recycle hydrogen in industrial processes.
After fuel cell customers qualified the product and started to order larger quantities, BASF invested in production capacities. A team of chemists and engineers set up a highly complex production process including the production of catalyst, polymer solution and membrane, coating and sintering processes, the automatized assembly of MEAs and a state-of-the art test and qualification facility (Figure 2 right).
Since market growth lagged behind expectations, BASF decided to terminate the MEA business. In order to secure the material supply for the fuel cell industry as well as for the hydrogen purification process, BASF approached potential licensees. Since no company could take over the complete production, the business was divided into three

main activities and products: membrane, gas diffusion electrode, and MEA. BASF initiated close links between the players of the value chain to promote the business success. The licensees agreed to pay a fix fee and royalties based on the quantity of the products sold. In return, they have access to the respective BASF patents, know how, and in the case of the membrane also to the production equipment.

- Membrane-license: The licensee took over the polymer solution and membrane casting line from BASF. During a technology transfer phase, the licensee was trained to run the sol-gel-process and meanwhile also produces a new generation membrane based on recent developments by BASF.
- Electrode-license: The gas diffusion electrodes (GDE) are responsible for the anode and the cathode reaction in the MEA. The production process is sensitive, and includes the production of catalyst, coating with microporous layer and with precious metal catalyst. BASF identified two licensees. One of them is the leading producer of electrodes for chlorine-alkaline electrolysis. The company acquired the former brand of the GDE and invested in coating equipment. The technology transfer covers all Standard Operating Procedures and Quality Processes, as well as practical support during coating and sintering runs. Additionally, a customer was asked to ensure the testing and qualification of the GDE.
- MEA-license: BASF found two companies to license the MEA-production technology. The licensees received all the necessary documentation, equipment specifications, quality procedures as well as a training session at the BASF MEA manual production facilities. BASF keeps the manual manufacturing lab for the time being to support licensees and to ensure the supply of large-area MEAs for hydrogen purification.

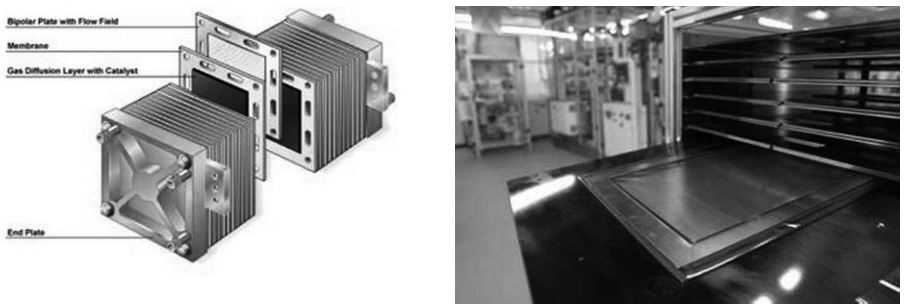

Figure 2: Left: Fuel Cell stack with MEAs (membrane, gas diffusion electrodes), separated by bipolar plates, endplates including current collector. Right: MEA production line

4.2. Selective hydrogenation SELOP®

An example of technology licensing on industrial stage is selective hydrogenation of hydrocarbon streams from steam crackers. Steam crackers are the main source of hydrocarbons for the chemical industry by cracking various hydrocarbon feedstocks to C1-C5+ streams serving as the basis for many value chains.

Depending on cracker feedstock and cracking conditions, the hydrocarbon streams are containing amounts of unwanted, for example unstable components, or compositions of isomers, that are not beneficial for downstream processing (Müller et al (1995). Catalysts have been developed during many years suitable for the different hydrocarbon chains and the specific selective hydrogenation purposes, e.g. hydrogenation of diolefins to olefins with low hydrogenation of olefins to paraffins or isomerization (Büchele et al (1996)). Selective hydrogenations have to be customized for each and every feedstock, steam cracker and site conditions based on different catalysts, reactor design and process flowsheets.
Technology licensing in the field means, to be able to select and supply the suitable catalyst and to design the optimum process flowsheet for the customer. Technology licensing in a mature industry often is not focused on patents, but more on know-how, that is only supplied to the licensee under confidentiality. A key success factor for licensing is, to provide know-how on the whole process in design, construction, start-up and operations. But, continuous development of such technology is also required to stay competitive.

4.3. Butadiene extraction

Butadiene is the raw material for many elastomers, ABS (acrylonitrile butadiene styrene polymer), in low quantities for nylon and few others. It is used in the industry since around 1930. Butadiene is mainly produced from liquid cracker's C4 fraction, but also from butane or butene dehydrogenation.
BASF is licensing a process for extractive distillation of butadiene based on the solvent N-methylpyrolidone (NMP). Other important solvents in the market are dimethylformamide and acetonitrile. The BASF process is successfully marketed for around 50 years and continuously improved to deliver economical and ecological benefits to the customer (Heida 2007). Improvements for example are made to increase capacity based on new distillation column packing (Hugo et al (2011)).
All technology licensors strive to have their technology recognised in the market as BAT (best available technology). Getting there requires a good invention or innovation, entrepreneurship and most of all a willingness to accept risk. Staying there requires to further invest in R&D over an extended period of time and to integrate key lessons learned or findings from all sources including licensees.

5. The roles of chemical engineers and process optimization in process technology licensing businesses

Some key factors for successful technology licensing businesses are, based on evaluation of several studies and own experience, market, competitor and technology evaluation, choice of partners, uniqueness of technology, unique selling proposition, customized design, service, continuous development, IP rights, marketing strategy, negotiation process and agreement conditions.
Engineers are playing a key role in process technology licensing since they are involved from the early beginning of technology development until a phase out of such technology in all of above mentioned key factors. Not only are engineers involved in classical engineering task like process R&D, process design and optimization, but also, they are involved in business tasks like identifying market need, market segmentation, set-up of business model, strategy development, and operative strategy implementation

in marketing and sales. Typical tasks in in-licensing and out-licensing as listed in Table 2 are corresponding and experience in one area greatly facilitates activities in the other. All of these tasks directly relate to the marketing and sales or purchasing of the technology license. Therefore, engineers usually are active in engineering as well as in marketing and sales to enable educated decisions to the benefit of supplier and customer.

Table 2: Typical engineering task for out- and in-licensing of process technologies

Out-licensing	In-licensing
• Offering and selling the technology: Engineers need to describe the advantages for licensees • Design and optimize the process • IP-generation • Calculate potential license fees by analyzing the benefits of the technology for the licensee	• Assess the technology • Evaluate own development options • Analyse technology fit within the companies' value chain • Calculate the cost benefit using the process technology

As described by examples in Section 4, one key factor for successful technology licensing is customization of the technology. Typically, boundary conditions and constraints for implementing the technology at customers differ in certain ranges and are given as so called battery limits. The battery limit conditions are used to design the process technology. In some cases, the realization of a technology requires equipment installation outside battery limits at the customer, creating additional investments. One important task for the engineer therefore is to optimize the technology in a way to minimize the total investment and at the same time keep production cost low so that the investment stays not only profitable but is more profitable than competitor's technology. At the same time, safety and environmental features of the technology and of the products produced with the technology have to comply with highest standards. Process design and optimization therefore are crucial elements in process technology licensing and need to take multiple objectives into account.

In recent years, process optimization underwent a strong development (Biegler (2014), Floudas and Gounaris (2009)). Methods and tools are slowly becoming implemented in industry. But currently optimization tools are still non-standard, for example due to parallel catalyst and process development or due to complex changes in battery limit conditions during the project planning phase so that the flow sheet has to be adapted quickly. But, there is implementation in industry ongoing (Asprion et al (2014), Burger et al (2014)). It can be assumed that the methods and tools will be further improved with regards to optimization of multi-objectives, flow-sheet, safety and environmental performance of process and products, but also with user friendliness.

6. Conclusions

Licensing is an interesting option to commercialize existing and new technologies, incremental and breakthrough innovations. Chemical engineers play key roles in licensing in the chemical industry in R&D, Engineering and in marketing and sales. Successful technology licensing requires specialized and dedicated marketing and direct interface of R&D, engineering and marketing with the customer.

Abstract

In this work, we consider the systematic economic plantwide control design procedure proposed by Skogestad (2004) and from this we derive practical rules that can be used to devise close-to-optimal control structures based on engineering insight. We attempt to present these rules in an easy-to-understand fashion and exemplify them on a simple but quite famous reactor-separator-recycle plant case study. We successfully demonstrate that while Skogestad's procedure requires an optimization of the plant model under various disturbances in order to be fully utilized, using its practical rules, combined with a good engineering insight of the process, can facilitate the design of a close-to-optimal control structure by suggesting what should be controlled and how.

Keywords: Self-Optimizing Control, Economic Plantwide Control, Advanced Process Control

1. Introduction

Designing a control structure for an entire chemical plant, that ensures safe and stable economic operation, is known as economic plantwide control. Energy integration, smaller in-process inventories and material recycles, all contribute to an increase of operational complexities and thus a plantwide perspective becomes crucial when designing control systems for such plants. Many different plantwide control methodologies have been proposed during the last decades, nonetheless, they can all be classified based on their approach. Vasudevan and Rangaiah (2011) suggest the following classification: mathematical, optimization-based, heuristic and mixed approaches. The first two approaches lead in many cases to an optimal control structure design but often require an optimization of rigorous process models in order to be fully utilized. Often, the entire plant model is not available and it is too time consuming to develop one. More seriously, the resulting mathematical and optimization problems are often difficult to formulate and even more difficult to solve. The alternative in such cases, is to attempt to apply the practical rules derived from heuristic/mixed procedures, that require only a good engineering insight in order to design a close-to-optimal control structure. In addition, these practical guidelines are usually easier to understand, thus easier to implement and support without requiring high expertise (Konda, 2005).

Many such practical rules that either focus on a complete plantwide control structure design or its specific parts, have been proposed in scientific literature. Just to mention a few, starting with the pioneering work of Page S. Buckley (1964), are: (Price et al., 1994), (Luyben et al., 1997), (Skogestad, 2004), (Aske et al., 2007). It should be noted that, Skogestad (2004) procedure is inspired by Luyben et al. (1997) procedure, but it clearly distinguishes between economic control for economic performance and regulatory control for stability and robustness and in order to emphasize this distinction, it is referred to as Economic Plantwide Control. For a more detailed overview of

plantwide control design methodologies we refer the reader to (Larsson and Skogestad, 2000) and (Vasudevan and Rangaiah, 2012).

When examining the suggested practical guidelines, we often find that the assumptions behind them are not stated clearly, leading to the likelihood of non-optimal control strategies. For example, the most famous of Luybens laws *"Fix a Flow in Every Recycle Loop"*, when applied to certain systems, can lead to poor economic performance and a small feasible range. The correct interpretation could be that the flow should only be fixed on a fast time scale. If it is indeed truly fixed, then it should involve moving the throughput manipulator to this location. This motivates this work's attempt to present and justify the practical rules derived from Skogestad's procedure in an easy-to-understand fashion .

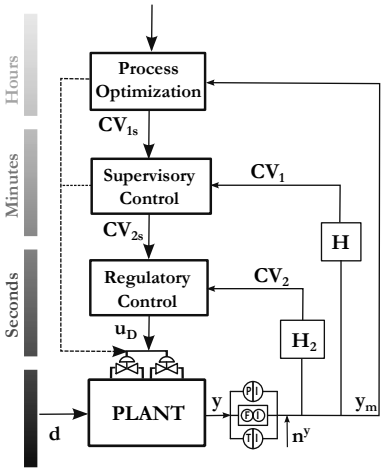
In this work, we briefly present the systematic plantwide control design procedure proposed by Skogestad (2004) in a simple Q&A form. We present its practical guidelines, with emphasis on those rules that can be used based on engineering insight and propose an additional rule, that is stated as follows: "*Never try to control a cost function*". We apply the presented rules and demonstrate their effectiveness on a simple but quite famous reactor-separator-recycle case study (T. Larsson et al., 2003). We conclude that, while Skogestad's procedure requires an optimization of the plant model under various disturbances in order to be fully utilized, using its practical rules, combined with a good engineering insight of the process, can facilitate the design of a close-to-optimal control structure by suggesting what should be controlled and how.

2. Economic Plantwide Control

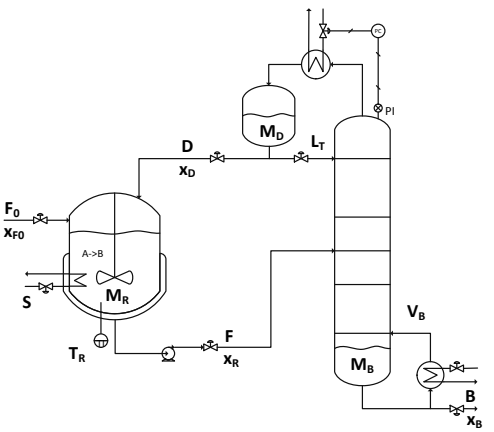
2.1. Preliminaries

The definitions and terms presented here are based on terminology used in (Larsson and Skogestad, 2000) and (Skogestad, 2012), unless otherwise noted. A typical hierarchical decomposition of the plantwide control structure is depicted in Figure 1a. The lowest layer, the regulatory (or stabilizing) layer, consists usually of single loop (decentralized) PID controllers and operates in a time scale of seconds. Next, the supervisory (or advanced, or economic) layer, which provides setpoints to the regulatory layer, may consist of a multivariable controller (MPC) or a mix of various decentralized "advanced" controllers, including PID controllers selectors, feedforward controllers and so on. We define some of the terms extensively used in this work, as follows:
Controlled variable (CV) is a variable with a given setpoint.
Manupulated variable (MV) is a degree of freedom used by the controller to control a CV.
Pairing is a selection of a MV to be used to control a specific CV.
Control structure design deals with the structural decisions of identification/selection of the following sets: controlled variables $\{\boldsymbol{CV}_1\boldsymbol{CV}_2\}$, physical manipulated variables $\{\boldsymbol{u_D}\}$, measurements $\{\boldsymbol{y_m}\}$, control pairings $\{\boldsymbol{H},\boldsymbol{H_2}\}$ and controller algorithms for the layers depicted in Figure 1a.
Plantwide control is a control philosophy of the overall plant with emphasis on the structural decisions and is used interchangeably with the term "control structure design".
Self-optimizing variables are controlled variables for which the optimal setpoints $\boldsymbol{CV}_{1s}$ can be kept relatively unchanged, i.e. their optimal values are insensitive to disturbances, at least on a fast time scale.
Optimal control structure is a control structure that achieves economically optimal -in addition to safe and stable- plant operation.
Rule in this work means a practical guideline, and both terms are used interchangeably.

Before describing the procedure for economic plantwide control it should be noted that, in general, it is simple to define the economic cost function J for a steady-state optimal operation of chemical processes. Since the plant has already been built and the operators are already at the site, there are no costs related to capital costs or other fixed costs. The cost function can be expressed as



(a) Hierarchical time-scale decomposition of the control structure.



(b) Reactor-separator-recycle process flow diagram

$J = p_F F + p_Q Q - p_P P$, where: p is the corresponding price, $p_F F$ is the sum of the costs of all the feed streams, $p_Q Q$ is the cost of all utilities (including energy) and $p_P P$ is the sum of the values of all products. In this context, we can define two main operational modes: **Mode 1** (nominal operation) where the feeds are given, so the term $p_F F$ is fixed. Furthermore, because of given product specifications, this may imply that the product rates P are also fixed. So, to minimize plant operation cost, we want to minimize the utility costs $p_Q Q$. This mode often has an unconstrained optimum, since there is a tradeoff between using too much or too little energy. This is the case for our simple example in Mode 1, where the optimal operation is the same as minimizing $J = V_B$, since the energy (boilup) to the column is the only utility; **Mode 2** (maximum throughput) that has high product prices and low energy prices, so the optimal operation corresponds to maximizing the product rate P. In general, we have more active constraints in Mode 2 than in Mode 1.

2.2. Economic Plantwide Control description

Any methodology that aims to facilitate the design of an optimal control structure, based on the hierarchical decomposition depicted on Figure 1a, should, independent of the approach, at least consider the following structural decisions:

1. **Decision 1:** Select primary controlled variables $\boldsymbol{CV}_1$ for the supervisory control layer or select $\boldsymbol{H}$. The setpoints $\boldsymbol{CV}_{1s}$ link the process optimization with supervisory control layer.
2. **Decision 2:** Select secondary controlled variables $\boldsymbol{CV}_2$ for the regulatory control layer or select $\boldsymbol{H_2}$. The setpoints $\boldsymbol{CV}_{2s}$ link the supervisory and regulatory control layers.
3. **Decision 3:** Locate the throughput manipulator (TPM) location. This is an important step, since it links the top-down and the bottom-up parts of the economic plantwide control.
4. **Decision 4:** Select pairings for the stabilizing layer controlled variables $[\boldsymbol{CV}_2 \leftrightarrow \boldsymbol{u}_D]$

Furthermore, the operational goals should be defined clearly and if possible separated into: i) economic objective ii) stabilization/regulation objectives. One reason for the separation is, that it is very difficult to measure them in the same units, for example, how much is a gain margin increase from 2 to 3 worth in dollars?

Skogestad's procedure clearly distinguishes between the economic control and regulatory control and decomposes the structural decisions, into two parts: the ***Top-down*** part, which attempts to find a slow-time-scale supervisory control structure that achieves a close-to-optimal economic

operation and the ***Bottom - up*** part that aims to design a fast-time-scale regulatory control structure that is stable and robust and works under all the conditions imposed by the economic supervisory layer. A brief description of the procedure is presented in Table 1 in the form of typical structural decisions (Q) and how it attempts to address those in a systematic manner (A).

Note that, the structural decisions related to the parings (steps *S5, S5, S6*) could in theory be avoided, if we used a single multivariable controller (e.g. MPC). Furthermore, the choice of economic controlled variables $\boldsymbol{CV}_1$ (related to steps S3, S7) could also, in theory, be avoided, if we used a single dynamic real-time optimizer, which combined optimization and control. However, designing, maintaining and tuning such a controller can be too difficult and too expensive for a large plant.

Top-down part	*(mainly steady-state)*
Step S1:	**Define the operational objectives (economics) and constraints.**
Q:	*What are the overall economic objectives for operation?*
A:	*Identify a scalar cost function J and the operational constraints. Identify the dynamic degrees of freedom (DOFs)* $\boldsymbol{u_D}$*. Determine how many steady state DOFs* n_{SS} *are available. Identify the expected economic disturbances* $\boldsymbol{d}$ *and and their range.*
Step S2:	**Determine the steady-state optimal operation**
Q:	*What are the operational conditions for an optimal steady state operation?*
A:	*Determine the optimal operation and, in particular, the optimal constraints regions (regions in the disturbance space with the same active constraints) for the expected disturbance* $\boldsymbol{d}$ *ranges*
Step S3:	**Select primary (economic) controlled variables** (Decision 1)
Q:	*What should be controlled to maintain a close-to-optimal economic operation in-spite of disturbances ?*
A:	*Identify the candidate measurements* $\boldsymbol{y_m}$ *and select the primary controlled variables such as* $\boldsymbol{y_m} \supset \boldsymbol{CV}_1 = \boldsymbol{H y_m}$*, where* $\boldsymbol{H}$ *is a selection matrix. The set* $\boldsymbol{CV_1}$ *should include active constraints* $\boldsymbol{A_C}$ *and if* $\#\boldsymbol{A_C} < n_{SS}$*, a* n_{SS} *number of "self-optimizing variables"* $\boldsymbol{CV}_{soc}$ *should be identified and included in* $\boldsymbol{CV}_1$*.*
Step S4:	**Select the location of throughput manipulator (TPM)** (Decision 3)
Q:	*Where should the plant's "gas pedal" be located ?*
A:	*The location of the TPM is a dynamic issue but it may have significant economic implications and, therefore, is located in the Top-down part. For TPM location see Rules 4 and 5.*
Bottom-up part	*(mainly dynamic)*
Step S5:	**Select the control structure for the Regulatory Control layer.** (Decisions 2 and 4)
Q:	*What variables should be controlled to stabilize the operation and how ?*
A:	*Select all the "drifting" process variables* $\boldsymbol{CV}_2 = \boldsymbol{H_2 y}$ *that need to be controlled to ensure safe and stable plant operation e.g. inventories, pressures, temperatures. The inventory control structure should be designed starting from the TPM location and following the radiating rule to achieve local consistency. Usually single loop (decentralized) PID controllers are used in this layer.*
Step S6:	**Select the control structure for the Supervisory Control layer.**
Q:	*How should the economic controlled variables* $\boldsymbol{CV}_1$ *be controlled ?*
A:	*The primary economic variables* $\boldsymbol{CV}_1$ *should be controlled at this layer, using the setpoints to the regulatory layer in addition to any unused valves. Two types of controllers are usually selected for this layer: multivariable controller (e.g. MPC) or a mix of various decentralized "advanced" controllers, including PID controllers selectors, feedforward controllers and so on.*
Step S7:	**Select the control structure for the Real-Time Optimization layer.**
Q:	*How often should the optimal setpoints for the economic controlled variables* $\boldsymbol{CV}_1$ *and their pairings be updated ?*
A:	*This layer should re-optimize the setpoints for* $\boldsymbol{CV}_1$ *and track any changes in the set of active constraints, in order to update the economic control structure, if necessary. A limiting factor for the updating frequency is the requirement that the plant has to settle, before the re-optimization problem can be solved. A successful mapping of the active constraints regions for the entire range of expected disturbances, combined with set of good self-optimizing variables, may remove the need for having this layer.*

Table 1: Economic Plantwide Control design procedure. The nomenclature used here is depicted in Figure 1a. For more details we refer the reader to (Skogestad, 2012)

3. Practical rules

Here we present a set of simple rules for economic plantwide control to facilitate a close-to-optimal control structure design in cases where the optimization of the plant model is not possible. Due to space limitations, only short justifications for the rules are given and, in addition, we attempt to exemplify the rules, when possible, using the reactor-separator-recycle process (Figure 1b). Note that, the rules may be conflicting in some cases and in such cases, human reasoning is strongly advised.

Rules for Step S3: Selection of primary (economic) controlled variables, $\boldsymbol{CV}_1$

Rule 1: *Control the active constraints.*
In general, process optimization is required to determine the active constraints, but in many cases these can be identified based on a good process knowledge and engineering insight. Here is one useful rule:

Rule 1A: The purity constraint of the valuable product is always active and should be controlled.
This follows, because we want to maximize the amount of valuable product and avoid product "give away" (Jacobsen and Skogestad, 2011). Thus, we should always control the purity of the valuable product at its specification. For "cheap" products we may want to overpurify (purity constraint may not be active) because this may reduce the loss of a more valuable component.
In other cases, we must rely on our process knowledge and engineering insight. For reactors with simple kinetics, we usually find that, the reaction and conversion rates are maximized by operating at maximum temperature and maximum volume (liquid phase reactor). For gas phase reactor, high pressure may increase the reaction rate, but this must be balanced against the compression costs.

Rule 2: *(for remaining unconstrained steady-state degrees of freedom, if any): Control the "self-optimizing" variables.*
This choice is usually not obvious, as there may be several alternatives, so this rule is in itself not very helpful. The ideal self-optimizing variable, at least, if it can be measured accurately, is the gradient of the cost function J_u, which should be zero for any disturbance. Unfortunately, it is rarely possible to measure this variable directly and the "self-optimizing" variable may be viewed as an estimate of the gradient J_u. The two main properties of a good "self-optimizing" variable are: (1) its optimal value is insensitive to disturbances (such that $\boldsymbol{F} = \frac{\Delta \boldsymbol{CV}_{1,opt}}{\Delta \boldsymbol{d}}$ is small) and (2) it is sensitive to the plant inputs (so the process scaled gain $\boldsymbol{G} = \frac{\Delta \boldsymbol{CV}_1}{\Delta \boldsymbol{u}}$ is large). The following rule shows how to combine the two desired properties:
Rule 2A: Select the set $\boldsymbol{CV}_1$ such that the ratio $\boldsymbol{G}^{-1}\boldsymbol{F}$ is minimized.
This rule is often called the "maximum scaled gain rule". For proof, see (Halvorsen et al., 2003).

Rule 3: *(for remaining unconstrained steady-state degrees of freedom, if any): Never try to control the cost function J (or any other variable that reaches a maximum or minimum at the optimal operating point).*
First, the cost function J has no sensitivity to the plant inputs at the optimal point and so $\boldsymbol{G} = 0$, which violates Rule 2A. Second, if we specify J lower than its optimal value, then clearly, the operation will be infeasible, see Figure 2a. From Figure 2a, we can also see that specifying J higher than its optimal value is problematic, as we have multiplicity of solutions. As mentioned above, rather controlling the cost J, we should control its gradient, J_u.

Rules for Step S4: Location of throughput manipulator (TPM)

Rule 4: *Locate the TPM close to the process bottleneck.*

The justification for this rule is to take advantage of the large economic benefits of maximizing production in times when product prices are high relative to feed and energy costs (**Mode 2**). To maximize the production rate, one needs to achieve tight control of the active constraints, in particular, of the bottleneck, which is defined as the last constraint to become active when increasing the throughput rate. For more details, we refer the reader to (Jagtap et al., 2013).

Rule 5: *(for processes with recycle) Locate the TPM inside the recycle loop.*
The point is to avoid "overfeeding" the recycle loop which may easily occur if we operate close to the throughput where "snowballing" in the recycle loop occurs. This is a restatement of Luyben's rule *"Fix a Flow in Every Recycle Loop"* (Luyben et al., 1997). From this perspective, snowballing can be thought of as the dynamic consequence of operating close to a bottleneck which is within a recycle system. In many cases, the process bottleneck is located inside the recycle loop and Rules 4 and 5 give the same result.

Rules for Step S5: Structure of regulatory control layer.

Rule 6: *Arrange the inventory control loops (for level, pressures, etc.) around the TPM location according to the radiation rule.*
The radiation rule (Price et al., 1994), says that, the inventory loops upstream of the TPM location must be arranged opposite of flow direction. For flow downstream of TPM location it must be arranged in the same direction. This ensures "local consistency" i.e. all inventories are controlled by their local in or outflows.

Rule 7: *Select "sensitive/drifting" variables as controlled variables $\boldsymbol{CV}_2$ for regulatory control.*
This will generally include inventories (levels and pressures), plus certain other drifting (integrating) variables, for example, a reactor temperature or a sensitive temperature in a distillation column. This ensures "stable operation, as seen from an operator's point of view.

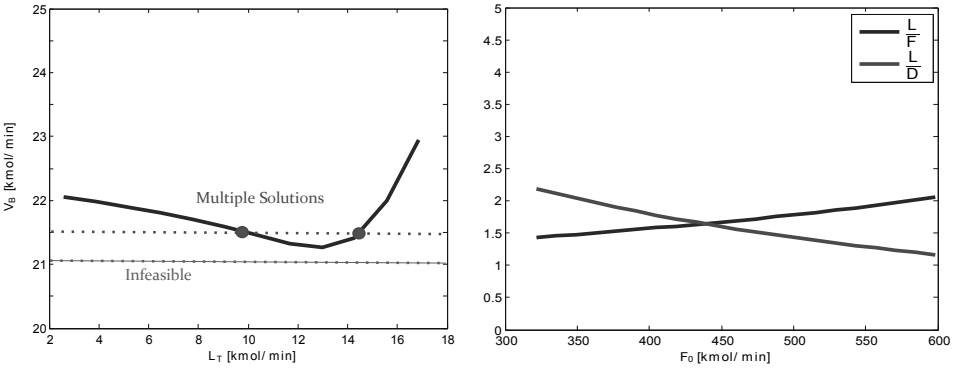
Some component inventories may also need to be controlled, especially for recycle systems. For example, according to *"Down's drill"* one must make sure that all component inventories are "self-regulated" by flows out of the system or by removal by reactions, otherwise their composition may need to be controlled (Luyben, 1999).

Rule 8: *Economically important active constraints, a subset of $\boldsymbol{A_C}$, should be selected as controlled variables $\boldsymbol{CV}_2$ in the regulatory layer.*
Economic variables $\boldsymbol{CV}_1$ are generally controlled in the supervisory layer. Moving them to the faster regulatory layer may ensure tighter control with a smaller backoff. The backoff is the difference between the actual average value (setpoint) and the optimal value (constraint).

Rule 9: *"Pair-close" rule: The pairings should be selected such that, effective delays and loop interactions are minimal.*

Rule 10: *: Avoid using MVs that may optimally saturate (at steady state) to control CVs in $\boldsymbol{CV}_2$.*
The reason is that we want to avoid re-configuring the regulatory control layer. To follow this rule, one needs to consider also other regions of operation than the nominal, for example, operating at maximum capacity (**Mode 2**) where we usually have more active constraints.

Rules for Step S6: Structure of supervisory control layer.



(a) Steady state boilup flow rates V_B w.r.t. reflux flow rate L_T changes while all the active constraints are kept constant

(b) Optimal steady state of suggested $\boldsymbol{CV}_{soc}$ candidates $\{\frac{L_T}{F}, \frac{L_T}{D}\}$ w.r.t. feed flow F_0 changes ± 30 percent while all the active constraints are kept constant

Rule 11: *MVs that may optimally saturate (at steady state) should be paired with the subset of* $\boldsymbol{CV}_1$ *that may be given up.*
This rule applies for cases when we use decentralized control in the supervisory layer and we want to avoid reconfiguration of loops. The rule follows because when a MV optimally saturates, then, there will be one less degree of freedom, so there will be a CV_1 which may be given up without any economic loss. The rule should be considered together with rule 10.

4. Case study

4.1. Process description

In this section we consider a quite famous example of a chemical plant that consists of a reactor, a separator and a recycle stream. For this case study, all the operational parameters have been taken from (Larsson et al., 2003). The process flow diagram of the process and all the required nomenclature are depicted in Figure 1b. An irreversible first order elementary reaction $A \rightarrow B$ takes place in continuous stirred tank reactor (CSTR). The effluent of the reactor, which consist of a solution of A and B is sent to fractional distillation column, where the products are separated and the distillate stream (mostly component A), is recycled back to the CSTR.

4.2. Applying the practical rules

S1: Assuming that the plant, depending on market conditions, will be switching between Mode 1 and 2, the objective for Mode 1 is to minimize energy consumption $J = V_B$ and for Mode 2, to maximize the production $J = -B$. The operational constraints are: $M_R \leq 2800\,kmol$, $x_B \leq 0.0105$, $V_B \leq 1500\,mol/min$, $T_R \leq 600K$. Assuming that the pressure in the column is kept constant by the condenser flow, the process has 7 DOFs: $\boldsymbol{u_D} = [L_T, V_B, D, B, F, F_0, S]$. Only two DOFs from $[L_T, V_B, D, B]$ can be set independently at a steady state, which means $n_{SS} = 5$ steady state DOFs.
S2: We assume, based on our engineering insight and *Rule 1A*, that the following constraints will be most probably be active $\boldsymbol{A_C} = [M_R, x_B, T_R]$.
S3: In addition to a DOF consumed by the TPM, all $\boldsymbol{A_C}$ need to be controlled, thus 1 DOF is left that can be used to improve the operational economics. Some candidates for $\boldsymbol{CV}_{soc}$ are $\{\frac{L_T}{F}, \frac{L_T}{D}\}$.
S4: The last constraint that becomes active in Mode 2 is V_B. In addition, there are two recycle loops in the process (one is the column itself) and V_B is inside both of the loops. According to the *Rule 4 and 5* the best candidate for TPM location is V_B.

S5: The selection of V_B as the TPM leads to the following pairings $(B \rightarrow M_B), (D \rightarrow M_D), (F_0 \rightarrow M_R), (S \rightarrow T_R)$ according to Rules 6 or 9. In order to get a tighter control of x_B and to stabilize the composition profile in the column, we can cascade the x_B control with some sensitive column temperature T_C such that $(F \rightarrow T_C \rightarrow x_B)$ according to Rule 7 and 8. The suggested pairings may remove the need to re-configure the structure when switching from one mode to another.
S6: The only available DOF for this layer is L_T, so it needs to be used to control one of the suggested $\boldsymbol{CV}_{soc} = \{\frac{L_T}{F}, \frac{L_T}{D}\}$. A preferable controller in this case would be a single loop PID.
S7: Assuming that the assumptions for the active constraints set and the "self-optimizing" controlled variable are correct, the additional benefits from having this layer would be quite limited.

5. Results and Conclusions

The validity of our practical analysis is checked using the optimization results presented in (Larsson et al., 2003). The practical choice of active constraints is in agreement with Larsson's findings. The optimal sensitivity of the $\boldsymbol{CV}_{soc}$ w.r.t to disturbances is depicted in Figure 2b, which shows that the optimal values of the suggested CVs change very little with quite large disturbances thus qualifying them as good "self-optimizing" variables. The dynamic performance of the plant control structure is omitted due to space limitations.

In conclusion, despite the fact that to fully utilize the true potential of the economic plantwide control procedure a series of plant model optimizations is required, the derived practical guidelines can be used to decide on "what to control and how" in order to improve the economics of the plant operation, even if the model is not available or optimization of the plant model is difficult.

Mixed-Integer Fractional Programming: Models, Algorithms, and Applications in Process Operations, Energy Systems, and Sustainability

Fengqi You

Northwestern University, 2145 Sheridan Road, Evanston, Illinois 60208, USA
you@northwestern.edu

Abstract

A wide range of optimization problems arising in practical applications can be formulated as mixed-integer fractional programming (MIFP) problems, which combine the combinatorial difficulty of optimizing over discrete variable sets with the challenges of handling the nonconvex fractional objective function. This paper reviews recent developments of tailored global optimization algorithms for large-scale MIFP problems. These MIFP methods are illustrated through three applications: (1) function-unit-based life cycle optimization of sustainable supply chains, (2) integrated optimization of production scheduling and process dynamics of multi-product continuous processes, and (3) optimal design of algae processes for fuel and chemical production.

Keywords: MINLP, algorithm, life cycle optimization, scheduling, biorefinery.

1. Introduction

Mixed-integer fractional programming (MIFP) refers to a class of nonconvex mixed-integer nonlinear programs (MINLPs), of which the objective is the ratio of two functions (see Figure 1). MIFP finds applications in a variety of fields that include, but are certainly not limited to, biopharmaceutical manufacturing (Liu et al., 2014), capital investment (Bradley & Arntzen, 1999), hybrid energy systems (Tong et al., 2014), polymerization processes (Chu & You, 2012), marketing (Hua et al., 2011), cyclic scheduling (Pochet & Warichet, 2008), water-energy nexus (Gao & You, 2015), and environmentally conscious process operations (Capón-García et al., 2010).

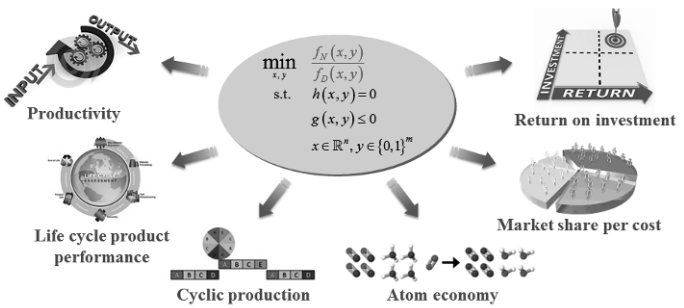

Figure 1. A general form of mixed-integer fractional programming and its applications.

Despite the wide applicability of MIFP, it is usually a challenging task to global optimize MIFP problems, especially for large-scale applications. This paper reviews recent developments of parametric algorithms for MIFP that can address some large-scale and complex problems, which are previously considered intractable by using

general-purpose MINLP and global optimization methods. These MIFP techniques are further illustrated through three recent applications.

2. Parametric algorithms for MIFP

2.1. Parametric form and its properties

For every MIFP problem with a positive denominator in the objective, i.e. $D(x, y)>0$, we can consider its parametric form with the same constraints and a parametric objective function as the difference between the numerator and the product of the denominator and a one-dimension parameter q, as shown in Figure 2.

$$\min_{(x,y)\in S} \frac{N(x,y)}{D(x,y)} \qquad F(q)=\min_{(x,y)\in S} N(x,y)-q\cdot D(x,y)$$

MIFP Problem Parametric MIP Subproblem

Figure 2. MIFP problem and its parametric MIP problem.

There is an equivalence property between the original MIFP problem and the parametric MIP problem: $(x, y)^*$ is the global optimal solution of the original MIFP problem if and only if $(x, y)^*$ is the global optimal solution of the parametric mixed-integer programming (MIP) subproblem for the parameter q^* such that $F(q^*)=0$. Thus, he global optimization of the MIFP problem is equivalent to solving $F(q^*)=0$. Due to the inner MIP problem $F(q)$ does not have a close-form analytical expression, but the equation $F(q^*)=0$ can be solved using a numerical root-finding algorithm. It has been proved that the one-dimension function $F(q)$ is concave, continuous, and monotonically decreasing (You et al., 2009). Since we only consider the cases with $D(x, y)>0$, there is a unique solution for $F(q^*)=0$. As the subgradient of $F(q)$ can be approximated with $-D(x, y)^*$, generalized Newton's method can be applied to solve a sequence of the parametric MIP subproblems for obtaining the value of q^* such that $F(q^*)=0$, as well as the global optimal solution to the MIFP problem (see Figure 3).

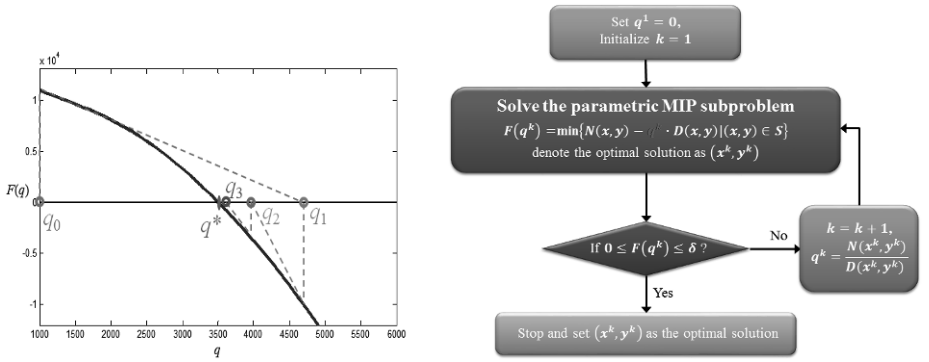

Figure 3. Generalized Newton's method for one-dimension root-finding of solving $F(q^*) = 0$ (left) and the algorithmic flowchart of the parametric approach using Newton's method (right).

2.2. Exact parametric algorithm

The flowchart of using generalized Newton's method for solving MIFP problems via the parametric approach is given on the right of Figure 3. This algorithm iteratively solves MIP subproblems by varying the value of parameter q, which is updated based on the optimal solution of the MIP subproblem in each iteration, until $F(q)$ falls into the neighbor of zero. It is important to note that all the MIP subproblems have exactly the

same number of variables and constraints. This method is called the "exact" parametric algorithm, because each MIP subproblem is expected to be solved to the global optimum, in order to provide the exact functional value for $F(q)$. The method has the same quadratic convergence rate as the generalized Newton's method.

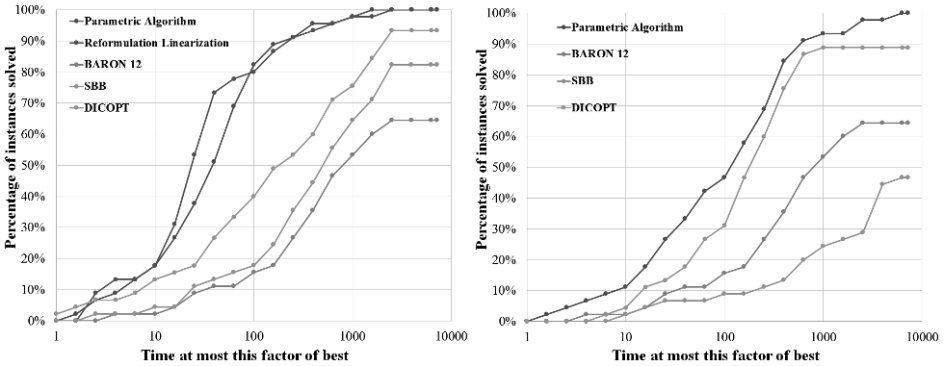

Figure 4. Performance profiles for solving general MILFP problems (left) and convex MIQFP problems (right) by comparing exact parametric algorithm with DICOPT, SBB and BARON 12.

This exact parametric algorithm based on the Newton's method was first applied to continuous linear fractional program (Isbell & Marlow, 1956) and convex nonlinear fractional program (Dinkelbach, 1967), although these continuous optimization problems can nowadays be solved more efficiently using the nonlinear programming (NLP) techniques directly. However, this exact parametric algorithm would have advantages for solving some MIFP problems, of which the corresponding parametric MIP subproblems are relatively easier to solve. For example, the MIP subproblems for mixed-integer linear fractional program (MILFP) and convex mixed-integer quadratic fractional program (MIQFP) problems are mixed-integer linear program (MILP) and convex mixed-integer quadratic program (MIQP), respectively, which can both be efficiently solved using the branch-and-cut algorithms. Figure 4 shows the performance profiles for solving randomly generated MILFP and convex MIQFP problems using this exact parametric algorithm (the corresponding MILP or MIQP subproblems were solved by CPLEX 12), and using the general-purpose MINLP solvers DICOPT and SBB, as well as the global optimizer BARON 12. We can see that the exact parametric algorithm clearly outperforms the general-purpose local and global MINLP solvers.

2.3. Inexact parametric algorithm

The efficiency of the parametric algorithm largely depends on the solution of the parametric MIP problem. It is known that MIP problems are usually NP-hard, and solving all MIP subproblems to 0% optimality gap might be very computationally challenging. Zhong and You (2014) recently theoretically proved that the convergence of the parametric algorithm shown in Figure 3 is still guaranteed if each MIP subproblem is solved to a relative optimality gap strictly less than 100%. This inexact parametric approach might require shorter computational time in each iteration to obtain a near-optimal solution of the MIP subproblem, although it has a superlinear convergence rate and may need more iterations than the exact one.

More importantly, this inexact parametric approach is applicable to general convex and nonconvex MIFP problems. It can be combined with other solution techniques to globally optimize complex nonconvex MIFP problems. An example is the following

MIFP problem, which comes from the application to be presented in Section 3.3. This MIFP problem includes a set of exponential terms, $(x_i)^{\alpha_i}$, where $1<\alpha_i<1$, in the numerator of the objective function to model the capital cost scaling functions.

$$\begin{aligned} \min \quad & \frac{A_0 + A_1 \cdot x + A_2 \cdot y + \sum_{i=1}^{n} \beta_i \cdot (x_i)^{\alpha_i}}{B_0 + B_1 \cdot x + B_2 \cdot y} \\ \text{s.t.} \quad & A + B \cdot x + C \cdot y = 0 \\ & x \in \mathbb{R}^n \quad \text{and} \quad y \in \{0,1\}^m \end{aligned} \tag{1}$$

Global optimization of the above MIFP problem could be challenging due to the multiple nonconvex terms. By applying the inexact parametric algorithm, we can consider a parametric subproblem, which is a separable concave minimization problem with the same constraints as (1) and a new objective function as follows:

$$F(q) = \min_{(x,y)\in S} \; A_0 + A_1 \cdot x + A_2 \cdot y + \sum_{i=1}^{n} \beta_i \cdot (x_i)^{\alpha_i} - q \cdot (B_0 + B_1 \cdot x + B_2 \cdot y) \tag{2}$$

Although this subproblem is still a nonconvex MINLP due to the presence of the exponential terms, it has a special structure that can be globally optimize by a successive piecewise linear approximation method (shown on the left of Figure 5). This method solves a sequence of MILP problems for the piecewise linear under-estimator to obtain the lower bound, and the upper bound is evaluated from the original functions based on the MILP solution. Thus, the tailored global optimization algorithm for solving the MIFP problem (1) includes two loops (on the right of Figure 5): The inner loop is for iteratively constructing the piecewise linear under-estimator for the parametric subproblem and the outer loop is for the inexact parametric algorithm.

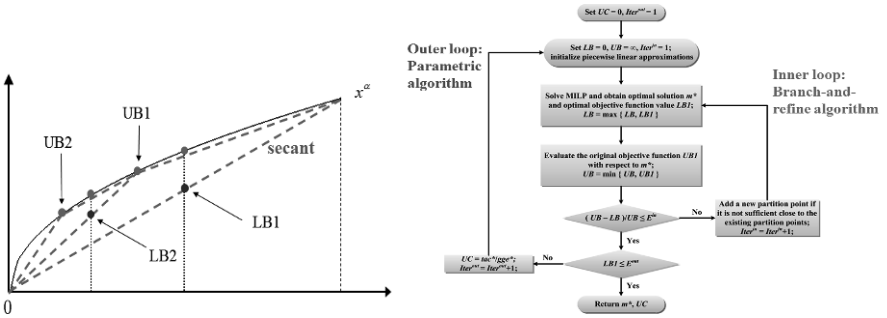

Figure 5. Successive piecewise linear approximation approach for separable concave minimization problems (left) and algorithmic flowchart for the global optimization of nonconvex MIFP problems with separable concave terms in the numerator of the objective function.

3. Applications

3.1. Functional-unit-based life cycle optimization of sustainable supply chains

Life cycle optimization, which explicitly combines life cycle analysis (LCA) with multi-objective optimization to simultaneously optimize the economic and environmental performances, is an emerging tool for sustainable supply chain optimization (Azapagic & Clift, 1999). Yet, almost all the life cycle optimization studies neglect the concept of "functional unit", which is a key element of LCA. To bridge this gap, Yue et al. (2013) proposed a functional-unit-based life cycle optimization approach for sustainable supply

chains. This framework considers a standard quantity of functional unit associated with the product systems. The functional unit provides a reference, to which the system's inputs and outputs can be related, and a logical basis for comparing the sustainability performance for different products. For example, gasoline equivalent gallon (GEG) is defined as the amount of alternative fuel it takes to equal the energy content of one liquid gallon of gasoline, which is 114,000 BTU lower heating values per gallon, so it is usually used as the functional unit to characterize different fuel products, e.g. 1 gallon of base-line gasoline is equivalent to 1 GEG and 1 gallon of biodiesel is equivalent to 1.0417 GEG. The use of functional unit in the life cycle optimization framework leads to a fractional objective function, where the denominator is the quantity of functional units involved in the product system, and the numerator is the economic/environmental sustainability indicator of the entire supply chain. Because most supply chain design models are formulated as MILP, the functional-unit-based life cycle optimization approach leads to the following multi-objective MILFP problem, which can be efficiently solved using the parametric algorithm presented in Section 2.

$$\begin{aligned} &\min \left\{ \frac{\text{total cost across life cycle}}{\text{quantity of the function unit}}, \frac{\text{total life cycle environmental impacts}}{\text{quantity of the function unit}} \right\} \\ &\text{s.t.} \quad A_k + \sum_{i \in I} B_{ik} x_i + \sum_{j \in J} C_{jk} y_j = 0, \forall k \in K \\ &\quad x_i \in \mathbb{R}^n, \forall i \in I \quad \text{and} \quad y \in \{0,1\}^m, \forall j \in J \end{aligned} \tag{3}$$

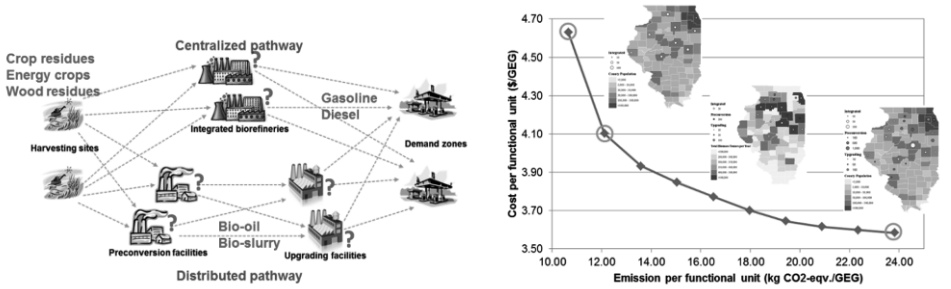

Figure 6. Superstructure (left) and Pareto optimal curve (right) of the case study on county-level biofuel supply chains in Illinois.

This framework was applied to a case study on hydrocarbon biofuels (gasoline and diesel from three cellulosic biomass sources) through a spatially-explicit model for the county-level supply chain in Illinois (see Figure 6). The problem is to optimize the number, sizes, locations, and technology selection for all the conversion facilities, as well as the profiles of the manufacturing, transportation, and storage activities, with respect to both the economic and environmental criteria. GEG was choose the functional unit. The resulting Pareto-optimal curve and the optimal design of the county-level hydrocarbon biofuel supply chain of Illinois are given in Figure 6. This case study leads to an MILFP problem with 224 discrete variables, 131,351 continuous variables, and 30,826 constraints. Neither BARON 12 nor SBB were not able to return any solution within 10% gap after 10 hours. DICOPT returned local optimal solutions within 1 hour, but their global optimality cannot be guaranteed. Yet, the parametric algorithm with CPLEX 12 can globally optimize the MILFP problems or all instances on the Pareto curve within 20 CPU seconds.

3.2. Integrated optimization of production scheduling and dynamics

Multi-product continuous processes can be operated in cyclic mode (Flores & Grossmann, 2006), in which each product is produced once per cycle and there is a transition period involving process dynamics from producing one product to another (see Figure 7). The scheduling problem determines the production sequence, and provides the initial condition and setpoint values to control the dynamic transition processes. The dynamic optimization problems provide the transition time and cost, which are input parameters for scheduling optimization. Thus, integrated optimization of scheduling and dynamics would lead to better process performance. The objective of this problem is to minimize the total cost rate, which includes the production cost, transition cost and inventory cost per unit of cycle time, by determining the production sequence, dynamic operating trajectories and the cycle time. The model formulation is given in Figure 8. Due to the triangular inventory profiles for cyclic production (lower left of Figure 8), the inventory cost is modeled by a quadratic function. Consequently, the objective function is quadratic fractional. This mixed-integer dynamic optimization (MIDO) problem can be reformulated to an MINLP using the colocation method by fully discretizing the differential equations into nonlinear systems (Biegler, 2007).

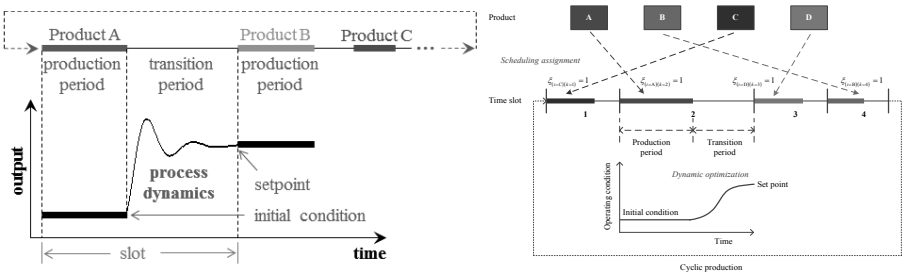

Figure 7. Integrated scheduling and dynamic optimization of multi-product continuous processes.

Because direct solution of this problem may be intractable for general-purpose MINLP solvers, Chu and You (2013) developed a solution method that combines the MIFP techniques with generalized Benders decomposition (GBD) by Geoffrion (1972). The GBD method first decomposes the full-space MINLP problem into a master problem and a set of primal problems, which are NLPs corresponding to the dynamic optimization of the transition periods (see Figure 8). The NLPs are optimized based on the solution of the master problem over every transition, iteratively constructing the Benders' cuts that are added to the master problem. The master problem has the same objective function as the MIDO problem; its constraints include the scheduling model, the linking equations, and the accumulated Benders cuts, which are mixed-integer linear inequalities. Thus, the master problem is a convex MIQFP that can be globally optimized by solving a sequence of convex MIQP problems, based on the parametric algorithm presented in Section 2. This framework was applied to a polymerization process producing 8 different grades products. The full-space MINLP has 63 binary variables, 32,156 continuous variables and 32,708 constraints. DICOPT encountered solver failure when solving this MINLP directly, and BARON 12 ran out of memory very quickly. SBB was able to solve this problem after 14,355 CPU seconds and returned a minimum cost rate of 223.0 m.u./h. Exactly the same optimal solution (minimum cost rate and optimal production schedule) was obtained by applying the GBD method combining with the parametric approach for the MIQFP master problem. Yet, this approach only requires 19.7 CPU seconds, reducing the computational time by 3 orders of magnitude and allowing online optimization.

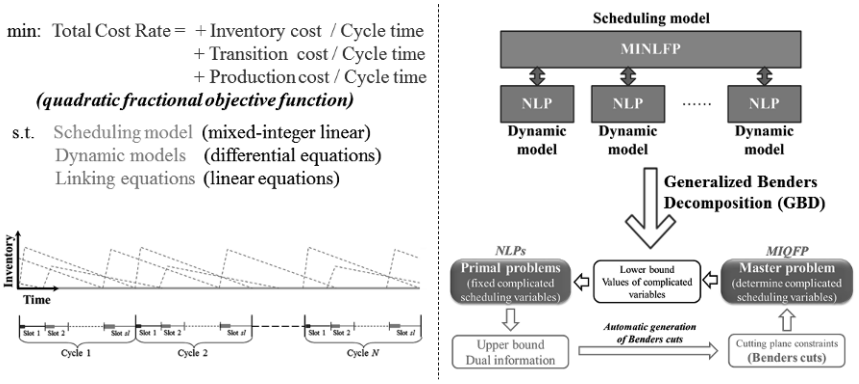

Figure 8. Integrated scheduling and dynamic optimization model and the nonlinear inventory profile (left), as well as the generalized Benders decomposition framework (right).

3.3. Optimal design of algae process making fuels and bioproducts

MIFP methods also find applications on superstructure optimization for process and energy systems design. An example is the work by You and Gong (2014) that investigates the economic and environmental implications of algae-based biorefinery for producing fuels and value-added products from *Chlorella vulgaris*. A main challenge on the design of algae-based energy systems is the diverse processing pathways and various possible products, e.g. biodiesel and renewable diesel (Rizwan et al., 2013). A process superstructure of the algae processing network was developed that includes more than 7,800 potential processing pathways. The algae process superstructure optimization involves various decisions such as the selection of technology, pathway, and processing methods, the determination of product portfolio under the given feed, the mass balance and size of each processing unit, and the energy and utility consumption. The objective is to determine the most cost-effective and environmentally sustainable design of the algae processing network. Because multiple fuel products can be produced from the processing the given algae feedstock, GGE was selected as the functional unit for optimizing the superstructure. The resulting model formulation, which follows the functional-unit-based life cycle optimization approach, is given in Figure 9.

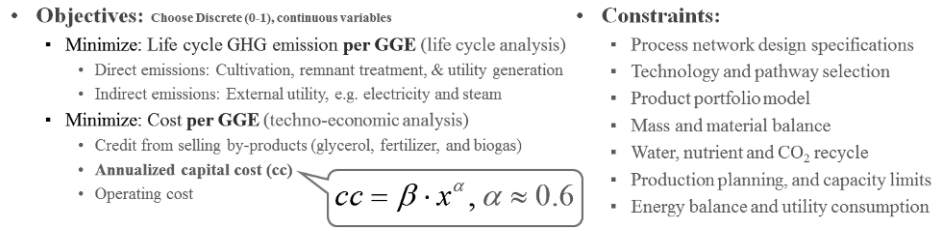

Figure 9. Nonconvex nonlinear MIFP model for superstructure optimization of algae processes.

Due to the capital cost scaling terms, this model is a nonconvex nonlinear MIFP, corresponding to Problem (1) presented in Section 2.2. The nonconvex MIFP problem for algae process superstructure optimization includes 49 binary variables, 32,958 continuous variables, and 56,274 constraints. Due to the nonconvexity, the global optimizer BARON 12 was not able to return any feasible solution after 20 hours, and the two local MINLP solvers, DICOPT and SBB, both return local infeasible within the same computational limits. However, this previously intractable MIFP problem was globally optimized to 0.01% global optimum within 10 CPU seconds (between 6 and 10

iterations for all instances) by using the solution method described in Section 2.3 that combines the branch-and-refine algorithm and the parametric approach.

4. Conclusions

This paper reviews three recent MIFP applications with increasing complexity: the first one is a linear MIFP problem for sustainable supply chain optimization, the second application involves quadratic (nonlinear) MIFP problems for process operations, and the last one handles nonconvex MIFP problems for energy systems design. These large-scale MIFP problems were all efficiently solved using the exact and inexact parametric algorithms that take advantage of MIFP properties and the powerful MILP techniques.

Advances and Challenges in Modelling of Processing of Lipids

Bent Sarup

Alfa Laval Copenhagen A/S, Maskinvej 5, DK-2860 Søborg, Denmark,
bent.sarup@alfalaval.com

Abstract

Unlike the processing of crude and petroleum oils, the lipid processing industry has until recently not taken much advantage of the progress made in property modelling or process - product design over the last few decades. While there are some similarities in the modelling and processing of petroleum and lipids, a number of features of both lipids and their processing present new challenges. A brief introduction will be given to the processing of lipids, emphasizing the refining of edible oil. Some examples are provided on advances in both modelling of the lipids properties (pure components, phase equilibria) as well as how such property modelling enables use of standard process simulation programs for design and process optimisation. These advances have for example lead to new insights on optimum withdrawal of valuable components (micronutrients) in by-products from refining operations.

Keywords: lipids, modelling, thermodynamics, transport properties

1. Introduction

Oils of biological origin are complex hydrocarbon mixtures. Fossil oils have furthermore undergone chemical transformations that increase their complexity. Nevertheless, petroleum oils can often be modelled in sufficient accuracy for process design by a pseudocomponent and group contribution approach (Fredenslund et a., 1977; Magnusson et al., 1981), dividing the oils a suitable number of boiling point fractions and based on estimated densities of each of these fractions through correlations establish thermodynamic and physical properties. Ultimately fossil hydrocarbons will be depleted and replaced from renewable sources. One such source is lipids, being "a loosely defined term for substances of biological origin that are soluble in nonpolar solvents. They consist of saponifiable lipids, such as glycerides (fats and oils) and phospholipids, as well as nonsaponifiable lipids, principally steroids" (IUPAC, 2006). The estimated 2013/14 world production of fats and oils is 208 mill t/y, most of which arise from processing of 524 mill t/y of oilseeds, but also include oils from palm fruits, marine and animal origins (Hallam et al., 2014). Fats and oils are used mainly for edible purposes, but also may others such as biofuels, detergents, personal care and pharmaceuticals. With only a few exceptions, such as olive oil, the crude fats and oils undergo extensive processing to provide the desirable end-product characteristics. Until recent years the fats and oil processing industry has not be able to benefit much from process simulators such as PRO/II and Aspen Plus. One reason being that the lipid mixtures could not be modelled with sufficient accuracy.

2. Lipid processing and modelling requirements

Components occurring in crude fats and oils can be classified as shown in Table 1. In addition the crude oil will contain oxidized compounds (lipid peroxides and secondary oxidation products such as aldehydes), the amount of which depends on oil storage conditions. Focus here will be a brief overview of edible oil processing, for details see e.g. Hamm et al. (2013). Other important areas are biodiesel and oleochemical processes, for which the advances described below also would apply. Normal requirements for a liquid, food grade refined oil is bland taste and smell, clear appearance with a faint yellow colour and being stable during storage for months. The oil refining scheme is shown in Figure 1. Phospholipids ("gums") are removed, optionally in two steps, the first being using a water wash to extract phospholipids which can be dried to make food or feed grade lecithins. Free fatty acids can be removed either as soaps by neutralisation with caustic (chemical refining) route, or stripping with steam under vacuum (deodorization, physical refining). For both processing routes a "bleaching" section removes impurities and some coloured components contacting a solid adsorbent as slurry. Most often a bleaching clay, but silica gels and activated carbon are also used in some cases. Dewaxing and winterisation steps remove high melting point lipids that otherwise would make the refined oil unclear with precipitates. Refining ends with a high temperature steam stripping operation (deodorization) to remove volatiles.

Modelling requirements include mixture temperature dependent properties as well as phase equilibria and transition enthalpies. The phospholipids pose a special challenge, being charged organic molecules with emulsifying properties (leading to oil losses) Phase equilibria include liquid-liquid (e.g. neutralisation), liquid-solid (crystallisation, adsorption during bleaching) and vapour-liquid (deodorization step). The deacidification step in the deodorized has earlier been modelled e.g. by Ceriani and Meirelles (2006).

Table 1. Components in crude fats and oils

Components	Description	Concentration (typical) % wt
Acylglycerides	Tri-, di- and monoacylglycerides	balance
Phospholipids	Free or as calcium and magnesium salts.	0.6 – 4%
Fatty acids	Free fatty acids	0.5 - 5
Tocopherols	Tocopherols and tocotrienols	0.05 – 0.15
Sterols	Free sterols and esterified to e.g. fatty acids,	0.1 – 0.2
Waxes	Esters of long chain fatty acid and alcohols	0.03 – 0.1
Squalene and other hydrocarbons		0.005 – 0.05
Carotenoids	Colour bodies, e.g. carotene	0.001 – 0.05
Trace metals	Iron, copper	0.003 – 0.01
Moisture and impurities	Water, oil seed residues, proteins	0.1 – 0.2

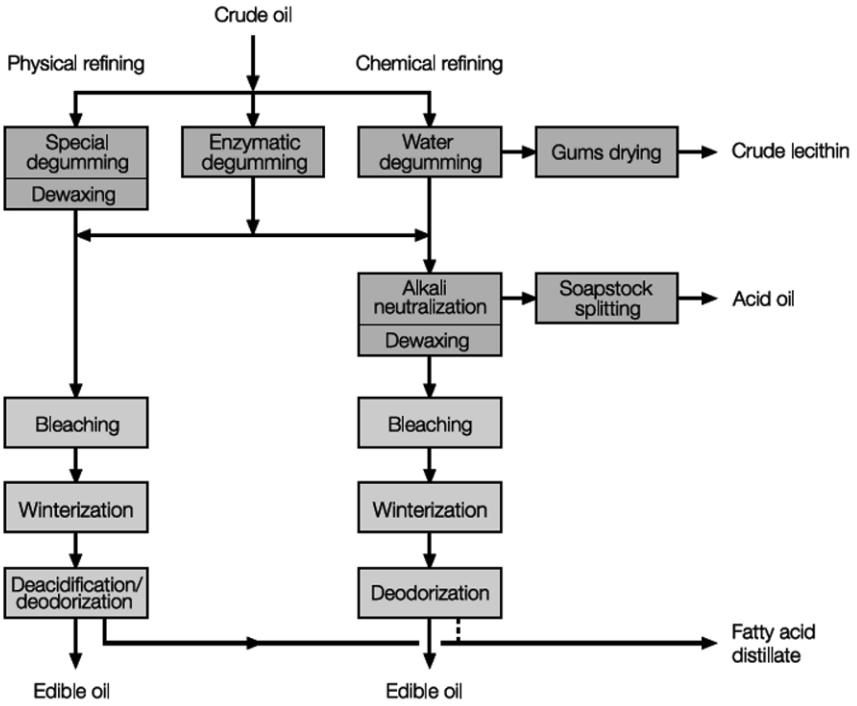

Figure 1. Refining of Fats and Oils (courtesy of Alfa Laval)

Fats used in solid form (in e.g margarines, shortenings, confectionary products) go furthermore through or more of the fat modification steps shown in Figure 2. Fractionation involves cooling the oil to crystalize out major amounts of high melting point lipids, applied extensively for palm oil. Hydrogenation saturates double bonds and increases the melting point. Interesterfication provides a random mixing of fatty acids on the glycerine backbone, and can produce lipids with sharp melting point curves. Which for example is required for confectionary fats, having to melt at mouth temperatures and not when handling by hand. Clearly SLE are of major importance in fat modification, complicated by new lipids being formed by the chemical reactions.

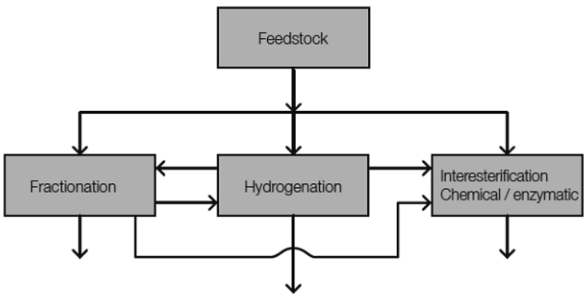

Figure 2. Fat Modification Steps (courtesy of Alfa Laval)

3. Modelling of lipid mixtures

The complexity of lipids is somewhat reduced by the fundamentals of their biological synthesis, resulting in even carbon numbers fatty acids. Most prominent are fatty acid carbon chain length 16 and 18. Fatty acids are either fully saturated, or having a few (non-conjugated) double bonds in well-defined positions. Furthermore, unsaturated fatty acids are all in cis-configuration. Even then, considerable simplification is required to make the modelling manageable, one approach being to select a sufficient number of components from each significant component class listed in Table 1.

Modelling begins with the pure compounds, moving on to single phase mixtures and finally to multiple phases. A fundamental difficulty is the lack of experimental data on lipid properties, and the time and cost associated with generating new data. However, a group contribution approach appears to quite suitable for a parametric fit to the data available and predict properties for other conditions and/or lipid compounds. See Diaz-Tovar (2011), Ceriani et al (2013) Cunico et al (2013, 2014) and references therein for details of the approach taken to build the CAPEC LIPID database. This LIPID database can then be made available to process simulators to take full advantage of the computational efficiency of such programs.

4. Deodorizer application example

Figure 3 depicts a deodorizer column. The oil enters the stripping section and flows counter-current to stripping steam in a packed column. Typical operating conditions are vacuum levels of 3 – 5 mbar and temperatures of 250 – 260 ºC. The stripped oil spends typically 30 – 45 min in a retention section to thermally break down coloured and other unwanted components. The stripping steam is scrubbed for lipid volatiles before entering the vacuum system.

Deodorizer destillates contain valuable compounds such as tocopherol and sterols; see e.g. Gunawan and Yi-Hsu Ju (2009). It is therefore of interest to recover these in yields and concentrations that makes further separation and purification processing feasible.

A number of processing schemes have been proposed to achieve this based on introducing a higher temperature intermediate scrubber. Faessler (1998) achieves this by quenching with a small amount of cold distillate and Copeland and Belcher (2001) by an additional full hot scrubber loop as shown in more detail in Figure 4.

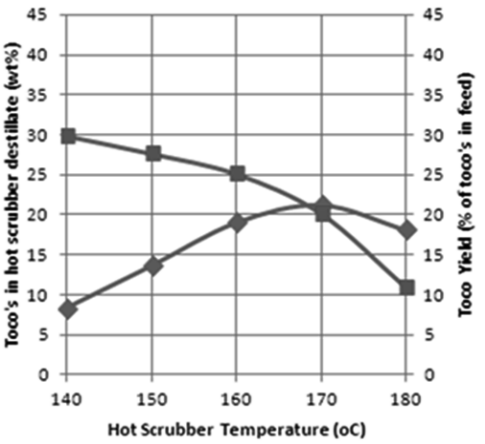

Figure 5. Double Scrubber Performance
(♦ concentration, ▪ yield)

A soybean oil deacidification column was modelled with PRO/II and based on the CAPEC LIPID database described above. The model provided insights for example as shown in Figure 5 for tocopherols in the condensate from the hot scrubber. The model quantifies the effects of more fatty acid condensing at lower hot scrubber temperature and increasing losses of tocopherol to the distillate from the cold scrubber at higher temperatures in the hot scrubber. Therefore a limitation of the double scrubber became clear, since a maximum concentration of the high valued tocopherol can only be achieved at expense of the yield of tocopherols.

The simulation framework could be used to quantify improvements with alternative processing schemes overcoming this limitation of the double scrubber system, simultaneously achieving quantitative recovery of tocopherols at high concentrations. (Marques de Lima and Sarup, 2011). Furthermore, the new scheme recovers oil that can be recycled and recovered as refined oil and the purity of the FFA distillate exceeds what is achievable in a double scrubber.

5. Conclusions

Modelling of lipids for process simulation purposes has progressed considerably within the last decade, with emphasis on fluid and thermodynamic VLE properties. However, much remains to be done, including LLE and SLE thermodynamics and charged organic molecules (phospholipids).

Validation remains a challenge as experimental data is scarce, but the combination of the fundamental work with commercial process simulators begins to prove useful for industrial design and as support for new technology development.

**kvg@kt.dtu.dk*

Abstract

Compared to the chemical industry, the use of PSE methods and tools is not as widespread in industrial fermentation processes. This paper gives an overview of some of the main engineering challenges in industrial fermentation processes. Furthermore, a number of mathematical models are highlighted as examples of PSE methods and tools that are used in the context of industrial fermentation technology. Finally, it is discussed what could be done to increase the future use of PSE methods and tools within the industrial fermentation technology area.

Keywords: control, fermentation, modelling, on-line sensor, optimisation

1. Introduction

Industrial fermentation processes are increasingly popular for the production of bulk and fine chemicals, pharmaceuticals etc. It is indeed remarkable that the term 'fermentation process' covers a broad range of production hosts: (1) Filamentous fungi are used for production of organic acids, where citric acid production by *Aspergillus niger* (Shu and Johnson, 1948) is a well-known example; (2) Penicillin, the first antibiotic that was discovered, is produced at large scale by fermentation of *Penicillium chrysogenum* (Moyer, 1948); (3) Recombinant proteins such as insulin are produced by fermentation with *Escherichia coli* (Johnson, 1983) and the yeast *Saccharomyces cerevisiae* (Ostergaard et al., 2000). Fermentation also plays a prominent role in 2nd generation bioethanol production processes. As a consequence, industrial fermentation processes are considered to form an important technological asset for reducing our future dependence on chemicals and products produced from fossil fuels.

However, despite their increasing popularity, fermentation processes have not yet reached the same maturity as traditional chemical production processes, particularly when it comes to using engineering tools such as mathematical models, process control algorithms and optimization techniques to support the search for improved and more efficient processes.

This perspective starts with a description of some of the most important engineering challenges within industrial fermentation technology, since a basic understanding of these challenges is an advantage when trying to understand the limitations in the current use of PSE methods and tools. Afterwards, the focus shifts towards PSE tools and their application in the fermentation area, with special focus on mathematical models. The paper ends with a number of future perspectives in this area: several potential solutions are proposed to facilitate the future use of PSE methods and tools in fermentation process development, operation and optimisation.

2. Engineering challenges within fermentation technology

An extended discussion of engineering challenges is given in Formenti et al. (2014).

2.1. Scaling up and scaling down

Most fermentations are operated as batch or fed-batch systems. Experiments in laboratory (0.5-20 L) and pilot scale (20-2000 L) have traditionally been used to screen for conditions that yield maximal volumetric productivity, since it is too expensive – due to loss of valuable production time – to do such screening in a full-scale reactor. In production of pharmaceuticals, where Good Manufacturing Practice (GMP) applies, performing experiments at large scale is usually completely out of the question.

Scaling up a fermentation process serves the purpose of transforming optimal operating conditions from laboratory/pilot scale to production scale bioreactors. The results from experiments at laboratory and pilot scale are, however, often difficult to compare to large industrial bioreactors, and scale-up is therefore still one of the major challenges in the fermentation industry. The main reason for this is that lab and pilot-scale fermenters can be considered well-mixed; in large scale, on the contrary, concentration gradients do exist, as for example documented in the study by Enfors et al. (2001), and such gradients are known to have a significant influence on the productivity of the host organism.

In practice, the scale-up to a production scale reactor is done iteratively: as soon as pilot plant experiments demonstrate a feasible business case, pilot plant results are attempted to be transferred to industrial scale. If similar performance can be demonstrated at large scale, scale-up is considered successful. If not, additional pilot plant experiments might be performed, to investigate the effect of additional process parameters on process performance.

Scaling down also poses a challenge in industrial fermentation technology. Most biotechnological processes are designed for existing equipment, since full scale bioreactors are very expensive and therefore used for several decades. As a consequence, the available process equipment ranges are known before a new process is designed, and it is important to find a setup of the small scale equipment that mimics the effect of full-scale process parameter changes on the process performance as closely as possible in order to develop new processes as efficiently as possible.

During the past decades, fermentation experiments at very small scale have become popular for gaining initial knowledge on fermentation process performance – sometimes the term ‘ultra-scale-down’ is used. This has resulted in the creation of completely new devices (microfluidic devices, microbioreactors and milliliter-scale stirred systems) that are considered suitable scale-down versions of larger bioreactors. Experience has shown that each small scale system brings benefits as well as problems during process development across scales, and it is especially important that the user is aware of this when applying such ultra-scale-down systems to a practical case. Successful scaling was reported by Isett et al. (2007), who demonstrated scalability from a 24-well plate (4-6 mL) to a laboratory scale stirred tank (20 L) using *S. cerevisiae*, while Islam et al. (2008) showed predictive scale-up from micro well plate (2 mL) to laboratory (7.5 L) and pilot (75 L) scale using *E. coli*. However, even with such positive results in mind, it is important to realize that there is still a long way if the aim is to demonstrate successful scale-up to industrial scale reactors, which can have a volume of 100 m^3 or more.

2.2. Mass transfer, morphology and rheology

Mass transfer is crucial for a fermentation process, as O_2 and nutrients have to be distributed, and possible toxic compounds, such as CO_2, have to be removed. The mass

transfer is strongly dependent on the viscosity of the fermentation broth, where the rheology of the broth is dependent on both the biomass concentration and the morphology of the production host cells (Cascaval et al., 2003). The complex relation between these variables is still not completely understood, which contributes to making scaling up/scaling down difficult. In general, stirring and aeration are a prerequisite for almost all types of cells, even for cell cultures with mammalian cells, in order to have a proper oxygen supply.

The most challenging expression systems are the filamentous microorganisms in terms of mass transfer and rheology: their morphology, both at the microscopic and macroscopic level, will have a major influence on mass transfer. At the microscopic level, the optimal morphology for a given bioprocess varies and cannot be generalized, and relies on the desired product (Gibbs et al., 2000). Dependent on the fermentation and the employed strain, pellet formation can occur. In some processes, a pellet type morphology is preferred since it allows for simplified downstream processing and yields a Newtonian fluid behavior of the medium (macroscopic level), which results in low aeration and agitation power input. However, the pelleted morphology has the disadvantage that it results in nutrient concentration gradients within the pellet. The latter is not observed in freely dispersed mycelia, although gradients can occur in such a system dependent on the mixing time of the reactor system, due to the high broth viscosity (Riley et al., 2000). Thus, freely dispersed mycelia allow enhanced growth and production. This has been attributed to the influence of morphology on the production kinetics at the microscopic level, e.g. higher enzyme secretion was observed from a more densely branched mutant of *Aspergillus oryzae* (Spohr et al., 1998).

It still remains challenging to estimate a reliable shear rate to evaluate the viscosity across scales for filamentous fungi, a problem that is usually not experienced in bacteria and yeast cultivation which exhibit a Newtonian behaviour which is attributed to the spherical shape of their morphology (Oniscu et al., 2003). This facilitates the work with these types of microorganisms considerably, and it also explains why many fermentation process optimization studies are focused on filamentous fungi.

2.3. Data handling, advanced sensors and control

The sensors in industrial bioreactors are most often limited to pH, dissolved oxygen and temperature sensors which are placed at a single location in vessels with large volumes, often with concentration gradients (Larsson et al., 1996). As a consequence, at best such standard univariate sensors display an average value for the entire process which can be correlated to the processes in the vessel, but little or no information on the spatial heterogeneity in the vessel is available.

A PID controller is the standard controller in fermentation processes to keep a controlled variable at or close to its set point or set point trajectory. However, the PID controller cannot guarantee that the fermentation is operated optimally. The set points (often time-varying trajectories in batch or fed-batch operation) only result in an optimal operation under certain nominal conditions. In most cases, a set point trajectory is the result of a time-consuming procedure where small adjustments are made to the ideal set point trajectory – the golden batch – whenever results of the last batch demonstrate an improvement. However, disturbances such as changes in substrate quality or composition take place, and ideally the set points should be modified accordingly. The latter optimization is difficult in industrial fermentations for a number of reasons: (1) Most common controlled variables, dissolved oxygen (DO) and pH, are only indirectly linked to the optimal operation of a fermenter, i.e. the operation that leads to the highest volumetric productivity. Important variables such as the biomass, substrate, product or

by-product concentration are only sporadically monitored (and less frequently controlled); (2) Models can be used to synthesize controllers that operate close to optimal conditions and to determine optimal trajectories for (fed-)batch operations. In the fermentation industry, however, sufficiently accurate models that can be used for this purpose are often lacking, as for example pointed out by Smets et al. (2004) in a review on optimal feed rate strategies.

Introduction of more advanced sensors in industrial scale fermentation could be beneficial and allow the introduction of more advanced or improved control strategies. However, this is not an easy development task. Cervera et al. (2009), in a literature review on the use of near infrared spectroscopy in fermentation and cell culture, concluded that most reported applications refer to at-line or off-line measurements. What industry really needs is a demonstration that such advanced sensors can be operated on-line to generate real-time data that can be used as input for controlling the fermentation process. Also worth mentioning is that a major limitation in the introduction of new sensors for process monitoring originates from GMP aspects, especially in the pharmaceutical biotechnology industry.

Process knowledge extraction from historical data is another area which has not been explored that much. The fermentation industry possesses large databases with historical data, but in most cases these are not used for a number of reasons: (1) Retrieval of the data is often experienced as far too time-consuming; (2) Data compression algorithms sometimes remove the most interesting dynamics from the data that are stored; (3) In many cases, especially for smaller companies, the knowledge and experience to work with large historical data sets is not available within the company. Furthermore, it is often problematic, due to proprietary reasons, to involve external partners – academia or consultants – in such a historical data interpretation task.

3. Fermentation process modelling

The main purpose of this section is to briefly illustrate the use of PSE methods and tools in the frame of fermentation projects, and this will be done by giving insight in the broad range of models that are available for studying fermentation processes.

3.1. Mechanistic models

Mechanistic models are useful for representing available process knowledge, and can therefore support process development. Reviews on mathematical models can be found in Nielsen and Villadsen (1992), Henson (2003) and Gernaey et al. (2010), among othres. The opinion article by Bailey (1998) is still highly relevant as well, and highlights both the history and the future of mathematical modelling in biochemical engineering.

Mechanistic fermentation process models are based on mass, heat and momentum balances, supplemented with an appropriate mathematical formulation of the key mechanisms (e.g. kinetic expressions to reflect process dynamics). The kinetic expressions are often empirical, thus providing a simplified and idealized view of a complex biological mechanism, with the Monod expression for microbial growth kinetics as the most well-known example. Assuming a homogeneous reactor environment, a generally accepted classification of mechanistic models of cell populations is presented in Figure 1 (Frederickson et al., 1970; Bailey, 1998). If the assumption of a homogeneous reactor environment does not hold, then a distributed model is needed (i.e. a model where not only time, but also space (1-, 2- or 3D), forms an independent variable): well-known examples are compartment models (Vrabel et al., 2000), as well as computational fluid dynamics (CFD). Unsegregated models are most

common, and rely on an average cell description. Within this category, unstructured models are the simplest – and also the most popular) models that use a single variable to describe biomass.

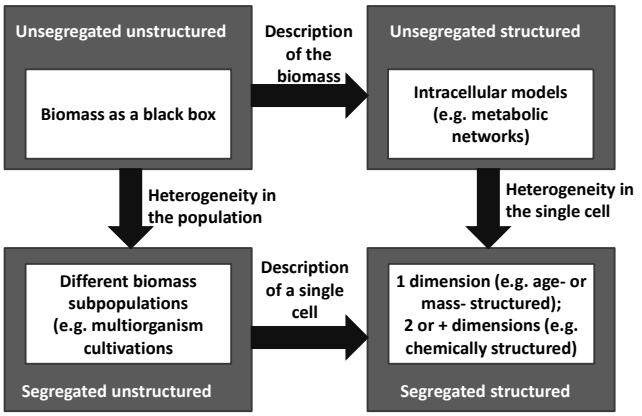

Figure 1. Schematic classification of mechanistic models for cell cultivations (Frederickson et al., 1970; Bailey, 1998; Lencastre-Fernandes et al., 2011).

Unsegregated structured models describe the biomass as consisting of several variables (such as NADH, precursors, metabolites, ATP, biomass), and have been used for modeling complex processes such as yeast intracellular metabolism (Nielsen and Villadsen 1992). Morphologically structured models (Agger et al. 1998) were specifically developed to describe growth of important production organisms, filamentous fungi,— and distinguish between different regions of the hyphal elements.
Segregated models consider individual cells, in recognition of the fact that cells in a population – a pure culture – are different, and are most often formulated as a population balance model (PBM). Lencastre Fernandes et al. (2011) provide a concise review of the status of PBM in the fermentation area. An unstructured segregated model characterizes cells by one distributed property (i.e. cell size or age of individual cells; Zamamiri et al., 2002) without considering intracellular composition. Obviously, structured segregated models are more complex, since the distribution of one or more intracellular variables is also considered. Solving the resulting multi-dimensional PBM is difficult, unless the intracellular state can be captured with just a few variables (Henson, 2003). One alternative to PBMs is cell ensemble modeling (Domach and Shuler, 1984; Henson, 2003), where the parameters of a single cell model are randomized to simulate a cell population. Apart from the cells, the PBM framework also offers the possibility to make detailed studies of other phenomena of interest, for example the behaviour of air bubbles in an aeration tank, where the bubble size will change when the gas bubbles move through the reactor as a result of the action of the impeller on the one hand, and coalescence of gas bubbles on the other hand.

3.2. Computational fluid dynamics (CFD)

Aeration and agitation design and scale-up have for a long time been performed based on empirical correlations and engineering experiences. Typical scale-up parameters that are used in practice are constant power to volume ratio, constant tip speed, constant Reynolds number and constant volumetric air flow rate. Scale up with constant power to volume ratio will result in an increased tip speed (i.e. shear) while the mixing time is decreased (Stanbury et al., 1995). However, none of these correlations includes vessel

geometry, mixing intensities, operating conditions, feed location, physical properties etc. (Leng et al., 2008).
In view of the general lack of sufficient understanding of aeration and agitation design/scale-up, there is general agreement that Computational Fluid Dynamics (CFD) is a valuable tool that can be used to support the scaling up and scaling down of bioreactors, and for studying mixing and the potential occurrence of gradients in a tank. Ideally, assuming that the kinetics of a process hold across scales, CFD can ideally be used to support transfer of research results across scales: from the first experiment in an ultra-scale-down reactor via well-mixed pilot scale experiments towards the full-scale reactor with its concentration gradients. One of the challenges in this area is the fact that many academic groups with an interest in CFD only have access to laboratory scale and pilot scale data. This is illustrated by the fact that one of the only published data sets in large scale (30 m^3) is almost 20 years old (Larsson et al., 1996).

4. Future perspectives

4.1. Industry-academia collaboration

Industrial scale data are proprietary, which forms a severe limitation. Data from process scale up studies can for example not be found as part of the scientific literature, and can thus not be used as a basis for extending the available knowledge about this important engineering task. Significant progress with respect to understanding the scaling up problem can thus only be made through a close collaboration between industry and academia: industry has equipment – large scale reactors which are not affordable for university – and knowhow about how to run a full-scale fermentation, whereas academia can contribute with expertise in for example CFD and detailed knowledge related to the cellular behavior at large scale to develop a better understanding of the major scaling up challenges. For the future, it should be considered to define a number of industrially relevant cases, using old production strains that are no longer in use or wild type strains with industrial value, which should be described in detail in order to allow people to compare results and make progress.
Another area where industry-academia collaboration is important is specifically on the transformation of historical data to useful information. Academia often lacks industrially relevant data sets of significant size that can be used to demonstrate the value of data mining tools. The main hurdle to be taken there, again, is the fact that data are proprietary, but this can often be solved by appropriate scaling of the raw data before they are transferred from industry to academia. Here as well, it could be useful to establish collaboration between several industrial partners, in order to make a number of data sets publicly available such that academic groups can test their research work on industrially relevant data, instead of solely relying on idealized toy examples with academic value which cannot be transferred to industrial practice.

4.2. Soft sensors

Introducing new, more advanced sensors is not straightforward. Therefore, one method to increase both data quality of on-line sensors and data quantity, even without violating GMP regulations, is by increased use of soft sensors. In a soft sensor, robust on-line measurements, which are not subject to time delay, are used to calculate the expected value of new variables of interest that could be useful to allow improved control of fermentation processes. A recent report by an expert group concluded that the use of soft sensors in the fermentation industry is very limited at this moment, despite the obvious potential (Luttmann et al., 2012). This is clearly a topic with a considerable unexplored potential that should be more in focus in the future.

4.3. Hybrid models

Hybrid models combine fundamental knowledge with data-driven techniques to model fundamentally unknown dependencies, and more attention should be paid to the future use of such hybrid models. It has indeed been demonstrated that the integration of knowledge from first-principles with multivariate data analysis methods, resulting into a hybrid semi-parametric modeling approach, has the potential to improve process understanding and can enable significantly increased prediction performance (von Stosch et al., 2012). The strength of hybrid models is that they can integrate different sources of knowledge in form of parametric and nonparametric structures, where the structure of the parametric models is a priori fixed on the basis of first-principles knowledge, whereas the structure of nonparametric models is identified from data.

4.4. Benchmarking of control strategies

In the wastewater treatment field, an area that is closely related to fermentation, the development of models to support benchmarking of control strategies – i.e. the objective simulation-based comparison of control strategies – has been very successful, and has resulted in the recent publication of a benchmarking report to document an effort that has lasted almost 20 years (Gernaey et al., 2014). The result of the benchmarking work is a set of validated models, a number of reference control strategies and a set of standardized evaluation criteria to compare performance of different control strategies. Such an effort should be repeated in the fermentation area as well with the aim of promoting the use of modelling and more advanced control in the fermentation area as well. The key to success in the benchmarking developments in the wastewater treatment area is the fact that validated simulation models were made available for free, such that the model user could focus on development and testing of control strategies instead of getting lost in the tedious task of writing and validating the model code.

5. Conclusions

The increased use of models and PSE tools in the fermentation area will result in improved understanding of reactor operation across scales, and can potentially support more efficient transfer of results across scales. However, for these efforts to be successful, close collaboration between industry and academia will be required.

Sustainable Production and Consumption: A Decision-Support Framework Integrating Environmental, Economic and Social Sustainability

Adisa Azapagic

School of Chemical Engineering and Analytical Science, The Mill, Sackville Street, The University of Manchester, Manchester M13 9PL,UK

adisa.azapagic@manchester.ac.uk

Abstract

The idea of sustainable production and consumption is becoming a widely-accepted societal goal worldwide. However, its implementation is slow and the world continues to speed down an unsustainable path. One of the difficulties is the sheer complexity of production systems that would need to be re-engineered in a more sustainable way as well as the number of sustainability constraints that have to be considered and satisfied simultaneously. This paper argues that bringing about sustainable production and consumption requires a systems approach underpinned by life cycle thinking as well as an integration of economic, environmental and social aspects. In an attempt to aid this process, a decision-support framework has been developed comprising a range of tools, including scenario analysis, life cycle assessment, life cycle costing, social sustainability assessment, system optimisation and multi-attribute analysis. An application of the framework is illustrated on a case study related to energy.

Keywords: decision-support framework, energy, life cycle thinking, sustainable production and consumption, systems approach.

1. Introduction

It is increasingly becoming apparent that the lifestyles and practices of modern society cannot be sustained indefinitely, with growing scientific evidence showing that we are exceeding the Earth's capacity with respect to resource use and emissions to the environment (IPCC, 2013; UNEP, 2012). One of the many challenges of moving towards sustainable production and consumption is to find out which options are sustainable and to balance a plethora of disparate economic, environmental and social aspects. The challenge is exacerbated by the complexity of production systems and a large number of different stakeholder groups with conflicting interests. It is also often unclear what sustainability criteria are relevant for which alternatives. An additional difficulty is related to the need to consider both quantitative and qualitative criteria, often based on imprecise or subjective information. However, probably the greatest challenge is that sustainability problems are "wicked" problems which are intractable and highly resistant to resolution (Rittel and Webber, 1973; Azapagic and Perdan, 2014). Different approaches have been proposed for dealing with "wicked" problems (e.g., Roberts, 2000; Brown et al., 2010) but this paper argues that the best way is taking a systems approach and considering all three dimensions of sustainable development – environmental, economic and social – on a life cycle basis. The main reason for that is that such an approach treats sustainability issues as complex systems, and instead of focusing just on 'cause and effect', recognises their complexity and interrelationships,

acknowledging that technological solutions must be considered in a wider social, environmental, economic, regulatory, political and ethical framework (Azapagic and Perdan, 2014).

In an attempt to facilitate the process of better understanding and solving "wicked" sustainability problems, this paper proposes a decision-support framework which is underpinned by a systems, life cycle approach that integrates all three dimensions of sustainable development. The framework is outlined in the next section, followed in Section 3 by its application to a decision problem related to identifying sustainable electricity options for the future.

2. Decision-support framework

The proposed decision-support framework is outlined in Figure 1. Engaging stakeholders and understanding their concerns is a prerequisite for sustainable production and consumption, so that stakeholder identification and involvement is the first and probably the most important step. Depending on the decision problem, stakeholders may be representatives from industry, government, non-governmental organisations (NGOs) and consumer groups. They help to identify alternative options and key decision-criteria that will be used for a sustainability assessment of the defined alternatives. The sustainability of the alternatives is evaluated on a life cycle basis considering environmental, economic and social aspects of interest to the stakeholders. Different tools can be used for these purposes, including life cycle assessment (LCA), life cycle costing (LCC) and social life cycle assessment (S-LCA). Depending on stakeholders' interests and the type of the decision problem, the sustainability assessment will result in a large number of often disparate decision criteria, usually with some alternatives being better for some sustainability aspects but worse for others. To help the stakeholders deal with this complex information, multi-criteria decision analysis (MCDA) can be used. MCDA tools used for these purposes include single and multiobjective system optimisation as well as multi-attribute analysis (for a review, see e.g. Azapagic and Perdan, 2005). At the end of this process, the stakeholders can choose the most sustainable alternative, based on their preferences for different sustainability criteria. The decision-support framework can be used in a modular and/or iterative manner to suit the type of the problem and stakeholders. A practical application of the framework is illustrated in the next section.

3. Applying the decision-support framework

3.1. Problem definition and stakeholders

The decision problem considered here is related to identifying sustainable options for future electricity supply in the UK, extending up to the year 2070. The example is based on the data reported in Stamford and Azapagic (2014). The aim is to evaluate the sustainability of a range of technological options and identify an electricity mix that would have the lowest negative economic, environmental and social impacts. The stakeholder groups relevant for this problem include the energy industry, government, NGOs and consumers. Over 30 organisations and more than 600 consumers were engaged and consulted and their input used to inform the next steps of the decision-support framework, as discussed below.

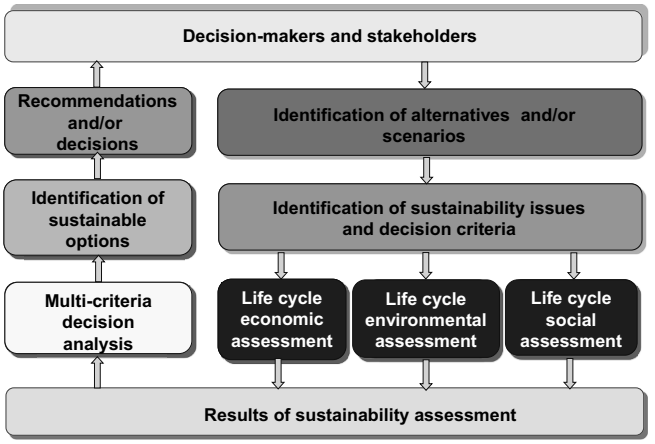

Figure 1 Decision-support framework for identifying sustainable production and consumption options

Table 1 Definition of scenarios (adapted from Stamford and Azapagic, 2014)

Scenario	Coal CCS and nuclear	Electricity mix
65%-1	Coal CCS, no new nuclear build	70% fossil and 30% renewables
65%-2	Coal CCS, new nuclear build	1/3 each of fossil, nuclear and renewables
80%	Coal CCS, new nuclear build	10% fossil, 30% nuclear and 60% renewables
100%-1	No coal CCS, no new nuclear build	100% renewables
100%-2	No coal CCS, new nuclear build	Equal proportions of nuclear and renewables

3.2. Identification of alternatives and scenarios

The following electricity generation options are considered, expected to play a major role in a future UK electricity mix (DECC, 2011): coal with and without carbon capture and storage (CCS), natural gas, nuclear, solar photovoltaics, wind and biomass. Taking a life cycle approach, all technologies are considered from 'cradle to grave', including the construction and decommissioning of power plants, extraction, processing and transport of fuels (if relevant), generation of electricity and waste management.

Five future scenarios up to 2070 have been formulated to examine the sustainability implications of different electricity mixes; the scenarios are summarised in Table 1. All scenarios are driven by the need to reduce greenhouse gas (GHG) emissions. Achieving the UK's legally-binding target of reducing the GHG emissions by 80% by 2050 on 1990 levels (DECC, 2012) will require a complete decarbonisation of the UK electricity mix (UKERC, 2009). This is considered in scenarios 100%-1 and 100%-2 (Table 1). The other three scenarios consider a case whereby the GHG targets are not achieved and the electricity mix is decarbonised by 65% or 80%. The scenarios also assume different penetration of the electricity technologies, as given in Table 1.

3.3. Identification of sustainability issues and decision criteria

Following extensive consultations with the stakeholders, 19 sustainability issues have been identified (Table 2) and translated in to 36 indicators or decision criteria (see Stamford and Azapagic, 2014). Each indicator addresses a particular sustainability issue on a life cycle basis, from 'cradle to grave'.

Table 2 Sustainability issues identified by stakeholders

Economic	Environmental	Social
Operability	Material recyclability	Provision of employment
Technological lock-in resistance	Water eco-toxicity	Human health impacts
Immediacy	Global warming	Large accident risk
Levelised cost of generation	Ozone layer depletion	Energy security
Cost variability	Acidification	Nuclear proliferation
	Eutrophication	Intergenerational equity
	Photochemical smog	
	Land use and quality	

3.4. Sustainability assessment

To assess the sustainability of different scenarios and technologies on a life cycle basis, LCA, LCC and S-LCA have been carried out. The results are shown in Figure 2 (owing to space constraints, only selective results are shown for illustration). For example, for all the scenarios the levelised costs would go up in the future relative to the present day, with scenario 100%-1 being the worst and 65%-2 and 100%-2 the least expensive options (Figure 2a). However, the sensitivity to fuel prices reduces significantly over the period for all the scenarios because of the lower contribution of fossil fuels than today (Figure 2b). Furthermore, all the scenarios would have lower life cycle environmental impacts than the current UK grid, including the global warming potential, GWP (Figure 2c). The exceptions are terrestrial eco-toxicity (Figure 2d) and land use (not shown) both of which would go up for all the scenarios. Finally, for the social impacts, some scenarios are better than today but others are worse. For instance, the employment in the supply chain would increase across the scenarios but so would the depletion of minerals and metals.

Therefore, as we can seen, the sustainability of different scenarios differs for different indicators, making it difficult to identify the most sustainable option. The next section shows how MCDA can help towards that.

3.5. Multi-criteria decision analysis and identification of sustainable options

The stakeholders were also consulted on their preferences for different sustainability issues as well as the electricity technologies. Example results are shown here for the UK public's preferences for different sustainability issues and electricity technologies (Youds, 2013). As indicated in Figure 3, water contamination is the most important and the cost of electricity least important in distinguishing between different electricity options. Solar photovoltaics, hydro and wind power are the most favourable options for the UK public while the fossil fuel options are least favoured.

To identify the most sustainable electricity scenarios, a simplified approach has been applied, assuming that all the criteria are equally important; the results are summarised in Table 3. Using a simple summed-rank method, the present and future scenarios have been ranked for each sustainability indicator and their individual ranks summed up to obtain a single score; the lower the score, the better the option (Stamford and Azapagic, 2014). Each scenario has then been ranked based on their overall summed score. The overall ranking suggests that all future scenarios are superior to the present electricity mix with the exception of 65%-1, which has the same ranking as the present mix. The best option, within the limitations of this simplified ranking approach, is 100%-2, followed by 80% (see Table 1 for scenario definitions).

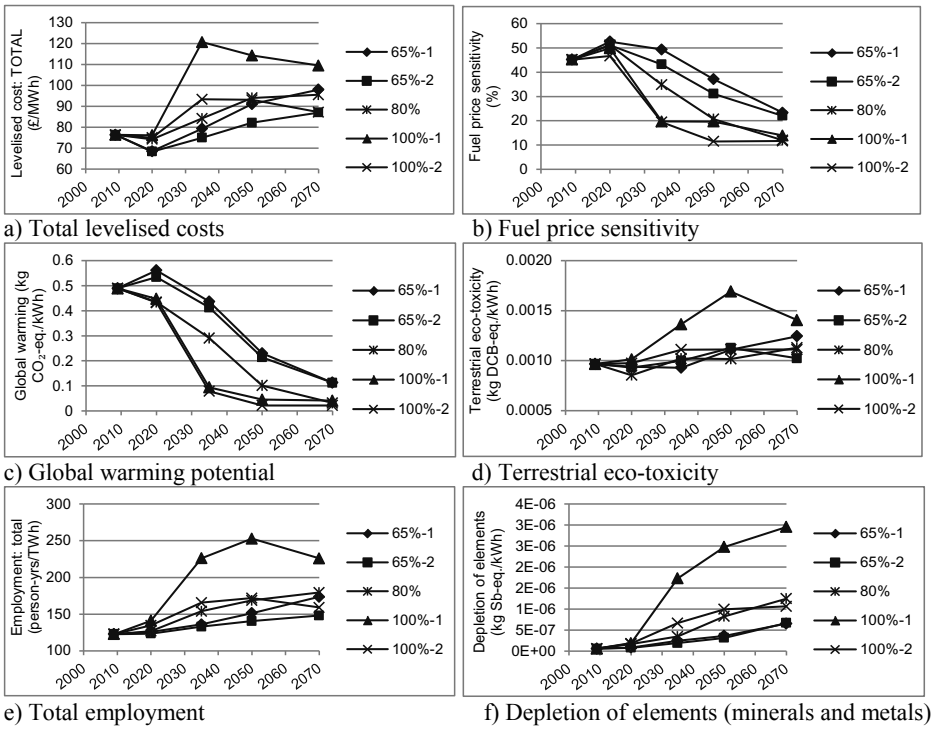

Figure 2 The results of the economic, environmental and social sustainability assessment (All indicators are on a life cycle basis. Only selective results are shown. For other indicators, see Stamford and Azapagic, 2014).

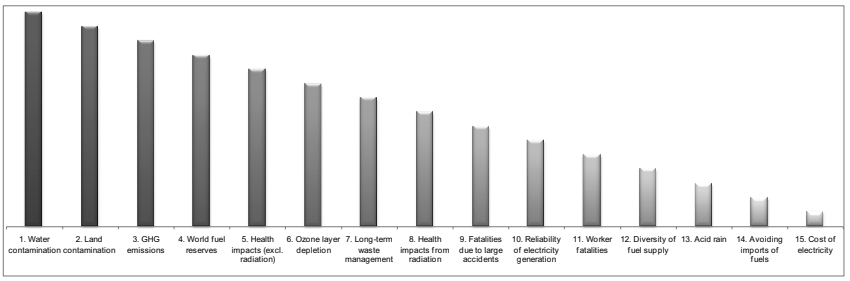

Figure 3 The importance of different sustainability issues to the UK public (Sample=625. Ranking order: 1=most important; 15=least important).

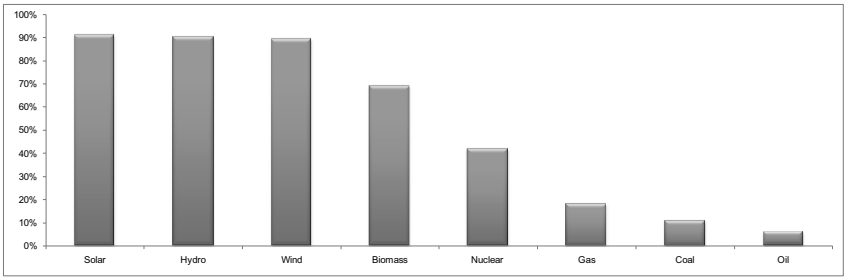

Figure 4 UK public's preferences for different electricity technologies (Sample=625. Values on the y-axis show the percentage of the respondents that favoured each electricity option).

Table 3 Ranking of scenarios

	Present UK grid	65%-1	65%-2	80%	100%-1	100%-2
Economic ranking	1	5	3	4	5	2
Environmental ranking	6	4	3	2	5	1
Social ranking	6	4	5	3	1	2
Overall ranking	5-6	5-6	3-4	2	3-4	1

However, if the scenarios are optimised, a different ranking emerges, depending on the objective function. For example, optimising on total life cycle costs favours scenarios 65% but the carbon targets are missed by a large margin; optimising on the total GWP favours the 100% scenarios but the costs are high (Bartezcko-Hibbert et al., 2014).

4. Conclusions

Unsustainable consumption drives unsustainable production and vice versa so that they cannot be tackled in isolation of each other. This calls for a systems, life cycle approach, taking into account environmental, economic and social concerns of different stakeholders. This paper has illustrated how such an approach can be incorporated within a decision-support framework to enable identification of sustainable production and consumption options. The framework facilitates engagement of different stakeholders and comprises a range of tools, including scenario analysis, life cycle assessment, life cycle costing, social sustainability assessment, system optimisation and multi-attribute analysis. The framework has been illustrated on an example related to future electricity options.

Control of Reaction Systems via Rate Estimation and Feedback Linearization

Diogo Rodrigues*, Julien Billeter and Dominique Bonvin

Laboratoire d'Automatique, EPFL, Lausanne, Switzerland
diogo.mateusrodrigues@epfl.ch

Abstract

The kinetic identification of chemical reaction systems often represents a time-consuming and complex task. This contribution presents an approach that uses rate estimation and feedback linearization to implement effective control without the use of a kinetic model. The reaction rates are estimated by numerical differentiation of reaction variants that are computed from measurements. The approach is illustrated in simulation through the temperature control of a continuous stirred-tank reactor.

Keywords: feedback linearization, rate estimation, numerical differentiation, reaction variants.

1. Introduction

Efficient control of reaction systems typically requires good kinetic models, whose identification however can be rather difficult and time consuming. As an alternative, one could try to infer the reaction rates directly from measurements, that is, without the help of a kinetic model, which can be done if the various rates can be decoupled (Mhamdi and Marquardt (2004)).

The concept of reaction variants and invariants has been proposed to decouple the dynamic effects in reaction systems, thereby facilitating their analysis and control (Asbjørnsen and Fjeld (1970); Asbjørnsen (1972)). A finer separation of the various dynamic effects in both homogeneous and heterogeneous open reaction systems has been proposed by Amrhein et al. (2010) and Bhatt et al. (2010), and reformulated recently as a linear transformation of the numbers of moles to so-called vessel extents by Rodrigues et al. (2015).

Although various control structures for continuous stirred-tank reactors based on reactions variants and extensive variables have been proposed throughout the years (Hammarström (1979); Georgakis (1986); Farschman et al. (1998); Dochain et al. (2009); Hoang et al. (2014)), there does not exist a systematic way of tackling the problem, in particular without the use of a kinetic model. The long-term objective of this research is the development of such a systematic control approach, which would utilize the linear transformation to vessel extents and control selected extents by adjusting the corresponding rates such as inlet flowrates or the power exchanged with the jacket.

This paper is a first step in that direction as it investigates the possibility of controlling chemical reactors without the explicit use of kinetic models. The reaction rates are estimated from concentration and temperature measurements via the concept of variants and then used via a feedback-linearization scheme to control the reactor temperature by manipulating the amount of heat that is exchanged with the environment in a continuous stirred-tank reactor.

2. System description

Let us consider an open homogeneous reactor with S species, R independent reactions, p inlet streams and one outlet stream. The mole and heat balances can be written as follows (Rodrigues et al. (2015)):

$$\underbrace{\begin{bmatrix}\dot{\mathbf{n}}(t)\\ \dot{Q}(t)\end{bmatrix}}_{\dot{\mathbf{z}}(t)} = \underbrace{\begin{bmatrix}\mathbf{N}^{\mathrm{T}}\\ (-\boldsymbol{\Delta}\mathbf{H})^{\mathrm{T}}\end{bmatrix}}_{\mathscr{A}} \mathbf{r}_v(t) + \underbrace{\begin{bmatrix}\mathbf{0}_S\\ 1\end{bmatrix}}_{\mathbf{b}} q_{ex}(t) + \underbrace{\begin{bmatrix}\mathbf{W}_{in}\\ \check{\mathbf{T}}_{in}^{\mathrm{T}}\end{bmatrix}}_{\mathscr{C}} \mathbf{u}_{in}(t) - \omega(t) \underbrace{\begin{bmatrix}\mathbf{n}(t)\\ Q(t)\end{bmatrix}}_{\mathbf{z}(t)}, \qquad \underbrace{\begin{bmatrix}\mathbf{n}(0)\\ Q(0)\end{bmatrix}}_{\mathbf{z}(0)} = \underbrace{\begin{bmatrix}\mathbf{n}_0\\ Q_0\end{bmatrix}}_{\mathbf{z}_0}, \quad (1)$$

where $\mathbf{n}$ is the S-dimensional vector of numbers of moles, $Q(t) = m(t)c_p(t)\big(T(t) - T_{ref}\big)$ the heat of the reaction mixture, $\mathbf{r}_v$ the R-dimensional vector of reaction rates, q_{ex} the heat power that is exchanged with the jacket and the environment, $\mathbf{u}_{in}$ the p-dimensional vector of inlet flowrates, $\omega(t) := \frac{u_{out}(t)}{m(t)}$ the inverse of the residence time, with u_{out} the outlet flowrate and m the mass in the reactor, $\mathbf{N}$ the $R \times S$ stoichiometric matrix, $\boldsymbol{\Delta}\mathbf{H}$ the R-dimensional vector of heats of reaction, $\mathbf{W}_{in}$ the $S \times p$ inlet-composition matrix, $\check{\mathbf{T}}_{in}$ the p-dimensional vector of inlet specific enthalpies, V the reactor volume, c_p the specific heat capacity, T the temperature and T_{ref} a reference temperature. The state vector $\mathbf{z}$ and the vector $\mathbf{b}$ are both of dimension $S+1$, while the matrix $\mathscr{A}$ has dimension $(S+1) \times R$ and the matrix $\mathscr{C}$ has dimension $(S+1) \times p$.

2.1. Transformation to reaction-variant states

If $\operatorname{rank}(\mathscr{A}) = R$, there exists a transformation matrix $\mathscr{T}$ of dimension $R \times (S+1)$ such that

$$\mathscr{T}\mathscr{A} = \mathbf{I}_R. \quad (2)$$

Applying the transformation $\mathscr{T}$ to Eq.(1) and defining $\mathbf{x}_{\mathbf{r}_v}(t) := \mathscr{T}\mathbf{z}(t)$ leads to

$$\dot{\mathbf{x}}_{\mathbf{r}_v}(t) = \mathbf{r}_v(t) + (\mathscr{T}\mathbf{b})\, q_{ex}(t) + (\mathscr{T}\mathscr{C})\, \mathbf{u}_{in}(t) - \omega(t)\mathbf{x}_{\mathbf{r}_v}(t), \qquad \mathbf{x}_{\mathbf{r}_v}(0) = \mathscr{T}\mathbf{z}_0. \quad (3)$$

The transformed states $\mathbf{x}_{\mathbf{r}_v}$ are reaction variants, with each state $x_{r_{v,i}}$ $(i = 1, \ldots, R)$ depending on the rate $r_{v,i}$, the manipulated variable q_{ex}, a combination of the inlet flowrates $\mathbf{u}_{in}$, and ω the inverse of the residence time. To be applicable, the transformation $\mathscr{T}$ requires that at least R elements of the vector $\mathbf{z}$ be measured (Rodrigues et al. (2015)). Note that transformations based on $[\mathscr{A}\ \ \mathbf{b}]$ or $[\mathscr{A}\ \ \mathbf{b}\ \ \mathbf{z}_0]$ could also be used, but they would require stricter rank conditions and thus more measured quantities, that is, $R+1$ or $R+2$ instead of R.

The proposed control scheme includes two steps, namely, the estimation of the reaction rates from the reaction-variant states $\mathbf{x}_{\mathbf{r}_v}$ and temperature control via feedback linearization.

3. Control Problem

The objective is to implement temperature control, that is, to control the heat signal $Q(t)$ to either the constant setpoint Q_s or the reference trajectory $Q_s(t)$ by manipulating the exchanged heat power $q_{ex}(t)$. The reaction rates $\mathbf{r}_v(t)$ will be estimated without the use of a kinetic model using the measured quantities $\mathbf{z}(t)$, $\mathbf{u}_{in}(t)$, $\omega(t)$ and the manipulated variable $q_{ex}(t)$.

3.1. Estimation of reaction rates

The estimation of $\mathbf{r}_v(t)$ proceeds via the differentiation of the reaction variants $\mathbf{x}_{\mathbf{r}_v}(t)$ that are obtained by transformation of $\mathbf{z}(t)$, or of subset of it (of dimension $S_a + 1 \geq R$), and the knowledge of the quantities $q_{ex}(t)$, $\mathbf{u}_{in}(t)$ and $\omega(t)$.

Reformulating Eq.(3) yields the reaction rates

$$\mathbf{r}_v(t) = \dot{\mathbf{x}}_{\mathbf{r}_v}(t) - (\mathscr{T}\mathbf{b})\, q_{ex}(t) - (\mathscr{T}\mathscr{C})\, \mathbf{u}_{in}(t) + \omega(t)\mathbf{x}_{\mathbf{r}_v}(t). \quad (4)$$

Different transformations $\mathscr{T}$ that satisfy the condition in Eq.(2) can be found. An example is the Moore-Penrose pseudo-inverse of the matrix $\mathscr{A}$. However, when only noisy measurements of the state vector $\mathbf{z}$ are available, a better alternative is to consider an estimator in the maximum-likelihood sense, for which the transformation (2) is computed as

$$\mathscr{T} = (\mathscr{A}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\mathscr{A})^{-1}\mathscr{A}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}, \tag{5}$$

where $\boldsymbol{\Sigma}$ is the $(S+1)$-dimensional variance-covariance matrix of the measurements. Note that the weighted transformation in Eq.(5) satisfies Eq.(2). The estimates $\hat{\mathbf{r}}_v(t)$ of the reaction rates given by Eq.(4) can be computed as described in Appendix A.

3.2. Temperature control via feedback linearization

The controller forces the heat signal $Q(t)$ to converge towards its reference trajectory $Q_s(t)$ at a desired rate. Defining the new input $v(t)$ to represent the right-hand side of the heat balance in Eq.(1) results in an integral relationship between the input $v(t)$ and the controlled variable $Q(t)$,

$$\dot{Q}(t) = (-\boldsymbol{\Delta}\mathbf{H})^{\mathrm{T}}\mathbf{r}_v(t) + q_{ex}(t) + \check{\mathbf{T}}_{in}^{\mathrm{T}}\mathbf{u}_{in}(t) - \omega(t)Q(t) \stackrel{!}{=} v(t). \tag{6}$$

Such an approach builds on feedback linearization, as shown in Figure 1. Solving Eq.(6) for q_{ex} and replacing $\mathbf{r}_v$ by its estimate $\hat{\mathbf{r}}_v$ according to Eq.(12) in Appendix A gives the following expression for the manipulated variable:

$$q_{ex}(t) = v(t) - (-\boldsymbol{\Delta}\mathbf{H})^{\mathrm{T}}\hat{\mathbf{r}}_v(t) - \check{\mathbf{T}}_{in}^{\mathrm{T}}\mathbf{u}_{in}(t) + \omega(t)Q(t). \tag{7}$$

One can design a feedback controller that forces the control error $e(t) := Q_s(t) - Q(t)$ to converge exponentially to zero at the rate γ,

$$\dot{e}(t) = -\gamma e(t), \qquad e(0) = Q_s(0) - Q(0), \tag{8}$$

by using the control law

$$v(t) = \dot{Q}_s(t) + \gamma\big(Q_s(t) - Q(t)\big). \tag{9}$$

Note that this control law uses $\dot{Q}_s(t)$, which ideally requires prior knowledge of the reference signal $Q_s(t)$.

4. Simulated example

Consider the simulated example of the acetoacetylation of pyrrole in a homogeneous CSTR of constant volume with $S = 4$ species (A: pyrrole; B: diketene; C: 2-acetoacetylpyrrole; D: dehydroacetic acid), $R = 2$ reactions (A + B $\rightarrow$ C, 2B $\rightarrow$ D), $p = 2$ inlets (of A and B) and 1 outlet, the flowrate of which is adjusted to keep the volume constant (Ruppen et al. (1998)).

For this simulation, the following values are used: $\mathbf{N} = \left[\begin{smallmatrix} -1 & -1 & 1 & 0 \\ 0 & -2 & 0 & 1 \end{smallmatrix}\right]$, $\mathbf{W}_{in}^{\mathrm{T}} = \left[\begin{smallmatrix} 67.09^{-1} & 0 & 0 & 0 \\ 0 & 84.08^{-1} & 0 & 0 \end{smallmatrix}\right]$ kmol kg^{-1}, $\boldsymbol{\Delta}\mathbf{H} = \left[\begin{smallmatrix} -70 \\ -50 \end{smallmatrix}\right] \times 10^3$ kJ kmol^{-1}, $\check{\mathbf{T}}_{in} = \mathbf{0}_p$ at $T_{ref} = 298.15$ K, $r_{v,1} = Vk_1c_Ac_B$ and $r_{v,2} = Vk_2c_B^2$, where $\mathbf{c}(t) = \mathbf{n}(t)/V(t)$, $k_1 = A_1 \exp\left(-\frac{E_{a,1}}{RT}\right)$ and $k_2 = A_2 \exp\left(-\frac{E_{a,2}}{RT}\right)$. The values of A_1, A_2, $E_{a,1}$, $E_{a,2}$, densities and specific heat capacities are adapted from Maria and Dan (2011). The volume is constant at $V = 90.16$ L. Furthermore, it is assumed that the density and the specific heat capacity are constant, which results in the constant heat capacity $mc_p = 129.5$ kJ K^{-1}.

The system is initially at steady state corresponding to the inputs $\bar{q}_{ex} = -4.9 \times 10^3$ kJ min^{-1} and $\bar{\mathbf{u}}_{in} = \left[\begin{smallmatrix} \bar{u}_{in,A} \\ \bar{u}_{in,B} \end{smallmatrix}\right] = \left[\begin{smallmatrix} 40 \\ 15 \end{smallmatrix}\right]$ kg min^{-1}, which gives the initial values $\mathbf{n}_0^{\mathrm{T}} = [0.833 \;\; 0.093 \;\; 0.143 \;\; 0.028]$

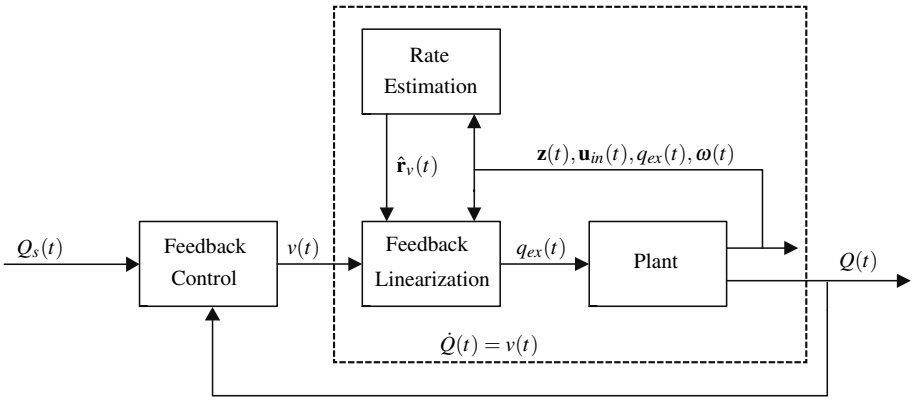

Figure 1: Temperature control based on feedback linearization and estimation of the reaction rates.

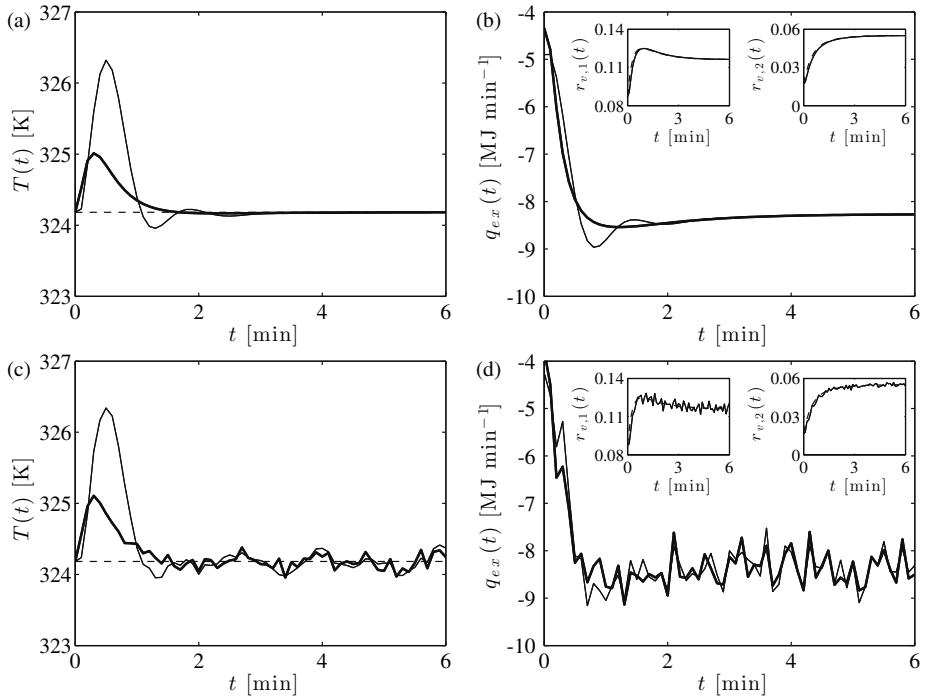

Figure 2: (a) and (c): Temperature profiles for feedback-linearization control (thick line) and PI control (thin line), with the setpoint shown by the dashed line; (b) and (d): Exchanged heat power and, insets, estimated (solid lines) and true (dashed lines) reaction rates in kmol min^{-1}. The subfigures (a) and (b) show results without measurement noise, whereas (c) and (d) show results with measurement noise.

kmol and $Q_0 = 3.37 \times 10^3$ kJ (corresponding to $T_0 = 324.2$ K). The reaction rates $\mathbf{r}_v$ are estimated from Eq.(12) in Appendix A. The control objective is to reject a 15 kg min^{-1} step disturbance in $u_{in,B}$ by manipulating $q_{ex}(t)$.

Measurements of $\mathbf{z}$, q_{ex}, $\mathbf{u}_{in}$ and ω are available at the sampling time $h_s = 0.4$ s. It is assumed that the measurement errors in q_{ex}, $\mathbf{u}_{in}$ and ω are negligible in comparison to those in $\mathbf{z}$, for which the standard deviation of the concentration measurements is 0.5% of the maximum concentration of each species and the standard deviation of the temperature measurements is 0.5 K. This results in the variance-covariance matrix $\mathbf{\Sigma} = \text{diag}\left(\left[0.004^2 \;\; 0.001^2 \;\; 0.001^2 \;\; 0.00025^2 \;\; 65^2\right]\right)$. A differentiation filter of order 1 and window size $q = 25$ is used (Savitzky and Golay (1964)).

Feedback-linearization control using the exponential convergence rate $\gamma = 5$ min^{-1} is compared to PI control with the gain $K_p = 5$ min^{-1} and the integral time constant $\tau_I = 0.2$ min. Figure 2 shows that the feedback-linearization scheme is able to reject the disturbance more quickly than the PI controller. However, if the standard deviation of the concentration measurements is larger than about 1% of the maximum concentration of each species, the estimated reaction rates become too imprecise or delayed (due to the choice of a larger window size q), and the advantage of feedback linearization over PI control is less clear (results not shown).

5. Conclusions

This paper has considered the control of the heat signal Q (or temperature T) by manipulating the exchanged heat power q_{ex} in an open homogeneous reactor. Control is implemented without the knowledge of a kinetic model. Instead, the reaction rates are (i) estimated via differentiation of reaction variants that are computed from measured states, and (ii) used in a feedback-linearization scheme that simplifies control design significantly. The parameters of the feedback-linearization controller are determined by readily available information, namely, the stoichiometry, the heats of reaction, the inlet composition and specific heat, and the inlet and outlet flow rates. Instead of linearizing the system around a given steady state, this controller implements feedback linearization that allows tracking a trajectory by forcing the control error to decay exponentially to zero. The resulting controller shows good performance for the case of frequent and precise concentration measurements of several species.

The controller requires $\text{rank}(\mathscr{A}) = R$, that is, at least as many measured quantities as there are reaction rates ($S_a + 1 \geq R$). The controller has two tunable parameters, namely, the exponential convergence rate γ and the parameter of the differentiation filter (the number of samples q in the case of the Savitzky-Golay filter) used for the rate estimation. These parameters need to be chosen to guarantee closed-loop stability. This study has shown that, at least in the case of low measurement noise, feedback linearization coupled to rate estimation can outperform PI control for the purpose of disturbance rejection.

A. Appendix

Let us approximate the derivative $\dot{\mathbf{x}}_{\mathbf{r}_v}(t)$ using a differentiation filter, such as the first-order filter proposed by Savitzky and Golay (1964), denoted as $\mathscr{D}_q(\mathbf{x}_{\mathbf{r}_v}, t)$, where q is the window size expressed in number of samples in the time interval $[t - \Delta t, t]$, with $\Delta t := (q-1)h_s$ and h_s the sampling time. It can be shown that, since $\mathbf{x}_{\mathbf{r}_v}$ is Lipschitz continuous, $\mathscr{D}_q(\mathbf{x}_{\mathbf{r}_v}, t)$ can be reformulated as

$$\mathscr{D}_q(\mathbf{x}_{\mathbf{r}_v}, t) = \sum_{k=0}^{q-2} b_{k+1} \int_k^{k+1} \dot{\mathbf{x}}_{\mathbf{r}_v}(t_\xi) d\xi \tag{10}$$

with the weighting coefficients $b_{k+1} = \frac{6(q-1-k)(k+1)}{q(q^2-1)} > 0$, such that $\sum_{k=0}^{q-2} b_{k+1} = 1$, and $t_\xi := t - \Delta t + \xi\, h_s$. Replacing $\dot{\mathbf{x}}_{\mathbf{r}_v}$ by its expression in Eq.(3) gives

$$\begin{aligned}\mathscr{D}_q(\mathbf{x}_{\mathbf{r}_v}, t) &= \sum_{k=0}^{q-2} b_{k+1} \int_k^{k+1} \left(\mathbf{r}_v(t_\xi) + (\mathscr{T}\mathbf{b})\, q_{ex}(t_\xi) + (\mathscr{T}\mathscr{C})\, \mathbf{u}_{in}(t_\xi) - \omega(t_\xi)\mathbf{x}_{\mathbf{r}_v}(t_\xi)\right) d\xi \\ &\approx \mathbf{r}_v(t) + \sum_{k=0}^{q-2} b_{k+1} \left((\mathscr{T}\mathbf{b})\, q_{ex}(t_k) + (\mathscr{T}\mathscr{C})\, \mathbf{u}_{in}(t_k) - \omega(t_k)\, \mathbf{x}_{\mathbf{r}_v}(t_k)\right), \end{aligned} \tag{11}$$

where $t_k := t - \Delta t + k\, h_s$.

The approximation in Eq.(11) is valid under the assumptions that $\mathbf{r}_v(t)$ is approximately constant in the time interval $[t - \Delta t, t]$ and the quantities $q_{ex}(t)$, $\mathbf{u}_{in}(t)$ and $\omega(t)\,\mathbf{x}_{\mathbf{r}_v}(t)$ are approximately constant in each time interval $[t_k, t_{k+1}[$.

Defining the operator $\mathscr{W}_q(f,t) := \sum_{k=0}^{q-2} b_{k+1} f(t_k)$ for any function $f(t)$, rearranging Eq.(11) for $\mathbf{r}_v(t)$ and using measured quantities, denoted as $\tilde{(\cdot)}$, yields

$$\hat{\mathbf{r}}_v(t) = \mathscr{D}_q(\tilde{\mathbf{x}}_{\mathbf{r}_v}, t) - (\mathscr{T}\mathbf{b})\, \mathscr{W}_q(\tilde{q}_{ex}, t) - (\mathscr{T}\mathscr{C})\, \mathscr{W}_q(\tilde{\mathbf{u}}_{in}, t) + \mathscr{W}_q(\tilde{\omega}\, \tilde{\mathbf{x}}_{\mathbf{r}_v}, t) \tag{12}$$

Eq.(12) approximates Eq.(4) for the case of measured quantities and can be used in Eq.(7).

Abstract

Reactor modeling is a very useful tool in the design and scale-up of commercial reactors, enabling prediction of the system behavior under different operating conditions without the need for expensive and time-consuming experimentation. In this paper we present our approach towards developing a comprehensive fixed-bed reactor model for Fischer-Tropsch synthesis (FTS) on a cobalt-based catalyst using a detailed mechanistic model to predict the FTS product distribution. In the current study, we developed a multi-scale approach to mode the FTS reactor whereby we combine the use of a detailed mechanistic kinetic model with a particle diffusion model to account for heat and mass transfer limitations both locally and in the whole reactor bed. Simultaneously, we have implemented a fixed-bed reactor model, also in MATLAB® that is capable of predicting the whole bed behavior taking into account the heat and mass transfer resistances in the reactor bed such as the loss in catalytic activity due to diffusion in the catalyst pores. For experimental validation of the model, a high pressure bench-scale reactor unit has been utilized. The kinetic model developed here is to be integrated into a model of the whole reactor bed, with a view towards facilitating the optimization and scale-up of novel FTS reactor bed designs for both the conventional gas phase FTS and the supercritical phase FTS.

Keywords: Gas-to-liquids, Fischer-Tropsch Synthesis, fixed-bed, reactor modelling, catalysis.

1. Introduction

The global rise in crude oil prices over the last several years, combined with the increase in production of natural gas, have meant that alternative pathways for natural gas monetization, such as Gas-to-liquids (GTL) technology (whereby natural gas is converted into easily-transportable liquid hydrocarbons and other value-added chemicals), are increasingly preferred. The key step in the GTL process is conversion of syngas (a mixture of CO and H_2 obtained from reforming methane or from coal/biomass gasification) via Fischer-Tropsch synthesis (FTS) into a range of hydrocarbon products such as paraffins, olefins and oxygenates of varying chain lengths by reaction over an active metal catalyst (typically Co, Fe, Ni, or Ru).

Despite the long history of FTS, there remained comparatively few studies (e.g. Liu et al. 1999, Wang et al. 2003) done on modeling the conventional gas-phase FTS fixed-bed reactor until recent years, wherein several significant modeling studies appeared in the literature. In many of these studies, the ‘psuedo-homogeneous’ approach, whereby the catalyst, reactants and products are treated as a single phase in the conservation

equations, remains the preferred means for modeling fixed-bed FTS reactors. Wang et al. (2003) employed a simplified pseudo-homogeneous model assuming and negligible axial or radial mass dispersion and only radial heat conduction, as well as a catalyst effectiveness factor of one; the resulting ideal plug-flow model was capable of achieving good agreement with experimental data for externally-cooled fixed-bed tubular reactors.

In the current study, we aim to model the fixed-bed FTS reactor using a multi-scale approach whereby we combine the use of a detailed mechanistic kinetic model with a particle diffusion model to account for heat and mass transfer limitations both locally and in the whole reactor bed. We attempt to validate the model under typical gas-phase FTS conditions using experimental data generated from our high-pressure FTS reactor unit. This work represents a first step towards developing a comprehensive model for FTS capable of accounting for the presence of different reaction media such as supercritical fluid (SCF) solvents, which have been shown to provide several advantages over operation in the conventional gas-phase FTS (Elbashir et al. 2010).

2. Methodology

2.1. Experimental Setup

The experimental data reported here was generated using an advanced high-pressure FTS reactor unit, a schematic of which is shown in Figure 1. The unit, which was designed in-house and custom-built by Xytel US, is capable of using supercritical fluid (SCF) solvents up to 85 bar. The analytical setup is composed of a single online custom-built Shimadzu GC setup composed of a dual oven system fitted with three TCD detectors and one FID detector for analysis of the permanent gases and low-boiling hydrocarbons up to C_{15}. This unit is capable of fully automated sampling and online analysis of permanent gases and low-boiling liquids in a single experiment, thus allowing for an accurate mass balance of reactants and products. In addition to the Shimadzu GC, an Agilent GC-MS/FID unit is available for offline analysis of the higher-boiling liquid compounds, up to C_{34}. As the data presented here is preliminary data from an ongoing study, further details regarding this unit are to be made available elsewhere.

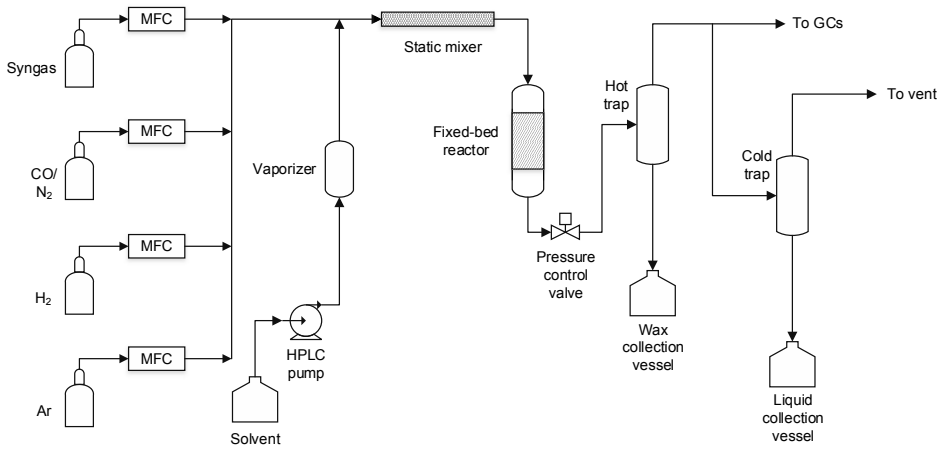

Figure 1: Schematic of the high-pressure FTS reactor unit.

The fixed-bed reactor, which consists of a single stainless steel tube of inner diameter 1.75 cm and wall thickness 0.4 cm, was loaded with a mixture of 0.5 g of 15 wt% Co/Al_2O_3 catalyst (150–250 µm particle size) and 10 g of crushed silica sand (Sigma Aldrich, 210–297 µm particle size). The catalyst and sand particles were mixed thoroughly prior to loading and the bed was loaded slowly while rotating the reactor tube in an effort to ensure a regular distribution of catalyst particles throughout the bed. The catalyst used for this study was provided by Dr Dragomir Bukur at Texas A&M Qatar. Catalyst reduction was done in-situ under a hydrogen flow of 100 sccm g_{cat}^{-1} at 350 °C for 10 hours. Subsequently, gas-phase FTS experiments were carried out on the activated catalyst at a feed temperature of 240 °C using syngas (2:1 H_2 to CO ratio) at a partial pressure of 20 bar, with Ar supplied at a constant flowrate of 10 sccm. The total pressure of the system was adjusted accordingly in order to keep the syngas partial pressure constant.

2.2. Reactor Bed Model

For the reactor simulations, a one-dimensional pseudo-homogeneous reactor model (as described in Froment et al. 2011) was used to calculate the overall CO concentration and temperature profiles in the fixed-bed FTS reactor. The model assumed plug-flow in the reactor bed and hence ignored temperature and concentration gradients in the radial direction. We justify this assumption by noting the relatively large particle-to-tube diameter ratio of ~1/70 (based on an average particle size of 250 µm, as was used in this study) and relative homogeneity of the bed packing used in experiments. The model, however, does account for diffusion limitations inside the catalyst particles through the use of the local bed effectiveness factor, η, which will be described in more detail in the following section. The steady-state conservation equations for mass (in terms of CO consumption), energy and momentum are therefore as follows:

$$-\frac{d(u_s c_{CO})}{dz} = \eta r_{CO} \rho_B \tag{1}$$

$$u_s \rho_g c_p \frac{dT}{dz} = (-\Delta H)\eta r_{CO} \rho_B - 4\frac{U}{d_t}(T - T_r) \tag{2}$$

$$-\frac{dp_t}{dz} = f\frac{\rho_g u_s^2}{d_p} \tag{3}$$

Here, u_s is the superficial gas velocity, c_{CO} is the concentration of CO, r_{CO} is the rate of consumption of CO, ρ_b is the bed density, ρ_g is the gas-phase density, c_p is the specific heat capacity of the reaction medium, ΔH is the heat of reaction for FTS, U is the overall heat transfer coefficient, T_r is the surrounding temperature, d_t is the tube diameter, p_t is the pressure across the reactor bed, and d_p is the average particle diameter. All other symbols have their usual meanings. The conservation equations were solved in MATLAB® using an ODE solver, ode45. In our model implementation, the length of the reactor bed was fixed, and the resulting CO conversion (defined as the percentage of CO consumed over the concentration of CO at the inlet), temperature and pressure profiles were obtained.

For the heat transfer in the bed, Equation (2), the coolant surrounding the reactor tube was modeled as air at a constant temperature T_r, which was set at 230 °C in order to match the furnace temperature used in experiments (as described in 2.1). The overall heat transfer coefficient U of the reactor bed was obtained experimentally as a function

of syngas flowrate at P = 20 bar and T = 513 K over a bed made from the sand particles used to dilute the catalyst (i.e. without Co/Al_2O_3 catalyst particles present). Two different temperatures were measured at a fixed distance over the bed and Equation (2) was used to calculate the corresponding U value. A straight line was fit to the data, as shown in Figure 2, with a gradient of 8.66×10^{-7} kW m^{-2} K^{-1} $sccm^{-1}$ and a y-intercept of 7.19×10^{-6} kW m^{-2} K^{-1}. As the reactor bed used in experiments was made up of a large excess of sand over catalyst (20:1 ratio by mass), it was assumed that the effect of the cobalt metal on the heat transfer properties in the catalyst bed could be neglected. The value of ΔH used in the model, -152 kJ mol^{-1}, was taken from a study by Jess and Kern (209). The c_p value of the gas-phase mixture was calculated using a weighted linear sum of the individual components of the mixture.

For the pressure drop in the bed, Equation (3), Hicks's correlation for the value of the bed friction factor f was used:

$$f = 6.8\frac{(1-\varepsilon_b)^{1.2}}{{\varepsilon_b}^3}Re^{-0.2} \tag{4}$$

The inter-particle porosity of the bed, assuming perfectly spherical particles, was calculated using the correlation of Benyahia and O'Neill (2005):

$$\varepsilon_b = 0.1504 + \frac{0.2024}{\phi_p} + \frac{1.0814}{\left(\frac{d_t}{d_p} + 0.1226\right)^2} \tag{5}$$

where ε_b is the bed porosity and ϕ_p is the sphericity ($\phi_p = 1$ in this case). The density of the diluted catalyst bed used in experiments was measured gravimetrically to be 1.60 ± 0.06 g cm^{-3}. In order to calculate the Reynolds number of the reaction mixture, its viscosity was estimated using Davidson's (1993) correlation for gas-phase mixtures.

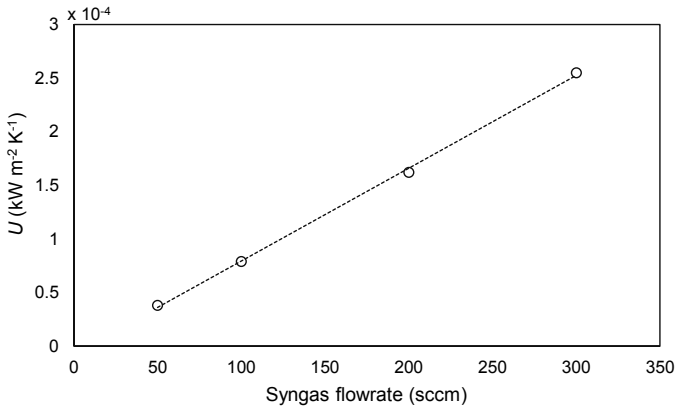

Figure 2: Overall heat transfer coefficient of a reactor tube filled with a bed of sand particles as a function of syngas flowrate at T = 513 K and P = 20 bar.

3. Results and Discussion

The experimental results for CO conversion and CH_4 selectivity obtained from the FTS reactor unit under the conditions as outlined in section 2.1 were compared with the

simulations as outlined in section 2.2. The comparison between experimental and simulation results is shown in Figure 4; as the figure shows, the CO conversion in the simulations is lower than the experiments by a factor of about 2 for all flowrates, whereas the CH_4 selectivity from simulations shows an excellent agreement with the experimental data. The discrepancy between the experimental and simulated data with regards to the CO conversion may be explained by a difference in activity between the catalyst used in Todic et al. (2013) and the current study. However, as both studies were done on a cobalt-based catalyst, it appears that the selectivity model of Todic et al. (2013), which accounts for deviations from the 'ideal' ASF product distribution, accurately captures the methane selectivity seen experimentally.

The temperature profiles obtained from the model at the different syngas flowrates are shown in Figure, and show a temperature rise ranging between 14–17.5 °C in the bed, with the higher temperature rise seen at lower flowrates, as expected. While an exact comparison cannot be made with experiments as limited temperature data was obtained experimentally, the results are consistent with data from Huang and Roberts (2003), who found a 15 °C rise in their reactor bed for gas-phase FTS on a Cobalt-based catalyst under similar conditions (T = 250 °C, P(syngas) = 20 bar, H_2/CO ratio 2:1, syngas flowrate of 50 sccm/g catalyst) as those used in the current study.

4. Conclusion

In the current study, the steady-state fixed-bed Fischer-Tropsch synthesis reactor was modeled using a one-dimensional approach, which incorporates a detailed kinetic and selectivity model taken from the literature and accounts for heat and mass transfer limitations on the performance of the catalyst through the use of a particle diffusion model. For model validation, a comparison was shown with preliminary experimental data from an ongoing study; the model showed good agreement with experimental data for methane selectivity but under-predicted CO conversion. Thus, we conclude that in order for the model to be predictive, the kinetic parameters for our experimental system need to be determined.

In future, we intend to incorporate an extended version of the PR EoS, as developed by Travalloni et al. (2014), into the model in order to account for the effect of confinement in heterogeneous porous media (such as catalyst pellets) on the thermodynamic properties of the FTS reaction mixture. Thermodynamic effects will become particularly important when modelling the effect on the FTS process of using non-ideal reaction media such as supercritical fluid solvents. Ultimately, our goal is to develop a comprehensive model to enable a direct comparison of the gas-phase and supercritical solvent-assisted FTS reactions under a variety of conditions; the current study represents an important first step towards this aim.

Acknowledgments

The authors are grateful to Dr. Dragomir Bukur for providing the catalyst used in the experiments. This paper was made possible by a NPRP award [NPRP 4-1484-2-590] from the Qatar National Research Fund (a member of the Qatar Foundation). The statements made herein are solely the responsibility of the authors.

Abstract

Steady state process simulators allow students to perform in-depth analyses of chemical process designs, including economic optimization, due to the ability to run multiple case studies rapidly. However, process simulators are not necessarily a panacea. The simulations should correspond to realistic equipment. Students often use them carelessly. Several typical examples of careless use of process simulators are presented. Process simulators also have their limitations in dealing with certain types of problems, like scale-up, scale-down, debottlenecking, and troubleshooting. Examples of situations in which simulation defaults should be changed and where problems might be more appropriately solved outside the simulation environment are presented.

Keywords: process simulators, student design, performance problems

1. Introduction

Process simulators allow students to perform in-depth analyses of chemical process designs. The ability to simulate different process configurations and to vary design parameters allows them to make decisions and move towards an optimum process based on an objective function, for example, a profitability criterion. However, students often use process simulators carelessly. It is also true that there are certain types of advanced problems for which process simulators are not well suited, including scale-up and scale-down of chemical processes. For some problems, the simulator defaults cannot be used, and in some cases, it is best not to use simulators.

That students can use simulators carelessly should come as no surprise to most instructors. Dahm, et al. (2002) discussed how students can use simulators to construct models without a full understanding of the process. Flach (1999) observed that students often resort to simulators when they are not needed and further observed the tendency of students not to evaluate critically the results of simulations.

In this paper, one example of careless use of simulators will be presented in detail. Several more are summarized briefly. The situations when simulators should not be used or must be modified from the defaults will be discussed in detail. In all of these cases, the relationship between simulation models and actual equipment behaviour is highlighted, because it is considered to be important that this relationship be appreciated by students.

2. Carless Use of Simulators

A very common example of careless use of process simulators is for heat exchangers involving phase change. In organic chemical processes, it is common for a liquid feed to be vaporized to perform a gas-phase reaction. The process feed may be subcooled and may need to be superheated before entering the reactor. An approximate *T*-*Q* diagram for this process is shown with the solid lines in Figure 1, assuming that steam is used to provide the heat, going from saturated vapour to saturated liquid.

In a process simulator, a heat transfer coefficient may be entered so the area can be calculated. However, the heat transfer coefficient is different for each zone. If only one heat transfer coefficient is entered for the whole heat exchanger, an incorrect area is be calculated. The *T*-*Q* diagram for the incorrect case is shown with the dotted line in Figure 1. The correct method for performing this simulation is to use a different heat exchanger for each zone, with an appropriate overall heat transfer coefficient for the respective zone. Alternatively, since the simulator will generate the *T*-*Q* diagram (often called a heat curve) for the heat exchanger, it may be simpler to do the area calculation outside the simulation environment.

When a correspondence to actual equipment is considered, there may not even be three zones. For example, in a kettle-type boiler, the boiling liquid acts like a stirred tank, and the subcooled liquid immediately comes to the boiling temperature. To superheat the effluent, there must be tubes that are not covered with boiling liquid. In this situation, there would only be two zones with two different heat transfer coefficients, with the heat load on the boiling zone being the sum of the desuperheating and vaporization enthalpy changes.

There are cases when the simulation can be done that will result in an impossible situation. Suppose a clever student decides to use a hot stream in the process to vaporize the feed. The *T*-*Q* diagram in Figure 2 with the solid lines shows the correct situation, and the *T*-*Q* diagram with the dotted line in Figure 2 shows the physically impossible situation that results if the different zones are not considered. With the dotted hot-stream line in Figure 2, there would be a temperature cross.

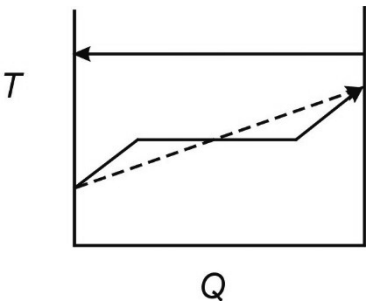

Figure 1: *T*-*Q* Diagram Requiring Analysis

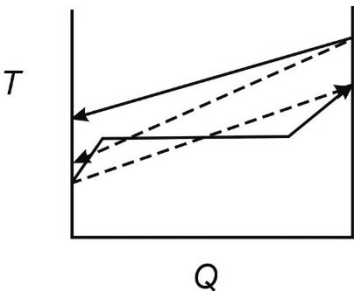

Figure 2: *T*-*Q* Diagram Resulting in Zoned Temperature Cross

Table 1: Commonly Observed Simulation Errors

Physical Situation	Error Observed	Correct Method
zoned analysis required	one heat transfer coefficient used for only one zone	simulate each zone as separate heat exchanger with separate heat transfer coefficient
LMTD correction factor required but ignored	assume standard 1-2 configuration for all heat exchangers not involving phase change	check approach temperatures to see if more shell passes are needed, often occurs if heat integration used
inappropriate reactor size	desired product rate approaches constant value or starts to decrease	examine reactor profiles to determine if reactor is oversized or if selectivity is decreasing
real vs. actual trays	column design and cost calculated for number of equilibrium trays	include tray efficiency in simulation before performing cost calculation
column pressure drop	column assumed to be at constant pressure or pressure drop chosen does not correspond to reality	include pressure drop and make sure pressure drop per tray roughly corresponds to weir height, and that weir height is not too small or not more than 50% of tray spacing
incorrect use of flash unit simulation	including flash unit with heat load	simulate as heat exchanger followed by flash unit at inlet conditions

This is just one case in which simulators have been observed to be used incorrectly. Table 1 summarizes several other situations that have been observed, and these are discussed in more detail in Shaeiwitz and Turton (2014). The observation is that students need to be taught the limitations of process simulators, where to find useful information within simulations, and to make their simulations correspond to actual process equipment.

3. Situations When Simulators Should not be Used

A class of problems that are not always appropriate for simulators is performance problems. Examples of these are debottlenecking and troubleshooting problems. In these cases, the equipment is specified; however, not always at the level of detail necessary to use a simulator. An example debottlenecking problem is to determine what part of a process limits scale-up, and an example troubleshooting problem is to determine the cause of a disturbance, which could be a flowrate disturbance.

For example, the individual heat transfer coefficients change as the stream flowrates change (for no phase change). However, in most simulators, the overall heat transfer coefficient is specified. If the simulator is used to calculate the individual heat transfer coefficients, the heat exchanger specifications must include number of tubes, tube pitch,

tube diameter, shell diameter, and baffle spacing. In general, most student designs do not include this level of detail, especially since a typical attribute for a cost estimate of a heat exchanger is the area. Outside the simulation environment, the NTU method may look attractive; however, the change in heat transfer coefficient with flowrate is not included in this method.

In order to solve this problem, the relevant heat transfer equations must be solved simultaneously for the new conditions, and the equations are the energy balance and the design equation

$$Q = \dot{m}_h C_{p,h} \Delta T_h = \dot{m}_c C_{p,c} \Delta T_c \tag{1}$$

$$Q = U_o A_o \Delta T_{lm} F \tag{2}$$

Solutions of Equations 1 and 2, which are actually three equations, require numerical methods. To make the equations easier to solve, it is recommended that ratios be used

$$\frac{Q_2}{Q_1} = \frac{\dot{m}_{h2} C_{p,h2} \Delta T_{h2}}{\dot{m}_{h1} C_{p,h1} \Delta T_{h1}} = \frac{\dot{m}_{c2} C_{p,c2} \Delta T_{c2}}{\dot{m}_{c1} C_{p,c1} \Delta T_{c1}} \tag{3}$$

$$\frac{Q_2}{Q_1} = \frac{U_{o2} A_o \Delta T_{lm2} F_2}{U_{o1} A_o \Delta T_{lm1} F_1} \tag{4}$$

where, the subscripts 1 and 2 refer to the original case and the new case, respectively. In Equation 2, the heat capacities are considered constant for small temperature changes, and in Equation 4, the area ratio is unity for the same equipment, and the ratio of the LMTD correction factors is generally assumed to be unity for small temperature changes. Therefore, the unknowns are the two outlet temperatures, the new heat duty, and perhaps the flowrate of a utility stream. The utility flowrate is often the parameter than can be varied to ensure controllability. The ratio of the heat transfer coefficients is based on the scaling of the individual heat transfer coefficients

$$h_i \propto \dot{m}^{0.8} \tag{5}$$

for turbulent flow in the tubes and

$$h_o \propto \dot{m}^{0.6} \tag{6}$$

for turbulent flow in the shell.

Examples of these problems and solution methods are presented in Turton, et al. (2012). Solution methods for situations involving phase change are also shown.

A related example involves heat removal from a reactor using a cooling loop, as illustrated in Figure 3.

In a scale-up or scale-down problem, the reactor loop must be analyzed simultaneously with the reactor. If the reactor is considered to be a heat exchanger for the purposes of this analysis, two sets of Equations 3 and 4 must be solved simultaneously. However, the problem is more complex, since the ability to scale-up, for example, also depends on the characteristic pump curve, which could be the bottleneck to scale-up. While some simulators allow pump curve information to be added, this might be a more advanced

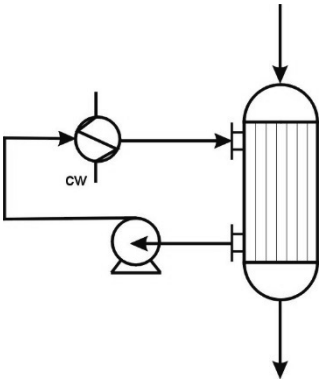

Figure 3: Reactor with Cooling Loop

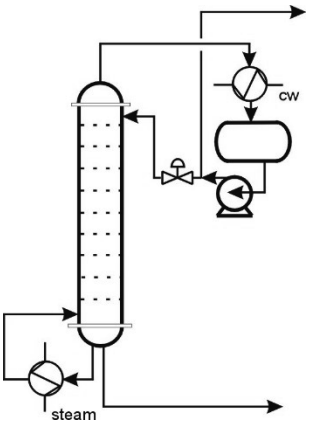

Figure 4: Distillation Column with Peripheral Equipment

simulation for a typical undergraduate. In this case, the problem is probably best solved outside the simulation environment.

Another example of the need either to modify a typical simulator default or not to use a simulator is in the simulation of a distillation column. The simulator calculates the heat load on the reboiler and condenser, and some simulators calculate the utility load if the utility is specified. However, no other calculations are done on those heat exchangers. If more detailed analysis is desired, the column should be simulated without a reboiler and condenser, and they should be added as distinct units. In this case, the reflux drum and reflux pump should also be included. Figure 4 illustrates the distillation column with all of the peripheral equipment shown.

For a performance problem such as scale-up, all of the units shown in Figure 4 must be analysed in detail. In fact, it is the condenser and reboiler that most strongly affect the ability to scale-up or scale-down the process. If a modest scale-up is required, an initial design at 75% of flooding should be able to handle the larger throughput. The relevant equations for the reboiler are

$$\frac{Q_2}{Q_1} = \frac{\dot{m}_{steam2}\lambda}{\dot{m}_{steam1}\lambda} = \frac{\dot{m}_{process2}\lambda}{\dot{m}_{process1}\lambda} = \frac{U_{o2}A_o\Delta T_2}{U_{o1}A_o\Delta T_1} \tag{7}$$

For a small temperature change, the latent heat, λ, is assumed constant. The increased process flowrate requires proportional increases in the heat load on the reboiler and on the driving force. This is illustrated on the *T*-*Q* diagram for a reboiler shown in Figure 5. It is assumed that the heat transfer coefficients for boiling and condensation are weak functions of flowrate, making the overall heat transfer coefficient approximately constant. If the steam temperature is fixed, the only way to increase the driving force is for the reboiler temperature and consequently the column pressure to decrease (dashed line). The condenser *T*-*Q* diagram is shown in Figure 6. If the column pressure drop is approximately constant, the condensation pressure and temperature both decrease, reducing the driving force in the condenser (dashed line). The driving force can only be increased by increasing the cooling water flowrate (dashed line); however, the required

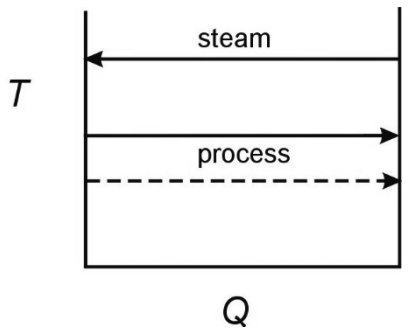

Figure 5: *T-Q* Diagram for Reboiler

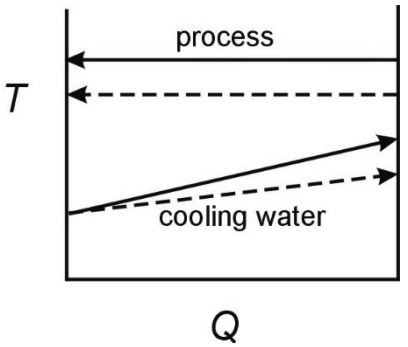

Figure 6: *T-Q* Diagram for Condenser

amount of increase is affected by the increase in the heat transfer coefficient for the cooling water. Another way to handle this problem is to have a desuperheater on the steam source in the reboiler to adjust its temperature, which can maintain the original boiling temperature and pressure. In either case, the simulator defaults do not provide a suitable method for analysing this problem. Related examples are presented in Turton, et al. (2014).

4. Conclusions

Process simulators, when used correctly, enable students to analyse and optimize a chemical process by allowing them to study different process configurations and to vary design variables. However, students must use the process simulator correctly by relating the simulation to actual equipment behaviour. Additionally, performance problems such as scale-up, scale-down, debottlenecking, and troubleshooting are not always solved correctly by the default simulation methods. At times, it is better to solve these problems in a different environment.

Learning to solve mass balance problems through a web-based simulation environment

Abstract

Being able to solve mass and energy balance problems on any given process is a key skill required for students in chemical, or, in general, process engineering. Yet, many students have serious problems solving such problems because the necessary equations do not come in a ready-to-use form; instead, the general and abstract balance equations must be tailored by the student to the problem and the data at hand before they can be used. To solve mass balance problems, students must first recognize the input/output structure of the system(s) around which balance equations can be written, identify the components present and, from all possible balance equations, choose those that, based on the available data, will lead to results in the fastest and more efficient way. In a typical textbook problem, there is no predefined structure in the input data (as it exists, for example, in a process simulator) and the solution process is completely data-driven.
We have developed a web-based environment that attempts to imitate the process of solving mass balances by hand. The webpage embeds a solution algorithm which identifies in a stepwise fashion the smallest subset of equations which, based on the available data, can yield results (even partial). A student will not do degrees of freedom analysis on the entire data set nor can he/she solve large sets of equations with many unknowns; the solution algorithm respects those restrictions. Two web pages embodying this problem-solving environment have been developed; one around a single continuous process with a collection of options on its input/output structure, and one around a batch process. Visual feedback is provided for the user to identify variables whose values can be calculated with the available data and the equations that can be used in the calculation. Through these web pages, users can solve their own problems or practice on predefined problems displayed at the bottom of the page in the form of multi-choice quizzes. The expectation is that such an environment of free, student-centred experimentation can provide structure and guidance on the process of formulating and solving mass balance problems.

Keywords: mass balances, process engineering, e-learning.

1. Introduction

Nowadays, e-learning tools in process or, in particular, chemical engineering abound. E-learning can be incorporated as a supplement to traditional teaching methodologies formulating what is called blended, hybrid or mixed learning, or used as a stand-alone tool to deliver teaching material in the context of synchronous or asynchronous learning (Krajnc, 2012). Web-based e-learning tools have been used to remotely operate actual labs (as in Selmer *et al.*, 2007 or Klein and Wozny, 2006), simulate virtual labs (as in Schofield and Lester, 2010), or as a means to deliver, enhance the understanding and test the student's knowledge of theoretical material, improve the collaboration between

students in team projects and in many other applications (Krajnc, 2012). In all cases, e-learning is celebrated for its ability to provide an always accessible, student-centred, self-paced environment for learning outside the confines of the traditional classroom or laboratory.

Mass and energy balances are everywhere in process engineering calculations; they formulate the basis for the development of any process model irrespectively of the nature of the process or the modelling detail. Students in chemical, food or, in general, any process engineering field should master mass and energy balance equations before they can cope with the detailed models of specific operations or integrated plants. Yet, formulating and solving mass and energy balance equations presents a difficult task to many students in process engineering. The main difficulty in coping with mass balance problems is that there are no predefined equations to use. Instead, students are taught the general form of the conservation equations and they must learn how to customize these equations to solve a problem at hand depending on the number of components involved, the number of input and output streams, the presence of reactions etc. What complicates the matter further is that the number of potential equations to form is large (if the number of components is large, as is the case in food processing) and the fact that there is great variability in the form that the problem data are given.

To efficiently solve a mass balance problem, the student must customize the general conservation equations not only to the specific problem but also to the available data of the problem and identify the (preferably small) subset of equations that lead to fast solutions. That teacher's challenge is to effectively guide and train the students in finding the fastest and most efficient solution strategy. This could be done with the help of heuristic rules such as to use balances for components with the most known data on their mass fraction or flow rate. Still, this knowledge can come only from laborious supervised practice but how feasible is it to have a teacher guiding every student in every problem?

This paper presents an approach to offer this guidance to the students through a web-based environment in the context of e-learning and as a supplement to traditional classroom teaching. The objective is to develop a generic environment where a student could interactively solve any mass balance problem with the environment providing structure and guidance in the solution process.

2. Automating the mass balance solution process

Consider a continuous steady-state process with an arbitrary number, m, of input and output streams carrying an arbitrary number, n, of components. Let us consider the case where no reactions take place into the process. The mass conservation principle suggests that the total input flow of each component must equal its total output flow. In other words, if $F_{j,i}$ is the mass flow rate of component i in stream j, then the following equation holds:

$$\sum_j F_{j,i} = 0 \quad \forall i \tag{1}$$

In Eq.(1), the flow rate is considered positive for input streams and negative for output streams. A similar equation can be written for the overall mass based on the stream flow rates F_j:

$$\sum_j F_j = 0 \tag{2}$$

The component flow rate $F_{j,i}$ is related to the component mass fraction $x_{j,i}$ and the total stream flow rates F_j through the relation:

$$F_{j,i} = x_{j,i} F_j \quad \forall i \, \forall j \tag{3}$$

Then, the component mass balance of Eq.(1) can be rewritten as:

$$\sum_j x_{j,i} F_j = 0 \quad \forall i \tag{4}$$

Component flow rates in each stream should sum up to the total stream flow rate:

$$\sum_i F_{j,i} = F_j \quad \forall j \tag{5}$$

Finally, the component mass fractions in each stream should sum to 1:

$$\sum_i x_{j,i} = 1 \quad \forall j \tag{6}$$

All above are candidate equations to use in solving a mass balance problem but, obviously, they are not independent. It is known that from the set of n+1 balance equations only n of them are independent. Considering that in each stream there exist only n independent variables (e.g. flow rate and n-1 mass fractions), there exist $m \cdot n$ variables and, therefore, (m-1)n degrees of freedom (DOF). An automated solution process (as, for example, applied in a process simulator) would first enforce that the DOF are satisfied and then solve the n independent balance equations in one shot.

Solving such a problem by hand, however, does not work like that. First, there is no 'discipline' in the way the DOF are covered with the available data as it exists in a process simulator. For example, a process simulator would typically assume that all data in input streams are given. In a student problem, known and unknown variables are spread in random ways among input and output streams; this variability in the provided data is purposely used to extend the breadth of the problems students are exposed to. Secondly, and more importantly, students do not (and are not encouraged to) think as process simulators. They do not do formal DOF analysis and cannot solve equation sets with more than 2 or, at most, 3 unknowns. Instead, from all the potential (and probably redundant) set of equations, they try to identify small solvable subsystems of equations, formulate partial solutions and repeat until the problem is solved.

We attempted to imitate this process by developing an automated algorithm that would work in the same way. The algorithm must have the following characteristics:

- All possible equations can be considered as candidate equations to use
- The solution process will have to be stepwise and recurrent
- The equation selection and solution must be data-driven.

The objective is to create an algorithm that would, as the data become available, create partial solutions by identifying the smallest solvable equation subsystem, feed the results as data back into the system and repeat until all variables are known.

The developed algorithm involves the following steps which are executed every time a single piece data becomes available (either as user-provided or as a result from a previous solution):

1. Formulate all (n+1) balance equations and incorporate the values of all known variables. In the component balance equations, each term corresponding to the flow of component i in stream j is represented as $x_{j,i}F_j$ if either $x_{j,i}$ or F_j is known; otherwise as $F_{j,i}$. In this way, unnecessary non-linearities arising from the product $x_{j,i}F_j$ are avoided and the set of equations is always linear.
2. Search for the smallest set of independent balance equations with the same common set of unknowns starting from a single equation with one unknown and gradually moving to larger sets. If found, solve the system and set the values to the variables.
3. For each stream, formulate the stream equations (Eqs. (3),(5) and (6)) and check what variables can be calculated.
4. Repeat the process if some variable has been calculated in steps 2 or 3 or if user provides new data until all stream variables in step 3 have known values.

It should be noted that, although all balance equations are considered as candidates to be used, the selected equations to use are always checked for independence. Also, as it is apparent from the description of the algorithm, the stream equations are considered and solved separately for each stream. This, however, is expected since streams do not share common variables; it is only through the balance equations that the stream variables are connected.

Solving the constraining equations for each stream requires the implementation of some rules that go beyond the typical mathematical solution process but are necessary to maintain the validity of the solution. For example, if the sum of mass fractions for any number of components in a stream is equal to 1, then the mass fractions for all remaining components (irrespectively of their number) should be set to 0 and considered known.

3. Web-page implementation

The above stepwise solution algorithm was implemented in a web-based environment where students would interactively solve mass balance problems. The iterative nature of the algorithm is exploited in the graphical implementation to help students see the solution unfold before them as data are entered. The algorithm was coded in C# and embedded in an ASP.NET webpage. For simplicity of the interface, the implementation of the algorithm was restricted to a single process with a total of at most 4 streams.

Figure 1 shows the webpage interface for a single continuous process. The user would have to first select the input/output structure of the process by clicking one of the five picture buttons at the top and, then specify, the components present in the process. The graphical display of the process in the middle shows the selected structure and, for each stream, there is a total flow rate field and a table with each component's mass fraction and rate. To use the page, the user will have to start entering whatever data are available for the problem at hand. As this process goes on, the embedded algorithm is run to identify what other variables can be calculated using the provided data.

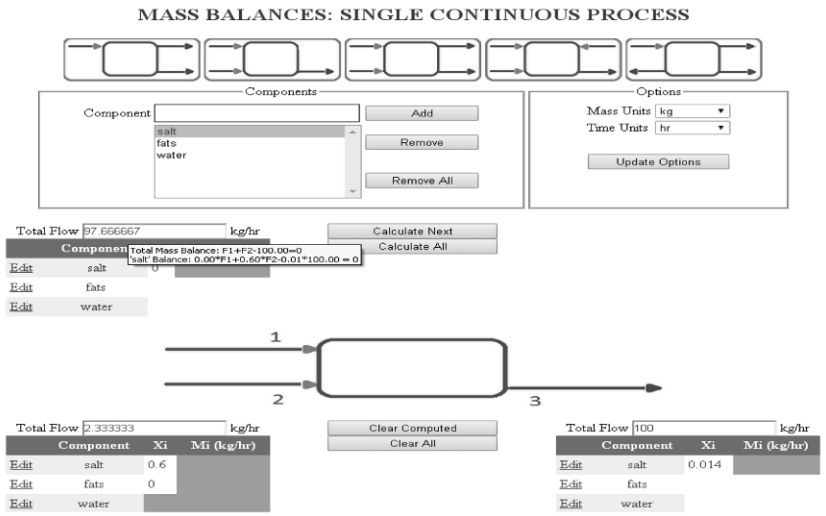

Figure 1. The Webpage Interface for Solving Continuous Mass Balance Problems

The values of the calculated variables are not immediately displayed but are blocked from user-editing. A colour-coding scheme is employed to differentiate variables set by the user, variables calculated and variables that could potentially be calculated. A grey background over a field in Figure 1 (orange in the actual webpage) indicates that the variable cannot be set because it can be calculated from the available equations. At this point, the student should wonder how it is possible to have this value calculated. By pressing the Calculate Next button the answer can be revealed both in terms of the value (the grey background is removed and the value is displayed) and in terms of what equation(s) can be used to calculate this value; the equations will show up in a flying tooltip if the user moves the mouse over the variable field.

A series of predefined problems posed as multiple-choice questions at the bottom of the page can be used by the student for practice. Alternatively, a student can use the webpage to solve their own mass balance problem. A similar in spirit, webpage was also developed for the solution of mass balances in batch processes (Figure 2). In the batch configuration, there is one (optional) input stream and one (optional) output stream along with the specifications for the initial and final state of the process. The user can edit any of the above to simulate any possible scenario (e.g. find the final state for given material addition or removal, or, find the stream flows that can result in given final state etc.) When calculations are done, the user can reset the initial state equal to the final state and continue with the implementation of a new scenario. In this way, the evolution of a stepwise batch process can be simulated.

Both web pages are available through the site www.food.teithe.gr/fepsim where a series of educational modules for basic process engineering topics are under development.

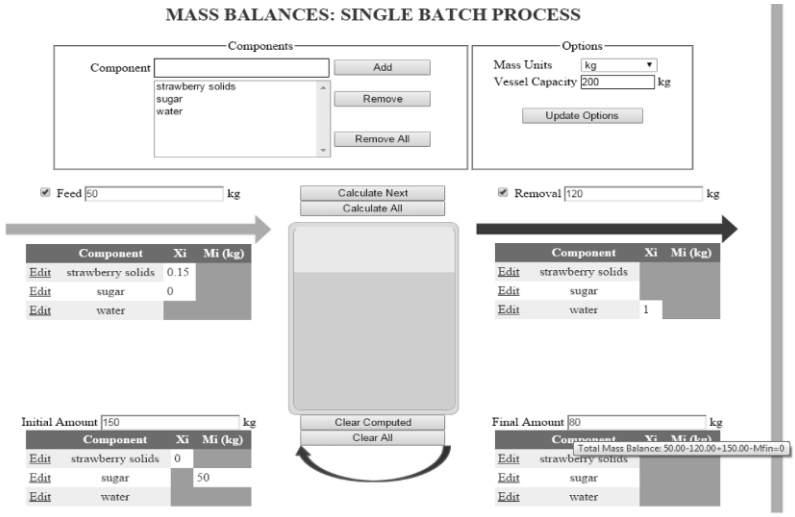

Figure 2. The Webpage Interface for Solving Batch Mass Balance Problems

4. Conclusions

The webpage presented in this paper attempts to imitate the mental process of solving a mass balance problem and is designed to provide to the novice engineer structure and discipline in the solution process. The embedded solution algorithm does not solve the problem as a process simulator would. Instead of immediately displaying the results, it tries to guide the user through the solution steps based on whatever data are available. It is hoped that the skills acquired after adequate experimentation in this webpage could be learned and transferred into solving more complicated problems by hand. This webpage can be used both for self-learning as well as an accessory to class work.

Abstract

The process of CO_2 capture and storage is a promising and effective way to control the emissions of CO_2 from large-scale power plants. One of the most used promising near-term options for large-scale deployment of CO_2 capture and storage (CCS) technologies is the post-combustion CO_2 capture. However, it is vital that the decarbonisation of power plants does not limit the ability of the plant to operate in a flexible, load following manner. Therefore, the integration of CO_2 capture process and power plants will increase the need to design advanced model-based control systems to account for the process interactions and maintain dynamic operability of power plant and CCS unit. In this work an advanced Model Predictive Control (MPC) scheme has been designed to evaluate the controllability of a post-combustion plant in the presence of disturbances associated with the dynamic operation of the power plant. The results have shown that the implementation of the MPC formulation proves to be a very good option to address such complex problems in CO_2 capture.

Keywords: Model Predictive Control(MPC), post combustion CO_2 capture, SAFT-VR, gCCS

1. Introduction

Owing to the continued use of fossil fuels in the global energy system for the foreseeable future, the International Energy Agency(IEA) suggests that CCS is an essential part of the technology portfolio needed to achieve deep reductions in global CO_2 emissions, with CCS expected to contribute around 14-20 % of total reductions in emissions by 2050. IEA. (2010)

One of the most promising near-term options for large-scale CCS deployment is post-combustion capture of with a mono-ethanol-amine (MEA) solevnt. The benefits of this process are high capacity of CO_2 capture, fast reaction kinetics, inexpensive and abundant solvent. On the other hand the main challenge with this process is the substantial decrease in the efficiency of the power plant owing to the energy required for solvent regeneration that would otherwise be used to produce electricity. Further, as the power plant ramps up and down, the variation in liquid-to-gas ratios in the absorption columns can impose an important effect on the efficiency of the capture plant. Therefore the dynamic modelling and controllability analysis of the complete capture process is quite important. Bui et al. (2014)

Most of the studies in literature implement a general control structure consisting of Proportional (P) and Proportional-Integral (PI) controllers. Lin et al. (2011) performed a plant-wide control study of the MEA-based CO_2 capture process using Aspen dynamics. A control structure is proposed in which CO_2 capture is guaranteed by manipulating the lean solvent feed rate to the top of

the absorber column. The system was tested by applying several disturbances, such as the flue gas flow, CO_2 concentration and H_2O concentration. In their work, Nittaya et al. (2014), presented a mechanistic dynamic model of post-combustion CO_2 capture plant using the MEA absorption process. They developed and tested three different control strategies based on Relative Gain Array (RGA) analysis and heuristics. Their analysis provided insight regarding the dynamic operation of a CO_2 capture plant in closed-loop and concluded that the control scheme based on heuristics which controls CO_2 removal with the lean MEA flowrate entering the absorber unit and the reboiler's temperature with the reboiler's heat duty, resulted in shorter closed-loop settling.

To our knowledge, only four studies have implemented MPC strategy for this process. Bedelbayev et al. (2008) presented a mechanistic model for the absorption process and MPC is only implemented for the standalone absorber. Arce et al. (2012), proposed and developed a multilevel model predictive control architecture for the solvent regeneration system of an amine-based CO_2 capture process. Focusing on minimising the operational cost associated with the post-combustion CO_2 capture,the two level control architecture maximises the flexibility of the solvent regeneration process whilst simultaneously ensuring cost-optimal performance and safety. Panahi et al. (2012), implemented an MPC-based control scheme which included only two control variables in their formulation, i.e. CO_2 recovery and reboiler's temperature. Sahraei et al. (2014), presented an advanced centralised multivariable model predictive control (MPC) technique to address the controllability of a post-combustion CO_2 capture process from a coal-based power plant and compared it to decentralised Proportional-Integral (PI) control schemes. The CO_2 capture model was developed on the Aspen Hysys dynamic simulator while the MPC was implemented in Matlab.The MPC performed significantly better than the PI controllers in terms of close-loop settling time, integral square error and compliance of operational and environmental constraints.

In this work we propose the use of model predictive control as the work of Sahraei et al. (2014) has shown that it provides better performance, in terms of close-loop settling time, integral square error and compliance of operational and environmental constraints than the PI control schemes when applied in a post-combustion CO_2 capture process.The purpose of this article is to explore the application of a multivariable model-based control technique to assess the controllability of a post-combustion CO_2 capture plant.

2. Process structure

2.1. Model development and controllability analysis

This section presents the CO_2 capture model used in this work. The first step of the model framework is the development of a high fidelity dynamic model of the system and the dynamic design optimisation. The quality of the model determines to a high degree the validity of the framework as it is both the cornerstone of the entire development procedure as well as the testing platform for the controller. The model was developed in gCCS a system modelling tool for support of design and operating decisions across the CCS chain. gCCS is built on PSE's gPROMS advanced process modelling platform, and inherits many of the platform's powerful capabilities. PSE (2014). The process flowsheet considered for this study is presented in Figure 1. As shown

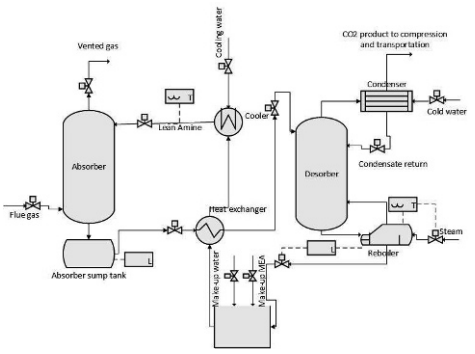

Figure 1: Base case flowsheet

in that figure, the flue gas enters the absorber at the bottom and is contacted with the counter current flow of the amine solution. The treated gas, leaves from the top of the absorber, while the rich amine solution, loaded with CO_2, leaves the absorber from the bottom and is collected in a sump tank. Then, this stream is heated in a heat exchanger by the hot lean amine solution coming from the bottom of the stripper. The heated amine solution is sent to the stripper column for the desorption process of CO_2 from the amine solution. The gas stream of CO_2 is collected at the top of the stripper while the lean amine solution is recycled back to the absorber. The two make-up streams of water and MEA are maintaining the solvent's stream concentration in the entire system. The thermophysical properties of the complex fluids used in this process are described using the statistical associating fluid theory Chapman et al. (1989), Chapman et al. (1990) for potentials of variable range Galindo et al. (1998) (SAFT-VR). SAFT-VR was also used to describe the effect of the reactions on the fluid-phase properties and phase behaviour of the MEA-H_2O-CO_2-N_2 fluid mixture in the CO_2 capture process. A detailed description of the thermodynamic modelling approach used and molecular models developed Mac Dowell et al. (2011) in addition to how the molecular models are integrated with the process models Mac Dowell et al. (2013), Mac Dowell et al. (2013) is provided in separate contributions and is not repeated here. In summary, all reactions are treated as equilibrium reactions, as is consistent with the SAFT-VR model used. This is a reasonable assumption as it is well accepted that in these systems, the mass transfer is limited by diffusion. This approximation has also been successfully used in conjunction with other dynamic, non-equilibrium models of MEA-based CO_2 capture processes. The main control objective of this plant is to maintain the CO_2 removal fixed at a specified rate and maintain a constant composition in the CO_2 product stream. Also based on the decentralised control analysis the liquid levels in the absorber sump and reboiler are controlled in order to maintain the solvent inventory within the system. Further the MEA concentration in the lean solvent stream needs to be below 30wt % to minimise corrosion in the equipment. Once the controlled variables have been identified, the next step is to identify the manipulated variables. The lean amine flowrate, condenser heat duty, absorber valve, reboiler valve and reboiler heat duty were selected similarly to the work of Nittaya et al. (2014). In keeping with the literature, the CO_2 removal rate is maintained constant at 90%. Similarly the temperature in the reboiler is held at 388K to avoid amine degradation Chi et al. (2002), Nittaya et al. (2014). Finally, the condenser temperature is kept at 325 K in order to keep the purity in the CO_2 stream at 95 mol% in line with the work of Harun et al. (2012).

2.2. Model Predictive Control

Model predictive control is a multivariable control stragety that has been successfully applied to a variety of industrial processes since the 1990s. The key advantage of MPC is that it uses an optimisation framework, which makes use of the explicit process models to predict the future behaviour of the plant, to determine the most suitable actions on the manipulated variables Camacho et al. (2004). The high fidelity dynamic model of the system described above is comprised by systems of Differential-Algebraic equations of high complexity. The DAE systems are approximated by linear discrete time models. These linear models are used to predict the behaviour of the real system and a compromise between the accuracy of these predictions and control performance should be found. The linear models are ob-

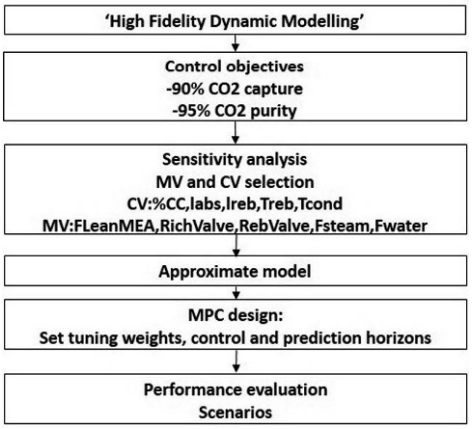

Figure 2: Controllability analysis

tained by performing a system identification
from a number of simulations of the non-linear model for a wide range of industrially relevant conditions. The evaluation has shown that these models represent in very detail the high fidelity models and can be therefore used for the development of the MPC.

The System Identification Toolbox of Matlab developed by Ljung (1995), is used to obtain linear transfer functions between each manipulated and controlled variable. The linear transfer functions obtained from the sensitivity analysis were transformed into controllable (state-space) canonical form. One Multiple Input-Multiple Output (MIMO) system of 5 inputs and 5 outputs was obtained. The MPC controller was designed in Matlab. The prediction and control horizon were 10 and 2 respectively, while the weights on the controlled and manipulated variables were set based on several case studies, as presented in the next section. Figure 2 illustrates the methodology followed to design and evaluates the MPC control structure. The last step of the framework enables the validation on the original high fidelity model, consequently determining the validity of the framework. The coupled system is put into test for different output set-points. The closed loop validation of the control system shows that the controller is able to capture the output set-points efficiently.

3. Results and discussions

The MPC controller as presented above, was evaluated under several scenarios, including changes in the flue gas flowrate that comes from the power plant and in the percentage of CO_2 captured in order to evaluate the amount of steam extracted from the thermodynamic cycle of the power plant during periods of high electricity demand.

3.1. Load changes

In this scenario we examine how the MPC control structure responds to a change in the flue gas flowrate. This is a common disturbance in the operation of power plants, e.g. changes in flue gas flow rate during plant start-up, shut-down, or during the course of the day. In this study a step increment of 20% in the flue gas flowrate with respect to its nominal operating point was introduced to the plant at the first hour of operation.

As we can observe from the results in Figure 3, the degree of CO_2 capture rate resumed to its set-point almost immediately, while the CO_2 capture did not show large deviation from its set-point. Also the CO_2 was kept above the lower limit 85%. In order to compensate for this disturbance, additional steam supply to the reboiler was required and also additional lean amine flowrate. The temperature of the reboiler reset to its set-point while the levels in the reboiler and absorber and the temperature in the condenser were not significantly affected by the disturbance.

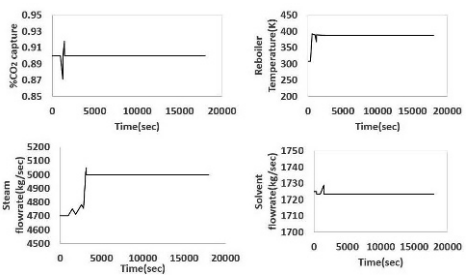

Figure 3: Results-Load change scenario

3.2. Set-point tracking

The steam supplied in the reboiler is supplied by extraction from the steam cycle of the power plant; hence an increase in the electricity demand may decrease the steam availability to the reboiler. This may result in a reduction of a plant's availability to capture CO_2 during peaks in

electricity demand. To evaluate how the plant will operate under this scenario, we consider a reduction of the CO_2 removal set-point from 90 % to 50 %. The ramp change which was introduced lasted 1h.

As we can observe from Figure 4, as soon as the change in the rate of CO_2 capture was introduced, the flowrate of the lean amine was decreased in order to keep the set-point, while the flue gas flowrate entering the absorber was kept unchanged. From this figure we can also observe the fast reduction in the steam provided to the reboiler, which shows how quickly the capture plant responds to changes, so that the amount of excess steam can used by the power plant to produce more electricity in times with high demands. Mac Dowell et al. (2014), Mac Dowell et al. (2014). Of course, it will be important to consider the trade-off in the additional cost associated with additional CO_2 emissions under this operational regime against the additional profit gained by selling the electricity for a few high-value MWh. Optimal techniques for the flexible operation of post-combustion CO_2 capture processes have been described elsewhere. The decrease in the rate of CO_2 increases the CO_2 stream coming from the top and so the water content is increased. The cooling water flowrate provided to the condenser is increased since higher duty in needed in order to maintain the temperature in a specific set-point and therefore the purity in the CO_2 stream coming from the top.

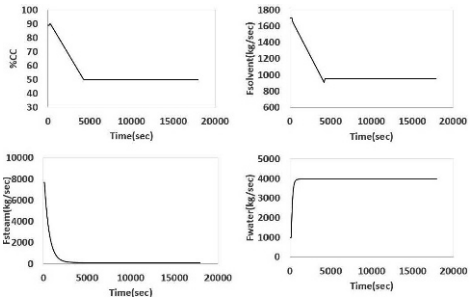

Figure 4: Results-Set-point tracking

4. Conclusions

In this paper we have presented the application of an advanced MPC approach to a dynamic model of a post-combustion CO_2 capture plant via chemical absorption using monoethanolamine (MEA) for a power plant. This model was implemented in gCCS, a tool developed as part of the gPROMS platform for the modelling of decarbonised power generation. A model predictive control strategy was implemented in Matlab in order to assess the dynamic operability of the CO_2 capture plant in the presence of changes in the power plant output (mediated through changing exhaust gas flowrates) and in the set-point tracking. In order to implement the MPC control strategy, the detailed dynamic model of the capture plant was represented by a state-space model of five inputs and five outputs. The approximation of the models was implemented by a sensitivity analysis on the high level model and the use of the System Identification toolbox in Matlab. Two scenarios were implemented: the flue gas flowrate disturbance and also the set-point tracking scenario. The results showed that the MPC control strategy can quickly adapt to any disturbance applied to the capture plant, which is essential for the profitable operation of decarbonised power plants.

A Framework to Structure Operational Documents for Chemical Processes

Hiroshi Osaka [a], Yuji Naka [a], Tetsuo Fuchino [a]

[a]*Tokyo Institute of Technology, 2-12-1, Oookayama, Megro-ku, Tokyo, Japan*

Abstract

It is widely recognized that inadequate and ineffective operational documents contribute substantially to the occurrence of plant downtime and often costly and dangerous industrial incidents. This is largely because the operational design for chemical processes is performed during the earlier process and plant design phase without carrying forward the key operational design information into the later operational documents. To improve the quality of operational documents for safer and more efficient operations, we propose a framework that structures operational documents so that the key operational information is retained.

Keywords: Framework, Operational Design, Operational Document, Operating Procedure, ANSI/ISA S88

1. Introduction

In the chemical process industry, it is well accepted that operational documents such as operating procedures and training manuals are often inadequate and ineffective. As a result, it is widely recognized that these inadequate and ineffective operational documents contribute substantially to the occurrence of plant downtime and often costly and dangerous industrial incidents.

The key reasons for these inadequate and ineffective documents are that the original operational requirements from plant owners are not clear, and the fundamental design intentions and design rationales by process designers are not incorporated into these operational documents. This is because the operational design for chemical processes is performed by the process designers during the earlier process and plant design phase, and, (in a largely separate and much later exercise), operational documents are created by the plant owners. This decoupling of design and operations means that these documents don't cover all the necessary operation modes and they don't support the design intentions and design rationales.

This paper presents a logical methodology and data structure whereby the key operational design output is carried forward into the operational documents producing efficient, easily understood and flexible procedural documents that will ultimately result in safer and more efficient operations.

To achieve this, first, we identify typical data elements for the operational documents by referring to generally accepted design guidelines. Next, we identify the operational design output during the process and plant design phase by utilizing a systematized business process models for plant lifecycle engineering (Fuchino *et al.*, 2011). In particular, with regard to the description of processes, operations and equipment, we apply the design philosophy of ANSI/ISA-88(ANSI/ISA-S88.01, 1995) to the methodology. (ANSI/ISA-88 is a widely accepted industry standard addressing batch process control). Finally, we integrate these techniques to construct effective, structured

operational documents. Documents structured using this methodology reflect all the underlying design intentions and design rationales and operation modes and, at the same time are easier to use and easier to maintain. We propose that this will substantially contribute to safer and more efficient operations for chemical processes.

2. Framework Overview

In this paper, we propose a framework to structure operational documents to meet the needs of chemical processes that have non-routine operations at startup and shutdown. The methodology we use to structure these operational documents is described as follows:

Step-1 We identify the required data elements for various types of operational documents.

Step-2 We identify the operational design output during the process and plant design phase by utilizing the systematized business process model for plant lifecycle engineering.

Step-3 We review the ANSI/ISA-S88 Model from the view point of the process and plant design to develop a model for the structured operational documents. Then, we apply the identified data elements and design output from Step-1 and Step-2 to the model for the structured operational documents.

Step-4 We create a database application to store the structured operational documents.

Figure 1 shows the framework used to structure operational documents. Please refer to the Framework Details in Section 3 below.

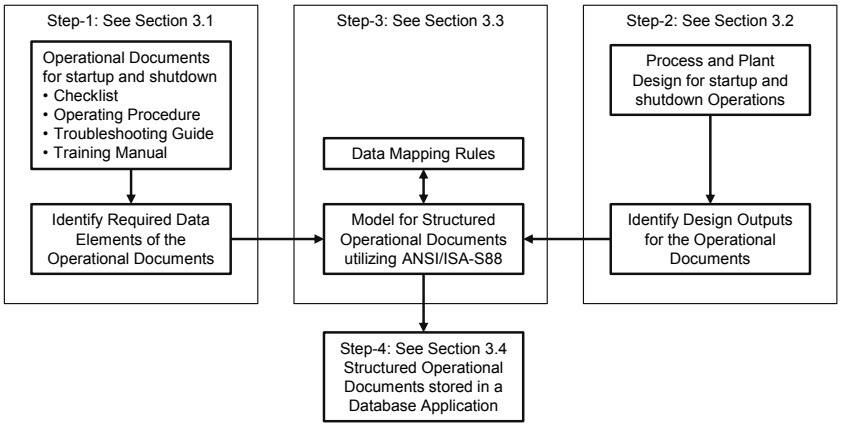

Figure 1 Framework to Structure Operational Documents

3. Framework Details

3.1. Identify the Required Data Elements for the Operating Documents

In general, operational documents are composed of various types of documents such as checklists, operating procedures, troubleshooting guides and training manuals. We identify the data elements for these operational documents using the technique described in an article of Create Effective Safety and Operating Manuals (Bridges *et al.*, 1997) and a widely-recognized guideline; Guidelines for Risk Based Process Safety published by Center of Chemical Process Safety (CCPS, 2007). The data elements for the operational documents are categorized into (i) background information and (ii) operational information about startup and shutdown. The background information

should include an overview of the process, its hazards, and its equipment and safety systems. Table 1 shows the required data elements for typical operational documents.

Table 1 Data Elements for Typical Operational Documents

Data Elements Required for Operational Documents	Typical Operational Documents (X: Applicable)			
	Checklist	Operating Procedure	Troubleshooting Guide	Training Manual
Background Information				
Process overview		X		X

Troubleshooting			X	X
Safe operation limits and limiting conditions		X		X
Warnings, cautions or notes	X	X		X
Other pertinent remarks				X
Theory of operation				X
Equipment description				X

3.2. Identify Design Output for Process and Plant Design for startup and shutdown Operations

The information for the operational documents should be created during the process and plant design phase. Fuchino *et al.* has developed the systematized business process model for plant lifecycle engineering that is an IDEF0 (FIPS, 1993) activity model specifying all the activities for the process and plant design. We utilize this model to identify relevant activities which create the operational information for the startup and shutdown operations. Figure 2 shows the node tree which highlights the activities related to the process and plant design for the startup and shutdown operations. Figure 3 shows the corresponding design output from the process and plant design for the startup and shutdown operations shown in Figure 2. This design output contains design intentions and design rationales that contribute to safer and more efficient operations for the chemical processes.

3.3. Model for Structured Operational Documents

i. We identify two sets of data elements for the operational documents from Step-1 and Step-2. This means we can clearly determine the required data elements for the operational documents at the process and plant design phase when these two sets of data elements are clearly interrelated. To manage these data elements properly, it is better to relate these data elements to actual processes, operations, and equipment so that users of operational documents can easily access the necessary data elements. So, we apply the design philosophy of ANSI/ISA-S88 model as a reference to represent the operational documents as shown in Figure 4.

ii. We review the ANSI/ISA-S88 model from the view point of the process and plant design. Then, we reconstruct a new model for the structured operational documents by considering the following four object models in this order: (i) process requirements, (ii) operational requirements, (iii) equipment requirements and (iv) plant structure. The general relationship among these four object models is illustrated in Figure 5. Each object model is made up of corresponding subdivisions that are combined in a hierarchical manner to accommodate the relevant data elements identified above. It is obvious that the activities related to the process and plant design for the startup and shutdown operations shown in Figure 2 correspond

to the gray area in Figure 5 and this gray area can represent the structured operational documents.

iii. To relate the identified two sets of data elements to the relevant object models shown in Figure 5, we introduce the data mapping rules as shown in Table 2.

iv. Finally, we combine the identified data elements with the model for the structured operational documents using the data mapping rules to represents the structured operational documents.

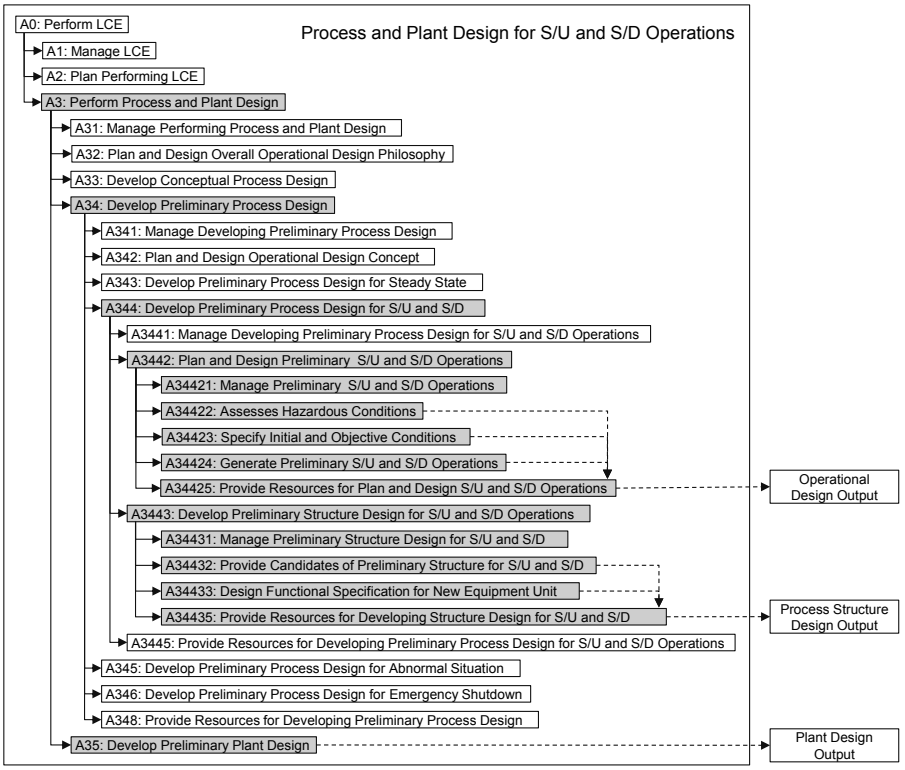

Figure 2 Systematized Business Process Model for Lifecycle Engineering

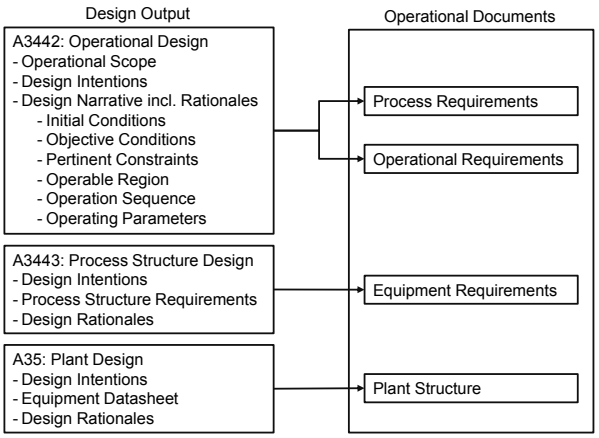

Figure 3 Process and plant design output for Startup and Shutdown Operations

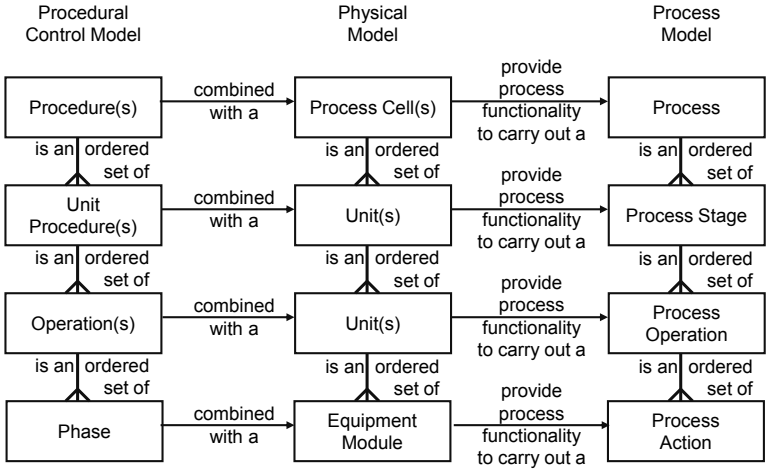

Figure 4 ANSI/ISA S88 Model

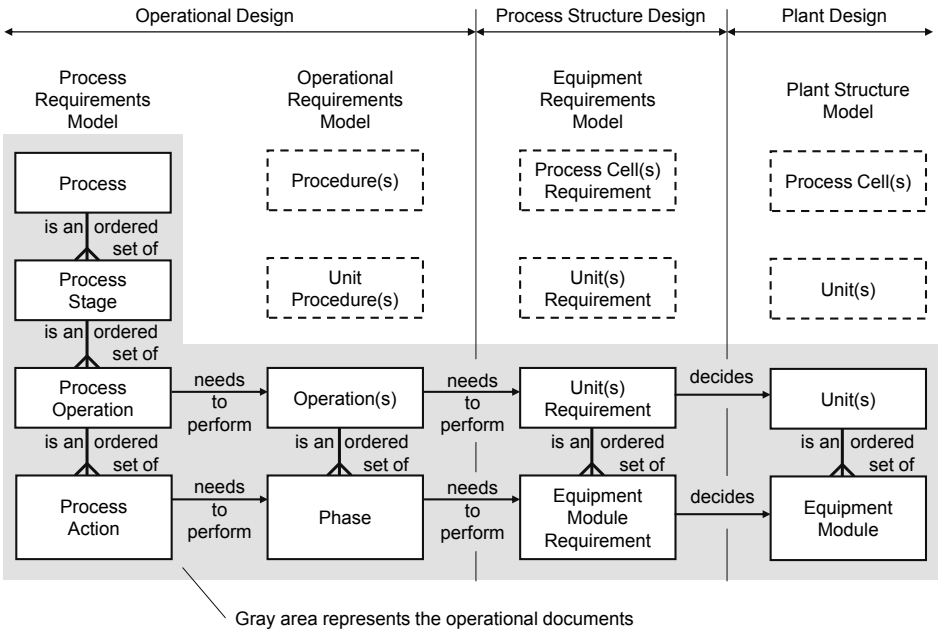

Figure 5 Model for Structured Operational Documents

v. When applying Step-3, it is important to ensure that the data elements for the operational documents from Step-2 are sufficient and comply with the required data elements from Step-1.

3.4. Structured Operational Documents stored in a Database Application

A database application can efficiently accommodate various types of operational documents into one place electronically. This is an integrated operational document environment. A user of the operational document environment can easily obtain various documents by selecting the different data elements that are listed in Table 1.

Table 2 Data Mapping Rules in the Model for Structured Operational Documents

4. Conclusions

This paper has introduced a framework to structure operational documents for chemical processes. In contrast to conventional methodologies, documents structured using this methodology reflect the rich underlying design output including the design intentions and design rationales that are generated during the process and plant design phase.

We will apply this framework to the actual implementation of a practical database of operational documents. The proposed framework should substantially contribute to safer and more efficient operations for chemical processes.

Teaching Sustainable Process Design Using 12 Systematic Computer-Aided Tasks

Deenesh K. Babi[a]

[a]*CAPEC-PROCESS Research Center, Department of Chemical and Bio-chemical Engineering, Technical University of Denmark, Søltofts Plads, Building 229, DK-2800, Kgs. Lyngby, Denmark*

Abstract

In this paper a task-based approach for teaching (sustainable) process design to students pursuing a degree in chemical and biochemical engineering is presented. In tasks 1-3 the student makes design decisions for product and process selection followed by simple and rigorous model simulations (tasks 4-7) and then sizing, costing and economic analysis of the designed process (tasks 8-9). This produces a base case design. In tasks 10-12, the student explores opportunities for heat and/or mass integration, followed by a sustainability analysis, in order to evaluate the base case design and set targets for further improvement. Finally, a process optimization problem is formulated and solved to obtain the more sustainable process design. The 12 tasks are explained in terms of input and output of each task and examples of application of this approach in an MSc-level course are reported.

Keywords: Education, Teaching, Sustainable Process Design, Chemical Engineering

1. Introduction

One of the fundamental courses in chemical and biochemical engineering education is a course related to chemical (and biochemical) process design. An example of such a course is the Capstone Design course taught in the USA at universities that offer undergraduate and post graduate studies in chemical and biochemical engineering.

The students taking the process design course need to gain fundamental understanding in four key areas. First, the students need to learn that process design requires the making of good design decisions, in order to generate a process flowsheet that converts some raw materials to desired products while satisfying process specifications. Second, to make appropriate design decisions, they need to have a good theoretical background and process understanding. Third, they should use process simulators only to verify/validate decisions/designs and must not use these tools to make design decisions by trial and error or blind simulations that are not based on prior analysis. Fourth, they should consider sustainability related issues (carbon footprint, toxicity, etc.) in the early stages of design when looking for more sustainable designs. It is important that students understand the scope and significance of performing sustainable process design because it is a requirement in proposing new and innovative designs for the industry that may want to hire them.

In the course, sustainable process design is introduced as the design of a process that corresponds to improved values of a set of targeted performance criteria related to economical, operational and sustainability factors (Babi et al., 2014). Therefore, matching these targets means a more sustainable design is obtained. In teaching sustainable process design, there is a need for a systematic task-based approach that

students can easily apply in order to generate, design and analyse process alternatives in their search for more sustainable solutions.
In this paper a task-based approach is presented for teaching sustainable process design. This approach is currently being used at the Technical University of Denmark (DTU), Denmark, the Sino-Danish Center for Education and Research (SDC), China and the Petroleum and Petrochemical College, Chulalongkorn University, Thailand.

2. Sustainable Process Design: Mathematical formulation

The students are first introduced to the definition of the (sustainable) design problem (Fig. 1) and then how to express it mathematically (Eq. 1 to Eq. 5)

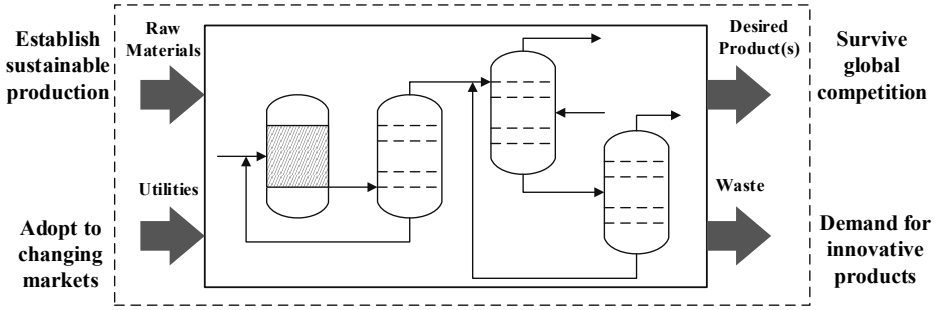

Figure 1: Graphical Definition of the (Sustainable) Design Problem

$$F_{OBJ} = \max\left\{C^T y + f(x)\right\} \quad (1)$$

$$f_1(x) = 0 \quad (2)$$

$$f_2(x, y) = 0 \quad (3)$$

$$l_1 \le g(x, y) \le u_1 \quad (4)$$

$$\underline{Y} = 0/1,\ \underline{X} \ge 0 \quad (5)$$

In Eq. 1 to Eq. 5, x represents a vector of continuous variables, for example, flowrates, design variables etc. and y represents the vector of binary integer variables, for example, unit operation identity, $f_1(x)$ and $f_2(x)$ represents equality constraints related to process specifications and process model equations, $g(x,y)$ represents a set of inequality constraints related to process design specifications and environmental impacts. The objective function, F_{OBJ} (to be maximized or minimized) consist of $f(x)$ that represents a system of linear and/or non-linear functions. From the mathematical formulation presented in Eq. 1 to Eq. 5, the process design problem is defined as a mixed integer non-linear programming problem (MINLP) because the objective function and/or constraints can be either linear and/or non-linear and binary, integer decisions are required. The solution of this generic problem, however, is decomposed into the solution of a hierarchal set of 12-tasks, where the final step is the optimization step.
In applying the task-based approach, the students solve the process design problem by first generating a base case design where constraints in Eq. 2-3 are satisfied. Then the environmental impacts and sustainability issues are considered (Eq. 4). This also leads

to an integrated process. Finally, the objective function is calculated and ordered for a feasible set of alternatives in order to determine the more sustainable design.

3. Sustainable Process Design: 12 Task approach

The sequential (hierarchal), task-based approach for teaching process design is divided into 12 tasks. Each task has required inputs and therefore, desired outputs. In order for the student to proceed from one task to another, the previous task must be completed and if necessary, they can return to a previous task and modify the required input, thereby, obtaining an updated output. It is not possible to skip a task, unless the problem allows it, because the output of a previous task is used as the input to the next task.

3.1. Task 1-2- Identify Chemical Product and Economic Viability

Task objective: To identify details about the chemical product to be produced and analyse its economic viability.

Input to the task:

- Properties of compounds

Output of the task:

- Product selection
- Chemical product uses and thermo-physical properties
- Manufacturers and yearly production rate of the chemical product
- Raw material, reaction pathway and reaction steps
- Economic potential

Action required: First, the student must select the chemical compound to be produced. This can be specified by the teacher or selected by the student. Second, details about the product is obtained, for example, why the product is needed, its uses and its thermo-physical properties. Third, using a selected reaction pathway, a yearly production rate of the chemical product and, raw material and product prices, an economic potential is calculated. It is based on an overall mass balance of the process, and stoichiometry of the selected reaction pathway. The economic potential at this stage must be sufficiently high in order to have a profitable process.

3.2. Task 3- Initial design selection and verification

Task objective: To select and verify an initial design.

Additional input to the task:

- Raw material, reaction pathway and reaction steps

Output of the task:

- Verified initial design

Action required: First, the student must select a process that utilizes the reaction pathway selected in task 2 to convert the raw material to the desired product. This selected process is referred to as the initial design. Second, the initial design is verified using the process synthesis method (Douglas, 1985). The student also has the option to generate a process using this method, taking into account the compounds present in the reactor inlet and outlet streams, recovery of the raw materials (where applicable) and recovery of the products.

3.3. Task 4- Mass balance

Task objective: To perform a mass balance on the initial design using a process simulator.

Additional input to the task:

- Raw material, reaction pathway and reaction steps
- Verified initial design

Output of the task:

- Mass balance for the initial design

Action required: First, the student, together with the reaction information, must decide on the product recoveries for all the separators present in the process flowsheet. Second, for the process flowsheet under consideration, a mass balance is performed using simple in/out mass balance models available in process simulators. Note, recycle streams are also included in this mass balance model and purge fractions must be decided.

3.4. Task 5- Identify process stream conditions

Task objective: To identify the process stream conditions.

Additional input to the task:

- Mass balance for the initial design

Output of the task:

- Stream condition

Action required: The minimum data needed to define a stream are the component flowrates, temperature, pressure and phase state (optional). Students are introduced to this concept, where the component flowrates are obtained already from task 4. Now using thermodynamic insights, they need to decide about temperature, pressure and phase state. The students are given a guideline, for selection of the appropriate thermodynamic model. This information is to be used in task 6 for the energy balance model. The design decisions here introduce also the concepts of phase equilibria.

3.5. Task 6- Mass and Energy balance

Task objective: To perform a mass and energy balance on the initial design using a process simulator.

Additional input to the task:

- Mass balance for the initial design
- Stream condition

Output of the task:

- Mass and energy balance for the initial design

Action required: First, the mass balance model is extended in order to include the energy balance. Second, the heat added or removed from each unit operation is calculated in order to verify the decision decisions made in task 5.

3.6. Task 7- Rigorous simulation

Task objective: To perform rigorous simulation by replacing simple models with rigorous models.

Additional input to the task:

- Mass and energy balance for the initial design

Output of the task:

- Rigorous simulation results

Action required: First, each simple in/out model for separation is replaced one at a time with its corresponding rigorous version, for example, a stream calculator used for representing the separation of a zeotropic multicomponent mixture is replaced with a rigorous model that use as input the results from tasks 4-6.

3.7. Task 8-9- Equipment Sizing & Costing and Economic Analysis

Task objective: To perform equipment sizing and costing and, an economic analysis on the rigorous design.

Additional input to the task:

- Rigorous simulation results

Output of the task:

- Equipment dimensions and costs
- Economic analysis

Action required: First, the results obtained from the rigorous simulation of the initial design are used to perform equipment sizing based on the power-law correlations developed by Guthrie (1969). Second, the cost (capital) associated with the initial design are calculated. Third, additional costs (direct and indirect) are calculated as factors of the equipment cost. Finally, an economic analysis is performed based on cash flow, depreciation and project lifetime in order to analyse whether the process is profitable. After performing the economic analysis, the initial design is referred to as a base case design. It is a feasible design because it satisfies all constraints but, it is not optimal.

3.8. Task 10-12- Process Integration and Optimization

Task objective: To perform a process integration and optimization.

Additional input to the task:

- Base case design

Output of the task:

- Heat and/or mass integrated design
- Environmental impact analysis
- Sustainable design

Action required: First, opportunities for heat integration are explored, that is, streams to be heated are integrated with streams to be cooled, for example, reactor inlet and outlet streams. Second, opportunities for mass integration are explored. Third, a sustainability analysis is performed on the integrated design in order to set targets for further improvement. Finally, an optimization problem is formulated and solved. Here any process alternative that improves the defined objective function is more sustainable solution.

4. Sustainable Process Design: Computer-Aided tools

The students learn to use different tools as they apply the 12 task approach. The software used in the course consist of both in-house and commercial tools. A list of the tools used in the course is given in Table 1.

Table 1: List of Computer-Aided Tools

Name	**Function**	**Notes**
ICAS	Compound database, experimental data	Model based analysis, database*
SolventPro	Solvent selection and Design	Model based analysis, database*
ProPred	Property prediction	Model based- group contribution*
ECON**	Economic analysis	Model & rule based analysis*
LCSoft**	LCA analysis	Model & rule based analysis*
SustainPro**	Sustainability analysis	Model & rule based analysis*
PROII	Process Simulation	PROII 9.3 (2015)

*Note: Part of ICAS suite (Gani et al., 1997, **Kalakul et al., 2014)

5. Sustainable Process Design: Examples of Designed Processes

The 12 task approach for achieving sustainable process design has been applied numerous times, for example, at DTU, the course is taught every spring semester, for the past 20 years, as an advanced course for the MSc degree (http://bit.ly/1G08Lk5). Table 2 lists some process designs developed by students taking the course.

Table 2: Selected Design projects

Design Project Product	**Payback period-** ***Tasks 10-12 (1-9)***	**Production target**	**Remarks**
DME	3.4 (5.4) yrs.	53000 kg/hr	Co-production of DME & methanol
Cumene	1.9 (2.3) yrs.	34247 kg/hr	Carbon footprint reduction
Styrene	2.4 (7.6) yrs.	17123 kg/hr	Reduction in environmental impacts
Phenol	2.5 (2.9) yrs.	45700 kg/hr	Novel reactor design without by-products

6. Conclusion and Future Perspectives

In this paper a task-based approach to teaching (sustainable) process design that explores different facets of theory/knowledge gained from previous courses has been presented. Process design text books such as Seider, Seader, Lewin, Widgado, Gani and Ng (2015) also employ a similar approach. In perspective, it is important that a design course is structured in such a way that research methods and tools that are currently being developed, can be incorporated into teaching, in order to provide meaningful and up to date insights to the students. This is important in the area of sustainability, for example, the use of sustainability and LCA analyses, for analysis of chemical processes. Finally students should also be given the opportunity to do a design project on ‘’product design’’, but how can this be done in a similar way?

Abstract

Superstructure approaches are the solution to the difficult problem which involves the rigorous economic design of a distillation column. These methods require complex initialization procedures and they are hard to solve. For this reason, these methods have not been extensively used. In this work, we present a methodology for the rigorous optimization of chemical processes implemented on a commercial simulator using surrogate models based on a kriging interpolation.

Several examples were studied, but in this paper, we perform the optimization of a superstructure for a non-sharp separation to show the efficiency and effectiveness of the method. Noteworthy that it is possible to get surrogate models accurate enough with up to seven degrees of freedom.

Keywords: process optimization, design, kriging algorithm, modular simulators.

1. Introduction

Computationally efficient process models have been recently demanded in many engineering applications. When we want to optimize a model, the process model has to trade-off the model accuracy against computational efficiency. The problem is that most of those models have a modular structure to which users have limited internal access (they see a “grey box model”) and some of these models introduce numerical noise, so that its derivatives cannot be accurately estimated.

In addition, the rigorous design of distillation column sequences is a difficult problem in chemical process engineering because it includes simultaneous optimization of continuous decisions related to the operational conditions, and discrete decisions allied to the number of trays in each column section or the columns connectivity.

In this work we study the replacement of complex systems of distillation columns by surrogate models based on a kriging interpolation generated from rigorous models, including continuous and discrete variables, and use these metamodels to design the distillation columns. Thereby, we keep the rigor of simulations models, removing most of the numerical problems and increasing the reliability of the synthesis algorithms.

In this work we use simulation data to build models for individual parts of a large system. We focus on kriging metamodels because they are computationally efficient and they use relatively small sampling data. Kriging can be applied to replace a complete system or to substitute one or some of the components of the model.

2. Kriging interpolation

Kriging was developed by a South African mining engineer in his geostatistics Master Thesis (Krige, 1951). Its fitting consists of two parts: a polynomial expression and a deviation from that polynomial:

$$y(x) = f(x) + Z(x) \tag{1}$$

where $Z(x)$ is a stochastic Gaussian process that represents the uncertainty about the mean of $y(x)$ with expected value zero. The covariance for two points x_i and x_j is given by a scale factor σ^2 and by a spatial correlation function $R(x_i,x_j)$. The most common alternative for kriging models is using the extended exponential correlation (Sacks et al., 1989).

$$R(x_i, x_j) = exp\left(-\sum_{l=1}^{d} \theta_l \left(x_{i,l} - x_{j,l}\right)^{P_l}\right) \tag{2}$$

where $\theta_l \geq 0$ and $0 \leq P_l \leq 2$ are adjustable parameters. To estimate the values of the parameters, θ_l and P_l, we maximize the logarithm of the likelihood function of the obtained data y.

$$log(L) = -\frac{n}{2} ln(2\mu) - \frac{n}{2} ln(\sigma^2) - \frac{1}{2} ln(|R|) - \left(\frac{-(y - 1\mu)^T R^{-1} (y - 1\mu)}{2\sigma^2}\right) \tag{3}$$

where y is the vector of obtained responses (n x 1), $\boldsymbol{1}$ is a vector of ones (n x 1), n is the number of sampled points and σ^2 and μ are parameters.

Differentiating Eq.(3) with respect σ^2 and μ, and equating it to zero, we obtain the optimal values for σ^2 and μ.

$$\hat{\mu} = \frac{1^T R^{-1} y}{1^T R^{-1} 1} \tag{4}$$

$$\hat{\sigma}^2 = \frac{(y - 1\hat{\mu})^T R^{-1} (y - 1\hat{\mu})}{n} \tag{5}$$

To interpolate a new point x_{new}, we add the point (x_{new}, y_{new}) to the data and compute the augmented likelihood function keeping the parameters constant. The value for y_{new} will be calculated maximizing the augmented likelihood function. With the Eq.(6) is given the final predictor of the kriging method (Sasena, 2002).

$$\hat{y}(x_{new}) = \hat{\mu} + r^T R^{-1} (y - 1\hat{\mu}) \tag{6}$$

where r (n x 1) is the vector of correlations $R(x_{new},x_i)$ between the sample design points and the points to be correlated.

Kriging allow us to estimate the accuracy with the correlation of the errors, from the formula for the mean-squared error (Sacks et al., 1989).

$$s^2(x_{new}) = \hat{\sigma}^2 \left(1 - r^T R^{-1} r + \frac{(1 - r^T R^{-1} r)^2}{1^T R^{-1} 1}\right) \tag{7}$$

3. Application of the kriging algorithm in distillation columns

The kriging algorithm implementation is as follows:

a. First, N points are generated, separated enough to ensure that the noise generated by the simulator has no effect on. These points are sampled.
b. Kriging metamodel is fitted with the simulation data.
c. Validate the accuracy of the model using cross-validation (Jones et al., 1998).
d. Substitute the actual model by the kriging metamodel.
e. Perform the (MI)NLP optimization. If the accuracy of the model is good, we can finish.
f. In case that the accuracy was not good, add the optimal point to the set of sampled points, and update and re-optimize kriging. If there is no improvement in two consecutive iterations, go to step g.
g. In this case, we have to contract the feasible search region within a trust region around the solution obtained and repeat steps d to f, until we can guarantee that the error in gradient is below a given tolerance.

In this work, sampling points are generated distributed throughout the search area using a max-min approach (maximizing the minimum distance between two points). For this, we fix the bounds of all independent variables and then we distribute the rest of the points through the max-min approach.

4. Examples and results

Several examples were studied to verify the effectiveness of the method, but in this paper only an interesting example is presented. It consists of a superstructure for a non-sharp separation. We enumerate the column trays from the top to the bottom of the column. The example was solved on a computer with a 2.60 GHz Pentium® Dual-Core Processor and 4 GB of RAM under Windows 7.

4.1. Objective function

The objective function consists of minimizing the total annualized cost (*TAC*) of a chemical process. The total annualized cost is function of the capital costs of the column shells, trays and exchangers, and function of the operating cost (we have considered the cost of cooling water and vapor stream).

The objective function is determined by the Eq.(8) (Turton, 2012).

$$min\ TAC\left(\frac{\$}{year}\right) = C_{op} + F \cdot C_{cap} \tag{8}$$

where C_{op} is the operating cost per year, F is an annualization factor and C_{cap} is the capital cost. Both are updated by the global CEPCI cost index of 2013. The annualization factor is calculated by the Eq.(9) (Smith, 2005).

$$F = \frac{i(1+i)^n}{(1+i)^n - 1} \tag{9}$$

where n in the horizon time and i is the fractional interest rate per year. We have used a horizon time of 5 years and a fixed interest rate of 10 %.

4.2. Distillation sequences. Nonsharp separations.

We want to separate a multicomponent feed stream given into several desired multicomponent product streams. Figure 1 shows the superstructure that contains all possible alternatives to get the desired products (Aggarwal and Floudas, 1990). The objective is to determine the optimal sequence and number of trays of the columns to minimizing the total annualized cost (TAC) for separating an iso-molar mixture of benzene, toluene and p-xylene. This cost is composed of the operational and fixed costs of both columns. Mixer and splitters costs are neglected. Peng-Robinson equation of state has been used.

Assume that the pressure is fixed (P = 101.3 kPa). The independent variables chosen for the rigorous design of the conventional distillation columns are the number of trays in the rectifying section, number of trays in the stripping section and the recoveries of key components for each column.

The problem is formulated as an MINLP. It can be solved by reformulating the disjunctions using a Big-M approach (Grossmann and Ruiz, 2012). Disjunctions are shown in Eq.(10).

$$\begin{bmatrix} Y_1 \\ [Q_{Reb}^{C1}, Q_{Cond}^{C1}, D^{C1}] = Kr_1(N_{R1}^{C1}, N_{S1}^{C1}, f_{LK}^{C1}, f_{HK}^{C1}, F5_i) \\ TAC_1 = \Omega(Q_{Reb}^{C1}, Q_{Cond}^{C1}, D^{C1}) \end{bmatrix} \underline{\vee} \begin{bmatrix} \neg Y_1 \\ TAC_1 = 0 \\ F5_i = F6_i = F9_i = 0 \; \forall i \end{bmatrix}$$
$$\begin{bmatrix} Y_2 \\ [Q_{Reb}^{C2}, Q_{Cond}^{C2}, D^{C2}] = Kr_2(N_{R2}^{C2}, N_{S2}^{C2}, f_{LK}^{C2}, f_{HK}^{C2}, F13_i) \\ TAC_2 = \Omega(Q_{Reb}^{C2}, Q_{Cond}^{C2}, D^{C2}) \end{bmatrix} \underline{\vee} \begin{bmatrix} \neg Y_2 \\ TAC_2 = 0 \\ F13_i = F14_i = F18_i = 0 \; \forall i \end{bmatrix} \quad (10)$$

Y_1 and Y_2 are Boolean variables that take the value of True if the corresponding column is selected and False otherwise. The symbol '*f*' makes reference to the key components recoveries.

The minimum objective function (TAC = 0.3129 M$/year) is obtained with the sequence shown in Figure 2.

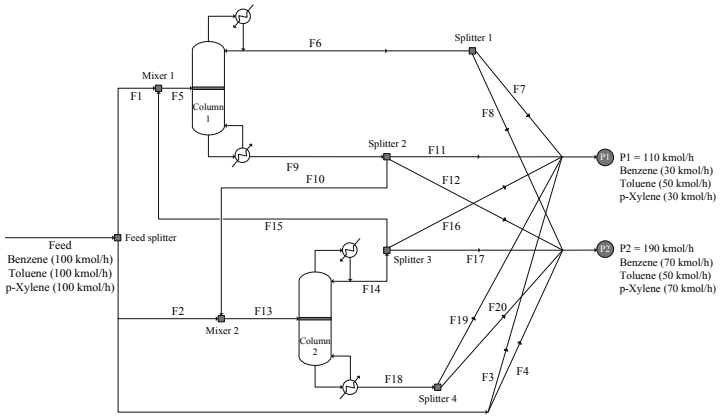

Figure 1. Superstructure for a three-component system.

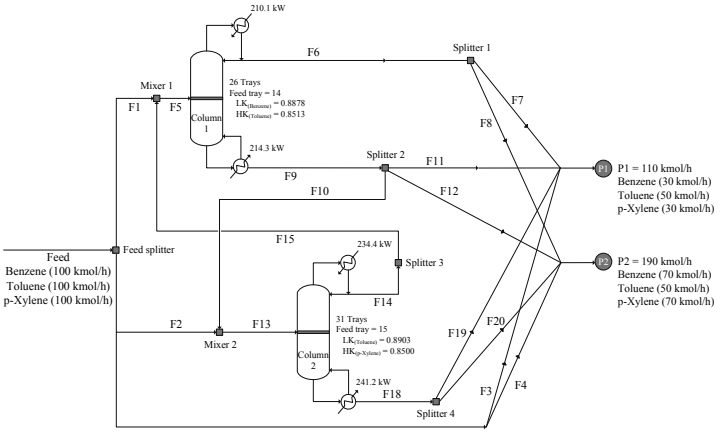

Figure 2. Optimal solution for the three-component system.

The column 1 has 26 trays and it is fed on the 14th tray. The column 2 has 31 trays and it is fed on the 15th tray.

A summary of results obtained is shown in Table 1. A contraction step around the optimal solution was performed. Then, a new resampling and kriging calibration was needed.

5. Conclusions

In this work, was presented and applied an algorithm for constrained optimization of distillation columns. This optimization includes implicit grey box functions which are substituted by a kriging metamodel.

Table 1. Summary of results obtained (optimal solution).

Optimal valued (after refining stage)			
Number of sampled points in each columns = 202 TAC = 0.3129 M$/year			
Column 1		Column 2	
$F5_{,benzene}$	13.1490	$F13_{,benzene}$	3.6504
$F5_{,toluene}$	11.2260	$F13_{,toluene}$	9.5000
$F5_{,p\text{-}Xylene}$	3.4158	$F13_{,p\text{-}Xylene}$	12.6589
Number of trays in the rectifying section	13	Number of trays in the rectifying section	14
Number of trays in the stripping section	12	Number of trays in the stripping section	16
Recovery (LK = Benzene)	0.8878	Recovery (LK = Toluene)	0.8903
Recovery (HK = Toluene)	0.8513	Recovery (HK = p-Xylene)	0.8500

The "quality" of the optimum will depend on how accurately the surrogate model represents the actual model. It is interesting remark that though the final model includes discrete variables the kriging surrogate can be generated without taking into account that fact.

The implementation presented in this work only guarantees a local optimum. However, we have checked that it is possible to get accurate global surrogate models with up to seven degrees of freedom, being necessary a high number of sampling points. The problem presented is that if the number of points is large, it will be necessary a large CPU time for calibrating the kriging. A reduced set of sampling points reduce the CPU time for calibrating the kriging and interpolation, but it is likely that we need more contraction, resampling and recalibrating stages.

The algorithm presented has proved to be robust, reliable and also allows a fast interpolation of new values.

Abstract

This paper implements global sensitivity analysis in the Savvopoulos et al. (2014) mathematical model of B cell chronic lymphocytic leukemia (B-CLL); this dynamic model represents a framework for modelling dynamic B-CLL trajectories. B-CLL is a heterogeneous, slowly-progressing disease where a type of white blood cell, B lymphocytes, accumulates in bone marrow, peripheral blood, lymph nodes and spleen. The Savvopoulos et al. (2014) modelling framework integrates both temporal and spatial disease aspects; delay differential equations capture latency in the cell proliferation cycle and population balance equations between disease centres represent inter-tissue B-CLL migration. This manuscript conducts global sensitivity analysis using the random sampling - high dimensional mathematical representation (RS-HDMR) method to: (1) uncover which are the most critical model parameters; (2) analyse the system of model equations; (3) provide clinically-relevant patient testing recommendations leading to effective model parametrisations.

Keywords: global sensitivity analysis, multi-compartmental model of B-CLL, cell cycle kinetics

1. Introduction

B-CLL is the most commonly-incurred leukemia or blood cancer; approximately 16,000 and 2,800 patients are diagnosed annually in the USA and UK, respectively (American Cancer Society, 2014). B-CLL is a heterogeneous disease representing with abnormally increased proliferation and reduced apoptosis (programmed cell death) of B lymphocytes. The disease progresses slowly with most cancerous cells arrested in the resting (G0) or growth (G1) phases of the cell cycle. B-CLL cells are monoclonal (*i.e.*, derived from a single cell) lymphocytes which accumulate abnormally in bone marrow (BM), peripheral blood (PB), lymph nodes (LN), and spleen (S) (Granziero et al., 2001).

Signs often include: (1) elevated lymphocyte count (lymphocytosis) with $> 5,000$ cells $/\mu$L in peripheral blood; (2) LN enlargement, (3) enlarged S (splenomegaly); (4) BM failure; (5) decreased red blood cells (anaemia, Hgb $< 11\text{g} \cdot \text{dL}^{-1}$); (6) decreased platelet count (thrombocytopenia) $< 100 \cdot 10^9$ / L (Galton, 1966), all leading to the widely-used Binet et al. (1981) system for staging (Binet Stage A – C): (A) lymphocytosis with fewer than 3 areas of enlarged lymph nodes; (B) lymphocytosis with both lymphadenopathy and splenomegaly; (C) lymphocytosis with bone marrow failure, anaemia and thrombocytopenia.

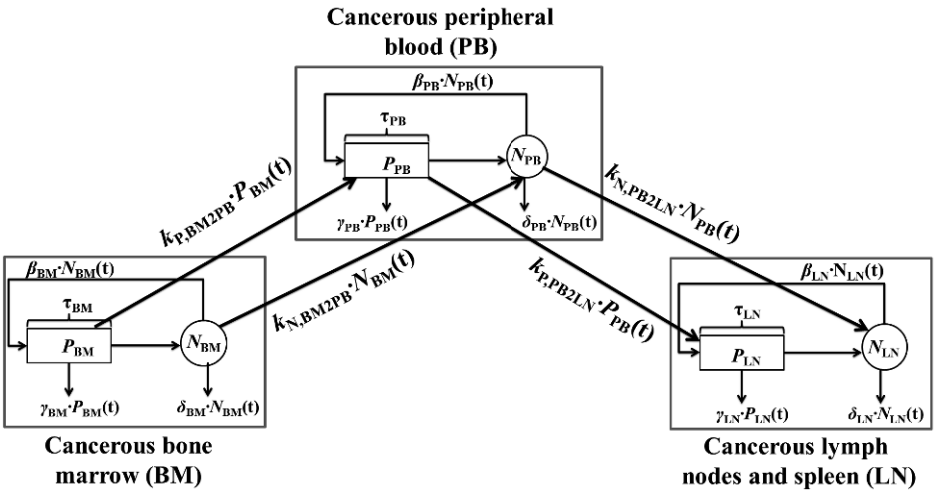

Figure 1: The compartmental analysis of B-CLL (Savvopoulos et al., 2014)

We (Savvopoulos et al., 2014) have developed a dynamic, physiologically-relevant mathematical model of B-CLL interconnecting the most affected tissues: PB, LN, BM and S. This modelling framework integrates both temporal and spatial disease aspects; delay differential equations capture latency in the cell proliferation cycle and population balance equations between disease centres represent inter-tissue B-CLL migration.

This manuscript proposes global sensitivity analysis (GSA) of the nonlinear model of B-CLL using the method that is alternatively called the Sobol method or random sampling - high dimensional model representation, RS-HDMR (Li et al., 2002). GSA has been repeatedly shown to highlight key elements of model structure such as in the works of Kiparissides et al. (2009, 2011) where they used the Sobol method in order to find the most experimentally validated parameters from nonlinear biological systems. In this paper, sensitivity indices derived from RS-HDMR are ranked according to their values; the results show which input parameters or interactions of two inputs contributes most significantly to the overall output variance (Ziehn and Tomlin, 2008).

Deducing key model parameters from global sensitivity analysis allows effective analysis of model equations and may provide clinically-relevant patient testing recommendations leading to effective model parametrisations; the goal is to provide insight into the development and subsequent personalised treatment of B-CLL. This manuscript uses as springboard the Acute Myeloid Leukemia model of Pefani et al. (2013, 2014) which similarly incorporates cell cycle analysis and compartmental models of disease centres. In this manuscript: Section 2 briefly introduces the Savvopoulos et al. (2014) model; Section 3 describes the GSA algorithm; Section 4 analyses the relevant model parameters; Section 5 discusses the results; Section 6 concludes the manuscript. This work belongs to an ongoing effort developing building blocks for modelling and optimising biomedical systems (Velliou et al., 2014).

2. Mathematical Model of B-CLL

Our model (Figure 1; Eqs (1) – (7)) integrates the most affected tissues: BM, PB, LN and S. The net flow of cancerous cells starts in BM, the site of pathogenesis, wherein CLL cells proliferate according to the time-delayed feedback function β; both non-proliferative (N_{BM}) and proliferative

(P_{BM}) cells may subsequently migrate to LN and S through PB or accumulate in BM and thereby change the bone marrow infiltration pattern. The LN microenvironment also promotes B-CLL proliferation and causes LN and S enlargement.

Bone Marrow (BM):

$$\frac{dN_{\mathrm{BM}}}{dt} = -\delta_{\mathrm{BM}}\, N_{\mathrm{BM}} - \beta_{\mathrm{BM}}(N_{\mathrm{BM}})\, N_{\mathrm{BM}}\, cc + 2\, \beta_{\mathrm{BM}}(N_{\mathrm{BM},\,\tau_{\mathrm{BM}}})\, N_{\mathrm{BM},\,\tau_{\mathrm{BM}}} \\ e^{-\gamma_{\mathrm{BM}}\,\tau_{\mathrm{BM}}}\, cc - k_{\mathrm{N,BM2PB}}\, N_{\mathrm{BM}} \tag{1}$$

$$\frac{dP_{\mathrm{BM}}}{dt} = -\gamma_{\mathrm{BM}}\, P_{\mathrm{BM}} + \beta_{\mathrm{BM}}(N_{\mathrm{BM}})\, N_{\mathrm{BM}}\, cc - \beta_{\mathrm{BM}}(N_{\mathrm{BM},\,\tau_{\mathrm{BM}}})\, N_{\mathrm{BM},\,\tau_{\mathrm{BM}}} \\ e^{-\gamma_{\mathrm{BM}}\,\tau_{\mathrm{BM}}}\, cc - k_{\mathrm{P,BM2PB}}\, P_{\mathrm{BM}} \tag{2}$$

$$cc = \frac{800 \cdot 10^9 - C_{\mathrm{NC,BM}} - N_{\mathrm{BM}} - P_{\mathrm{BM}}}{800 \cdot 10^9} \tag{3}$$

Peripheral Blood (PB):

$$\frac{dN_{\mathrm{PB}}}{dt} = -\delta_{\mathrm{PB}} \cdot N_{\mathrm{PB}} - \beta_{\mathrm{PB}}(N_{\mathrm{PB}}) \cdot N_{\mathrm{PB}} + 2 \cdot \beta_{\mathrm{PB}}(N_{\mathrm{PB},\,\tau_{\mathrm{PB}}}) \cdot N_{\mathrm{PB},\,\tau_{\mathrm{PB}}} \cdot e^{-\gamma_{\mathrm{PB}} \cdot \tau_{\mathrm{PB}}} \\ + k_{\mathrm{N,BM2PB}} \cdot N_{\mathrm{BM}} - k_{\mathrm{N,PB2LN}} \cdot N_{\mathrm{PB}} \tag{4}$$

$$\frac{dP_{\mathrm{PB}}}{dt} = -\gamma_{\mathrm{PB}} \cdot P_{\mathrm{PB}} + \beta_{\mathrm{PB}}(N_{\mathrm{PB}}) \cdot N_{\mathrm{PB}} - \beta_{\mathrm{PB}}(N_{\mathrm{PB},\,\tau_{\mathrm{PB}}}) \cdot N_{\mathrm{PB},\,\tau_{\mathrm{PB}}} \cdot e^{-\gamma_{\mathrm{PB}} \cdot \tau_{\mathrm{PB}}} \\ + k_{\mathrm{P,BM2PB}} \cdot P_{\mathrm{BM}} - k_{\mathrm{P,PB2LN}} \cdot P_{\mathrm{PB}} \tag{5}$$

Lymph Nodes and Spleen (LN):

$$\frac{dN_{\mathrm{LN}}}{dt} = -\delta_{\mathrm{LN}} \cdot N_{\mathrm{LN}} - \beta_{\mathrm{LN}}(N_{\mathrm{LN}}) \cdot N_{\mathrm{LN}} + 2 \cdot \beta_{\mathrm{LN}}(N_{\mathrm{LN},\,\tau_{\mathrm{LN}}}) \cdot N_{\mathrm{LN},\,\tau_{\mathrm{LN}}} \cdot e^{-\gamma_{\mathrm{LN}} \cdot \tau_{\mathrm{LN}}} \\ + k_{\mathrm{N,PB2LN}} \cdot N_{\mathrm{PB}} \tag{6}$$

$$\frac{dP_{\mathrm{LN}}}{dt} = -\gamma_{\mathrm{LN}} \cdot P_{\mathrm{LN}} + \beta_{\mathrm{LN}}(N_{\mathrm{LN}}) \cdot N_{\mathrm{LN}} - \beta_{\mathrm{LN}}(N_{\mathrm{LN},\,\tau_{\mathrm{LN}}}) \cdot N_{\mathrm{LN},\,\tau_{\mathrm{LN}}} \cdot e^{-\gamma_{\mathrm{LN}} \cdot \tau_{\mathrm{LN}}} \\ + k_{\mathrm{P,PB2LN}} \cdot P_{\mathrm{PB}} \tag{7}$$

Auxiliary Helper Functions (Temporal Delays & Feedback Functions):

$$N_{i,\,\tau_i} = N(t - \tau_i);\ \beta_i(N_i) = \beta_{N_i,0} \cdot \theta_i^{\mathrm{n}} / (\theta_i^{\mathrm{n}} + N_i^{\mathrm{n}});\ \theta_i = \theta_{i,1} \cdot t + \theta_{i,2}; \qquad \forall\, i \in \{\mathrm{BM, PB, LN}\}$$

where in each tissue $i \in \{\mathrm{BM, PB, LN}\}$, N_i, P_i are the number of B-CLL cells in non-proliferative and proliferative phase, δ_i, γ_i are the cell death rates in non-proliferative and proliferative phases, β_i, θ_i, n are parameters defining the time-delayed cell proliferation feedback function, $\beta_{N_i,0}$ is the maximum number of cells entering the proliferative phase, τ_i is the time spent in proliferative phase, $k_{\mathrm{N,BM2PB}}$, $k_{\mathrm{P,BM2PB}}$, $k_{\mathrm{N,PB2LN}}$, $k_{\mathrm{P,PB2LN}}$ are the B-CLL migration rates in non-proliferative phase and proliferative phase from BM to PB and from PB to LN and S, cc denotes the BM carrying capacity, $C_{\mathrm{NC,BM}}$ is the number of normal BM lymphocytes which equals $50{\cdot}10^9$ cells (Savvopoulos et al., 2014). The cell cycle formulation in each disease compartment is derived from Mackey (1978).

The delay differential equations incorporate the temporal aspect of cell division τ; Andersen and Mackey (2001) show that explicitly incorporating a time delay will, in future work, allow proper modelling of chemotherapy response. We capture the spatial elements of the disease via the migration rates k between compartments of the most affected tissues; the approach is similar to population balance modelling. Observe that this model is fundamentally a modular framework that could incorporate advanced aspects such as the interaction between B and T lymphocytes (Nanda et al., 2013); the baseline cell cycle equations taken from Mackey (1978) could be augmented if we could expect additional clinical and experimental data.

3. Global Sensitivity Analysis

In RS-HDMR, model output is decomposed into summands of first-, second- and higher-order terms (Li et al., 2002):

$$f(\mathbf{x}) = f_0 + \sum_{i=1}^{n} f_i(x_i) \quad + \sum_{i,j}^{n} f_{i,j}(x_i, x_j) + \ldots + f_{12\ldots n}(\mathbf{x})$$

where:

$f_0 = \int_{K^n} f(\mathbf{x})\mathrm{d}\mathbf{x}$; $f_i(x_i) = \int_{K^{n-1}} f(\mathbf{x})\mathrm{d}\mathbf{x}^i - f_0$; $f_{ij}(x_i,x_j) = \int_{K^{n-2}} f(\mathbf{x})\mathrm{d}\mathbf{x}^{ij} - f_i(x_i) - f_j(x_j) - f_0$; $\ldots$

and $\mathbf{x} = [x_1, x_2, \ldots, x_n]$ is the input of parameters whose values change; $\mathrm{d}\mathbf{x}^i$ represents the product $\mathrm{d}x_1\mathrm{d}x_2\ldots\mathrm{d}x_n$ without $\mathrm{d}x_i$; $\mathrm{d}\mathbf{x}^{ij}$ is the same product without $\mathrm{d}x_i$ and $\mathrm{d}x_j$.

This decomposition, also called analysis of variance (ANOVA), creates unique, orthogonal terms; first order and higher order effects to the model output are revealed via variance-based methods. The total variance D can be obtained by (Ziehn and Tomlin, 2008):

$$D = \int_{K^n} f^2(\mathbf{x})\mathrm{d}\mathbf{x} - f_0^2$$

and the partial variances $D_{\mathrm{i}_1,\ldots,\mathrm{i}_1}$ are calculated by:
$D_i = \int_0^1 f_i^2(x_i)\mathrm{d}x_i$; $D_{ij} = \int_0^1\int_0^1 f_{i,j}^2(x_i,x_j)\mathrm{d}x_i\mathrm{d}x_j$; $\ldots$
The sensitivity indices are given by: $S_{i_1,\ldots,i_s} = \frac{D_{i_1,\ldots,i_s}}{D}$, $1 \leq \mathrm{i}_1 < \ldots < \mathrm{i}_s \leq \mathrm{n}$, so that all terms add up to 1: $\sum_{i=1}^{n} S_i + \sum_{1\leq i<j\leq \mathrm{n}} S_{i,j} + \ldots + S_{1,2,\ldots,n} = 1$

The main effect of the input variable x_i on the output is showed by each first order sensitivity index S_i, the effect of x_i and x_j on the output is estimated by the second order sensitivity indices and so forth for parameter ranking.

4. Parameters of the Studied Hypothetical Cases

An algorithm developed by Savvopoulos et al. (2014) indirectly calculates cell death and migration rates using experimentally measureable data; these values change between disease phases and thereby influence trajectories from one stage to the next. The 19 parameters are given in Table 1.

We applied the RS-HDMR to the outputs N_{BM}, N_{LN}, N_{PB}, P_{BM}, P_{LN} and P_{BM} by varying the 19 input parameter values $\pm 50\%$. Figures 2 and 3 show the results for the non-proliferative (N_{BM}, N_{LN}, N_{PB}) and proliferative (P_{BM}, P_{LN}, P_{BM}) cell populations.

5. Results and Discussion

Using the cell cycle model mentioned above, RS-HDMR shows that parameters $\theta_{\mathrm{BM},1}$, $\theta_{\mathrm{BM},2}$ and $\theta_{\mathrm{LN},2}$, representing the transition from the non-proliferative to proliferative phase, are the most important parameters affecting the number of non-proliferative cells in BM and LN. Secondarily important to the number of non-proliferative cells is the apoptotic rate δ_{LN} in LN. Our final observation for the non-proliferative cells is that their population in PB is mainly affected by $k_{\mathrm{N,BM2PB}}$ and $k_{\mathrm{N,PB2LN}}$.

For the proliferative B-CLL population, the most important parameter for all outputs is τ_{BM}, followed by migration parameters $k_{\mathrm{P,BM2PB}}$ and $k_{\mathrm{P,PB2LN}}$, and feedback function parameter $\theta_{\mathrm{BM},2}$. Proliferative populations in BM are also highly affected by the apoptotic rates of proliferative cells γ_{BM} and γ_{LN}; any proliferation in PB is primarily affected by recent cellular migration $k_{\mathrm{P,PB2LN}}$.

Table 1: Cell cycle parameters of the five studies in each case

Patient No	**1**		**2**		**3**		**4**		**5**

6. Conclusions

RS-HDMR analysis reveals the most important parameters of the Savvopoulos et al. (2014) B-CLL model and may be useful for applying personalised treatment based on inter- and intra- patient leukemia heterogeneity. Personalised treatment for improved efficacy and reduced toxicity of chemotherapy is feasible because B-CLL is slow progressive, giving time to apply what is learned from the model. These important parameters are not simple to calculate *ex vivo* because B-CLL cells undergo apoptosis spontaneously in *in vitro* cultures, but they could be derived from experiments simulating the microenvironment (Mortera-Blanco et al., 2012) or from *in vivo* labelling studies (Messmer et al., 2005).

Abstract

This paper investigates data based modelling of complex nonlinear processes, for which a first principle model useful for process monitoring and control is not available. These empirical models may be used as soft sensors in order to monitor a reaction's progress, so reducing expensive offline sampling and analysis. Three different data modelling techniques are used, namely Ordinary Kriging, Artificial Neural Networks and Support Vector Regression. A simple case is first used to illustrate the problem, assess and validate the modelling approach, and compare the modelling techniques. Next, the methodology is applied to a photo–Fenton pilot plant to model and predict the reaction progress. The results show promising accuracy even when few training points are available, which results in huge savings of time and cost of the experimental work.

Keywords: Kriging, support vector machines, neural networks, chemical kinetics.

1. Introduction

The photo-Fenton process is a photochemical advanced oxidation process widely investigated for its efficiency in degrading emerging contaminants, especially pharmaceuticals and personal care products, through the formation of highly reactive hydroxyl radicals (•OH). Different approaches have been used to model treatment systems based on the photo-Fenton process and, among them, some First Principle Models (FPMs) have been proposed to match the degradation of very simple organic molecules (Farias et al., 2009), but the complexity and nonlinear nature of these systems hinders the development of a comprehensive FPM including all the involved reaction mechanisms in more general cases. Moreover, most of the measures available from the online sensors of pilot or industrial plants are not easy to link with the variables included in such FPMs, which complicates their application for process monitoring and control. Empirical simple regression models based on experimental results have been also used (Pérez-Moya et al., 2008). Despite their importance, these regression models tend to excessively simplify the complex nonlinear behaviour of the process, they have limited capabilities to correlate larger sets of process variables (Shokry et al. 2014) and they are usually applied as linear or lower-order models, unable to capture sophisticated nonlinear relations. Conversely, multivariate data based modelling requires more sophisticated and advanced techniques that can capture highly nonlinear system behaviours (Nagy, 2007, Shokry et al., 2014); in this line, Artificial Neural Networks (ANN), Support Vector Regression (SVR), or Ordinary Kriging (OK) have been widely used in many areas to provide efficient alternatives to construct simple and accurate

data-based models (metamodels), saving time and cost of experimental work and reducing the complexity of fitting and using FPMs simulation.

This work addresses the data-based modelling of a photo-Fenton process, using data measured and recorded from a batch pilot plant (Pérez-Moya et al., 2008). The model is aimed to predict the reaction progress as a function of other online measured variables. The SCADA system of the plant provides thousands of cheap on-line measurements of these variables along each batch run. But, on the other hand, the reaction progress is measured by expensive off-line sampling and analysis of Total Organic Carbon (TOC) at a significantly coarser time grid/resolution, which results in very few measurements during the batch time. This large difference between the number of the available online and offline data makes the modelling task problematic and challenging, since for each batch only few input/output (online/offline) sets of measures are really available.

An additional challenge is caused by the different nature of the uncertainties and errors in the online and the offline data (i.e.: relatively small errors or white noise in the online data and relatively high experimental errors in the offline measurements). The rest of the paper investigates the mentioned techniques (OK, ANN, and SVR) for the modelling of such challenging case study, describing the modelling approach adopted, and their application to an illustrative example and to the photo-Fenton pilot case.

2. Modelling techniques (data based models)

2.1. Ordinary Kriging (OK)

Given a set of training data $[x_i,y_i]$, $i=1,2,..n, x \in R^k, y \in R$ (where k is the number of input variables), the OK assumes a stochastic process in which the error in the predicted value is a function of the input variables x. The predictor $\hat{y}(x)$ is composed by a polynomial term $f(x)=\mu$, and a deviation $Z(x)$ from that polynomial. So, $\hat{y}(x)=f(x)+Z(x)$, where $Z(x)$ is a stochastic Gaussian process with expected zero value, $E(Z(x))= 0$, and a covariance between x_i, x_j as $cov(Z(x_i),Z(x_j))=\sigma^2 R(x_i,x_j)$. Being σ^2 is the process variance, and $R(x_i,x_j)$ is a correlation function $R(x_i, x_j) = exp\left(-\sum_{l=1}^{k} \theta_l \left|x_{i,l}-x_{j,l}\right|^{p_l}\right) + \delta_{i,j}\,\lambda$, being δ_{ij} the Kronecker delta, and λ the regularization constant that enables the Kriging predictor to regress noisy data and not passing through them (over-fit) (Azman et al., 2007). To estimate the μ, σ^2, θ_l, p_l, λ values, the likelihood function of the observed data $[y]_{n*1}$ is maximized (this work uses the "*fmincon"* function of the Matlab library). The Kriging predictor (Eq.(1)) is obtained by driving the augmented likelihood function of the original training data set and a new interpolating point (x_{new},y_{new}). In Eq. (1), r is the $n\times1$ vector of correlations $R(x_{new}, x_i)$ between the point to be predicted x_{new} and the training data points. The variance of the predictor is given by Eq.(2).

$$\hat{y}(x_{new}) = \mu + r^T R^{-1}(Y - 1\mu) \quad (1)$$

$$\hat{s}^2(x_{new}) = \hat{\sigma}^2(1 + \lambda - r^T R^{-1} r + (1 - r^T R^{-1} r)^2/(1^T R^{-1} 1)) \quad (2)$$

2.2. Artificial Neural Networks (ANN)

A well-known efficient method, widely used for nonlinear system modelling, is the use of ANN. Feedforward ANN are frequently used in engineering applications for system modelling and identification (Z. K. Nagy, 2007). Although they exhibit very powerful capabilities, ANN have some specific limitations as the huge effort and time consumed in selecting the ANN configuration (T. Masters, 1993), and the cruse of dimensionality (Azman et al., 2007). In this work, the Matlab ANN toolbox and the function "*feedforwardnet*" have been used to create a feed forward ANN; the number of neurons and layers (one hidden layer of eight neurons), and the training algorithm ("*trainbr"* using the Levenberg-Marquardt optimization method - Bayesian regularization) were selected to balance simplicity and accuracy.

2.3. Support Vector Regressions (SVR)

Recently, SVR are used in many applications in the area of chemical process engineering, showing promising capabilities (P. Jain et al., 2007). Given a set of *n* input-output training data *[x_i,y_i], i=1,2,..n,* $x \in R^k, y \in R$, SVR map the input data's original space into a higher dimensional feature space usually through nonlinear Gaussian kernel function $\phi(x_i, x_j) = exp(-\|x_i, x_j\|^2/2\sigma^2)$. In the feature space the problem becomes the construction of an optimal linear surface $f(x) = \mu + w^T \Phi(x)$ that fits the data, where μ is a base or bias, and $w \in R^k$ are weights. So, the flattest function *f(x)* is sought by minimizing the vector norm w^2, subjected to a set of constraints: the error in the predicted value of each of the training data should be at most equal to ε. To allow for outliers, the data that have prediction error bigger than ε is penalized using the so called ε-sensitive loss function. The constrained optimization problem is then reformulated into a dual problem form by using Lagrange multipliers α_i, α^*_i for each constraint. The Lagrange multipliers are determined by solving the problem using Quadratic Programming (QP). Once α_i, α^*_i are determined, the optimal weights *w* and the base μ can be computed, and the final predictor is given in Eq(3).

$$f(x_{new}) = \mu + \Sigma_{i=1}^{n}(\alpha_i - \alpha_i^*)\phi(x_{new}, x_i) \quad (3)$$

3. Modelling approach

The main idea is to use OK, ANN and SVR to obtain a static correlation of TOC as a function of the on-line variables in the same time instant. Assuming no control (no perturbation along the batch run) these models will predict the expensive offline variable *y(t)* as a function of the cheap online variables *x(t)*, and the initial conditions.

$$y(t) = f[\ x(t), y(t=0), x(t=0)] \quad (4)$$

4. Simulation-based case study

A mathematical example of a series of reactions $A \xrightarrow{k1} B \xrightarrow{k2} C$ is used to mimic a case study, illustrate the approach and validate and compare the different techniques. For a batch operation with no perturbations, the process depends only on the initial values. Hence, during a 30-minute batch, the concentration of product *C* is calculated at 8 specific time instants, simulating expensive offline sampling and analysis. On the contrary, the concentrations of products *A*, *B* are calculated every second, simulating online measured variables (1s sampling time). To generate the training data, 24 batches are simulated in this way, using different initial values [$C_a(t=0)$, $C_b(t=0)$, $C_c(t=0)$] generated by a Hammersley sampling procedure within the limits [14:20, 0:2, 0:2]. Small white noise $N(\mu=0,\sigma=0.07)$ is added to the simulated online values (C_a, C_b), while a higher error $N(\mu=0,\sigma=0.7)$ is also added to the simulated offline data (C_c). Figure 1(a) shows the results obtained for one batch.

The online data of the 24 batches are smoothed by using a moving average approach, with a period of 50 seconds. Then, the 8 input-output (offline-online sets) training points are collected for each one of the 24 batches, and the three metamodels (Eq.(5)) are fitted into these 192 data values.

$$C_c(t) = f[c_a(t=0), c_b(t=0), c_c(t=0), c_a(t), c_b(t)] \quad (5)$$

An extra set of 100 batches with different initial concentrations (within the same range used to generate the training set) are then simulated and used as validation set to test the predictions of the offline variable C_c obtained by each one of the trained metamodels.

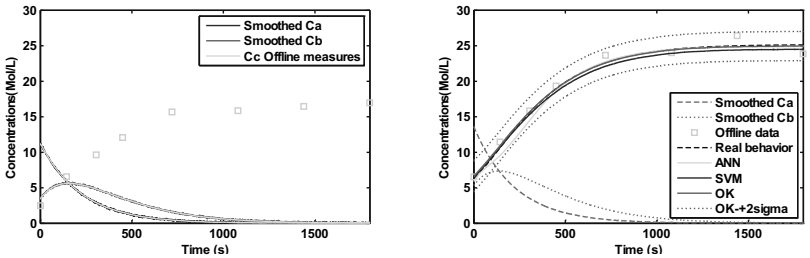

Figure 1: (a) Data of one of the 24 batches used as training set, (b) Prediction of one the 100 batches used as validation set.

Figure 1(b) shows the prediction of C_c produced by each metamodel for one of such validation batches. Table 1 shows the Average Root Mean Square Error (ARMSE), the Pearson coefficient, and the fitting and interpolation computational effort required for each one of the metamodels used. Figure 2 shows the ARMSE for each validation batch. The errors are given respect to the noisy training data and also respect to the not noisy FPM describing the system's underlying theoretical behaviour.

Table 1: ARMSE, Pearson coefficient, and fitting and interpolation times.

	ARMSE		*Pearson*		*CPU Time (s)**	
	W.R.T. Experiments	W.R.T. FP model	W.R.T. Experiments	W.R.T. FP model	Fitting	Interpolation
OK	0.367462	0.25554	0.99922	0.999986	036.0	0264.0
ANN	0.382541	0.29265	0.99916	0.999882	459.0	2019.0
SVM	0.407109	0.30128	0.99915	0.999976	000.9	0149.0

* HP-dc7900, Intel core 2-duo 3.16 GHz, RAM 6 GB.

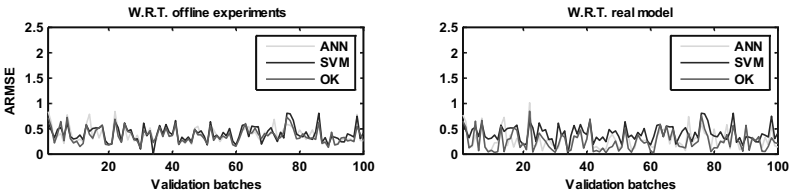

Figure 2: ARMSE for 100 validation batches.

Kriging not only provides slightly higher accuracy, but its tuning is robust and fast, since all the model parameters [θ_l, p_l, μ, σ, λ] are implicitly optimized, the modeller just makes a guess about the parameters initial values and the optimization/training procedure provides their optimal values. Conversely, significant effort and time is required to decide the ANN structure and the SVR parameters [σ, ε, C]. Additionally, OK outperforms the results obtained by the other compared methods, by providing the estimated variance (Eq.(2)) of the prediction (Figure 1(b) red dotted line) that can be used as quantitative confidence assessment when the system's real behaviour is unknown or it is hard to estimate the prediction accuracy.

These conclusions are confirmed by expanding the range of initial values to [*10:20, 0:7, 0:7*] and using 8 batches for training and 100 batches for validation.

5. Applications to the Photo-Fenton pilot plant

A real photo-Fenton batch pilot plant is used to produce experimental data. Along the batch time (90 min), the SCADA system registers two variables, Temperature (T) and

Redox potential (R), which are expected to determine the process performance. Both variables are on-line measured and recorded every second at a minimum cost (5400 measurements per batch). Instead, the reaction progress is measured by expensive off-line sampling and analysis of TOC every 15 minutes, which results in only seven input/output (online/offline) set of measurements available for each batch run.

Table 2: Set of twelve experiments used for training and validation.

BATCH	*[TOC]t=0 (mg/L)*	*[H_2O_2]t=0 (mg/L)*	*TRAINING*	*VALIDATION*
1	21	99		●
2	21	99	●	
3	21	198		●
4	42	99		●
5	42	198	●	
6	42	198	●	
7	42	395	●	
8	42	395	●	
9	84	395		●
10	84	395		●
11	84	791	●	
12	84	791	●	

Data for twelve batches (Table 2) with different initial concentration of TOC and H_2O_2 (the oxidizing agent) have been selected to train and validate the three selected metamodels. It should be noticed that the use of Redox potential as online variable, implicitly allows to take into consideration one of the most significant factors in photo-Fenton process, such as the Fenton reagent ratio with respect to the amount of contaminant ($TOC/H_2O_2/Fe^{2+}$). Figure 3 shows data of two of these batches.

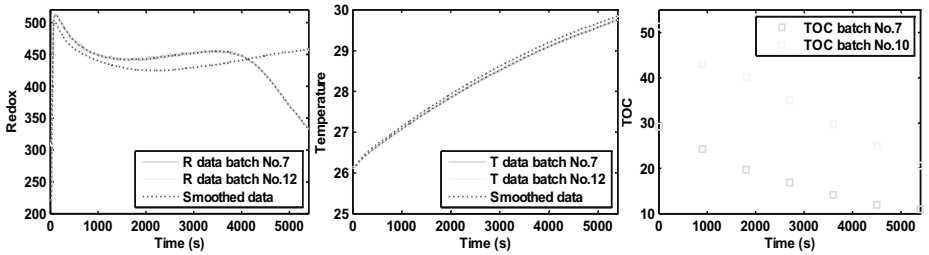

Figure 3: Online and offline data of two Fenton batches.

Table 3: ARMSE for the validation batches.

	ARMSE of each validation batch					*Total*
Batch No.	1	3	4	9	10	*ARMSE*
OK	1.093	1.146	0.738	3.662	1.753	1.6790
ANN	1.404	1.048	1.653	3.718	2.340	2.0324
SVR	1.126	1.040	0.986	3.821	1.616	1.7185

To reduce the sensor noise, the online data (T, R) are smoothed using a moving average with a 60 s period. Then, 7 input-output training points are collected from each batch of the training group, and the metamodels Eq.(6) are fitted to the 49 training points.

Figure 4 and Table 3 show how the three methods accurately predict the TOC for different batches of the validation set, as well as the confidence interval given by OK.

$$TOC(t) = f[TOC(t=0), T(t=0), R(t=0), T(t), R(t)] \quad (6)$$

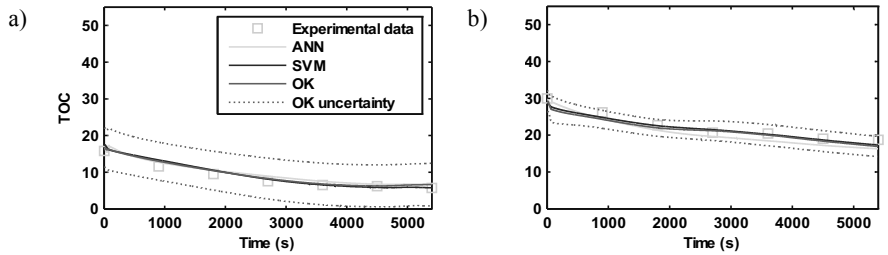

Figure 4: TOC prediction: a) batch 3, b) batch 4.

6. Conclusions

The results show how data based models can be used as soft sensors to monitor complex processes, difficult to follow through FPMs, without expensive offline sampling, saving huge costs and time. In addition, a simple static modelling approach has shown to be capable of accurately estimating a dynamic behaviour. Based on the proposed approach, three types of metamodels have been built to infer the progress of a chemical process from cheap on-line data. The results produced reveal that all methods exhibit high prediction accuracy with a significant low number of training data. Especially, OK shows a slightly higher accuracy and more importantly, higher flexibility and robustness in terms of easiness and rapidness of tuning the model parameters, while providing the modeller with a quantitative confidence interval of the prediction. An immediate extension of the presented approach would allow to use these methods for Advanced Control, by building autoregressive models to predict several steps ahead.

Abstract

In this work, the number density function in the population balance equation (PBE) is approximated in terms of field nodes through a complete set of orthogonal basis functions in a semi-logarithmic space. We proposed the functional values at these field nodes to satisfy the maximum entropy solution. This hybridization of function approximation and information theories based on Shannon Maximum Entropy principle, allowed us to construct a sequence of positive continuous approximations of the PBE. The Lagrange multipliers, which result from the maximization of the Shannon entropy subject to the available average information, was estimated by solving a well-conditioned linear system of algebraic equations. As an application, this meshfree solution of the PBE is validated using an analytical solution of the microbial cell dynamics in a constant abiotic environment with simultaneous cell growth and division for which the analytical solution was derived by using the Adomian method.

Keywords: Population balances, Maximum Entropy Method, Meshfree method.

1. Introduction

Many applications in physical and engineering sciences are discrete either at the micro or macroscopic levels. The transport equation governing the evolution of such systems is a Boltzmann-like equation which is called the population balance equation (PBE) (Ramkrishna, 2000). Being an equation that describes the transport of a number density concentration function, it can be theoretically viewed as an infinite system of integro-partial differential equations which are strongly coupled through nonlinear integral source terms. Therefore, general solutions of this equation in complex flow fields is impossible due to its geometrical and functional dependencies on particle property states. This justifies the growth of interest in the numerical solution during the last decade. Attarakih (2013) and Attarakih and Bart (2014a) presented a condensed review on the available numerical solutions for the PBE including the classical finite difference schemes (CFDS), the Quadrature Method of Moments (QMOM) and the Differential Maximum Entropy Method (DMaxEntM), to name but a few. The CFDS has the advantage of tracking the full number density concentration using finite number of grid points along the particle property space with difficulties to estimate population mean properties (e.g. mean particle diameter, interfacial area concentration etc.) unless high number of grid point is used. The other extreme, is full concentration on the population moments and total relaxation on the particle size distribution using the QMOM. To have a compromise between accurate population mean properties and particle size recovery, Attarakih (2013) introduced the Cumulative QMOM. In this method, the full particle distribution is recovered using a continuous version of the QMOM. Parallel

to this work, Attarakih and Bart (2014a) introduced a novel idea for continuous approximations of the particle number density concentration using the DMaxEntM. The approximate solutions are recovered by solving a few number of transport equations, which are consistent with the first N+1 moments of the particle size distribution. Compared to the QMOM which has difficulties in dealing with bivariate PBEs (Favero et al., 2014), the DMaxEntM can be extended without running in trouble by the wrong choice of the targeted moments. In an advanced step, Attarakih and Bart (2014b) extended the DMaxEntM to a meshfree MaxEntM for particle growth in one and two dimensions by maximizing the Shannon entropy functional using pointwise sampling as filed nodes for the continuous number density concentration. In this way, the optimal Lagrange multipliers appearing in the continuous solution were estimated using these field nodes instead of solving a convex nonlinear program or transporting the Lagrange multipliers. Instead of this, the logarithm of the MaxEnt functional is expanded using a complete set of orthogonal basis functions with and imposed regularity conditions.

In this work, we extend this meshfree MaxEntM to solve the PBE in the presence of particle growth, breakage and aggregation using complete set of orthogonal functions. As a case study, the method is applied to solve the microbial cell population balance dynamics which includes cell growth and division in a constant abiotic environment. Additional assumptions are placed on the growth and division rates and daughter cell distribution function to get a dynamic analytical solution. The Adomian method is used to obtain this analytical solution (Hasseine et al., 2011) which is compared to the meshfree MaxEnt method.

2. Meshfree Maximum Entropy Solution of the PBE

The PBE in one dimensional particle property space with particle growth, breakage and aggregation is written as:

$$\frac{\partial f(x,\mathbf{r},t)}{\partial t}+\nabla\cdot\left(\langle\mathbf{v}\rangle f(x,\mathbf{r},t)\right)+\frac{\partial[G(x,S)f(x,\mathbf{r},t)]}{\partial x}=R\{f\}\quad(1)$$

$$\begin{aligned}R\{f\}&=-\Gamma f(x,\mathbf{r},t)+\int_x^\infty \upsilon(x')\Gamma(x',S)\beta(x,x')f(x',\mathbf{r},t)dx'\\&-f(x,\mathbf{r},t)\int_0^\infty \omega(x,y)f(y,\mathbf{r},t)dy+\frac{1}{2}\int_0^x \omega(x,y)f(y,\mathbf{r},t)f(x-y,\mathbf{r},t)dy\end{aligned}\quad(2)$$

In Eqs.(1) and (2) $f(x,\mathbf{r},t)$ is the number density concentration as function of particle size (x), physical space vector ($\mathbf{r}$) and time t and $\langle\mathbf{v}\rangle$ is the mean particle velocity vector in physical space which is function of particle size and other continuous environment variables. The particles are supposed to undergo relatively slow growth at a rate of $G(x,S)$, and relative instantaneous breakage at a frequency of $\Gamma(x,S)$ with daughter particle distribution $\beta(x,x')$ and mean particle number $\upsilon(x')$, while $\omega(x,y,S)$ is the aggregation frequency among particles of sizes x and y. The dependency of these functions on the continuous phase environment is taken into account through the variable S.

To solve Eq.(1) with general dependency of $\{G, \Gamma,\omega\}$ on particle size, one can use the Quadrature Method of Moments due its compactness and accuracy to avoid classical discretization methods which ends up with dozens of transport equations (Mantzaris et al., 2000). Like any other moment methods, the QMOM loses the particle density concentration (f) because of averaging of(f) over the particle property space. Unfortunately, the reconstruction of (f) in simple or complex physical space domains is

by no means trivial (Gzyl & Tagliani, 2010). This is well-known in theoretical physics literature as a classical moment problem and in particular as Hausdorff moment problem. In this regard, the attempt is to reconstruct the non-negative number density concentration from a finite set of low-order moments (m_r, r = 0, 1, …N). Difficulties face this problem are twofold: Ill-conditioning and uniqueness of the recovered number density function (Lawrence & Papanicolaou,1984). To overcome the first problem, the maximum entropy method was used to reconstruct a continuous number concentration function constrained by the available mean integral properties of the distribution. The uniqueness issue is solved by maximizing the Shannon entropy functional, which results in a distribution that is statistically most likely to occur (Baker-Jarvisa, 1989). The solution of this constrained NLP results in the following optimal functional:

$$f_N(x,\mathbf{r},t) = g(x)\exp\left(\sum_{j=0}^{N}\lambda_j(t)\pi_j(x,\mathbf{r})\right) \quad (3)$$

In Eq.(3), λ_r are the Lagrange multipliers which can be generally estimated by solving a convex potential function (Mead and Papanicolaou,1984), $\pi_j(x)$ are set of orthogonal basis functions and $g(x)$ results from the particle property space coordinate transformation. This coordinate transformation is necessary such that $f_N(0) = 0$ to satisfy the left regulatory condition. To estimate the Lagrange multipliers in Eq.(3), we applied the orthogonal collocation method in a weak-form sense to transform Eq.(1) into into a set of PDE that are exactly satisfied at the particle property field nodes x_i , i = 0, 1, ..$N \in [a,b]$ where f($\mathbf{x}$,t) is supported on [a,b]. The solution of these PDEs will produce a set of field variables f_i , i = 0, 1, ..N which reflect local information about $f(x)$ in space and time. This local information is then used to estimate the Lagrangian multipliers by solving the system of linear equations $P_N(\mathbf{x}) = \prod\boldsymbol{\lambda}$. The elements of the square matrix $\prod$ are $ln(g(x_i)) + \pi_j(x_i) = j$, i =0,1,.. N and $P_N(\mathbf{x}) = ln(f(\mathbf{x}))$. This matrix is invertible and well-conditioned since its columns are a complete set of orthogonal functions. The approximate density function $f_N(x)$ is then used to close the integrals in Eq.(2) with the desired accuracy since $f_N(x)$ does not depend on the nodal points x_i. On the other hand, the derivative of $f(x)$ in the convective term of Eq.(1), with respect to x, is found exactly by differentiating Eq.(3):

$$\frac{\partial f_N(x,\mathbf{r},t)}{\partial x} = f_N(x,\mathbf{r},t)\left[g(x)^{-1}\frac{dg(x)}{dx} + c(\mathbf{x})^T\Pi^{-1}\mathbf{P}(\mathbf{x},\mathbf{r},t)\right] \quad (4)$$

Where $c(\mathbf{x})$ is a vector of ($\pi_j(x)$, j= 0,1, .. N) derivatives with respect to x. This alleviates the discretization problem of the particle convection term using CFDS which require huge number of grid points. Note that the solution of Eq.(1) using Eq.(3) is a true meshfree solution because of the continuity of $f_N(x,\mathbf{r},t)$. The consistency of this solution with respect to the continuous PBE is guaranteed since the maximum entropy solution satisfies the given integral constraints imposed on $f(x,\mathbf{r}, t)$. The only assumptions required to derive Eq.(4) are that $f(x,\mathbf{r},t)$ and $G(x)$ should be smooth enough to allow at least the existence of their first order derivatives. Two advantages are achieved by using the meshfree MaxEntM: Firstly, the need for solving a NLP to estimate Lagrange multipliers is replaced by a solution of linear system of equations. Secondly, the field nodes used in the reconstruction of f(x,$\mathbf{r}$,t) provides rich information about the number density concentration (Attarakih and Bart, 2014b). In this work, we used the coordinate transformation function $g(x) = x^{\alpha}$, where α is estimated along with the Lagrange multipliers as described above.

3. Numerical results and discussion

3.1. Numerical Analysis

In this section, the proposed meshfree MaxEntM is tested against a known solution of the population balance equation. This is used to analyze the numerical features of the method in terms of the effect of the left regulatory condition and the numerical accuracy when solving for Lagrange multipliers ($P_N(\mathbf{x}) = \prod \boldsymbol{\lambda},$).

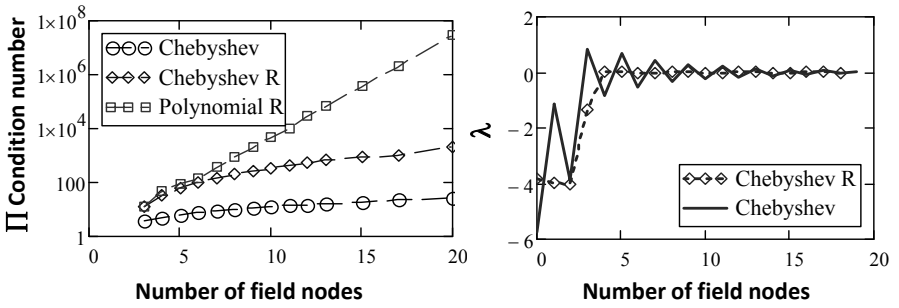

Figure (1): (Left): Effect of bases functions on ∏ matrix condition number. (Right): Variation of Lagrange multipliers (λ) as function of filed nodes with and without left regulatory condition.

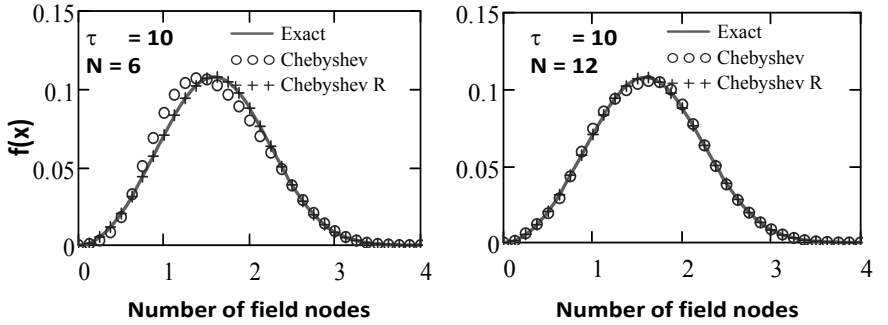

Figure (2): Constant frequency particle aggregation (Ramkrishna, 2000) in closed system reconstructed using the Meshfree MaxEntM using Chebyshev polynomials as basis functions.

Figure (1-upper panel) shows the effect of number of field nodes (transformed Chebyshev polynomial roots such that $x_i \in (a, b)$) on the condition number of the ∏ matrix using $\pi_j(x) = x^j$ (simple polynomials) and $\pi(x)$ as Chebyshev basis functions. The symbol (R) in the legend indicates that the left regulatory condition is included in Eq.(3) with $g(x) = x^{\alpha}$. The left side of the upper panel of this figure shows the remarkable reduction in the ∏ matrix condition number which is ~ 100 for Chebyshev basis functions, while it is ~ 10^8 for simple polynomial basis functions when $N = 20$. This result is not surprising since the ∏ matrix is reduced to the well-known ill-conditioned Vandermonde matrix when using the simple polynomial basis functions. On the other hand, the regulated maximum entropy solution with Chebyshev basis functions is increased to ~ 10^4 due to the introduction of the simple polynomial $g(x) = x^{\alpha}$. However, the condition number of the ∏ matrix remains bounded when using the Chebyshev polynomials and increases without bound using simple power polynomials. In the left

hand side of the upper panel of Figure (2), the estimated Lagrange multipliers are shown as function of field nodes when N = 20. It is clear that the gain of using regulated Chebyshev polynomials is remarkable by the fast non-oscillatory convergence Lagrange multipliers for these polynomials when compared to the non-regulated ones. This accuracy is reflected directly on the predicted number density function as can be seen in the lower panel of Figure (2). This is in particular at low number of filed nodes, where the prediction error decreases when N is increased from 6 to 12. This is attributed to the extra degree of freedom we imposed on the maximum entropy functional through the dynamic fitting parameter α in $g(x) = x^{\alpha}$.

3.2. Analytical validation using the Adomian method

In this section, we present a practical case study of microbial cell dynamics in abiotic environment with a constant quantity of substrate (S). This case study is modified from the work of Mantzaris et al. (2000) to allow for analytical solution of simultaneous cell growth and division.

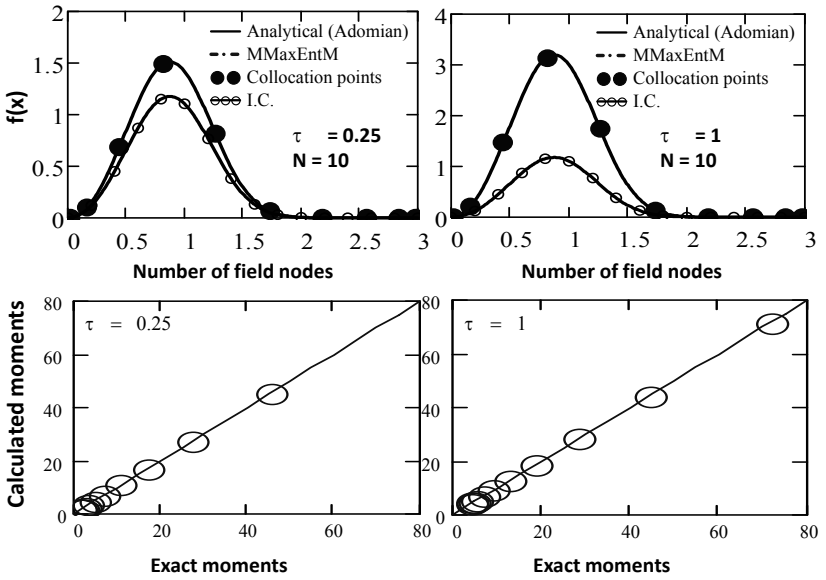

Figure (3): Prediction of microbial cell dynamics in constant abiotic environment with binary division and growth using the Meshfree MaxEntM as compared to the Adomian analytical solution. Upper panel: Evolution of f(x,τ). Lower panel: Evolution of first 10 moments.

The assumptions used here are as follows: An isothermal batch chemostat, constant abiotic environment, the single cell growth rate is proportional to its mass, and the dividing cells partition their material uniformly to the two daughter cells. These conditions can be mathematically translated into: $G(x) = (1/3)G_0x$, $\Gamma(x) = G(x)x^2$, $\beta(x,x') = 3(x^2/x'^3)$, $f(x,0) = 3x^5\exp(-x^3)$, $\tau = G_0t$ and $x = d/d_0$. The intercellular state is represented here by the cell biomass which reflects its size (x). The cell property mass is transformed into cell diameter (d) with an assumed spherical shape. These assumptions allows us to apply the Adomian decomposition method as follows (Hasseine et al., 2011):

$$f_{n+1} = \int_0^t \left(-\partial G f_n(m,t)/\partial x + \int_v^\infty \beta(m,m')\Gamma(m') f_n(m',t)\,dm' - \Gamma(m) f_n(m,t) \right) dt \qquad (5)$$

Where the index n runs from zero to infinity. The Adomian decomposition method finds the analytical solution recursively starting from the given initial condition ($f_0(m) = m\exp(-m)$). Using symbolic integration, the final solution to this case study is found to be $f(x,t) = 3x^2[x^3\exp(-x^3) + 2\exp(-x^3)[\exp(G_0 t)-1]]$. This analytical solution is compared to the meshfree MaxEntM as shown in Figure (3-upper panel) at two different dimensionless times ($\tau = 0.25$ and 1). This figure shows the dynamic evolution of the microbial cell population which undergoes simultaneous growth and division. As can be seen, the meshfree MaxEnt method captures with a high accuracy the evolution of the population dynamics using only 10 field nodes. Note that due to simultaneous cell growth and division the cell density evolution to the small size range is slower when the cell division is dominant. The lower panel of Figure (3) shows a parity plot of the evolution of the first 10 low-order moments of $f(x,\tau)$. The accuracy with which these moments were estimated could not be offered by any other explicit methods for solving the PBE thanks to the maximum entropy solution.

4. Summary and conclusions

The Shannon Maximum Entropy method and the approximation theory of functions are combined to provide a novel and effective solution method for the population balance equation. This results in a meshfree method which is consistent with particle population mean properties with an accuracy that can be controlled through the number of filed nodes. The proposed approach for estimating the coefficient of expansion (in a semi-logarithmic space) of the orthogonal functions is proved to be numerically efficient by solving a well-conditioned linear system of algebraic equations.

Abstract

In this contribution, we used a reduced population balance model to describe the hydrodynamics of bubble columns, which play a major role in in determining the bubble size distribution and hence the interfacial area concentration. This model consists of a set of transport equations to track the total number and total interfacial area concentrations and the gas phase volume fraction of bubbles. The model is essentially derived using the One Primary and One Secondary Particle Method (OPOSPM) and its higher extension using an Implicit Two-Equal Weight Quadrature (TwoEqWQ). This is coupled with the Shannon Maximum Entropy Method to predict the bubble size distribution along the bubble column axial direction. The model predictions show good agreement with the published experimental data in the bubbly flow regime.

Keywords: Bubble column, Population balances, Maximum Entropy Method.

1. Introduction

Bubble columns are multiphase equipment which is widely used in the chemical, petrochemical and biochemical industries (Kantarci et al., 2005). Estimation of the specific interfacial area is necessary in bubbly flows (e.g. the two-fluid model) to provide a closure for the momentum, mass and energy transport equations which are solved for each phase. The design and operation of these two-phase equipment are dependent on the adequate modelling of these transport phenomena (Jakobsen, 2008).

In such equipment, the gas phase is dispersed in a continuous environment with a population of bubbles that may undergo breakage, coalescence, expansion and growth. Modelling such a process using the mixture models, which could not take into account these instantaneous discrete events, is not sufficiently accurate to predict the hydrodynamics and mass transport. On the other hand, using the multi-fluid models which could include bubble-bubble interactions were proved to be computationally expensive when detailed column geometry is concerned. For example, typical number of groups is ~ 15-20 as used by the MUSIG model (Jakobsen, 2008). As a result, the need for a transport equation to describe the transport of the interfacial area concentration has been reflected by the interest of many researchers during the last two decades (Ishii and Hibiki, 2010). Among these is the work of Hibiki and Ishii (2000) which is of great importance. They used the population balance equation (PBE) to derive an Interfacial Area Transport Equation (IATE) for bubbly flow in vertical tubes using section averaging. As the PBE is concerned, many issues arise with respect to the

accuracy and consistency of the reduced interfacial transport equation (Drum et al., 2010). These authors developed a two-equation model that is consistent w.r.t the continuous PBE and hence its accuracy can easily be extended. This is unlike the IATE of Ishii and Hibiki (2000) that could not be further improved in terms of accuracy and consistency w.r.t. the continuous PBE.

In this work, we used a reduced population balance model to describe bubble transport, expansion, breakage and coalescence . The reduced population balance model consists of a set of transport equations to track the total number and volume concentrations, which are coupled through mean mass diameter (d_{30}), while the interfacial area concentration is calculated from the number and volume concentrations of bubbles. This model is essentially derived using the One Primary and One Secondary Particle Method (OPOSPM), which is coupled with the Shannon Maximum Entropy Method (MaxEntM) to predict the bubble size distribution along the bubble column axial direction. To increase the quadrature order for approximating source terms in the continuous PBE, an implicit TwoEqWQ is proposed, which require an additional transport equation for interfacial area concentration.

2. Bubble hydrodynamics

The present model for the bubble column hydrodynamics is derived from the population balance equation which is a special type of the Boltzmann transport equation. This equation evolves the number concentration function in space, time and the particle property space. The transported quantity, which is used to describe the population of bubbles, is the number concentration function $f(\boldsymbol{x},d,t)$. This is assumed to be continuous, satisfies regulatory conditions and describe the number density concentration of bubbles moving with velocity ($\langle v_g \rangle$) at a given time t, in a spatial space (x) and along particle size (d). The rth moment of this bubble number concentration function is written as:

$$\frac{\partial m_r}{\partial t} + \nabla \cdot \left(\langle v_g \rangle m_r \right) = \int_0^\infty \frac{\partial \psi}{\partial \zeta} \dot{\zeta} f(x,\zeta,t) d\zeta + S_r^b + S_r^c \quad (1)$$

In Eq.(1), $\langle v_g \rangle$ is the mean bubble velocity which is function of a pre-defined mean bubble diameter, $\psi = d^r$ (where r = 0, 1,2, …), $\zeta = v$ (where v is the bubble volume) and the dot over ζ denotes derivative with respect to time. The last two source terms on the right hand side S^b and S^c describes the the rth moment of particle appearance by breakage and disappearance by coalescence respectively(Attarakih and Bart, 2014).These sources terms contain unclosed integrals due to the general dependency of bubble breakage and coalescence kernels on bubble size (Hibiki and Ishii, 2000).

To close these source terms, Hibiki and Ishii (2000) and Ishii and Hibiki (2010) used two sets of bubble mean diameters: The mean volume (d_{30}) and the Sauter mean diameters (d_{32}) and derived what is called the Interfacial Area Transport Equation (IATE) followed by the simplifications of the source terms by assuming an equal-size binary bubble breakage and the bubble coalescence was allowed by only two bubbles of the same size. By following Coulaglou and Tavlarides (1977), they derived bubble breakage and coalescence kernels which were included in the source terms (S^b and S^c). Unfortunately, these kernels were merged with the numerical parameters which were used to close the integrals in the IATE. This approach has two major disadvantages: Firstly, it complicates the addition of new bubble kernels to the IACE, and secondly, it prevents increasing the numerical accuracy of the model by further increasing the order of quadrature approximation of the integrals in the source term (Drumm et al., 2010).

Due to the mixing between two types of mean droplet diameters: Sauter mean diameter (d_{32}) and volume mean diameter (d_{30}), conflicting source term for the IATE with that

derived from the PBE is observed as shown in Table (1). This is because d_{30} is a quadrature node based on OPOSPM (Drumm et al., 2010) while d_{32} is only a physical definition which is not related to a quadrature approximation of the source terms in the PBE. Therefore, using this mathematically consistent mean droplet diameter (d_{30}), the bubbly flow hydrodynamics is derived from Eq.(1) using the One Primary and One Secondary Particle Method (OPOSPM) as a reduced population balance model. OPOSPM for the bubble flow is obtained by using the zero, 2nd and 3rd moments (r =0, 2, 3) from Eq.(1) with proper transformations to obtain the total bubble number concentration $N = m_0$, interfacial area concentration $a = \pi m_2$ and volume fraction $\alpha = (\pi/6)m_3$:

$$\frac{\partial N}{\partial t} + \nabla \cdot \left(\langle v_g \rangle N \right) = \sum_{j=b,c} S_0^j \qquad (2)$$

$$\frac{\partial a}{\partial t} + \nabla \cdot \left(\langle v_g \rangle a \right) = \frac{2}{3} \left(\frac{a}{\alpha} \right) \left[\frac{\partial \alpha}{\partial t} + \nabla \cdot \left(\langle v_g \rangle \alpha \right) \right] + \left(\frac{\alpha}{a} \right)^2 \sum_{j=b,c} k_j S_0^j \qquad (3)$$

$$\frac{\partial (\alpha)}{\partial t} + \nabla . \left(\langle \mathrm{v_g} \rangle \alpha \right) = \frac{1}{3} \left[\frac{\partial \alpha}{\partial \mathrm{t}} + \nabla \cdot \left(\langle \mathrm{v_g} \rangle \alpha \right) \right] \qquad (4)$$

Where $S_0^b = \Gamma(d_{30})N$ and $S_0^c = -\frac{1}{2}\omega(d_{30}, d_{30})N^2$. The mean gas velocity for counter current flow is defined as $\langle v_g \rangle = j_f / (1-\alpha) + u_r$, where j_f is the superficial velocity of the liquid phase and u_r is the relative velocity of the bubbles which is given by (Ishii and Hibiki, 2010):

$$u_r = \sqrt{\frac{d_{30} g \Delta\rho}{3 C_D \rho_f}} \qquad (5)$$

In the above equation, C_D is the drag coefficient that is function of the mixture Reynolds number. Note that in Eqs.(3 and 4) the term in the square brackets represent bubble expansion due to pressure drop in the physical space.

It is worthwhile to mention that the interfacial area concentration could be predicted from $a = 6\alpha/d_{32}$ using the N and α transport equations. However, we proposed here Eq.(3) for consistent prediction of (a) since d_{32} could not be estimated from the N and αtransport equations (only d_{30} can be expressed in terms of N and α).

Table (1): Constants for the source term in the interfacial area concentration equation.

	OPOSPM	Ishii and Hibiki (2010)
k_b	$36\pi\left(2^{1/3}-1\right)$	$36\pi/3$
k_c	$36\pi\left(2^{2/3}-2\right)$	$36\pi/3$

According to the model numerical constants (k_b and k_c) in Table (1), the bubble breakage and coalescence kernels (Γ and ω respectively) of Hibiki and Ishii (2000) with their adjustable parameters need to be modified. This is to recover the internal consistency with respect to the continuous population balance equation, which allows the increase of the quadrature order approximation to achieve the desired accuracy in closing the integral source term.

3. The Maximum Entropy Method

The Quadrature Method of Moments (QMOM) is one of the most used solver for the PBE because of the low number of transport equations and its high accuracy. This is required to overcome the long CPU time when coupling discrete population balances with CFD codes (Drum et al.,, 2010). The QMOM solves the PBE, where a finite set of population moments is transported. Due to its inherit averaging principle, the QMOM cannot reproduce the particle size distribution, which is replaced by a few set of non-physical moving particles along the particle property space. However, in industrial particulate system applications, the particle size distribution has a significant impact on the physical, chemical and mechanical product properties (Attarakih and Bart, 2012). To preserve the advantages of the QMOM and concentrating on distribution reconstruction away from the discrete methods, the MaxEntM seems to be natural candidate for the problem at hand. The MaxEntM is used to estimate the least biased probability density function subject to the available moment information about the sought distribution. The consistency of the recovered solution is achieved by maximizing the Shannon entropy functional with the constraint that the available moments of the averaged distribution are reproduced from the reconstructed one.
Following Attarakih and Bart (2014), this constrained nonlinear program has a unique positive solution provided that the sequence of the targeted moments is completely monotone. This maximum entropy solution is function of Lagrange multipliers, which can be found by minimizing the a convex potential function or using the MaxEntM:

$$f(x,d,t) = d^{\delta} \exp\left(\sum_{j=0}^{N} \lambda_j d^j\right) \tag{6}$$

In Eq.(6) λ_j's (λ_j corresponds to m_j) are the Lagrange multipliers which guarantee the reproduction of the targeted moments and δ is a positive real number that is introduced here to satisfy the regulatory conditions ($f(0) = f(d\to\infty) = 0$). In this work, we selectively chose $\{m_0, m_2, m_3\}$ as a set of moments which are satisfied by the transport equations (Eq. (1)). In addition to this, an Implicit Two-Equal Weight Quadrature (TwoEqWQ) was derived which reproduces exactly the above targeted set of moments. This TwoEqWQ is used to close the integral source term in Eq.(1) which is given by the following set of weights and nodes $\left\{w_1 = w_2 = 0.5\mu_0, d_1 = \sqrt{z}, d_2 = \sqrt{2\hat{m}_2 - z}\right\}$ andz is a solution of $\left\{(2\hat{m}_2 - z) - (2\hat{m}_3 - z^{3/2})^{2/3} = 0\right\}$. The hat denotes normalization w.r.t. m_0. This equation has two roots, where the first onelies in the interval [0, $(\hat{m}_3)^{2/3}$].

4. Numerical results and discussion

4.1. Analytical validation

In this section, the proposed two-equal weight implicit quadrature to close the source term in Eq.(1) is validated analytically along with the MaxEntM to reconstruct the averaged distribution. The Lagrange multipliers (λ_j, j = 0, 2,3) were found by solving a convex potential function (Attarakih and Bart, 2014) using the Levenberg-Marquardt algorithm. The case study is particle aggregation with constant kernel and an exponential (w.r.t. particle volume) initial condition. The left panel of Figure (1) shows the evolution of the targeted moments $\{m_0, m_2, m_3\}$ as function of dimensionless time (τ). Due to the remarkable accuracy of of the QMOM, not only the targeted moments were produced with high accuracy, but also the interpolated moment (m_1).

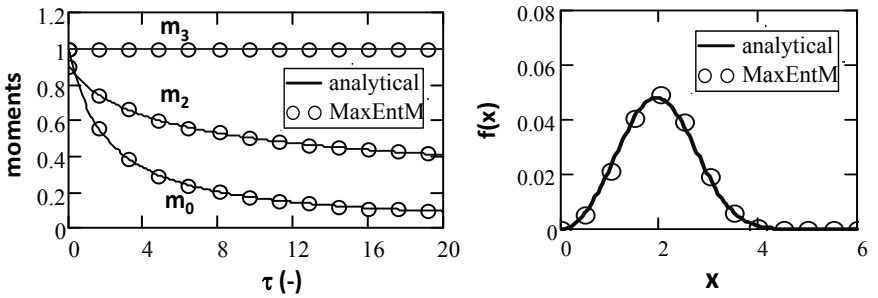

Figure (1): Validation of the MaxEntM with two implicit equal-weight quadrature for constant kernel aggregation in batch system against analytical solution (Gelbard and Seinfeld, 1978).

This moment was predicted using the implicit two-equal weight quadrature and the reconstructed MaxEnt solution (Eq.(6)) with Lagrange multipliers (λ_0 = -3.830, λ_1 = 0.090, λ_3 = -0.115) at τ = 20. The mean percentage relative error in the prediction of m_1 using the two-weight quadrature is 0.311 and that predicted from the MaxEntM is 0.519. The recovered distribution at τ = 20 is shown on the right panel of Figure (1) and compared to the analytical solution (Gelbard and Seinfeld, 1978). It is clear that the coupled implicit TwoEqWQ and the MaxEntM achieved two targets: Accurate tracking of distribution moments and accurate reproduction of the particle number concentration.

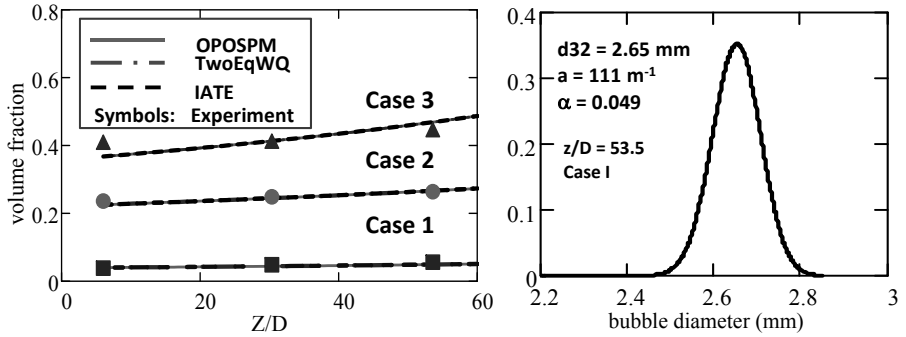

Figure (2): Experimental and numerical validation of OPOSPM, the implicit TwoEqWQ using air-water bubbly flows in a 50.8 mm diameter column (Hibiki and Ishii, 2000) . In Case 1: j_g = 0.0275 m/s , j_f =0.491 m/s, $d32^{in}$ = 2.49 mm, Case 2: j_g = 0.19 m/s, j_f = 0.491 m/s, $d32^{in}$= 3.31 mm, and Case 3: j_g = 3.90 m/s, j_f = 5.00m/s, $d32^{in}$ = 2.83.

4.2. Experimental validation

As shown in the previous section, the results show that the present model can be extended to higher-order approximations of the PBE using more secondary particles(quadrature nodes) with distribution reconstruction. This is an obvious advantage over the existing models such as that of Hibiki and Ishii (2000). As a first step of model validation, the pilot plant bubble column of Hibiki and Ishii (2000) was modeled and simulated after the necessary modifications of the adjustable parameters in the breakage and coalescence kernels to recover the mathematical consistency with the PBE. The column diameter is 50.8 mm with 3060 mm height which is operated adiabatically in the bubbly flow regime using air-water mixture in a cocurrent flow. The

investigated inlet superficial gas velocity ranges from 0.0275 to 3.90 m/s and that for the liquid phase is from 0.491 to 5.00 m/s with a void fraction in the range 0.0127-0.468. The axial measuring points (z/D) are at 6, 30.3 and 53.5 with detailed boundary conditions as described by Hibiki and Ishii (2000).

Figure (2-left) shows the variation of the gas void fraction along column height and the recovered bubble size distribution (right) as compared to the experimental data Hibiki and Ishii (2000) using three different models (OPOSPM, Implicit TwoEqWQ and IATE). The results are almost identical after adjusting the IATE model parameters to reflect the changes imposed by the new consistent formulation (see Table 1). As discussed by Hibiki and Ishii (2000),the simulated bubbly flow is dominated by bubble expansion for Case 1 due to the axial pressure drop along the column height. This is reflected by the increase in the mean size of the bubbles when compared to the mean inlet size (2.49 mm) as shown in Figure(2-right).For this case, the Lagrange multipliers used in Eq.(6) are found to be ((λ_0 = -369.825, λ_1 = 156.147, λ_3 = -39.335)).

5. Summary and conclusions

In this work, we derived the transport equations of bubble column hydrodynamics using OPOSPM and an implicit TwoEqWQ as reduced population balance models. The equations from the latter method were found consistent with the bubble number, interfacial area and volume concentrations and the Sauter mean bubble diameter. The coupling of these reduced bubble hydrodynamic models with the constrained MaxEntM allowed the reconstruction of a unique bubble number concentration by minimizing a convex potential function. A very good agreement between the predictions of the present model and those of the IATE and the Experimental data was obtained.

Abstract

A detailed flowsheet of natural gas fired Combined Cycle Power Plant (CCPP) is introduced and modelled by ASPEN PLUS software in this paper. The results obtained by this model were compared with the operation data of a plant in Europe whose capacity is 420 MW of electricity. The model consists of Gas Turbine (GT) and Heat Recovery Steam Generation (HRSG) sections. The simulation results are in good agreement with the operating data.

Keywords: Cogeneration; Electricity and steam; Natural gas; APEN PLUS

1. Introduction

It is believed that combustion of natural gas is the most efficient means for generating electricity from fossil fuels (Zheng and Furimsky, 2003). However, only one paper thus far is found to simulate the gas-fired power plant, and just general and some key data rather than detailed information was reported (Zheng and Furimsky, 2003). Obviously, such information is far from enough to lay a basis to carry out an effective integration of Post-Combustion Capture (PCC) to a gas-fired power plant. Under such situation, a typical 420MW gas-fired CCPP in Europe is modelled in detail. The plant is divided into three sections: (1) Feed gas preparation and gas turbine, (2) HRSG and steam turbine, (3) water recycle system. The model of first two sections was developed using Aspen Plus software of version 8.0 (Aspen Technology, 2011) while only mass balance is calculated by hand for the third section. Comparing with the operating data of the commercial plant, the simulation results are in good agreement with the operating data.
The novelties of this paper are: (1) the most complete process model of a gas-fired CCPP thus far is built and validated by operating data. The boundary of the model covers the whole range of the CCPP; (2) much more detailed and rigorous models of gas turbine and HRSG than ever before are built although some key parameters cannot be disclosed to protect the power plant.

2. Brief process description

A schematic flowsheet of the combined cycle power plant is shown in Figure 1. In this process, electricity is produced by means of the Alston gas turbine and steam turbine. The gas turbine shaft and the steam turbine shaft are coupled together to drive the generator, which produces the 420 MW output. Nature gas and excess air are feed to the gas turbine, and burned in two combustion chambers in serial under a firing temperature of 1100 ℃ and 1280 ℃ separately. The hot exit gas (mainly N_2, O_2, CO_2 and H_2O)

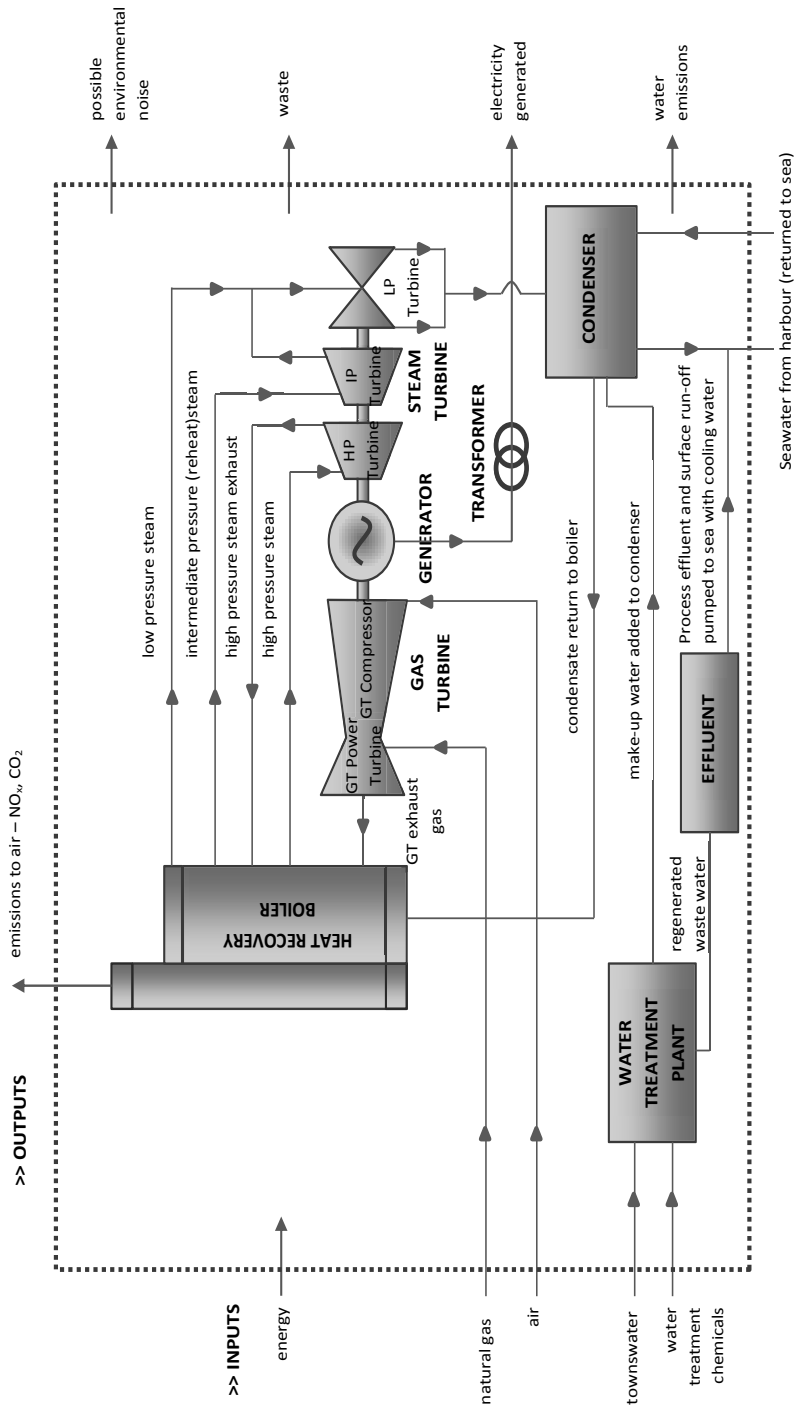

Figure 1: The CCGT power plant flowsheet

are sent to HRSG unit, from which three steam streams of HP(High Pressure, 110 bar (absolute pressure, the same rule will be followed in the rest part)), IP(Intermediate Pressure, 26 bar) and LP (Low Pressure, 4.2 bar) are generated. The steam turbine consists of a high pressure, intermediate pressure and a low pressure turbine. The HP steam produced in HRSG unit is fed to the high pressure turbine, producing an outlet stream of 27 bar. The IP stream from the HRSG is mixed with the outlet stream of HP steam turbine and reheated by HRSG and then fed to the IP steam turbine, producing an outlet stream of 5 bar. Similarly, the LP steam produced in the HRSG is mixed with the outlet stream of the IP steam turbine first, and then fed to the LP steam turbine. The exhaust steam of the LP steam turbine is condensed in the condenser by sea water and the condensate is returned to HRSG for recycle reuse. The lost water is made up by town water after pretreatment.

3. Aspen model of the CCPP

The simulation flowsheet of the power plant is divided into two sections as shown in Figure 2, the gas turbine section(Gasturb) and the heat recovery and steam generation section(HRSG). All important parameters are provided in the flowsheet. Note that the predicted output electricity power is 413 MW which is lower than 420 MW by 1.7% . The detailed description of the model is given below.

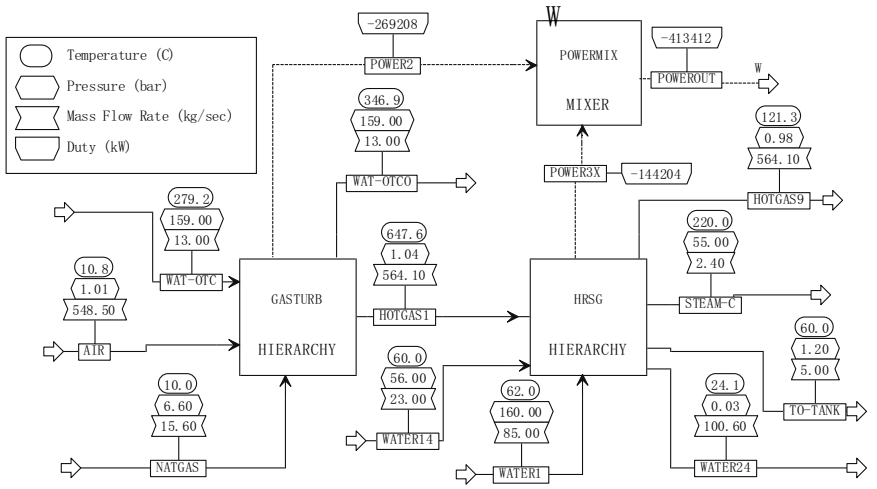

Figure 2: Simulation floweet of the power plant

3.1. Feed preparation and Gas turbine

3.1.1. Natural gas pressurization

As shown in Figure 3, the natural gas with 10 ℃ and 6.6 bar is fed to a two stage compressor and an intercooler is installed immediately after each stage to cool down the output streams to 25℃ and 50 ℃ respectively. The cooling media of these two coolers is seawater. The output pressures of the two-stage compressor are 20 bar and 48 bar separately. The output stream of the later intercooler is then equally split into two branches: One branch goes to the preheater and its temperature is raised to 150 ℃ and the hot stream of the preheater is a branch of hot water of 2.4 kg/s leaving the IP economizer in HRSG. Then, it goes to the first set of burners (EV) and an excess of air of 436.8 kg/s is sent to EV at the same time. The other branch goes to the second

combustion chamber (SEV) and burned with the output stream of EV and a new air stream of 111.7 kg/s. A High Pressure Gas Turbine (HPGT) and a Low Pressure Gas

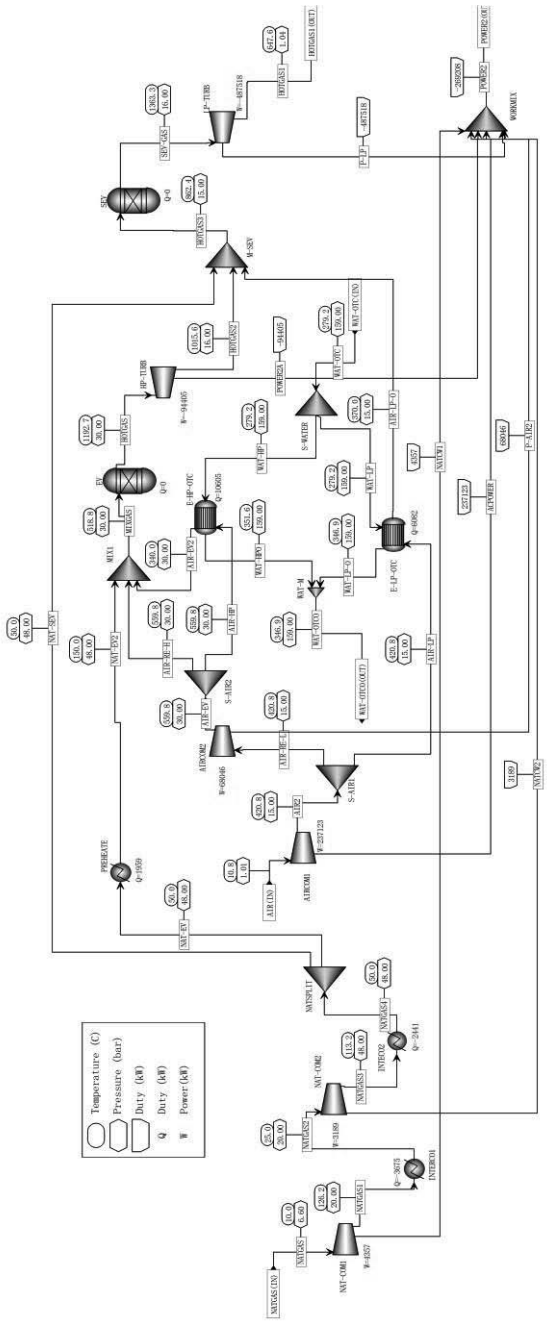

Figure 3: Flowsheet of section GASTURB

Turbine (LPGT) immediately follow the EV and SEV respectively, and the discharge pressure of the HRGT and LPGT are 16 bar and 1.04 bar separately.

3.1.2. Air pressurization

The air with flowrate of 548.3 kg/s is fed to a two-stage compressor. The first stage consists of 17 row blades while the second stage consists of 5 row blades. The discharge pressure of these two stages are 15 bar and 30 bar respectively. Two large heat exchangers named as HP Once Through Cooler (HPOTC) and LP Once Through Cooler (LPOTC) are attached to GT in order to cool the pressurized air from the GT and vaporize the water stream from the HRSG, the water flow is about 13 kg/s. A branch of the output stream of the first stage (Unit Aircom1) is fed to LPOTC and its inlet temperature is 420.8℃ and outlet temperature is 370 ℃ and returns to SEV. The remaining of the output stream of Unit Aircom1 is fed to the second stage and pressurized further to 30 bar. Similarly, a branch of the output stream of the second stage (Unit Aircom2) goes to HPOTC and its temperature is reduced from 560 ℃ to 340℃ and returns to GT at EV. After Units LPOTC and HPOTC, the water returns to the HP superheater of HRSG as steam.

3.1.3. Gas turbine

Gas turbine consists of a HP and LP gas turbine. The HP gas turbine accepts the output stream of EV as its input and drive its shaft to produce electricity, and its output pressure is 16 bar. The output pressure of the LP gas turbine is 1.04 bar. The flue gas leaving the LP gas turbine is entering HRSG as the only heat source.

3.2. HRSG and steam turbine

The HRSG system is a triple reheat system. It consists of HP steam and IP/LP steam system. Three drums and three steam turbines are involved. Details on HRSG and steam turbine is not provided here because of limit on paper length.

3.3. Water recycle system

The plant has its own on site water treatment facilities where potable water is demineralized and then used in the HRSG and water and steam cycle (WSC) system as shown in Figure 4. Specifically, WSC consists of two main water cycles, i.e., HP water cycle and IP water cycle. The pressures of HP and IP feed water are 58 bar and 170 bar respectively, which are produced by the sixth and the end stage of a ten-stage water pump. After the water pump, the feed water is split into two branches, one branch with flowrate of 85 kg/s is fed to HRSG HP steam system while the other branch of 23 kg/s is fed to HRSG IP/LP steam system. The feed water is heated and vaporized and superheated in HRSG, then, the produced HP, IP and LP steam are used to drive the shaft of steam turbine, and finally condensed in the condenser and recycled to the water feed tank.

Note thant a hot water stream of 2.4 kg/s is withdrawn from the HRSG before it entering the IP drum and used for preheating the fuel gas to 150 ℃. At the same time, a steam stream of 5 kg/s is withdrawn from the middle of the LP steam turbine and fed to the water tank feed to heating the feed water to HRSG to about 60 ℃. Seawater is only used for cooling in the main condenser to control the discharge pressure of the LPST in the HRSG to be 30 mbar.

4. Simulation result

The key results of our model is compared with plant data and provided in Table 1. It is safe to say that the obtained results are in good agreement with the operating data.

Table 1: Comparison of key results

Variable	plant data	simulation
Nat. Gas inlet flow (kg s^{-1})	15.6	15.6
GT Exhaust Flow (kg s^{-1})	564.1	564.1
Fuel to air ratio ((g/g))	0.0278	0.0284
GT Exhaust temperature (°C)	645	647.6
Net Power (MW)	420	413
GT Exhaust pressure (bar)	1.03	1.04
Condensing pressure(mbar)	30	30
Condensed water temperature (°C)	25-30	24.1

5. Conclusions

A detailed model for the gas-fired CCPP has been developed and compared with a set of data from the operation. The obtained results match well with the plant data. Based on these findings, it is concluded that the built model is suitable for CCPP simulation and can be adopted as a useful tool to predict the impact of operation parameters and explore opportunities for further integration with other plants.

Abstract

Commercial ecological gasoline is being obtained by blending multiple components. Increasing a refinery's economic performance depends, among other things, on obtaining optimum blending recipes for the available components. To determine the optimum blending recipe, knowing the mathematical blending model for blending properties estimation and a linear optimization algorithm are necessary. As a blending properties estimation model, the authors used a mathematical model which can be found in the literature, validated through own laboratory experiments. Based on the Simplex algorithm developed by Jean-Pierre Moreau, the authors elaborated a software program, program that was used to study different blending recipes. The studied recipes varied from recipes that took into consideration one restrictive blending property, to recipes that took into consideration two restrictive properties and recipes that took into account one restrictive property, but a fixed proportion of bioethanol in the final blending.

Keywords: blending, modelling, linear optimization, optimization program.

1. Introduction

The commercial ecological gasoline is obtained by blending a number of components, process which is called formulation. The finished product must fulfill some quality standards, set by today's legislation. To fulfill the imposed quality standards, blending the gasoline's components using different blending recipes is necessary (Suciu, 1993). Commercial gasoline is a blending of three types of components: base components (in proportion of about 60%), correction components (about 40%) and additives (less than 1%). The blending recipes for obtaining commercial gasoline are conceived so as the finished product is suitable in terms of quality. An essential condition for a refinery to function is profitability. Because of this reason, the blending recipes must be chosen so as they bring profits to the refinery. The blending recipe that will yield the highest profit is the optimum blending recipe. To determine the optimum blending recipe, the optimization problem has a linear nature, containing an objective financial function, and a restrictions system. In literature, program packages strictly destined to linear programming and which implement the Simplex algorithm are described. Among these, the following are exemplified:

a) ASLO – represents an advanced implementation of the Simplex method, destined to solve general linear problems of large dimensions (Andrei, 2001).
b) C-WHIZ – the Simplex algorithm containing procedures regarding the problem analysis, which is used to solve problems up to 32000 restrictions (Andrei, 2001).
c) LPAKO – is a program package written in C++, which implements the Simplex method to solve the general linear programming problem (Park et al., 1998).

The purposes of this work are:

a) The elaboration of a dedicated optimization tool.

b) The synthesis of blending recipes using different scenarios.
c) The study the optimal blending properties in relation to the blending quantity.

2. Optimization problem

The optimization problem is a mathematical application which selects a solution, among many possible solutions, based on the evaluation of the objective function (Pătrăşcioiu, 2005). The objective function has a financial nature, representing the commercial gasoline cost, computed like the sum of the products between the component cost c_i and the utilized quantity, x_i

$$F_{ob} = \sum_{i=1}^{nc} c_i x_i \ . \tag{1}$$

The restrictions system has three components: a) the finished product quality, estimated by a mathematical component blending model; b) components quantities; c) variables non-negativity restrictions (Pătrăşcioiu, Nicolae, 2012).

2.1. Property Estimation Model

To estimate the gasoline properties, obtained by blending its components, a linear model, existent in the literature, was utilized (Bărbatu et al., 1970). The model taken into account was validated by Doicin (Doicin, 2014). The model contains mathematical relations for the estimation of the following properties: density, Research octane number, Motor octane number, benzene content, vapor pressure, olefin hydrocarbons content, aromatic hydrocarbons content and oxygen content.

2.2. Quality and quantity restrictions

The quality restrictions are derived from the EN228 standard and they refer to the commercial gasoline properties, obtained by its component blending. For the studied problem, the quality restrictions have the form presented in table 1.

Table 1 Gasoline quality restrictions

Restriction	UM	Restriction Type	Restriction Value
Blending density	g/cm^3	max	0.775
Research octane number	-	min	95
Motor octane number	-	min	85
Final boiling point	°C	max	210
Aromatic hydrocarbons content	%volume	max	35
Olefin hydrocarbons content	%volume	max	18
Oxygen content	%volume	max	2.7
Vapor pressure	kPa	max	90
Benzene content	%volume	max	1

The quantity restrictions refer to the total obtained quantity of the gasoline, M, and the available quantities of each component. $D_i, i = 1,\ldots,nc$.

The two restriction types have the following expressions:

$$M = \sum_{i=1}^{nc} x_i \tag{2}$$

$$x_i \le D_i, \quad i = 1,\ldots,nc \tag{3}$$

2.3. Non-negativity restrictions

To solve the optimization problem, the Simplex algorithm uses non-negativity restrictions of the x_i variables:

$$x_i \ge 0, \quad i = 1,\ldots,nc \tag{4}$$

3. Optimization program

To study the optimum blending recipes, the authors have developed a dedicated software program that allows the interactive study of the blending recipes. The authors have used the Simplex program developed by Jean-Pierre Moreau (Moreau, 2009). The program developed by the authors was written using the Embarcadero Delphi XE3 integrated development environment and it has the following characteristics:

a) A maximum of 9 properties for the determination of the optimum blending recipe can be used;
b) The possibility of selection, from the input data, of both the blending components and the properties that will be taken into account to determine the optimum blending recipe;
c) The possibility of modifying the total quantity of commercial gasoline that can be obtained.

The main window of the program is presented in figure 1. The program determines the optimum blending recipe of the commercial gasoline, being able to be used as a study tool, by modifying the following variables:

- The property or properties that form the restrictions system for the determination of the optimum recipe;
- The total quantity of the finished product that must be obtained;
- The fixed bioethanol quantity (between 0 and 5% volume).

4. Optimum blending recipe synthesis

The optimum blending recipes were studied using the following variants:

a) Recipes that take into consideration one restrictive property;
b) Recipes that take into consideration two restrictive properties;
c) Recipes that take into consideration one restrictive property with an imposed bioethanol proportion in the final blending.

4.1. Recipes that take into consideration one restrictive property

The objectives followed by this study are the following:

- Dependence of the restrictive property's value of the optimum blending with the total blending quantity that must be obtained;
- The components' distribution with the total blending quantity.

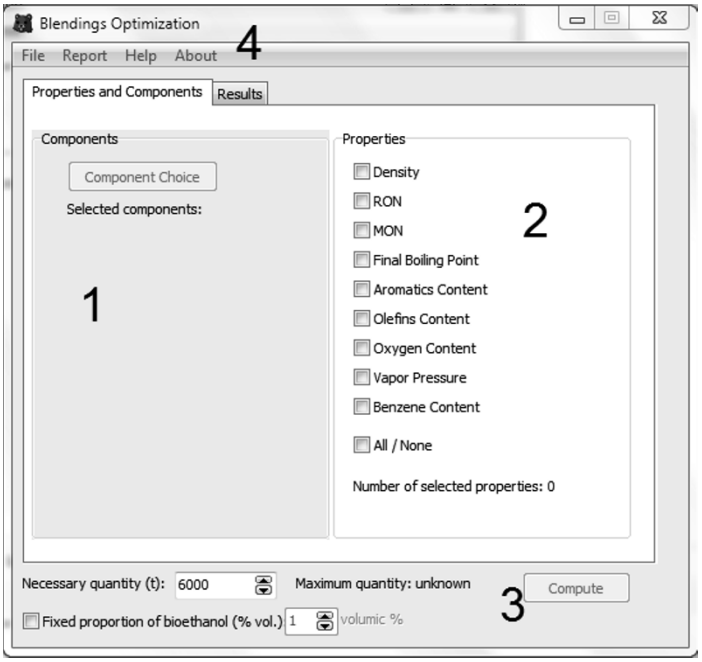

Figure 1:The main window of the optimum blending recipe determining program: 1 –component selection area; 2 –restrictions selection area; 3 –total quantity of gasoline selection zone; 4 – auxiliary menus.

The optimum recipes based on one restriction, from the 9 restrictions present in table 1, were determined. For every restriction taken into consideration, the optimum blending recipes for a total quantity of commercial gasoline varying between 4000 and 9000 t were determined. To exemplify, in figure 2 is presented the variation of the commercial gasoline density with the total quantity of gasoline that must be obtained.

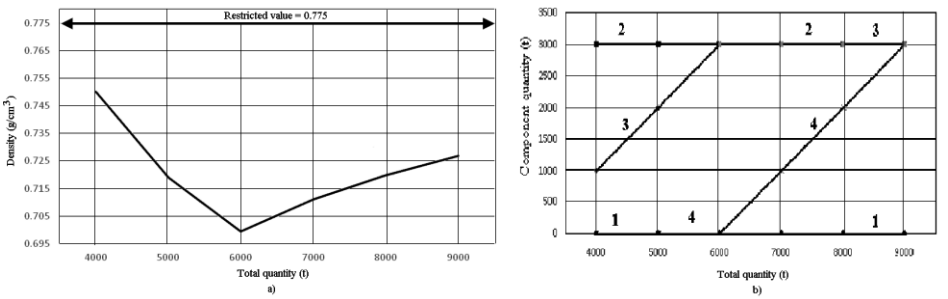

Figure 2 a) commercial gasoline density; b) commercial gasoline composition: 1 – FCC gasoline; 2 – catalytic reforming gasoline; 3 – iC_5 fraction; 4 – bioethanol.

The gasoline density obtained using the optimum recipe is under 0.775 (table 1) for the entire variation scope of the total quantity of gasoline. Figure 2b exemplifies the way in which the four components of the commercial gasoline are being used, regarding the total quantity. In the presented case, the components are used, successively: catalytic reforming gasoline (all quantity), iC_5 fraction (increasing quantity from 1000 to 3000 t);

bioethanol (increasing quantity from 0 to 3000 t). Because of its high density, the FCC component is not used in the optimum recipe.

4.2. Recipes that take into consideration two restrictive properties

The optimization program allowed the study of the dependence of the values of two restrictive properties of the optimum blending with the total blending quantity. In figure 3 the results regarding the density and Motor octane number behavior with the total quantity of gasoline are presented. The blending density constantly increases with the total increase of the quantity of commercial gasoline, this being caused by using a larger increasingly quantities of catalytic reforming gasoline and bioethanol, the components with the highest densities (figure 3a).Meanwhile, the Motor octane number decreases because of using catalytic reforming gasoline, component with lower MON(figure 3-b). From a numerical standpoint, both properties are within the admissible limits. Figure 3-csynthesizes the way in which the optimization program uses successively the four components, along with their quantities.

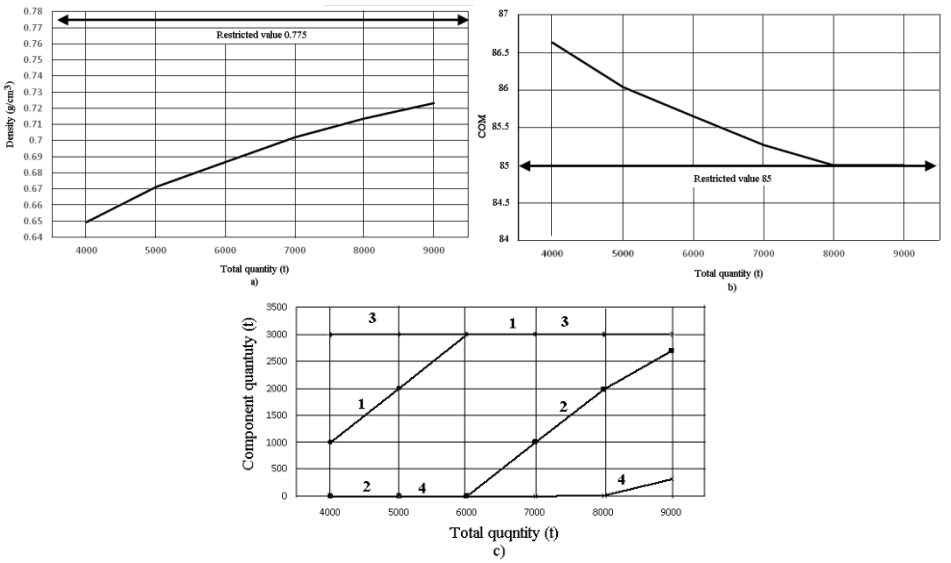

Figure 3 a) commercial gasoline density; b) Motor octane number c) commercial gasoline composition: 1 – FCC gasoline; 2 – catalytic reforming gasoline; 3 – iC5 fraction; 4 – bioethanol.

4.3. Recipes which have one imposed bioethanol proportion and one restrictive property taken into consideration

Because of the EN228 standard, the mandatory use of a fixed quantity of bioethanol in the commercial gasoline is necessary. The study of the influence of the bioethanol concentration on the commercial gasoline properties can be made using the same optimization problem. To exemplify, in figure 4 the variation of the gasoline COM with both the total quantity of gasoline and the imposed bioethanol concentration in the commercial gasoline is presented. The bioethanol concentration has varied in steps, between 0 and 5 % volume. The figures 4b and 4c present the variation of the gasoline components both the total quantity of gasoline and the imposed bioethanol concentration.

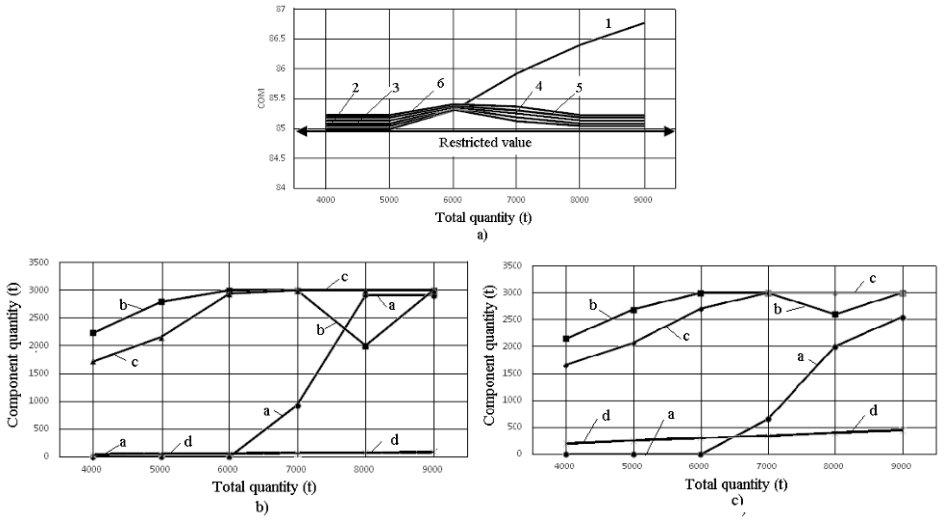

Figure 4 Optimum recipe corresponding to the bleedings with imposed bioethanol quantities: a) COM variation (1 – 0%; 2 – 1%; 3 – 2%; 4 – 3%; 5 – 4%; 6 – 5% bioethanol); b) Component quantitiesfor 1% bioethanol; c) Component quantities for 5% bioethanol (a – FCC gasoline; b – RC gasoline; c – iC5 fraction; d – bioethanol).

5. Conclusions

To study the process of obtaining commercial gasoline by optimal blending of different components, the authors have developed: a mathematical model for the estimation of the gasoline properties and an optimization software program to calculate the optimum blending. Using their own software tool, the authors studied the variation of the optimum recipe with the optimal blending quantity. A special attention has been given to study the influence of the bioethanol quantity on the optimum blending properties. The obtained results have confirmed the authors' software potential and this program can be used to quickly verify the optimum blending recipes.

Population balance model for enzymatic depolymerization of branched starch

Christoph Kirse and Heiko Briesen

Chair of Process Systems Engineering; Technische Universität München, Freising, Germany
heiko.briesen@mytum.de

Abstract

A population balance model to describe the enzymatic depolymerization of branched starch is proposed. This model is based on the subsite theory which is established for the enzymatic depolymerization of linear polymers. Extensions of this theory to branched polymers by including hindering by branchings have been published. In this study, this model is transformed in a form suitable for usage with efficient numerical techniques for solving population balance equations, such as the Direct Quadrature Method Of Moments. Such methods are necessary to perform model based optimization and control for this process. A novel numerical method recently developed by the authors was employed. A preliminary comparison to experimental data shows that the data can be reproduced reasonably well. Possible reasons for the deviations from the experimental results are discussed and improvements to the model are suggested.

Keywords: Bivariate population balance; Depolymerization; Starch; Enzyme; Subsite theory

1. Introduction

Starch is a large (mean amount of monomer units up to 10^6) and highly branched (average of around one branching per 20 bonds) biopolymer with a broad distribution in amount of monomer units. It is one of the most abundant polymers in the world (Pérez and Bertoft, 2010). In several industrial processes (e.g., the mashing process during beer brewing (Eßlinger, 2009)) starch is depolymerized into saccharides by enzymes. The saccharides are normally used as the feedstock for a fermentation process. It might be possible to improve the performance and economic feasibility by using an optimal temperature profile. In order to perform such an optimization without having to run many experiments accurate models are needed. Like most bioproducts starch has a large variability (Pérez and Bertoft, 2010) which might necessitate an optimization for each specific batch run. Then, efficiency of the simulation technique becomes crucial. The first models proposed to describe the depolymerization of starch used very simple reaction schemes that are unable to reproduce experimental results such as the evolution of the variation in the amount of monomer units (Rollings and Thompson, 1984). Recent models were solved using Monte Carlo (MC) techniques (Besselink et al., 2008). This enabled consideration of the full complexity of reaction and substrate. However, MC techniques are computationally very expensive. A more promising approach is to develop and use a population balance model. In this work such a model is developed for α-amylase, one of the important enzymes in mashing (MacGregor, 1987).

2. Population balance model

To describe the depolymerization process using a population balance equation the same basic assumption as in Kirse and Briesen (2015) are made. It is assumed that all polymers with the

same number of monomer units k and bonds associated with branching (called branching bonds) b behave identically and deterministically. This only allows a statistical, instead of an explicit, treatment of the steric hindrance due to branchings which introduces several problems that are solved in this study. Furthermore, the polymers are assumed to be ideally dissolved.

2.1. Structure of starch

Because starch/amylopectin does not crosslink, the number of branching bonds must be less than or equal to the number of monomer units minus one. However, not every glycosidic α-(1-6) bond (called branching bond) must be the start of a newly branched chain. Accordingly, it is possible to have a dimer with a branching bond. For the purpose of this work a chain is defined as the α-(1-4) (linearly) connected monomers between the start of a chain at either the reducing end or at monomer unit with a branching bond up to either the end of the polymer or to another branching bond. Accordingly, every branched starch polymer has $2 \cdot b + 1$ chains: $b+2$ chains are end-chains and $b-1$ chains are inner chains. The average amount of monomer units per chain is $\frac{k}{2 \cdot b+1}$. A limitation of a bivariate population balance modelling is that the chain length distribution is not available. It is therefore assumed here that all chains have the average chain length which changes with time. This assumption was not necessary in the previous study (Kirse and Briesen, 2015).

2.2. Numerical solution of the population balance equation

The enzyme considered in this study only performs hydrolytic cleavage of the linear bonds (MacGregor, 1987). The population balance equation is therefore a pure binary breakage population balance equation. The algorithm developed in a previous study (Kirse and Briesen, 2015) to solve such equations is used and the notation is adopted. The algorithm divides the domain into three subdomains as shown in Figure 1. In Subdomain I the population balance equation is completely continuous and the bivariate Direct Quadrature Method of Moments (DQMOM) is used to solve the population balance equation in this subdomain. In Subdomain II the amount of monomer units is continuous but the amount of branching bonds is discrete. The resulting population balance equation is solved using monovariate DQMOM. In Subdomain III the population balance equation is completely discrete and only a system of coupled ordinary differential equations needs to be solved. The accent $\bar{}$ and $\check{}$ indicate that the variable is continuous or discrete, respectively. Furthermore, the accent $'$ shows that the variable belongs to a polymer that is cleaved into two smaller polymers. Because the action of the mechanisms $\bullet$ create polymer in the other subdomains, the algorithm discretizes the birth by conserving the amount of monomer units and branching bonds. The normalized fragment distribution functions $\gamma_\bullet$ and the hydrolysis rates $D_\bullet$ need to be determined for all the mechanisms (see Sections 2.4-2.7). For further detail about the algorithm the reader is referred to (Kirse and Briesen, 2015).

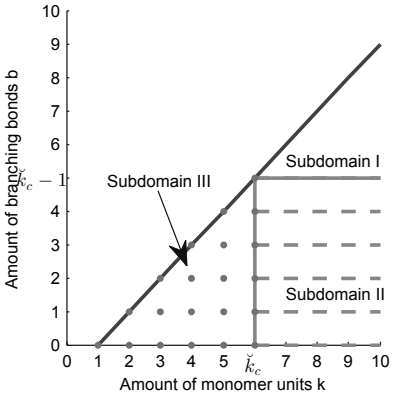

Figure 1: Division of the domain, where $\check{k}_c = 6$ for illustrative purposes.

2.3. Hydrolysis rate

Under the assumption that the product-forming reaction is much slower than the generation of the enzyme complex a competitive Michaelis-Menten kinetics is obtained for the hydrolysis rate

(Hiromi, 1970):

$$\breve{D}_{\bullet}(\breve{k}',\breve{b}') = c_{cat,\bullet}(\breve{k}',\breve{b}') \cdot N_{\text{chain},\bullet} \cdot K'_{\bullet}(\breve{k}',\breve{b}') \cdot \frac{E \cdot n(\breve{k}',\breve{b}')}{1+\sum_{\breve{k}'=1}^{\infty}\sum_{\breve{b}'=0}^{\breve{k}'-1}\frac{n(\breve{k}',\breve{b}')}{K_{m,\text{total}}(\breve{k}',\breve{b}')}}, \tag{1}$$

where $c_{cat,\bullet}$ is the catalytic constant, $N_{\text{chain},\bullet}$ is the number of chains that can be attacked by the specific mechanism, $K'_{\bullet}$ is the constant to relate the equilibrium concentration of the enzyme-polymer complex to the polymer concentration, E is the amount of enzyme, n is the polymer amount, and $K_{m,\text{total}}$ is the Michaelis-Menten constant.

There are three possible mechanisms. One is the attack of linear polymers which is completely characterized using established results from the subsite theory (see Sec. 2.4 and 2.5). The remaining two mechanisms are the attack of an end-chain (see Sec. 2.6) or an inner-chain (see Sec. 2.7) of a branched polymer. One can then show that the Michaelis-Menten parameter $K_{m,total}(k,b)$ can be obtained as follows:

$$\frac{1}{K_{m,\text{total}}(k,b)} = N_{\text{chain,inner}}(b) \cdot K'_{\text{inner}}(k,b) + N_{\text{chain,end}}(b) \cdot K'_{\text{end}}(k,b) + \frac{N_{\text{chain,linear}}(b)}{K_{m,\text{linear}}(k)}. \tag{2}$$

2.4. Subsite theory

According to the subsite theory (Hiromi, 1970) the active site of an enzyme consists of several subsites and a catalytic site. The binding of a polymer to the enzyme is a reversible binding of some monomer units of the polymer to the subsites which do not interact with each other. The subsites are numbered in direction from the reducing end to the non-reducing end. There are $\breve{z}_-$ and $\breve{z}_+$ subsites with lower and, respectively, higher numbers than the catalytic center. If the cleavage rate of the bond is much slower than the formation rate of enzyme-polymer complex, the equilibrium concentration of the enzyme-polymer complex is related to the energy of the occupied subsites. The Michealis-Menten constant can then be computed (Hiromi, 1970). A bond can only be broken if the two subsites adjacent to the catalytic center are occupied. The catalytic coefficient for a specific binding position $c_{cat,s,\breve{k}}$ of productive bindings was assumed by Allen and Thoma (1976) to be a function of the number of occupied subsites $N_{oc}(s,\breve{k})$. For an unproductive binding $c_{cat,s,\breve{k}}$ is equal to zero. The fragment distribution γ_{linear} can then also be computed:

$$c_{cat,\text{linear}}(\breve{k}) = K_{m,\breve{k},\text{linear}} \cdot \sum_{s=1}^{\breve{z}_-+\breve{z}_++\breve{k}-1} c_{cat,s,\breve{k}} \cdot K'_{s,\breve{k}} \tag{3}$$

$$\breve{\gamma}_{\text{linear}}(\breve{k},\breve{k}') = \frac{K_{m,\breve{k},\text{linear}}}{2 \cdot c_{cat,\text{linear}}(\breve{k})} \cdot \left(c_{cat,\breve{z}_{minus}+\breve{k},\breve{k}'} \cdot K'_{\breve{z}_{minus}+\breve{k},\breve{k}'} + c_{cat,\breve{z}_{minus}+\breve{k}'-\breve{k},\breve{k}'} \cdot K'_{\breve{z}_{minus}+\breve{k}'-\breve{k},\breve{k}'} \right), \tag{4}$$

where s is the index of the highest occupied subsite and $K'_{s,\breve{k}}$ is the association constant that can be computed using the subsite theory. Once a polymer is large enough to occupy all subsites, the binding specific catalytic coefficient and the association constant have a constant value K'_{int} and $c_{cat,int}$ for certain binding positions which allows a simplification of the equation for the Michaelis-Menten constant (Allen and Thoma, 1976). Furthermore, for $\breve{k}' > 2 \cdot \max(\breve{z}_-,\breve{z}_+)+2$ and $\max(\breve{z}_-,\breve{z}_+)+1 < \breve{k} < \breve{k}' - \max(\breve{z}_-,\breve{z}_+)-1$ the fragment distribution function has a constant value and in this study those monomers are called inner monomers. The enzyme performs an attack similar to random-chain scission for those monomers.

2.5. Linear polymers

For a discrete population balance equation one can directly use the results from the subsite theory. However, for large polymers this would necessitate the consideration of many products which

would be computational expensive. Therefore, all polymers larger than $\breve{k}_c$ were considered to be continuous. The summation in Equation (1) is accordingly split into a summation and an integral, the simplified equation for K_m is used, and the same arguments lead to a similar equation for $c_{cat,\text{linear}}$. The products generated by attack on non-inner monomers are still considered to consist of one discrete product and one continuous product. However, all the products generated by attack on inner monomer units are considered to be continuous. This yields the fragment distribution function for attack on a continuous polymer:

$$\begin{aligned}\bar{\gamma}_{\text{linear}} = \Big[&\breve{\gamma}_{\text{linear}}(\max(\breve{z}_-,\breve{z}_+),2\cdot\max(\breve{z}_-,\breve{z}_+))H(k-\max(\breve{z}_-,\breve{z}_+)-1)\cdot H(k'-k-\max(\breve{z}_-,\breve{z}_+)-1)\\ &\cdot\frac{k'-2\cdot\max(\breve{z}_-,\breve{z}_+)}{k'-2\cdot\max(\breve{z}_-,\breve{z}_+)-2}+\sum_{j=1}^{\max(\breve{z}_-,\breve{z}_+)}\breve{\gamma}_{\text{linear}}(j,k')\cdot\big(\delta(k-j)+\delta(k'-k-j)\big)\Big]\\ &\cdot\frac{1}{1+(k'-2\cdot\max(\breve{z}_-,\breve{z}_+))\cdot\breve{\gamma}_{\text{linear}}(\max(\breve{z}_-,\breve{z}_+),2\cdot\max(\breve{z}_-,\breve{z}_+))}\cdot\delta(b).\end{aligned} \tag{5}$$

2.6. Attack on end-chains

The attack on end-chains is similar to the attack on a linear polymer with as many monomer units as the average chain length. However, the enzyme is assumed to be unable to bind to a monomer unit with a branching bond. Together with the assumption that the polymer is always oriented with the index of the subsite increasing towards the reducing end, the association constant for the binding on an end-chain of the average chain length on the i-th monomer unit counting from the free end can be computed by taking into account which subsites are occupied. The association constant K'_{end} is obtained by summing up the binding specific association constants. The number of occupied subsites is $\min(i,\breve{z}_-+\breve{z}_+)$ and the binding is only productive if $i>\breve{z}_+$. On every attack on an end-chain scissors, one linear fragment is removed and leaves the large remaining polymer with the same amount of branching bonds. If i is larger than or equal to $\breve{z}_++\breve{z}_-$, the association constant and the catalytic constant again become a constant, and the products generated by this attack are considered to be continuous. One should note that in this study the end-chain that carries the reducing end is treated the same as all other end-chains. The fragment distribution function is not shown due to space limitations.

2.7. Attack on inner-chains

It is assumed that the enzyme can only bind to an inner chain if all subsites can be occupied. This implies that the average chain length must be greater than or equal to $\breve{z}_++\breve{z}_-$ for a binding to be possible. It follows that K'_{inner} is zero for a chain length less than $\breve{z}_-+\breve{z}_+$. According to the subsite theory the reaction constant then is $c_{cat,int}$. Under the assumption that all monomer units of a chain have the same probability of being attacked, the association constant is obtained

$$K'_{\text{end}}=\left(\frac{k'}{2\cdot b'+1}-\breve{z}_-+\breve{z}_++1\right)\cdot H\left(\frac{k'}{2\cdot b'+1}-\breve{z}_-+\breve{z}_+\right)\cdot K'_{int}. \tag{6}$$

Every hydrolysis forms two products with at least $\min(\breve{z}_-,\breve{z}_+)+1$ monomer units and at least one branching bond. The fragment distribution function is independent from the size of the product formed for all physically possible polymers but cannot be shown here due to space limitations.

2.8. Simulation parameters

Using the algorithm described by Kirse and Briesen (2015) but the much more complex model derived in this study the experiment performed by Besselink et al. (2008) is simulated. The critical amount of monomer units for discrete computation $\breve{k}_c$ was 14. Furthermore, 3 quadrature points in the continuous subdomain and 1 in the semi-discrete subdomain were used. The constant C

that converts from simulation to experimental time was found by finding the best fit between the simulated and the experimental dextrose equivalent for the first two measurement points. In this study, a value of $1.34 \cdot 10^5$ s was obtained. The binding energies, the acceleration factor, the percentage of amylose, and the initial mass concentration of starch were taken from Besselink et al. (2008). The amount of monomer units distribution was assumed to follow a Schulz-Zimm distribution where the parameters for amylopectin were taken from Rolland-Sabate et al. (2007) as waxy wheat starch and for amylose from (Hanashiro and Takeda, 1998). Amylose was assumed to be linear and the degree of branching for amylopectin was assumed to follow Equation (15) from Rolland-Sabate et al. (2007) with the parameters for waxy wheat starch.

3. Results and discussion

Figure 2 shows the experimental and simulation results by Besselink et al. (2008), which have been obtained using Monte Carlo techniques, and the simulation results from this study. One can see that the fit between the experimental data and our simulation is slightly worse than for the one obtained by Besselink et al. (2008). We postulate that this discrepancy is due to the fact that in the ad hoc inhibition due to proximity of branching introduced by (Marchal et al., 2003) and used by Besselink et al. (2008) was not used and rather a total inhibition was assumed in this study. Therefore, a different behavior of the depolymerization velocity was obtained.

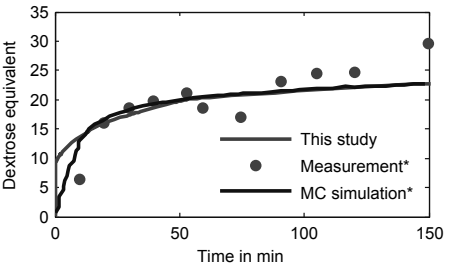

Figure 2: A comparison of the simulated and measured dextrose equivalent. *Besselink et al. (2008)

The simulated and experimental mass percentage of two linear saccharides is shown in Figure 3. The fit for the glucose concentration is very good and even better than the MC results. However, the fit for the maltotriose concentration is poor. Again this is likely due to the different inhibition model used in this study. The simulated maltotriose concentration in our study slowly decreases for larger times. This is in agreement with data measured by Steverson et al. (1984). However, the experimental data used in this study (Besselink et al., 2008) was not measured for a sufficiently long time to observe this effect.

4. Conclusion

In this study, the subsite theory for depolymerization was extended to branched polymers. For the first time this was done with a population balance equation. A decrease in computational effort is expected, but could not be shown because the computation time for the reference Monte Carlo simulation is not available. Furthermore, for the first time the subsite theory was used for polymers that have a realistic number of monomer units. The agreement with experimental data was worse than using Monte Carlo simulations but acceptable. However, in this study the inhibition by proximity to branchings was not modeled using the ad hoc model introduced by Marchal et al. (2003). The inclusion of this model is possible in a population balance framework. After inclusion of this effect the improved model should be compared to more experimental data such as data measured for longer times (Steverson et al., 1984) or the amount of longer chained saccharides (Rollings and Thompson, 1984). An additional reason for the deviation from the experimental data is that the initial condition was not measured directly but estimated from different measurements.

It was shown that the algorithm developed in a previous study (Kirse and Briesen, 2015) is able to

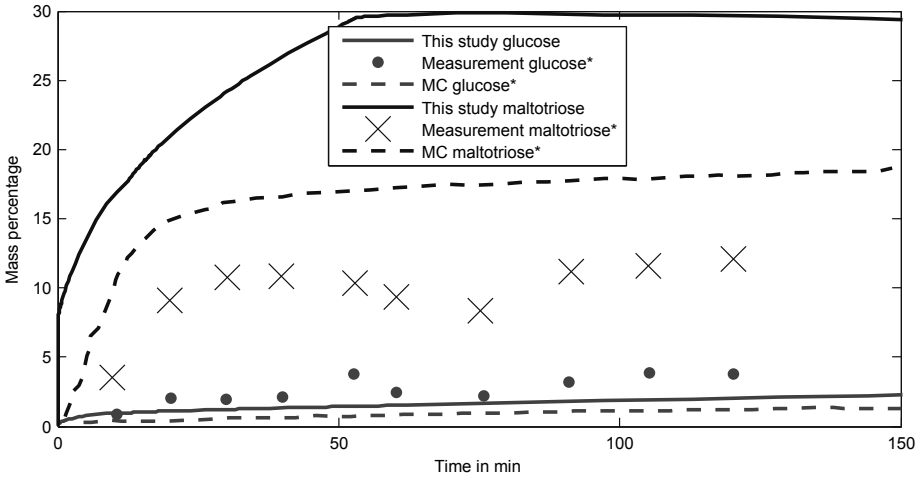

Figure 3: A comparison of the simulated and measured mass concentration of some saccharides. *Besselink et al. (2008)

deal with more complex hydrolysis rates and product distributions, but the convergence properties of this algorithm still need to be studied for such a complex case.

Abstract

Continuous production in tubular reactors has the advantages of better product uniformity and better space-time yield compared to the traditional semi-batch production mode. In this work the transferability of the production of co-polymers from a discontinuous semi-batch process to a continuously operated plug flow reactor is investigated. The critical aspect of the transfer is that the continuous addition of one of the monomers in the semi-batch process is changed to an addition at discrete injection points in the continuous plant. This leads to different product properties. The feasible ranges of product properties for both plants are determined by means of optimisation. The presented method can be used to analyse whether a given polymer production can be transferred to a continuous plant or which changes in the product qualities have to be considered.

Keywords: Radical copolymerisation, batch-to-conti transfer, product properties

1. Introduction

The production of copolymers with different reaction rates of the two monomers is nowadays mostly done in discontinuous batch or semi-batch reactors. The idea of transferring such production processes to the continuous mode of operation has been investigated during the European research project F3 Fast Flexible Future Factory, that started in 2009 (Buchholz 2009). The continuous plants, which were considered for co-polymerisations of monomers with different reactivities, are modular plug-flow reactors (PFR) with side injections. By the switch to continuous production, the continuous feed of reactants is replaced by lumped feeds at the injection points. This poses the question for which copolymers it is possible to obtain the same product in the continuous mode of operation as in the semi-batch mode. If this is possible, the better heat transfer characteristic in the continuous plant enables higher production rates and better space-time yields which, together with the improved uniformity of the production, make the continuous production an interesting alternative. The transfer of a batch process to a continuous PFR plant is restricted by the minimum flow velocity needed for sufficient heat transfer, narrow residence time distributions and the possible residence time in the PFR. Additionally the question arises whether the transfer to a continuous plant enables the production of new products, which cannot be produced in discontinuously operated plants.

In this paper the transferability is investigated by analysing the product ranges that result from the two modes of operation for a broad range of combinations of two monomers. Section 2 contains the description of the considered processes and of the possible combinations of monomers, which are represented by four reactivity ratios

within a simplified terminal model. The optimization algorithm used for the investigation of the space of attainable product properties is introduced in Section 3. In Section 4 the results for an example reaction system are presented. The work is concluded in Section 5.

2. Radical Polymerisation Model and Reactivity Ratios

In this work, the radical copolymerisation of linear copolymers containing two monomers is investigated. For a concise description of the possible combination of reaction rates, four ratios of kinetic constants are introduced.

2.1. Radical Polymerisation Model

The mechanism of radical polymerisation is based on the transfer of a radical functionality from a thermally decomposed initiator to a growing chain of monomer units. A suitable model to describe the mechanism of radical polymerisation is the terminal model. The assumption of the model is that the reactivity of a polymer chain can be described by kinetic constants which depend only on the terminal monomer of a growing chain, that carries the radical functionality. Zargar et al. (2009) presented a terminal model using the method of moments to describe the evolution of the product qualities within a radical copolymerisation. As the product qualities of copolymers, produced by the radical polymerization mechanism, are determined by the statistical process of chain growth and termination, the resulting product qualities have to be described by distributions. The most important product qualities in a copolymerisation process are the chain length distribution and the sequence length distributions of both monomers. The sequence length describes the number of subsequent identical monomer units for each monomer in a copolymer chain. During this work, the distributions are described by the number average and the weight average of the chain length distribution (NACL, WACL) and of both sequence length distributions ($NASL_{M1}$, $WASL_{M1}$, $NASL_{M1}$, $WASL_{M2}$). The full set of kinetic rate constants needed to calculate the product qualities in the terminal model from Zargar et al. (2009) contains 27 parameters if an Arrhenius-type temperature dependency is considered.

Our goal is to investigate the transferability from batch to continuous production for a broad range of combinations of monomers. This necessitates the reduction of the number of independent parameters, which are used to describe the combinations of monomers. The assumptions for the simplification of the model concern the chain initiation and the termination of polymer chains. It is assumed that the reaction rates of the chain initiation are equal to the corresponding homo propagation rates, furthermore that the cross termination can be described as the mean value of the homo termination rates. In total four different ratios of reaction rates are used within this work to define the combinations of two monomers and an initiator. The decomposition kinetic of the initiator is assumed to be known. The reactivity ratios are given in Eq. (1). The parameters r_1 and r_2 describe the ratios of the homo polymerisation rate to the cross propagation rates for both monomers, while the third ratio relates the homo propagation rates of both monomers. The fourth parameter describes the ratios of the homo termination rates.

$$r_1 = \frac{k_{p,11}}{k_{p,12}} \quad r_2 = \frac{k_{p,22}}{k_{p,21}} \quad \frac{k_{p,11}}{k_{p,22}} \quad \frac{k_{t,1}}{k_{t,2}} \tag{1}$$

In most cases the polymerisation reaction is exothermic. Therefore semi-batch processes are investigated, where the feeding strategy is to prefill the slower reacting monomer to the reactor in advance and to dose the faster reacting monomer and initiator during the

reaction. Such strategies are applied to reaction systems where the cross propagation is preferred for both monomers. Thus the investigated range for r_1 and r_2 is between 10^{-4} and 10^{0}. The definition of the faster reacting monomer is implied by the ratio of the homo propagation rates being between 10^{-4} and 10^{0}. The termination ratio is not restricted, which results in an investigated range for this ratio between 10^{-4} and 10^{4}. Acrylic acid is used as the reference substance for the kinetics. It acts as the faster reacting monomer 2 during the reactions. The kinetic values were taken from Cutie et al (1997).

2.2. Modelling the Plants, Feeding Strategies and Process Windows

The plants considered in this work are on the one hand a stirred tank reactor and on the other hand a modular plug flow reactor plant with side injections. It is assumed that the discontinuous semi-batch reactor is operated isothermally. In the plug flow reactor plant the temperature of the cooling liquid is assumed to be constant. The temperature in the discontinuous reactor is assumed to be controlled perfectly via the jacket, but in the continuous plant a non-ideal temperature control is assumed. The modular plant consists of eight modules of two different diameters, equipped with static mixers and cooling jackets. As the progress of the reaction depends on the spatial coordinate, a constant reactor temperature cannot be achieved within a module by using the cooling jacket. This results in temperature profiles with hot spots due to the injection of the feed streams. We assume a fixed reactor configuration, consisting of four consecutive groups. Each group contains one injection point at the beginning followed by two modules. A larger number of feeds would facilitate the approximation of the semi-batch operation but will increase the cost of the reactor and most likely make the continuous reactor economically unattractive.

The feeding strategy that is applied to both plants is to prefill the slower reacting monomer or to add it at the first injection point into the continuous plant, while the second monomer and the initiator are fed with a constant feeding rate to the discontinuous reactor or via all injection points into the modular PFR plant.

In order to determine the possible process windows for both plants, the inputs to the plants, i.e. the feeding rates, are varied to design reaction recipes that do not violate reasonable process constraints. These constraints enforce minimal values for the conversions of both monomers, for the concentration of the initiator at the end of the reaction and for the NACL. Furthermore upper and lower limits for the composition of the copolymer chains are assumed. In the discontinuous process the volume of the reactor and the minimum temperature of the cooling jacket, to achieve an isothermal process, are restricted. Additional constraints in the continuous process are a minimum flow velocity, as required by the static mixers to achieve a sufficient mixing, and a maximum hot spot temperature difference in each module.

3. Method for the Analysis of the Transferability

The range of possible products for each reaction system is defined by the combination of the kinetics and the process constraints. An optimization based approach is applied to compute the set of feasible recipes for both reactor concepts. The optimization approach used in this work is based on an evolutionary algorithm as presented in Ashlock (2006) in combination with a local optimization. The combination of both types of algorithms was proposed in Urselmann et al (2010) and is called a memetic algorithm. Within the evolutionary algorithm, different fitness functions are applied to explore the space of feasible processes. Within the selection step, a two stage-cost function is used to first find solutions, which are feasible, and if there are feasible solutions, to maximize their distance from known solutions within the space of the input variables. The definition of

a feasible solution is that v_{viol} in Eq. (2) is zero. In Eq. (2) u_i denotes the i^{th} input and c_j represents the j^{th} constraint. The indices u and l indicate the upper and the lower bounds on the inputs/constraints.

$$v_{viol} = max\left(0,\ [u_{i,l} - u_i], [u_i - u_{i,u}], [c_{j,l} - c_j], [c_j - c_{j,u}]\right) \tag{2}$$

If a feasible solution is found, the sum of the Euclidean distances to each previously computed feasible solution is calculated according to Eq. (3). N_{feas} denotes the number of feasible solutions found during the execution of the algorithm, the index m refers to the currently investigated feasible solution.

$$D_m = \sum_{k=1}^{N_{feas}} \frac{\|u_m - u_k\|}{N_{feas}} \tag{3}$$

Hence during the selection step feasible solutions, which are located at a larger distance in space spanned by the input variables, i.e. the feed rates, to the previously found solutions are preferred. In addition to the global search by the evolutionary algorithm, a local search is applied. A combination of KNITRO and CONOPT from the TOMLAB toolbox (Holmström et al., 2003) is used to solve the local optimization problems. If no feasible solution is found, KNITRO is used to minimise (2), while CONOPT is used for the local optimization of feasible solutions. Starting from a feasible solution, the distance to the constraints is minimized and the resulting solutions are added to the population. The cost function of the local optimization is shown in Eq. (4). $D_{c,m}$ denotes the distance between the value of the constraint function for the current solution c_m and the desired constraint c.

$$D_{c,m} = \|c - c_m\| \tag{4}$$

The presented combination of global search and local optimization turned out to be efficient to explore the boundaries of the ranges of feasible processes.

Within this set, each feasible process results in another product quality. The resulting product qualities of the two processes can be analysed by projections on the 2-dimensional product parameter spaces. The six different product qualities that are used to characterize a product of a copolymerisation process are shown in three different graphs. Figure 1 shows an example of the resulting graphs. From these graphs the information which products can be transferred with the same values of two of the product quality parameters can be detected. If no overlapping areas for a group of product quality parameters exist, the transferability must be judged based upon the acceptable change in the product quality parameters, e.g. in the sequence length distributions. In addition to the changes in the product qualities, the space-time-yields of the two processes can be compared for a given product to be able to trade the change in product properties with the space time yield due to the change of the operation mode.

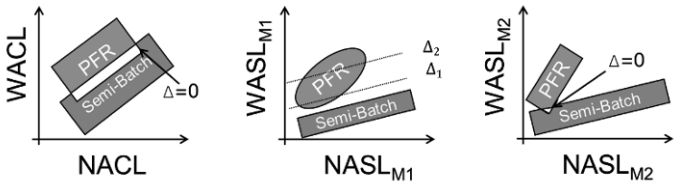

Figure 1 Representation of the resulting product ranges (conceptual representation)

4. Results

The analysis of the transferability can be performed on three different levels by applying the presented approach. On the kinetic level, the variation of the four kinetic ratios followed by the determination of feasible processes show the feasible combinations of monomers, within the assumed limitations concerning the feed strategy and the process constraints. In Figure 2, the reaction systems where feasible solutions were found are marked. For values of r_1 close to one the heat removal limits the possibility to generate the product in the pure semi-batch mode where the complete amount of monomer 1 is fed at the beginning of the batch run. In the continuous process the production is possible.

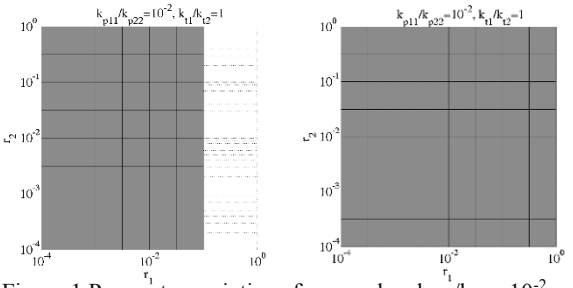

Figure 1 Parameter variations for r_1 and r_2, $k_{p11}/k_{p22}=10^{-2}$, $k_{t1}/k_{t2}=1$; feasible processes marked in green; left: discontinuous process, right: continuous process

The second level of detail is the investigation of a specific reaction system, which is described, as an example, by the four ratios $r_1=10^{-3}$, $r_2=10^{-2.5}$, $k_{p11}/k_{p22}=10^{-2}$ and $k_{t1}/k_{t2}=1$. In Figure 3 the resulting ranges of product properties are shown for both modes of operation. While the range of products of the discontinuous process is narrow, the range is broadened in the continuous process due to the change in the type of monomer addition. The narrow range is caused by the fact, that in the chosen feed strategy the slower reacting monomer is added slowly to the reactor and controls the polymerisation of the faster reacting monomer. In the continuous plant the addition takes place at fixed injection points, thus the amount of faster reacting monomer compared to the amount of slower reacting monomer is increased. This fact leads to the production of chains that contain longer sequences of the faster reacting monomer. The broadening of the range of products however is in the direction of higher poly-dispersity indices, which may not always be desirable.

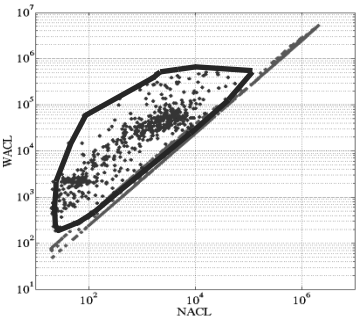

Figure 3 Resulting product ranges with respect to the chain length distribution for the example reaction system

As shown in Figure 3, overlapping regions exist for the two processes, where the transfer can be executed without a difference in the quality of the product. To investigate a possible trade-off between process intensification and differences in product qualities, a third level of detail in the analysis can be used. This level concerns the analysis for a specific recipe. For the chosen reaction system a discontinuous process is taken from the set of feasible processes, e.g. one with

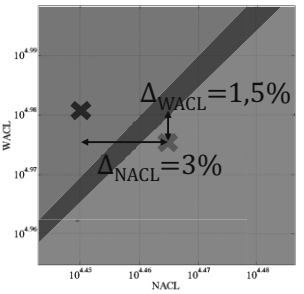

Figure 4 Changes in the product qualities shown for the chain length distribution; feasible area for discontinuous processes in the lower right corner; overlapping region marked in dark

a maximized product output. The resulting product is the reference for the transfer to a continuous plant, with the restriction of a maximum change of the product quality parameters of e.g. 5 % with respect to the discontinuously generated product. The limiting factor usually is the sequence length distribution of monomer 1. For this example, the change in the total chain length parameters is less than 3 % as shown in Figure 4. The space time yield for this specific process is increased by a factor of 150 due to the change to a continuously operated plant with side injections.

5. Summary

The analysis presented helps to explore the potential of continuous co-polymerization processes for a broad range of monomers. The transferability of existing processes and products can be investigated in terms of the resulting changes in the product quality parameters. The trade-off between process intensification and changes of the product can be evaluated, providing information, if a possible transfer to a continuously operated modular plug flow plant is worthwhile from a chemical and economical point of view.

Abstract

'Systems Biocatalysis' is a term describing multi-enzyme processes *in vitro* for the synthesis of chemical products. Unlike *in-vivo* systems, such an artificial metabolism can be controlled in a highly efficient way in order to achieve a sufficiently favourable conversion for a given target product on the basis of kinetics. However, many of the most interesting non-natural chemical reactions which could potentially be catalysed by enzymes, are thermodynamically unfavourable and are thus limited by the equilibrium position of the reaction. A good example is the enzyme ω-transaminase, which catalyses the transamination of a pro-chiral ketone into a chiral amine (interesting in many pharmaceutical applications). Here, the products are often less energetically stable than the reactants, meaning that the reaction may be thermodynamically unfavourable. As in nature, such thermodynamically-challenged reactions can be altered by coupling with other reactions. For instance, in the case of ω-transaminase, such a coupling could be with alanine dehydrogenase. Herein, the aim of this work is to identify thermodynamic bottlenecks within a multi-enzyme process, using group contribution method to calculate the Gibbs free energy change, $\Delta G_r^{o\prime}$, of the overall cascade. The findings show that unfavourable reactions in the cascade can be improved by coupling to a favourable reaction giving more energetically stable products.

Keywords: Systems Biocatalysis, multi-enzyme, thermodynamics, group contribution

1. Introduction

Servi and co-workers (2013) recently introduced the term 'Systems Biocatalysis' to describe the science associated with multi-enzyme cascades via the use of isolated enzymes *in-vitro* for the synthesis of chemical products. To date, several promising multi-enzyme processes have been reported in the scientific literature and no doubt many more examples will be forthcoming in the future as such systems are established as a useful approach for industrial synthesis (Riva, 2014). In an example of a multi-enzyme processes (Figure 1), the primary enzyme (E1) is the main enzyme that determines the synthesis of the target product (P1) while a second enzyme (E2) is added to the system to assist the main reaction. This secondary enzyme acts in such a way as to aid the primary enzyme to achieve the desired product in a high enough yield. In this representative example, the second enzyme requires a cofactor (X) which is crucial for the functionality of the secondary enzyme. Addition of a cofactor is frequently expensive and it must therefore be re-generated *in-situ*, and thus a third enzyme (E3) is introduced to the system. In this way, the multi-enzyme system is built.

The production of methylbenzylamine from acetophenone using ω-transaminase (EC.2.6.1.18) as a catalyst provides a good example of such a scheme. In this chiral amine synthesis, the equilibrium constant of $4.03*10^{-5}$ has been determined

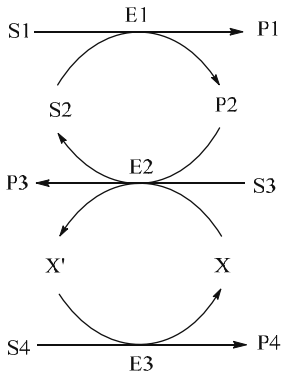

Figure 1: Representative scheme of multi-enzyme processes. E: enzyme, S: substrate, P: product, and X: cofactors.

determined experimentally where alanine was employed as the amine donor (Tufvesson et al., 2012). The value shows that the reaction alone is thermodynamically unfavourable and thus the maximum achievable conversion is only 0.63 %. Interestingly, a sufficiently favorable conversion of methylbenzylamine can be achieved, when transaminase is coupled with secondary enzymes. Using alanine as the same amine donor, the transamination achieved >70 % conversion (Truppo et al. 2009). The secondary enzymes were lactate dehydrogenase, LDH (EC 1.1.1.27) and glucose dehydrogenase, GDH (E.C.1.1.1.1). The LDH was added to remove the co-product pyruvate that hinders the formation of the target amine while GDH was used to re-generate cofactor *in situ* required by the LDH. An alternative option could be to use transaminase coupled with alanine dehydrogenase, AlaDH (EC.1.4.1.1), which was used to achieve 96 % conversion. In this system, alanine was re-generated *in situ* by recycling the pyruvate. As well as LDH, the AlaDH requires cofactors, in which the third enzyme (GDH) was also added to complete the multi-enzyme system. Even though the study claimed that the role of LDH and AlaDH was to drive the reaction to completion, there was no thermodynamic analysis to support this. Likewise, for many other multi-enzyme processes reported in the scientific literature (Simon et al., 2014), there is remarkably little thermodynamic background. Herein, this work is aimed to identify thermodynamic bottleneck in multi-enzyme processes, using the group contribution method to calculate the Gibbs free energy change $\Delta G_r^{o\prime}$. Such thermodynamic evaluation is fundamental to successfully apply systems biocatalysis.

2. Thermodynamic analysis

The thermodynamic favourability of biocatalytic reactions can be quantified by the standard Gibbs free energy change of reaction, $\Delta G_r^{o\prime}$, using Eq. 1. The data on thermodynamic properties, the standard Gibbs free energy of formation, $\Delta G_f^{o\prime}$, of reactants and products, are thus required. These data can be obtained from group contribution (GC) methods developed by Jankowski and co-workers (2008). To date, the Jankowski-GC method is established tools for estimating such properties of

biochemical molecule. It has a large training set that allows for accurate estimation of $\Delta G_f^{o\prime}$.

$$\Delta G_r^{o\prime} = \sum_j^p n_j \, \Delta G_{f,j}^{o\prime} - \sum_i^r n_i \, \Delta G_{f,i}^{o\prime} \tag{1}$$

Usually, $G^{o\prime}$ is used to denote the standard Gibbs free energy of biochemical compounds (pH 7, a temperature of 298 K, and zero ionic strength), while G^o refers to the standard state for chemical compounds. However, in practice, biocatalytic reactions are not operated at the standard state conditions. Therefore, the Eq. 2 is used to calculate the Gibbs free energy change of reaction under different conditions, which is termed as ΔG. *R* is the gas constant, *T* is the temperature, *c* is the concentration of component *i* in reactant *r* and component *j* in product *p* which obtained from experiments, and *n* is the stoichiometric coefficient of component *i* and *j*.

$$\Delta G = \Delta G_r^{o\prime} + RT \ln \frac{\prod_j^p c_j^{n_j}}{\prod_i^r c_i^{n_i}} \tag{2}$$

The sign of ΔG shows the favourability of a reaction; a minus ΔG means that the reaction will proceed towards the products, whereas, a positive ΔG means the opposite direction. When the reaction is at equilibrium, the value of ΔG is equal to zero, which in turn gives the apparent (concentration-based) equilibrium constant, K' of a reaction can be determined (Eq. 3).

$$\Delta G_r^{o\prime} = -RT \ln K' \tag{3}$$

3. Case study

In this paper, we have chosen one interesting case study from the scientific literature in order to demonstrate a suitable thermodynamic analysis for a multi-enzyme processes (Tauber et al., 2013). In this case, the artificial multi-enzyme process is constructed for the transformation of 4-phenyl-2-butanol (**a**) to a chiral amine, 4-phenyl-2-butanamine (**b**). Figure 2 illustrates the reaction scheme of the ADH/ωTA/AlaDH coupled system to produce the chiral amine. The first step is on oxidation step catalysed by an alcohol dehydrogenase (ADH), consuming cofactor (NAD+) leading to the formation of an intermediate product, 4-phenyl-2-butanone (**b**). Secondly, ω-transaminase (ωTA) catalyses the intermediate product and alanine (amine donor) to produce the desired product. In this system, alanine and the cofactor NAD+ are re-generated *in situ* through alanine dehydrogenase (ADH). The system reportedly gave 25 % conversion of the ketone (**b**) and 47 % conversion of the amine (**c**).

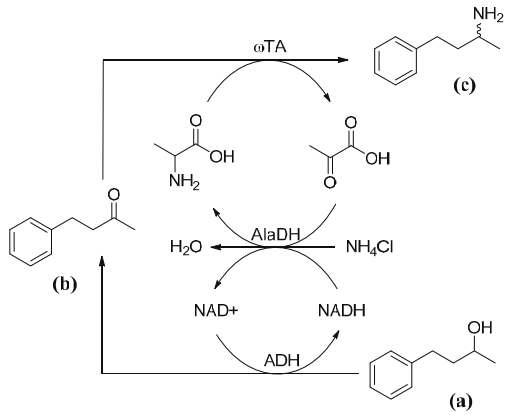

Figure 2: ADH/ωTA/AlaDH coupled system. Reaction conditions: NADH (1 mM), alanine (250 mM), NH_4Cl (200 mM) and 4-phenyl-2-butanol, (**a)** (50 mM). ADH: alcohol dehydrogenase (EC1.1.1.1), ωTA: ω-transaminase (EC2.6.1.18), and AlaDH: alanine dehydrogenase (EC1.4.1.1).

4. Results and discussion

In principle, a favourable reaction proceeds spontaneously towards the minimum energy level state (equilibrium). In the case of ADH/ωTA/AlaDH coupled system, the thermodynamic feasibility was determined and used to make the energy profile as shown in Figure 3. This diagram describes the free energy content between reactants and products (vertical axis) through the progress of reaction steps (horizontal axis) from starting material (**a**) to the final product (**c**).

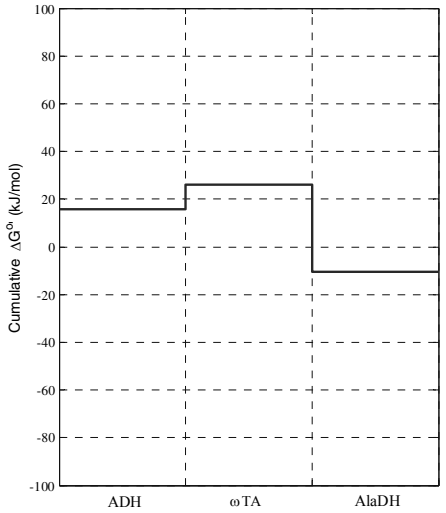

Figure 3: The energy profile represents the cumulative energy $\Delta G_r^{o'}$ at the standard state conditions for producing 4-phenyl-2-butanamine through pathways of ADH, ωTA and AlaDH. ADH: alcohol dehydrogenase, ωTA: ω-transaminase and AlaDH: alanine dehydrogenase.

In the standard state conditions, it was found that ωTA-catalyzed reaction is the thermodynamic bottleneck within the ADH/ωTA/AlaDH coupled system which is shown by the uphill reaction in the cumulative energy of $\Delta G_r^{o\prime}$. However, a positive $\Delta G_r^{o\prime}$ does not necessarily indicate a bottleneck within the system. In the ADH and ωTA reactions, both have the $\Delta G_r^{o\prime}$ constraint of positive values of 15.73 kJ/mol and 10.29 kJ/mol respectively. The values signify that the reactions are unfavourable since both products (**b** and **c**) are energetically unstable which contribute to the positive values of $\Delta G_r^{o\prime}$. The overall $\Delta G_r^{o\prime}$ for the ADH/ωTA/AlaDH coupled system is thermodynamically downhill where AlaDH is identified as a thermodynamic driving force to push the equilibrium system to completion and ending with a negative $\Delta G_r^{o\prime}$ value (-10.33 kJ/mol). At equilibrium, the apparent equilibrium constant, K' of ADH/ωTA/AlaDH system is 60.4, calculated using Eq. 3. The GC-method can be useful to determine the feasibility of the cascades when experimental thermodynamic data is not available. To date, very few data on equilibrium constants are available from experiments, in particular for multi-enzyme cascades.

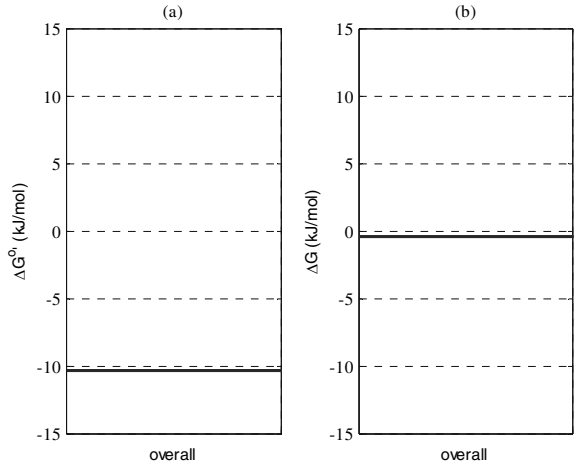

Figure 4: The free energy difference in ADH/ωTA/AlaDH coupled system. (a) $\Delta G_r^{o\prime}$ (Reaction conditions: pH 7, 298 K) and (b) ΔG (Reaction conditions: pH 7.5, 303 K, $C_{10}H_{14}O$ (37.5 mM), $C_{10}H_{15}N$ (5.9 mM), NH_4Cl (194.1 mM), and water (55.6 M)).

A system is rarely operated at standard state conditions and thus it is interesting to find the thermodynamic feasibility of ADH/ωTA/AlaDH system using the actual ΔG which calculated as a function of concentration of products and reactants (Eq. 4). From the calculation, the ΔG of the system has changed from -10.33 kJ/mol to -0.75 kJ/mol. Here, the concentration of pure water is 55.6 M and the regeneration system of NAD+ and alanine is assumed run efficiently using AlaDH. The results show that the system is thermodynamically feasible and the value of ΔG describes how far the free energy has changed from the standard state conditions. In most cases, biocatalytic reactions are controlled at pH >7. However, in this ΔG calculation, the pH value is not taken into account. Recently, Hoffmann and coworkers (2013) has found that the activity coefficient strongly correlates with pH in which the $\Delta G_r^{o\prime}$ changed accordingly. Further study on activity effect is currently carried out as more data is needed to confirm such an effect.

$$\Delta G = \Delta G_r^{o\prime} + RT \ln \frac{[C_{10}H_{15}N][H_2O]}{[NH_4^+][C_{10}H_{14}O]} \quad (4)$$

5. Conclusions

In conclusion, multi-enzyme system can be a useful approach for biocatalytic processes, but it requires fundamental knowledge of the thermodynamics. The thermodynamic bottlenecks can be identified through the energy profile of reaction steps in the overall reactions. It is, however, it is necessary to obtain values for the thermodynamic properties of Gibbs free energy of formation of a compound to draw the diagram. For an unfavourable reaction such as transaminase, it can be improved by coupling with thermodynamically favourable reactions to drive the system to completion. Such multi-enzyme processes if successfully designed can yield high conversions of unfavourable transformation. Likewise, high conversion of the multi-enzyme processes is also attractive in the downstream processes since fewer unit operations are required to remove intermediates/by-products within the reaction step. Nevertheless, more work should be done to evaluate the multi-enzyme systems in term of economics, determine whether designed cascades can reduce the downstream cost.

Abstract

Equation-oriented approach (EO) is an important method for process simulation and optimization. A large scale EO model consists of a very large number of nonlinear equations, resulting in the solving process a challenging and time-consuming task. In this project, a parallel computation method for solving EO model is proposed and discussed. During the solving process, function evaluation of residual errors at each iteration is an essential step. With the EO feature, this step can be parallelized in a natural way. By dividing the equations into several groups, the function evaluation can be conducted by using multiple threads on a parallel hardware platform simultaneously. In this paper, the theoretical analysis on speedup ratio is first discussed. The implementation of the proposed method on the NVIDIA GPU platform and multi-core processor platform is presented with a number of numerical examples. The results are compared and discussed to show that how the hardware platform can greatly affect the performance of the proposed method.

Keywords: equation-oriented model, function evaluation, parallel computing, GPU, multi-core processor.

1. Introduction

Process simulation and optimization are of great importance for the design and operation of chemical manufacturing process as they can help improve productivity, performance and product quality in a reliable and economical manner. In many cases, EO approach is the most efficient way to deal with process simulation and optimization. It assembles all the variables and equations corresponding to the process model and then solves the whole model simultaneously. Though the EO approach has the credit in computation speed and convergence efficiency, the solving for large-scale models could also be challenging and time-consuming, which requires considerable computational efforts. Parallel computation enables multiple tasks to be performed simultaneously (Almasi & Gottlieb, 1989). Several popular parallel computing platforms become available, including multi-core processor platforms, graphics processing unit (GPU) computing platforms and cloud computing platforms. In chemical manufacturing process, parallel computing has also been widely applied (Vegeais & Stadtherr, 1992; Radeke, Glasser, & Khinast, 2010; Laird, Wong, & Akesson, 2011; Chen, et al., 2013). In the current paper, a parallel computation method based on function evaluation is

proposed to accelerate the solving of EO models. A brief theoretical analysis is conducted. The proposed method is implemented on both NVIDIA graphics-processing-unit-based and Intel multi-core-processor-based parallel platforms. To demonstrate the applicability and efficiency of parallel computing, three large scale EO models are presented. Finally, further analysis and discussion is conducted to interpret the different performance of the proposed methods on the different platforms.

2. Parallel computation method based on function evaluation

A typical procedure of the EO approach in process simulation and optimization consists of several steps, including initialization, function evaluation and/or gradient evaluation, iterate updating, and termination judgment. The flowchart is presented in the left part of Figure 1. During the solving process, the function evaluation of residual errors is conducted at each iteration. It describes the infeasibility at each iterative point from the equation point of view. For a gradient-based algorithm, the gradient should be calculated at each iteration, which is also through function evaluation basically. Due to the simultaneous feature of an EO model, the function evaluation can be computed in a parallel mode.

The natural way to speed up the calculation is to implement the function evaluation step using parallel threads, as illustrated in the right part of Figure. 1. The equations to be calculated in an EO model are divided into several groups and parallelized by N_t threads, through which the function evaluations can be calculated simultaneously. After all the threads complete their task, the function evaluation of residual errors is gathered from each thread and then return to the iteration process.

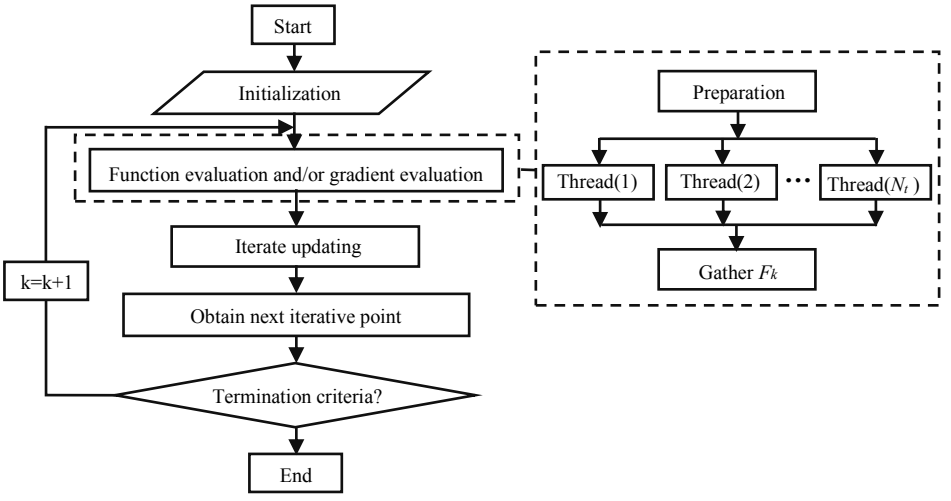

Figure 1. Schematic of the parallel computation method

The time cost of the function evaluation is a very significant component of the total time cost of the solving process. If we accelerate the function evaluation step, we can thus accelerate the whole solving process. The theoretical analysis on the parallel performance of the proposed method can be elaborated as follows.

Denote the computing time required for function evaluation in a conventional way as t_f, and the time required for the rest as t_r. In the parallel mode, we can use multiple

threads for this task. Meanwhile, the acceleration is also limited by the processor number. Denote the parallel thread number as N_t and the real hardware core number as N_{core}. The speedup ratio of the function evaluation step is bounded by $N_p = \min(N_t, N_{core})$. Thus, the theoretical speedup ratio of the whole process can be derived as $SR_i = (t_f + t_r)/(\frac{t_f}{N_p} + t_r + t_c)$, where t_c is the extra communication time caused by parallelization on different processors.

In this paper, the EO models are solved by SNOPT, which uses a sequential quadratic programming (SQP) algorithm. The function evaluation is parallelized during the solving process. It is implemented on both Intel multi-core-processor platform and NVIDIA GPU platform.

3. Numerical examples for parallel computation method

Three examples are used for the demonstration of the proposed method.

3.1. Homopolymerization model

Homopolymerization is a type of polymerization which forms a homopolymer from a single type of monomer. The model used here only involves the kinetic part with propagation and transfer to hydrogen. The total equation number is determined by the maximum chain length. Assuming that the homopolymerization in a CSTR operates at steady state with given residence time, we can derive population balances for the living and dead chains (Soares & McKenna, 2012). By solving the equations, the molecular weight distribution (MWD) of the product can be obtained.

3.2. Cubic equations model

This case studies a cubic numerical example as follows. It consists of *n* equations and variables.

$$\begin{aligned} &f_1 = x_1^3 + x_2^3 + x_3^3 - 2x_1 / x_2 - x_2 / x_3 = 0 \\ &\vdots \\ &f_{n-2} = x_{n-2}^3 + x_{n-1}^3 + x_n^3 - 2x_{n-2} / x_{n-1} - x_{n-1} / x_n = 0 \\ &f_{n-1} = x_{n-1}^3 + x_n^3 + x_1^3 - 2x_{n-1} / x_n - x_n / x_1 = 0 \\ &f_n = x_n^3 + x_1^3 + x_2^3 - 2x_n / x_1 - x_1 / x_2 = 0 \end{aligned} \tag{1}$$

3.3. Crude argon column model

Argon is a product of air separation through cryogenic distillation. This case deals with the steady state simulation of a crude argon column with 191 stages. The column is modelled using the rigorous equilibrium stage concept with thermodynamics based on the Redlich-Kwong-Soave-Boston-Mathias (RKS-BM). According to the reference (Kamath, et al., 2010), the thermodynamics can be handled with an EO approach. But to reduce the variable number and avoid complex terms, intermediate variables are introduced into the thermodynamic model. This results in a partially sequential feature for the function evaluation.

3.4. Accuracy analysis for proposed parallel method

First, tests are conducted on the above-mentioned examples to prove that the solutions are not affected by the parallel computation. Figure 2 presents the MWD results of the homopolymerization simulation using different methods. There are totally three curves,

which are obtained by the analytical, serial and parallel methods. The analytical solution was obtained by Flory methods. The serial was conducted by solving the equations using SNOPT. The parallel was conducted similarly, except that the function evaluation was implemented on a GPU platform. Obviously, these three curves overlap very well, which indicates that the numerical solutions are correct and the parallelization does not affect the results. This is also proved by the other two examples. Due to the length limitation, detailed results are skipped here. Considering that only function evaluation part is parallelized during the solving process, we will focus on the parallel performance of function evaluation in the following sections.

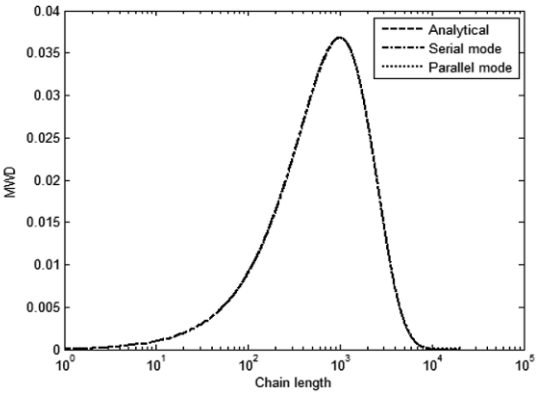

Figure 2. Flowchart for parallel computation method

4. Implementation results on GPU platform

The parallelization was first studied on a GPU platform under NVIDIA Compute Unified Device Architecture (CUDA) programming environment. The GPU mode is NVIDIA Tesla C 1060 with 240 scalar processor cores.

4.1. Implementation of homopolymerization example

The equation number of this model is determined by the maximum chain length. We can vary it to construct models with different dimensions. Each thread executes the function evaluation of one equation. Because of core restriction from the hardware, all threads would be conducted when any core is free. Table 1 compares the time costs for function evaluation in serial mode and in GPU parallel mode. The model size varies from 5000 to 20000, which results in that the number of function evaluation called by SNOPT (the last column in Table 1) also varies. As Table 1 shows, the parallel strategy applied on the homopolymerization example is less efficient than that of the serial strategy. The communication between CPU and GPU costs too much time. After analysing the model, we find that all equations are either linear or quadratic. It does not need much effort to compute. Thus, the time spent on communication exceeds the time saved by parallel computing by 240 cores.

4.2. Implementation of cubic-equation example

In this example, each thread also deals with one-function-evaluation task, which means that the parallel performance is limited by GPU cores. The results of running time for function evaluation are shown in Table 1. The model size ranges from 10000 to 30000. As the model size increases, the acceleration of the proposed methods comes out with a maximum speedup ratio as 1.33 when the model size is 30000. Compared with the previous example, this cubic model has higher computational complexity. The computation time on GPU occupies a larger proportion in the total time for function evaluation, which enables the parallel performance satisfied.

4.3. Implementation of crude argon column example

As mentioned in Section 3.3, the thermodynamic model has sequential feature. Therefore, unlike the former two cases in which the thread number can be set as many as the equation number, this case is implemented with much fewer threads. We arranged all equations of a stage to be calculated by a thread. The results are also listed in Table 1. The existence of the intermediate variables in the thermodynamics results that the equation number is triple of the variable number. This greatly reduces the ratio of the communication time over the computation time, as shown in Table 1. It may be thought the higher compute utilization would contribute to good parallel performance. However, the parallel method did not perform well in this case. Although the proportion of communication time cost is reduced relatively, the hardware resource is not fully exploited in this case as the thread number is bounded by the stage number. Thus, the proposed method did not accelerate the computation as expected.

Table 1. Performance on GPU platform

Model	Model size	CPU	GPU	GPU computation	Communication	Numbers of FE called
Homopolymerization model	5000	1.579	2.855	1.396	1.459	35036
	10000	6.004	8.386	3.817	4.569	70034
	20000	25.937	28.225	11.315	16.910	140036
Cubic-equation model	10000	15.272	15.350	7.638	7.712	120017
	20000	65.417	54.262	27.415	26.847	260017
	30000	184.687	138.762	68.697	70.065	480026
Crude argon column model	17191	21.552	34.070	30.378	3.692	92281

4.4. Summary & Discussion

In this part, three examples were implemented with the parallel method on the GPU platform. The solving process of an EO model requires communication between CPU and GPU at each iteration. This results that the communication time cannot be ignored in this work. In addition, to obtain good parallel performance, the equation size in each thread should be large, which can lead to higher compute utilization. All these factors limit the performance of the proposed method on the GPU platform.

5. Implementation on multi-core processor platform

A multi-core processor can process instructions of each core at a time. Compared with GPU, few cores are available on a CPU processor chip. But a multi-core processor has an obvious advantage on computing and communication. Since each core shares the global memory in the multi-core processor, the extra time cost for the communication under the GPU situation are avoided. Here, the equations of function evaluation are distributed evenly into several threads, which have the same number as the available core number. The *pthread* is selected as the multi-threaded programming model, and the *pthread mutex* is employed for the communication and synchronization among all threads. The examples in Section 3 are also tested on a 4-core CPU platform. The parallel performance is shown in Table 2.

The calculations in all the three examples are accelerated significantly by the proposed method on the multi-core processor platform. The speedup ratio (SR) reaches up to 3.73, which is quite close to the ideal value, 4. For each model, the speedup ratio increases with model size, which means that mass amount of computations is preferred in CPU thread. Better than GPU platform, calculation on multi-core CPU does not have

extra communication time like that between GPU and CPU. Besides, all cores in CPU have high performance in computing consistently. For the reason that in most solving process the time cost of function evaluation part takes 30-60 percentage of total time, the function-evaluation-based parallel method is quite favoured on the multi-core platform.

Table 2. Performance on multi-core processor platform

Model	Model size	CPU single-core(s)	CPU multi-core(s)	SR	Numbers of FE called
Homopolymerization model	5000	1.579	0.827	1.91	35036
	10000	6.004	2.336	2.57	70034
	20000	25.937	7.474	3.47	140036
Cubic-equation model	10000	15.272	5.051	3.02	120017
	20000	65.417	18.342	3.57	260017
	30000	184.687	49.470	3.73	480026
Crude argon column model	17191	21.552	6.709	3.21	92281

6. Conclusions

To accelerate EO model solving, this paper proposes a parallel computation method based on function evaluation. A theoretical analysis is conducted on the speedup ratio of the proposed method. Implementation on both NVIDIA GPU-based and Intel multi-core-processor-based parallel platforms are carried out. Three numerical examples are tested. Acceleration can be achieved by both platforms. But the good performance is more favoured to the multi-core processor platform than the GPU platform due to the large demand of the communication in this work.

Abstract

Due to technological developments new small-scale mobile production concepts have become available in the processing industry. These novel production concepts have mobility as an attribute and the profitability of the production concepts depends, amongst others, on how well this attribute can be exploited as an important part of the cash flows of these concepts may depend on optimal location choice in volatile markets. Current investment appraisal techniques do not take the effect of these dynamics into account and therefore typically disregard the value of mobility, which may lead to the underestimation of the novel production concepts' value and consequently prohibits their deployment. In this paper we combine an agent-based model simulation with a net present value calculation to account for these dynamics in the appraisal of these new production concepts. The agent-based model uses a q-learning algorithm to simulate an existing dynamic world scale market in which we introduce the new production concepts and let them compete with the existing industry. During the simulation, we measure the cash flows of the production concepts, which are used in the net present value calculation to appraise the concepts. We illustrate the approach with a case study in which we appraise a stationary and mobile production concept. We show that quality of investment decisions may be improved with a simulation that is able to capture the dynamics of mobile production concepts. Future work will focus on removing some of the current limitations and on introducing lead times in the simulation to enable the valuation of the new production concepts' shorter time to market.

Keywords: agent-based model, investment appraisal, market forecast, market simulation, q-learning

1. Introduction

In the last years new small-scale production concepts, based on process intensification and modularization principles, have been developed for the processing industry (e.g. the F3Factory (F3Factory, 2014)). One of the main attributes of these novel production concepts is that their small size enables relative easy relocation if new business opportunities arise (Lier, et al., 2013). However, despite flexibility being a major competitive advantage in an increasingly volatile world (Seifert, et al., 2014), to date the novel production concepts are deployed very sparsely. And if they are deployed, they are typically used to replace equipment within a traditional environment (e.g. a continuous reactor replacing a batch reactor in a world-scale plant), thereby eliminating the advantage of mobility.

One of the issues limiting the deployment of the novel production concepts is that the commonly used investment appraisal techniques have difficulties appraising the value

of mobility and thus may underestimate the value of mobile production concepts. The value of mobility is difficult to appraise because the orders and prices (and hence the cash in- and outflows) in the market are affected by a decision to relocate the production concept. Market entry effects change the balance of supply and demand at the new location. This makes exogenous forecasting of price and demand development inaccurate, because it does not take into account the changed market situation.
To support the deployment of mobile production concepts at an operational scale, this paper presents an investment appraisal approach that integrates market forecasting with the appraisal in a dynamic way. We use an agent-based market model to simulate an existing market, deploy a mobile production concept in that market, and let its cash flows emerge from its operations and interactions with the market. By comparing its cash flows to those of a stationary production concept we can determine the value of the mobility.
In section 2 we review the main investment appraisal techniques, assess their suitability to value mobility, and discuss the requirements to enable the appraisal of a mobile production concept. In section 3 we present our dynamic investment appraisal approach. We illustrate this approach in section 4, through a case study. In section 5, we end this paper with conclusions and recommendations for future work.

2. Investment appraisal

When confronted with a number of alternatives to invest in, one has to decide which investment is the most worthwhile. Investment appraisal is the process of assessing how the future benefits of an investment relate to the initial expenses, in order to compare different investment alternatives (Götze, et al., 2008). Over the years a wide range of investment appraisal techniques have been developed, that each regard an investment from a different perspective. The main investment appraisal techniques can be grouped in three categories: economic analysis methods (e.g. net present value), strategic approaches (e.g. how the investment contributes to the competitive advantage) and analytic models (e.g. scoring models) (Karsak and Tolga, 2001). An approach that is becoming increasingly popular is the real options approach, which acknowledges uncertainty in market forecasts and the possibility to make decisions after the initial investment decision (Amram and Kulatilaka, 1998).
The investment appraisal techniques differ in a.o. the target measure(s) they use as decision criterion (Götze, et al., 2008); economic analysis methods and real options only consider financial metrics, while strategic approaches and analytic models are capable of also considering other metrics, such as emissions, flexibility, etc. We set out to improve the market forecasts used for economic analysis, and therefore focus on the financial metrics. The financial metrics of the investment appraisal techniques rely on market forecasts, which specify the expected market development, i.e. order volumes and prices over a certain time horizon (Götze, et al., 2008). In the appraisal cash flows are combined in a certain target measure. The linearity of this approach makes it impossible to include effect of a relocation decision in the market forecast and therefore makes the approach unsuited to appraise the value of mobile production concepts.
To consider how the market is influenced by the relocation decisions, the market forecasting has to be integrated with the investment appraisal (as illustrated by figure 1). Instead of forecasting the market outcomes for the entire time horizon, the market outcomes for a single time period need to be determined, on basis of which a relocation

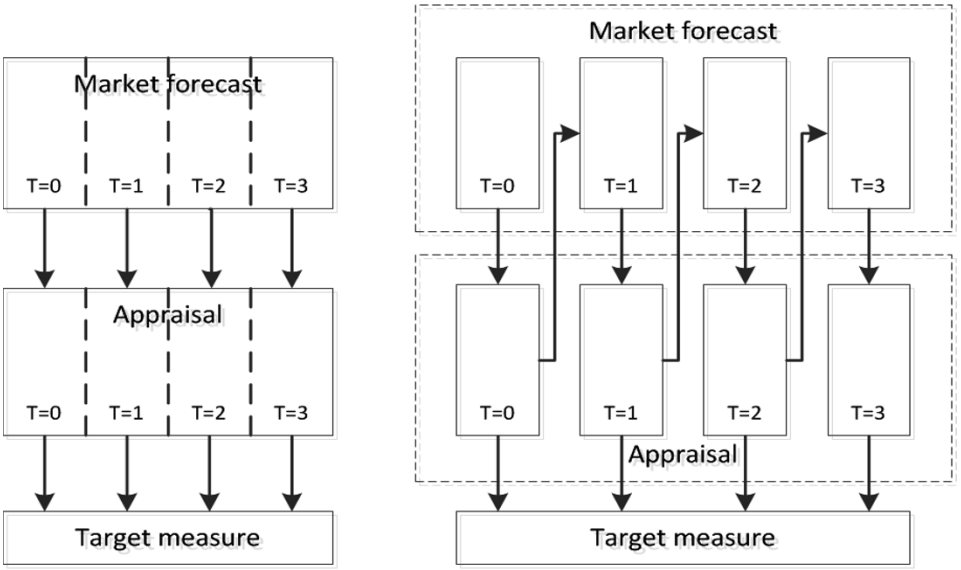

Figure 1: External market forecast (left) and integrated market forecast (right)

decision is made. This relocation changes the market situation (supply, demand, and market structure), which is used for determining the market outcomes in the followingtime period. This way the market entry effects are accounted for.

3. Integrating market forecasting with investment appraisal

We model the market from an agent-based computational economics perspective. Modeling a market as autonomous negotiating agents enables the representation of strategic behavior, bounded rationality, learning, and adaptation, which is not possible with the often applied general equilibrium market models (Farmer & Foley, 2009). The production concept is deployed in this market. The resulting cash flows are used to appraise the production concept, for which we use a net present value calculation. These cash flows influence the decision where to relocate the production concept to. If the production concept is relocated it changes the supply in the market in enters, thereby changing the price and orders of goods in that market.

3.1. Market simulation

The simulation consists of two markets: one market for feedstock and one for produced product. Following Moyaux, et al. (2010), the two markets are connected by the production concept and its competitors (i.e. the processors) buying in one market and selling in the other. Besides the processors, we also consider suppliers of feedstock and customers of product that negotiate with the processors in respectively the feedstock and product market. The conceptualization of both markets builds on the work of Dogan and Güner (2013). In each market buyers purchase from the sellers that can supply at the lowest costs and each seller applies Q-learning to learn – on basis of the received orders – a pricing strategy that maximizes its profits. The pricing strategy specifies what price is the most profitable at a given market price.

3.2. Relocation decisions

To assess the value of mobility, the mobile production concept decides every couple of time periods autonomously where it wants to be located. We assume that mobile

production concepts (represented by agents) can be located at the site of potential customers. First, the mobile agent selects the site with the highest margin between product and feedstock price, which is assumed to be public knowledge. Second, for that site the mobile agent assesses its profitability, by negotiating with suppliers and customers as if it would be situated at the new site. It compares that profitability with the profitability at its current site. A decision to relocate is made when a profitability threshold is met. This is expressed as a percentage of profitability and represents the risk aversion of the mobile production concept.

4. Case study

To illustrate our approach we use a global polymer case. Two alternatives are being appraised, a mobile plant and a stationary plant. Both plants use monomers, which are supplied by monomer suppliers, as feedstock to produce polymers, which are consumed by compounders.

In total the market consists of 16 plants, each of which is represented as an agent in the simulation. All plants are situated in either one of three regions: North-America, Europe, or Asia-Pacific. Concerning monomers we assume that they are available near all processors, i.e. the distance from a supplier to a processor (in the same region) is 100 kilometers. Table 1 shows how the plants and capacity are distributed over the regions. Due to confidentiality it is not possible to present the initial market situation in greater detail. Both the mobile and stationary plants are initially located in Europe and have a capacity that is 10% of the global market. Besides the mobility, the two alternatives are identical.

A period of 10 years is simulation in weekly intervals. Every quarter the agents renegotiate global prices and every half year the mobile agents will assess whether to relocate or not. During the simulation we consider a scenario in which the demand declines after 5 years and demand in the Asia-Pacific region increases.

To compare the mobile and stationary plants we determine the net present value of the mobile and stationary production concept. We use a discount rate of 14% to discount the cash flows and calculate the net present value. The cash flows considered are the sales revenues, the costs of feedstock, the operating expenses, and the shipping expenses. As the purpose of this case is to illustrate how a market simulation can be used to appraise the value of mobility, we focus on the cash flows that influence the value created by mobility. Consequently, the initial expenses are not considered as they do not affect the value created by mobility.

Besides comparing the mobile and the stationary production concept we also assess the effect of different risk aversion percentages, knowing 0, 10, 20, 30, 40, and 50%. The risk aversion only needs to be considered for the mobile production concept, and consequently we run 7 different experiments. To reduce the impact of stochasticity on the experiment results, each experiment is run 100 times.

4.1. Experiment results

Table 2 presents the net present values of the stationary and mobile production concepts. Depending on the risk aversion, the net present value of a mobile production concept is 7.06% to 9.72% higher than that of the stationary production concept, with an average increase of 8.46%. The ANOVA and Tukey's HSD test indicate that for each risk aversion the difference between the mobile and stationary production concept is statistically significant, which implies that the mobility a production concept increases its value.

Table 1: Distribution of global capacity over regions

	North-America		Europe		Asia-Pacific	
	Plants	Capacity	Plants	Capacity	Plants	Capacity
Suppliers	33%	42%	33%	15%	33%	42%
Processors	20%	43%	40%	29%	40%	27%
Customers	25%	43%	37%	29%	37%	27%

Table 2: Experimental results

Production concept	Risk aversion	Net present value	Difference from stationary	Relocations
Stationary	N/A	211,501,770	N/A	N/A
Mobile	0%	232,058,766	9.72%	8.26
	10%	228,610,754	8.09%	7.27
	20%	231,163,872	9.30%	6.51
	30%	226,438,525	7.06%	6.13
	40%	228,326,574	7.95%	5.02
	50%	229,853,863	8.67%	4.58

The increase of the net present value due to mobility is in line with expectations, since the mobile production concept can relocate free of charge from Europe to Asia-Pacific to follow the demand. Being able to follow the demand saves the mobile production concept, in comparison to the stationary production concept, the expenses of shipping its products from Europe to Asia-Pacific. As a consequence it has higher net cash flows and a higher net present value.

The tests also indicate that the risk aversion has no significant effect on the net present value. We expected a higher risk aversion to result in a higher net present value, as it reduces the number of erroneous relocation decisions. The prices in individual runs of the simulation are volatile and therefore the projections of a location's profitability have a high margin of error. A high risk aversion makes that a mobile production concept only relocates if the rewards are high enough for the risk of an erroneous relocation. The experimental results show that the number of relocations decreases as the risk aversion increases. However, this does not result into a higher net present value. An explanation is that a higher risk aversion not only reduces the number of erroneous relocation decisions, but also makes that profitable opportunities are missed. As these two factors cancel each other out, the net present value effectively remains the same.

5. Conclusions and recommendations

In this paper we set out to support the deployment of mobile production concepts at an operational scale, by combining an agent-based market simulation with a net present value calculation. Using this approach the market entry effect of a relocation decision can be taken into account, which is essential for appraising the value of a mobile production concept. The case study has indicated that this approach is capable of appraising the value of a mobile production concept, as it indicated that there is a significant difference in the value of a stationary and mobile production concept.

In its current form the approach requires some improvements to be made, in order to enable the actual application of the approach. First, the stochastic volatility of the price needs to be reduced as it appears to impact the relocation decisions. This may be done through simplifying the pricing strategy to just the most profitable price. This is

expected to reduce the price volatility and enables an increase in the price resolution of the pricing strategy. Second, the relocation expenses and relocation duration need to be considered in the relocation decision, to improve that decision. Third, the relocation expenses need to be included in the net present value calculation. And fourth, the initial expenses need to be included in the calculation of the net present value. The current approach assumes that for both alternatives the initial expenses are similar, but in reality mobile production concepts are usually more expensive.

Besides those essential improvements, the dynamic investment appraisal approach can be expanded in a number of ways. An expansion could be the expansion of the agents' operational behavior and the supplier selection decision. Currently, processing and shipment durations are not represented in the simulation. Nor is the lead time an issue in the supplier selection decision. As a lower time to market is one of the advantages of the novel mobile production concepts, including the durations and expanding the supplier selection decision might have a significant effect on those concepts' value. A second improvement would be to relax the assumption that, besides their mobility, the stationary and mobile production concepts are identical. In reality mobile production concepts typically have a smaller throughput and a different cost structure. To support the materialization of mobile production concepts, it is necessary that all characteristics – including the disadvantages – of those concepts are appraised, in order to present the full picture of the concepts' value. This requires that we enable more differentiation between the stationary and mobile production concepts.

Prediction of Heat Capacity of Ionic Liquids Based on COSMO-RS $S_{\sigma\text{-profile}}$

Yongsheng Zhao, Ying Huang, Xiangping Zhang*, Suojiang Zhang

Beijing Key Laboratory of Ionic Liquids Clean Process, State Key Laboratory of Multiphase Complex Systems, Institute of Process Engineering, Chinese Academy of Sciences, 100190, Beijing, China.
xpzhang@ipe.ac.cn

Abstract

Multiple linear regression (MLR) and artificial neural network (ANN) algorithms have been used to establish the quantitative structure-property relationship (QSPR) models for predicting the heat capacity of ionic liquids based on the $S_{\sigma\text{-profile}}$ descriptors calculated by COSMO-RS. To validate the two novel models, heat capacity data for 2416 experimental data points of 46 ILs was applied. The average absolute relative deviation (AARD) of test set of the MLR and ANN is 2.72 % and 0.64 %, respectively. Although the MLR and ANN can both be applied to predict the heat capacity, ANN algorithm has better performance.

Keywords: Quantitative structure-property relationship (QSPR), Ionic liquids (ILs), Heat capacity.

1. Introduction

Ionic liquids (ILs) are considered as an important family of "green" solvent which have attracted much attention for their remarkable properties, such as negligible vapor pressure, thermal and electrochemical stability, non-inflammability and tunable property (Rogers and Seddon, 2003). All these characteristics make ILs promising options for the use in the chemical processes including catalytic synthesis, extraction separation, electrochemistry, etc (Zhang et al, 2012). However, there are too many possible combinations of ions to create easily useful ILs, thus measuring the properties of various ILs under a wide range of conditions through experimental techniques is impractical and costly due to these large amount of ILs. Therefore, it was essential to develop new model to predict the properties of ILs.

The heat capacity is one of the basic thermodynamic and thermophysical properties of ILs (Gardas and Coutinho, 2008), which is generally used in the process of chemical thermodynamics, and is also the indispensable parameter in the process of design and research of petroleum and chemical industry. Due to the new or required certain compound heat capacity cannot be detected from the manual of chemical thermodynamics. In addition, the different experimental conditions and equipment are also resulted in the uncertainty of measurement (Shi et al, 2013). Thereby, it is necessary to predict the heat capacity of ILs through various accurate predictive tools.

Quantitative structure-property relationship method (QSPR) provides a solution to this problem. QSPR is an effective approach to connect physical or chemical properties to a set of molecular descriptors related to the molecular structure. After a QSPR model is developed, it is not only capable of estimating the property of one compound or

screening the compound with the desired property, but is also capable of uncovering the underlying relationship between macro-property and micro-structure (Zhao et al, 2012). $S_{\sigma\text{-profile}}$ is an a priori quantum-chemical parameter that quantitatively represents the molecule's polar surface screen charge on the polarity scale, and can be obtained from the histogram function σ-profile given by COSMO-RS computation. It has been used effectively as a parameter of QSPR models to predict the density (Palomar et al, 2007) and toxicity (Torrecilla et al, 2010) of ILs. However, to the best of our knowledge, it has not been utilized to predict the heat capacity of ILs.

In order to progress in predicting heat capacity of ILs, the first aim of this work is to collect a large amount of heat capacity data. Secondly, the multiple linear regression (MLR) and artificial neural network (ANN) algorithms are utilized to construct the linear and nonlinear QSPR models for predicting the heat capacity of ILs from the $S_{\sigma\text{-profile}}$ descriptors. In this study, the characteristic parameters that have great impact on the heat capacity of ILs were screened, and the performances of the obtained models were investigated and compared.

2. Data and methods

2.1. Heat capacity data points and $S_{\sigma\text{-profile}}$ of ILs

In the present study, all experimental data points were taken from IL Thermo Database (IL Thermo, 2010). A total of 2416 experimental heat capacity data values of 46 ILs were investigated. The collected heat capacity data points (254.0-1805.7 J mol^{-1} K^{-1}) cover a wide range of temperature (223.1-663 K). To develop a reliable model, all the selected experimental data points are divided into a training set of 1933 data points to develop the models and a test set of the remained 483 data points to verify its prediction performance. Each category (nearly 80 % of the data as training set, 20 % as test set) of the total data points is separated at random.

$S_{\sigma\text{-profile}}$ represents molecule surface area of surface screening charge density, which is a priori two-dimensional quantum-chemical parameter to characterize electronic stucture and molecular size of ILs. The deatailed introduction of the $S_{\sigma\text{-profile}}$ can be found elsewhere (Torrecilla et al, 2010). All the $S_{\sigma\text{-profile}}$ of ILs in this study are taken from the COSMO IL database, which were calculated in terms of the BP-TZVP quantum chemical level (Eckert and Klamt, 2013).

2.2. Artificial neural network (ANN) algorithm

ANN is a flexible method that can model the nonlinear behavior of properties through learning processes emulated the functioning of a human brain (Huang et al, 2014). More detailed introduction of the ANN theoretical basis can be referred in elsewhere (Gasteiger and Zupan, 1993). The ANN employed in this study is a multilayer perceptron (MLP) neural network, which usually consists of three layers (topology of ANN), including input, hidden, and output layers, respectively.

2.3. Evaluation of the model performance

Model performance can be measured by different metrics. R^2, which gives the fraction of explained variance for an analyzed set, is used to measure the model's fit performance. Average absolute relative deviation (AARD) is used to evaluate the model's predictive effectiveness, as shown by the following equation:

$$\text{AARD (\%)} = 100 \times \sum_{i=1}^{N_p} \left| \frac{y_i^{cal} - y_i^{exp}}{y_i^{exp}} \right| / N_p \qquad (1)$$

where y_i^{cal} is the desired output (experimental property), y_i^{exp} is the actual output of the models, and N_P is the number of compounds in the analyzed set.

3. Results and discussion

3.1. Results of MLR model

Based on the collected ILs heat capacity data points, the MLR Eq.(2) is established by using stepwise regression algorithm:

$$C_P = 1.454M - 3142.507S_{A\text{-}0.011} + 0.394T + 4.477S_{C\text{-}0.003} + 6.490S_{A0.016} - 7.862S_{A0.018} - 192.002 \quad (2)$$

(n=1933, R^2=0.985, AARD=2.58 %)

where C_p stands for the heat capacity of ILs, S represents molecular suface area with a specific surface screening charge density, subscript A is anion, C is cation, and the numerical value after A or C represents surface screening charge density of ILs. T and M are the temperature and molecular weight respectively. As shown in Table 1, all of the linear correlation coefficient of any two descriptors is less than 0.8, which means that there is no strong linear relation between the descriptors. It is observed that all the descriptors contained in the MLR model have physical meaning, and these descriptors can account for structural features affecting the heat capacity of the ILs studied.

Table 1. Correlation matrix of six descriptors

	M	$S_{A\text{-}0.011}$	T	$S_{C\text{-}0.003}$	$S_{A0.016}$	$S_{A0.018}$
M	1					
$S_{A\text{-}0.011}$	0.495	1				
T	0.111	0.305	1			
$S_{C\text{-}0.003}$	0.786	0.043	0.022	1		
$S_{A0.016}$	0.073	0.138	0.199	0.076	1	
$S_{A0.018}$	0.071	0.093	0.104	0.398	0.363	1

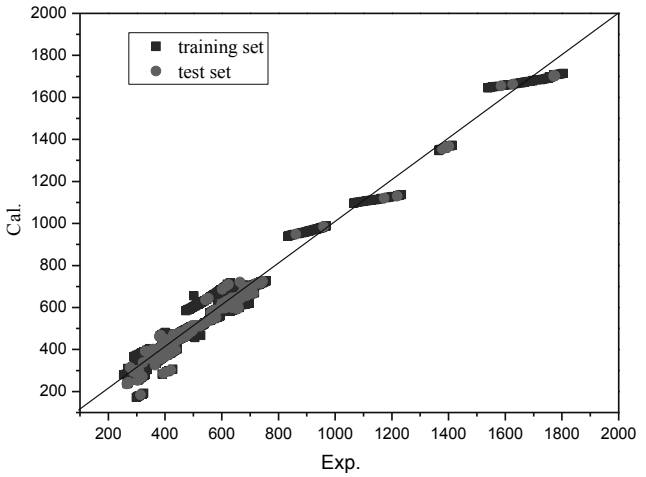

Figure 1. Calculated versus experimental heat capacity values using the MLR algorithm

In Eq.(2), positive sign in front of a parameter suggests positive correlation between the parameter and ILs heat capacity, and negative sign stands for negative correlation. The structure descriptors in Eq.(2) have been arranged in the descending order of t-test values so that the most improtant one comes firsy.
Eq.(2) with R^2=0.985, which is established by 1933 data points could be useful for predicting the heat capacity of ILs. As can be seen from Figure 1, most of the data points of heat capacity are near by diagonal line, and it can be observed from Figure 2 that relative deviation of most substances are within 20 %, and the AARD of the whole data set is 2.72 % (Table 2), so the MLR model can be used to predict the heat capacity of ILs.

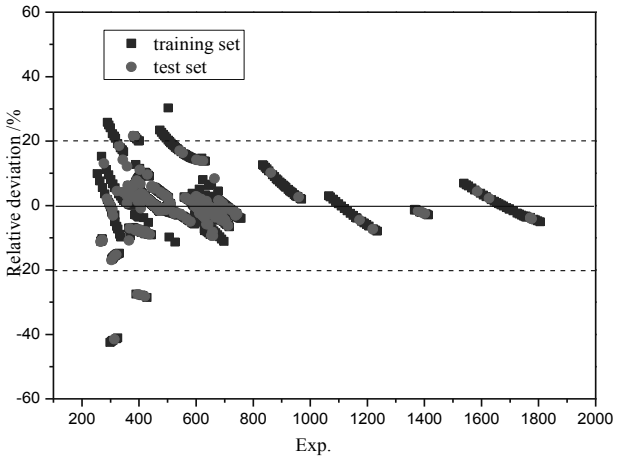

Figure 2. Relative deviation of the MLR algorithm

3.2. Results of ANN model and comparison

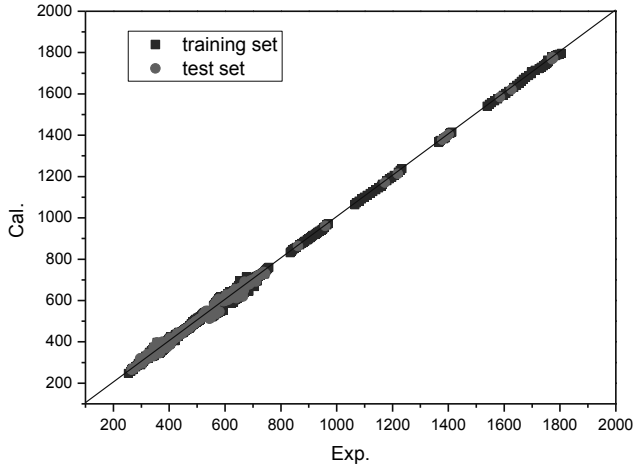

Figure 3. Calculated versus experimental heat capacity values using the ANN algorithm

The same descriptors applied by the MLR algorithm were utilized as the input parameters to develop an accurate nonlinear model by the ANN. To get the optimal model, 1933 data points are used as the training set to construct the model, 483 data

points are carried out as the test set to monitor the quality of the generalization performance of the ANN model. When the number of neurons is 10, the overall MSE is the least, and the R^2 is the largest, so we can determine that the optimized network structure is 6-10-1.The plot of predicted in comparison with experimental heat capcacity values for each data set are recorded in Figure 3. The statistical parameter R^2 for the training, test, and whole sets are 0.999, 0.998, and 0.999 respectively. Relative deviations of the predicted heat capacity values versus experimental data are depicted in Figure 4. It is seen that the relative deviation of the most of data points is within 5 %, and the overall AARD of all the data points is only 0.64, which explains that the model has good results.

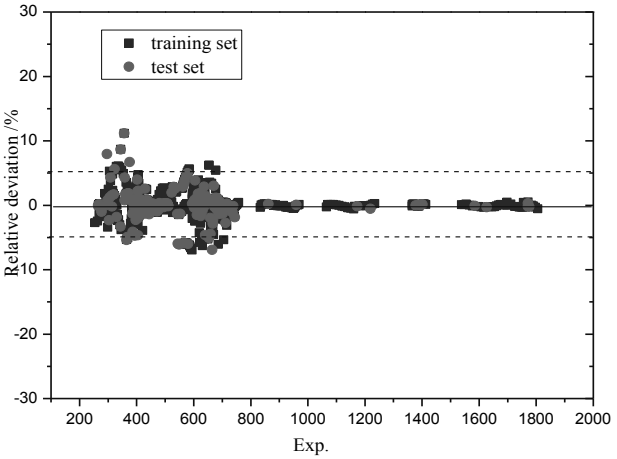

Figure 4. Relative deviation of the ANN algorithm

A summary of the performance of the MLR and ANN models for the all the data set is given in Table 2. In general, judging by R^2 and AARD, although the MLR and ANN can both be used to predict the heat capacity, ANN algorithm has better performance, for example, the R^2 of the training set, test set and the whole set of ANN model is bigger than the R^2 of the MLR model, and the AARD of the ANN model is less than the MLR model. Therefore, the ANN algorithm can be better used to predict the heat capacity of ILs.

Table 2. Comparison of the statistical parameters by MLR and ANN algorithms

Algorithms	Data set	No.	R^2	AARD %
MLR	Training	1933	0.985	2.58
	Test	483	0.984	2.88
	Total	2416	0.985	2.72
ANN	Training	1933	0.999	0.61
	Test	483	0.998	0.76
	Total	2416	0.999	0.64

4. Conclusions

In this work, two novel QSPR models for heat capacity estimation using 2416 experimental data points of 46 ILs were developed based on the $S_{\sigma\text{-profile}}$ descriptor calculated by COSMO-RS method. The AARD and R^2 of the whole data set by MLR and ANN algorithms are 2.72 %, 0.64 % and 0.985, 0.999, respectively. The results

show that both the linear (MLR) and nonlinear (ANN) models can provide acceptable results. Comparatively, the models developed by the ANN algorithm gives a higer R^2 and lower AARD, thereby the ANN model has better performance than MLR model. Furthermore, since the heat capacity is the function of $S_{\sigma\text{-profile}}$ of ILs, the presented derived models can provide some insight into what structural features are connected with the heat capacity of ILs.

Abstract

Dynamic behaviour, control and design strategies for liquid extraction equipment are faced by the complex hydrodynamic behavior of the dispersed phase with many droplet interactions (e.g. breakage and coalescence). To take this into account, the population balance modelling framework is used by implementing the bivariate OPOSPM (One Primary and One Secondary Particle Method) with a one-dimensional finite volume method in the physical space. To narrow the gap between the steady state and dynamic design during process synthesis, OPOSPM is implemented in a MATLAB/Simulink flowsheeting environment. As an outcome of this, we present a new OPOSPM-MATLAB/Simulink module which is called OPOSSIM for modeling and simulation the coupled two-phase flow and mass transfer in a Kuhni liquid extraction column.

Keywords: Population balances, OPOSPM, OPOSSIM, Liquid-extraction.

1. Introduction

Liquid extraction columns are multiphase equipment with wide applications in the petrochemical, pharmaceutical, biochemical industries, hydrometallurgy, nuclear technology and wastewater treatment (Kislik, 2012). The key physical phenomena, which take place in such equipment including momentum, mass and energy transfer, require an accurate estimation of the interfacial area concentration. Therefore, the design and operation of these two-phase equipment are dependent on the adequate modelling of these transport phenomena (Mohanty, 2000). In liquid extraction columns, one of the phases is dispersed in a continuous environment which results in a population of droplets that may undergo breakage, coalescence, and growth (Attarakih et al., 2013). The lumped modelling approach (e.g. mixture models), which could not take into account these instantaneous discrete events, is generally not accurate from dynamic and steady state point of views, where coupled hydrodynamics and mass transfer take place. On the other hand, using the multi-fluid models based on direct discretization of the population balances to include droplet-droplet interactions were proved to be computationally expensive when detailed column geometry is concerned in CFD simulations (Drumm et al., 2010). For example, Drumm et al., (2010) used FLUENT software to simulate an RDC column DN 150 with 50 compartments, where 178 hours were needed to perform 4000 computational steps with 0.05 s step size using 1.5 GHz single core processor. Therefore, due to this computational cost and

mathematical complexity of the detailed population balance modelling, they had not been utilized in control system design and computer-aided flowsheeting. In this regard, Wachs et al (1997) developed an empirical Simulink module for controlling a Kar liquid extraction column followed by the work of Weinstein et al. (1998) who derived a nonlinear dynamic model for both Kar and Kuhni extraction columns based on the dispersed phase mean droplet diameter and neglecting droplet-droplet interactions. Mjalli (2005) derived and implemented a non-equilibrium backflow mixing cell model with no droplet interactions to control the product composition in Scheibel extraction column. Goryunov and Mikhaylov (2012) implemented a simplified non-equilibrium dynamic model and automatic control system using MATLAB/Simulink package. Therefore, the need for a an efficient population balance model is obvious and will be described in section 2. This contribution extends the work of Attarakih et al. (2013) where its implementation and validation in SIMULINK are described in detail.

2. Droplet hydrodynamics and mass transfer using OPOSPM

OPOSPM for droplet hydrodynamics is derived from the Sectional Quadrature Method Of Moments (Attarakih et al., 2013), where the whole distribution function is collapsed into one particle. This particle has four attributes: Number concentration (N), volume fraction (α_y), position (d_{30}) and concentration (C_y) along the particle property spaces (size & concentration respectively). These equations of the state variables $\{N, \alpha_y, C_y\}$ describe the evolution of the dispersed phase droplets which move with velocity ($\langle u_y \rangle$) at a given time t, in a spatial space ($\mathbf{r}$) and along droplet property space $\{d_{30}, C_y\}$. These equations are given in a vector form as follows (Attarakih et al., 2013):

$$\frac{\partial \mathbf{U}}{\partial t} + \nabla \bullet \left(\langle u_y \rangle \mathbf{U} - \langle D_y \rangle \nabla \mathbf{U} \right) = \mathbf{U}^{in} \delta(\mathbf{r} - \mathbf{r}_y) + \mathbf{S} \tag{1}$$

In Eq.(1), $\langle u_y \rangle$ is the mean droplet velocity which is function of a pre-defined mean droplet diameter and is defined as $\langle u_y \rangle = j_x / (1 - \alpha_y) + \mathbf{u}_r$, where j_x is the superficial velocity of the continuous phase and $\mathbf{u}_r$ is the relative velocity of the droplets which is given by (Attarakih et al., 2013):

$$\mathbf{u}_r = \frac{g(\rho_x - \rho_y) {d_{30}}^2}{18 \mu_x} \left(\frac{24}{C_D \, \mathrm{Re}} \right) \tag{2}$$

In the above equation, C_D is the drag coefficient that is function of the mixture Reynolds number (Re) and could be found using suitable correlation, μ and ρ are the density and viscosity of the respective phases. $\langle D_y \rangle$ is the mean axial dispersion coefficient , $\mathbf{U} = [N \; \alpha_y]$, $\delta(\mathbf{r}\text{-}\mathbf{r}_y)$ is the Dirac delta function specified at the dispersed phase inlet ($\mathbf{r}_y$), $\mathbf{U}^{in} = [u_y / \langle v_y \rangle \; u_y]^{in}$, (where $\langle v \rangle$ is the mean volume of inlet droplets, u_y is the superficial dispersed phase velocity) and the source term ($\mathbf{S}$) is given by (Attarakih et al., 2013):

$$\mathbf{S} = \begin{pmatrix} (\upsilon(d_{30}) - 1) \Gamma(d_{30}, C_y) N - \frac{1}{2} \omega(d_{30}, d_{30}, C_y) N^2 \\ G(d_{30}) N \end{pmatrix} \tag{3}$$

In Eq.(3), υ is the mean number of daughter droplets formed upon breakage at a frequency Γ, ω is the droplet coalescence frequency and G is the particle growth rate due to solute transfer which approaches zero at thermodynamic equilibrium.

The transport equations which describes the solute transport in both phases (x) and (y) are given by (Attarakih et al., 2013):

$$\frac{\partial}{\partial t}\begin{pmatrix} X \\ Y \end{pmatrix} + \nabla \bullet \begin{pmatrix} -\langle u_x \rangle X - D_x \nabla X \\ \langle u_y \rangle Y - D_y \nabla Y \end{pmatrix} = \begin{pmatrix} u_x c_x \delta(\mathbf{r} - \mathbf{r}_x) \\ u_y c_y \delta(\mathbf{r} - \mathbf{r}_y) \end{pmatrix}^{in} + \frac{6K_{oy}(d_{30}, C_y)}{d_{30}} \left(m' X - Y\right) \begin{pmatrix} +1 \\ -1 \end{pmatrix} \quad (4)$$

Where $X = \alpha_x C_x$, $Y = \alpha_y C_y$, K_{oy} is the overall mass transfer coefficient which depends on the individual film mass transfer coefficients in both phases using the two-resistance film theory (Attarakih et al, 2013). The mean droplet diameter d_{30} is related to the dispersed phase volume fraction and number concentration as $d_{30} = [(6/\pi)N/\alpha_y]^{1/3}$ and (m') is related to the distribution coefficient (m) Through $m' = \alpha_y/\alpha_x m$.

3. OPOSPM SIMULINK/MATLAB implementation

The system of Eqs.(1-4) and the other constitutive relations (droplet interaction functions, droplet rise velocity, individual mass transfer coefficients) were discretized using a first-order upwind scheme with flux vector splitting (Attarakih et al., 2013) and then converted to a set of ODEs. The size of this ODE system is equal to $4 \times n$ (n is number of numerical cells along the column height) which is classified as a stiff system. This is because each droplet has its own time scale inside the column. As a result, the diffusional mass transfer process takes longer time to reach steady state than that of droplet hydrodynamics (Attarakih et al., 2013). These different time scales call for a special ODE stiff solver to ensure numerical stability such as MATLAB/SIMULINK ode15s and ode23tb, where ode23tb could be more efficient than ode15s if high accuracy of dynamic solution is not needed. The structure of the algorithm is shown in detail in Figure (1), where the dashed boundaries represent the time loop, while the continuous ones represent the flow of information in one direction. The algorithm is self-explanatory which is implemented using SIMULINK and MATLAB GUI. This is referred to as OPOSSIM (OPOS SIMULINK) module. The OPOSSIM is shown in Fig.(2) which consists of three main sections: The input section, the implementation section, and the output section. These sections allows the user to define and model the Kuhni extraction column in terms of geometry, operating conditions, chemical system, hydrodynamic parameters and correlations and numerical inputs. OPOSSIM can be utilized at two levels: Steady state and dynamic simulation where different step changes can be introduced in inlet flow rates, concentration and rotor speed. The results are viewed using SIMULINK scopes or using standard MATLAB graphical output.

4. Numerical results and discussion

4.1. Steady state analytical and experimental validation

In this section, OPOSSIM is validated analytically using 1D CFD-PBM model which is implemented in PPBLAB software with a detailed bivariate population balances for different agitated columns including the Kuhni column (Attarakih et al., 2012). In this case study a DN32 Kuhni column (with total height of 1.53 m and 40 compartments) is simulated. The chemical system is toluene-acetone-water with total throughput 14 $m^3/m^2/h$ and 200 rpm rotor speed. More details about this case study and the used mass transfer models (oscillation droplet model) can be found in Hlawitschka (2013). The second analytical validation for the same case study is the implementation of bivariate OPOSPM in a 3D CFD OPENFOAM module to simulate the coupled hydrodynamics and mass transfer (Hlawitschka, 2013). Figure (3) shows a full comparison of the three

software predictions of the acetone concentration profiles in the Kuhni column at steady state along with the experimental data which was measured by Hlawitschka (2013).

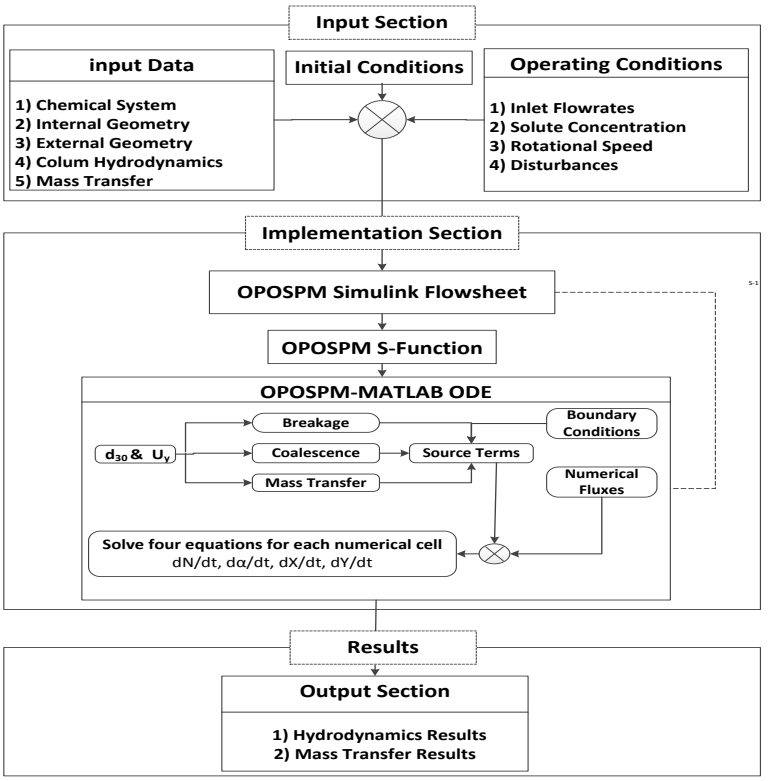

Figure (1): Algorithm structure of OPOSSIM Module for Kuhni extraction column.

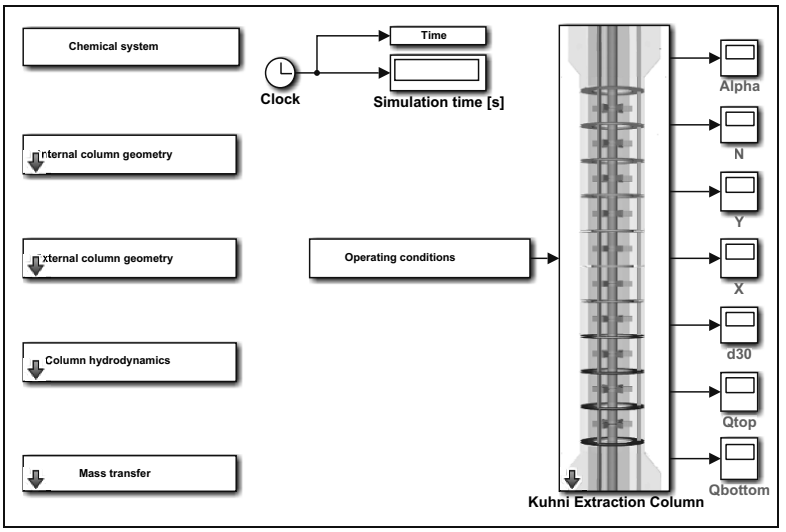

Figure (2): Structure of OPOSSIM Module which is implemented using SIMULINK/MATLAB.

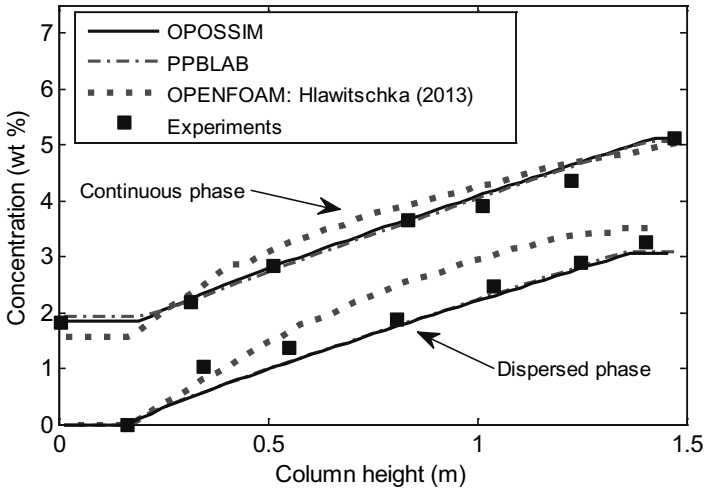

Figure (3): Comparison between the simulated acetone mass fraction profiles in both phases using three different software: OPOSSIM, PPBLAB and CFD (OPENFOAM), and experimental data (Hlawitschka, 2013) along the column height using the chemical system toluene-acetone-water with mass transfer direction is from C→D.

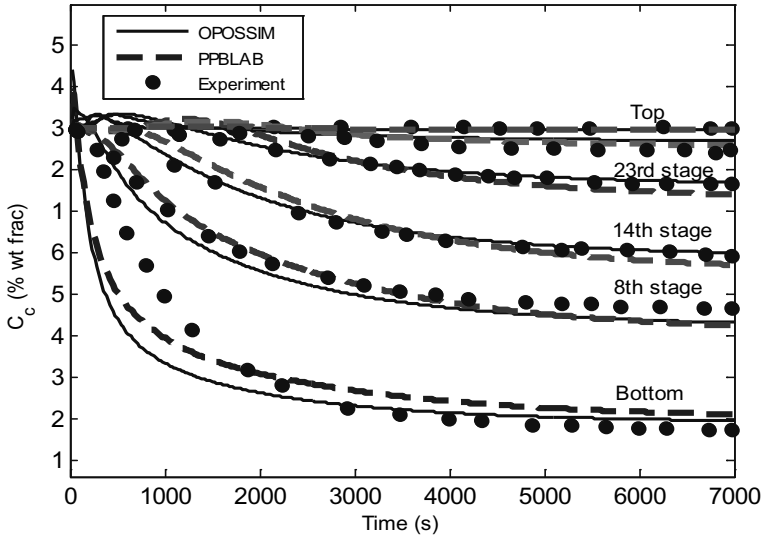

Figure (4): Comparison between the simulated solute mass fraction in the continuous phase using the OPOSSIM and PPBLAB software and the experimental data (Zamponi, 1996) due to positive step change in the dispersed phase inlet flow rate from 0 to 160 liter/h at t = 0. Q_x = 125 *l*/h, Q_y = 160 *l*/h, C_x = 4.5 % , C_y = 0, rotor speed 160 rpm direction and mass transfer C → D.

The results shown in Figure (3) are very impressive as OPOSPM (which is a reduced PBM) predicts in an excellent way the solute concentration profiles of PPBLAB software and the experimental data as well. The 3D Simulations compare well with the continuous phase solute concentration, while the deviation is relatively large when the dispersed phase is considered. The simulation times are in order of seconds using, minuets and weeks for OPOSSIM, PPBLAB and OPENFOAM respectively. Therefore, the advantages of OPOSSIM are simplicity and efficiency as a 1D CFD Model.

4.2. Dynamic analytical and experimental validation

To further validate OPOSSIM during transient simulations of extraction columns and its ability to follow column scale up, mass transfer in Kuhni extraction column of DN150 and active height of 2.52 m with 36 compartment is used (Zamponi, 1996). The chemical system is toluene-acetone-water and the individual mass transfer coefficients are those for circulating droplets. Firstly, OPOSSIM is compared to the detailed model of PPBLAB software to predict the dynamic behaviour of the acetone concentration in the continuous phase. This is due to the start-up of the column where it was initially at steady state with 4.5 percent acetone in the continuous phase which flows at 125 *l*/h and the stirrer speed is 160 rpm . At $t = 0$, the solute-free dispersed phase was introduced at the bottom of the column with a flow rate of 160 *l*/h.

As shown in Figure (4) OPOSPM follows well the dynamic behaviour of the acetone concentration where most of acetone was removed in the first 23 stages measured from the bottom. The predictions of the transient acetone concentration by the two models (OPOSSIM and PPBLAB) are comparable when compared to the experimental data of Zamponi (1996) with slight improvement in favor of PPBLAB as a detailed population balance solver.

5. Summary and conclusions

The OPOSPM as a reduced population balance model is implemented in a new SIMULINK/MATLAB module which offers steady state and dynamic simulation of Kuhni extraction column. The OPOSSIM module was found to predict both steady state and dynamic behaviour of a Kuhni extraction column in the order of second CPU time. As a conclusion, the reduction of the PBM into OPOSPM did not lose much of the information contained in the detailed model. Hence, OPOSPM has been used in SIMULINK flowsheeting environment and CFD complex geometry as well.

Abstract

In the present study, a fluidization process in a fluidized bed crystallizer is examined using multiphase CFD-DEM (CFD: Computational Fluid Dynamics; DEM: Discrete Element Method) simulations. The simulations were carried out using the coupled open source software CFDEMcoupling. After validating the simulation results with first experimental measurements, have been used for process understanding and improvement. In particular, regions with complex flow features but important for process outcome have been identified within the crystallizer. Moreover the simulations delivered valuable information that are difficult or even impossible to measure experimentally with sufficient accuracy.

Keywords: CFD-DEM, fluidized bed, crystallization reactor

1. Introduction

Liquid/solid fluidized beds are important in the chemical, pharmaceutical and food industry. Contrary to solid-gas fluidized beds, studies pertaining to solid-liquid fluidization are rare in the scientific literature. For this reason a fluidization process in a fluidized bed crystallizer is examined in this study.

The fluidized bed crystallizer is the main component of a complex innovative reactor concept developed for the continuous separation and crystallization of enantiomers, as examined by Lorenz and Seidel-Morgenstern (2014). Enantiomers are chemical molecules that spatially behave like mirror images of each other. A mixture of enantiomers is separated by selective crystallization in the fluidized bed crystallizer. By controlling reactor parameters, small starter crystals can be added continuously, and grown crystals (with the desired final diameter) are discharged continuously from the fluidized bed. The flow conditions in the fluidized bed crystallizer affect the fluidization process significantly. A model for the simulation of the fluidization process has been developed by Mangold et al. (2014). To investigate the flow conditions detailed, CFD-DEM simulation were used in this study.

Coupled CFD-DEM simulations (CFD: Computational Fluid Dynamics; DEM: Discrete Element Method) constitute relatively new methods, for the simulation of multiphase flows. CFD-DEM calculations are so-called four-way coupling methods, which means that 1) the particles can collide with each other and with the reactor walls, 2) the fluid (continuous phase) influences the particles, 3) particle disturbance of the fluid locally affects another particle's motion (an effect known as particle swarm), and 4) the particles have an influence on the fluid flow. The strong advantage of CFD-DEM-simulations toward other multiphase models, e.g., Discrete Phase Simulations (DPM) is that particle-particle-interactions are directly taken into account, and the flow modifications taking place in dense, which is examined by Ashraf Ali et al. (2014). In the studied fluidized bed crystallization reactor, these interactions have an impact, as the solid volume fraction is high in the examined crystallizer.

At first the employed CFD-DEM model is briefly described. Next, details of the applied simulation models are given. Thanks to the coupled simulation, areas with complex features but important for process outcome have been detected in the crystallizer. In order to validate the simulation results with experimental results, the fluidization process was performed with colored, equal-sized glass beads instead of heterogeneous crystals. Finally, CFD-DEM simulations provided valuable information for the process, such as fluidization limits, mean particle velocities and crystal pathlines. Experimental results are not in agreement with simulations. Possible reasons for this behavior are provided. Further model improvements are currently being implemented.

2. Model

In this section the computational details of the CFD-DEM simulation is briefly described. Further details can be found, e.g., in Goniva et al. (2012).

DEM - The physical particles are mathematically approximated as spheres. The particle motion is based on the Lagrangian approach, which means that each trajectory is solved explicitly. The basis for computing the translational and angular accelerations of each particle are the corresponding momentum balances. Summing up all forces acting on a particle, one obtains:

$$F_{total} = F_n + F_t + F_f + F_b \tag{1}$$

where F_n is the normal force associated to repulsion between the particles, F_t is the tangential contact force that depicts the elastic tangential deformation of the particle surfaces and the energy dissipation of the tangential contact, F_f is the force that the fluid exerts on the particles and F_b is the body force that encompasses gravity, as well as possible electrostatic and magnetic forces.

CFD-DEM - To describe the movement of an incompressible fluid with particles, the Navier-Stokes equations can be used in a modified form:

$$\frac{\partial(\varrho_f \alpha_f)}{\partial t} + \nabla \cdot (\varrho_f \alpha_f u_f) = 0 \tag{2}$$

$$\frac{\partial(\varrho_f \alpha_f u_f)}{\partial t} + \nabla \cdot (\varrho_f \alpha_f u_f) = -\alpha_f \nabla p + R_{f,p} + \nabla \cdot \partial(\varrho_f \tau_f) \tag{3}$$

where α_f represents the volume fraction occupied by the fluid, ρ_f the density, t the time, v_f the velocity, p the pressure, τ_f the stress tensor and $R_{f,p}$ the momentum exchange between fluid and particles.

In practice, where very many particles are simulated (as in the present case), a so-called non-resolved approach is used. In this case the particles are smaller than the computational grid. Consequently the particles are not resolved in the CFD simulation. Only their interaction with the fluid phase (e.g. momentum exchange and resulting porosity) is considered in the calculations.

3. Computational Details

CFD-DEM simulations with a lot of particles require a high computational effort. Therefore, the application of powerful parallel computers is absolutely necessary. In this work, a complete three-dimensional model of the fluidized bed crystallizer was simulated using an in-house Linux cluster.

CFD simulation - CFD simulations provide valuable information about the flow conditions in the crystallizer geometry. Therefore, in a first step a pure CFD simulation was carried out using the open source software OpenFOAM without considering the particles. The complete three-dimensional geometry of the fluidized bed crystallizer and the applied block-structured computational mesh are illustrated in figure 1. The fluid is considered as incompressible (water) and the flow is completely laminar, since the maximum Reynolds number is 1710, as found at the smallest cross-section, near the inlet. For the CFD simulation the transient solver pisoFoam was used. The solver uses PISO algorithm (Pressure Implicit with Splitting of Operator) and is the only CFD solver that is available in the coupled software (for DEM) so far.

Figure 1: Computational Grid

CFD-DEM simulation - The CFD-DEM simulations were performed using the coupled open source software CFDEM- coupling. The software CFDEMcoupling contains a solver that was developed by combining the C++-based open source software environments OpenFOAM (for CFD) and LIGGGHTS (for DEM). The solver carries out the fluid (CFD) and particle (DEM) calculations using two separate codes. The

interaction is realized by exchanging relevant information with a predefined time step. The simulation parameters for the CFD-DEM simulation are shown in Table 1.

Number of cells	40,000
CFD time step	10 µs
Kinematic viscosity	$1 \cdot 10^{-6} \frac{m^2}{s}$
Relative pressure at outlet	0 Pa
Inlet velocity	$0.15 \frac{m}{s}$
Velocity at wall	$0 \frac{m}{s}$
DEM time step	1 µs
Coupling interval	10 µs
Number of particles	100,000 (real: about 1,500,000
Total physical simulation time	30 s

Table1: CFD-DEM simulation parameters. The simulation was performed on a grid with 40,000 cells. Simulations on a finer grid (400,000 cells) showed no significant changes for both, the fluid and the solid phase. The time after that the fluidized bed height has reached a quasi-steady state is 30 s (end of the simulation). During the entire physical simulation time no particles are discharged from the crystallizer. The simulation of particle growth is principally possible in the DEM. However it becomes more difficult to validate the model, so that experiments and simulations are carried out without crystal growth here.

4. Results

Geometrically difficult areas of the reactor - The velocity magnitudes determined by CFD are shown in Figure 2 (a). The figure shows the crystallizer in a section plane in the center of the reactor at a physical time of 30 s (end of simulation). The highest velocities are found at the reactor inlet and outlet. The lowest flow rates are at the product outlet nozzles at the side of the reactor. The velocity distribution agrees well with the results expected from the continuity equation, stating that magnitude of velocity decreases with increasing cross-sectional area.

In order to experimentally estimate the fluidization process in the fluidized bed crystallization reactor, experiments were also performed with colored, equal-sized glass beads instead of heterogeneous crystals. A comparison between experimental data and CFD-DEM solutions first showed a noticeable difference concerning the fluidized bed height. After analyzing the computed velocity field, it was found that the product outlet nozzles are associated to complex flow features in the crystallizer.

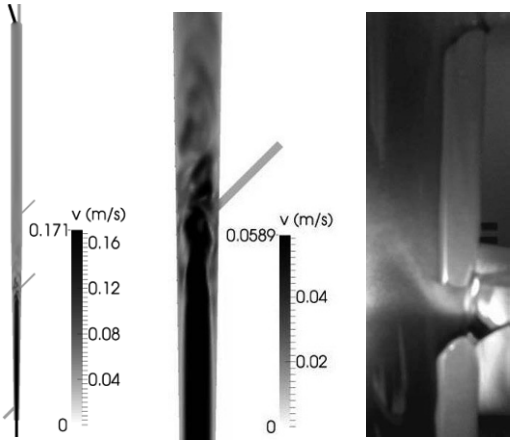

Figure 2: (a) - velocity field in a section plane in the center of the crystallizer at 30 s, (b) - velocity field of the crystallizer without product outlet nozzle (left) and with product outlet nozzle (right), (c) - experiment with fluidized glass beads.

Figure 2 (b) shows the velocity magnitudes near the lower product outlet nozzle. Figure 2 (c) shows a close-up view of an outlet nozzle during an experiment with glass beads. The product outlet nozzles are closed during the process and act as a sudden change in flow cross-section. In agreement with the continuity equation lower velocities are found at these areas. Additionally, disturbances like separation bubbles and recirculation zones are found near the nozzles. This leads to a significant change in the fluidized bed height. For further comparisons, the outlet nozzles will be sealed in such a manner that such effects are avoided, leading to a smooth evolution of flow cross-section. Nevertheless, these first comparisons have demonstrated that detailed flow simulations are a valuable tool for the identification of complex flow areas in the fluidized bed crystallizator.

CFD-DEM simulation of the fluidized bed crystallizer - The starting point of the CFD-DEM simulation in the fluidized bed crystallizer with 100,000 particles is shown in figure 3 (a). CFD-DEM simulations and experiments were performed again with glass beads. This time, glass beads with two different colors and sizes (d_{purple} = 175 µm; d_{orange} = 108 µm) were used. Figure 3 (b) shows the simulation after a physical time of 30 s. Figure 3 (c) shows the experiment for glass beads with different sizes and colors.

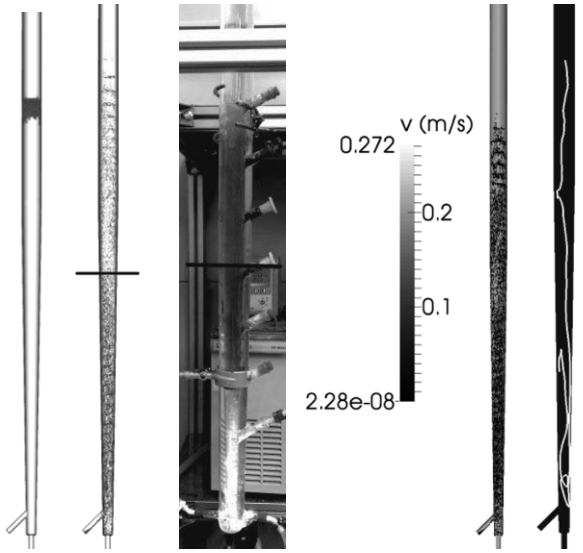

Figure 3: (a) - Initial conditions of the simulation in the fluidized bed crystallizer, (b) - CFD-DEM simulation with 100,000 particles after a physical time of 30 s, (c) - experiment with different sized and colored glass beads, (d) - section plane in the center of the crystallizer with particles colored by velocity, (e) - pathline of an arbitrarily selected particle.

A comparison between figures 3 (b) and 3 (c) shows qualitatively a good agree-ment. The separation process of large and small particles takes place in a similar manner in both figures. The 'separation line' that separates orange and purple particles is marked in both figures. Figure 3 (d) depicts the crystallizer with particles colored by velocity in a section plane in the center of the geometry. The mean particle velocity is an important information for the process. From the simulations, a mean particle velocity of 1.34 cm/s could be determined. Simultaneously, the pathlines of the particles are obtained from the CFD-DEM simulations, as exemplified in Figure 3 (e).

Comparison with experimental data - To validate further the CFD-DEM simulations, experimental measurements were carried out by means of a camera (Canon EOS 600D). The camera is focused on the crystallizer at a height of 54 cm (from the bottom of the crystallizer). By image analysis, the proportion of orange and purple pixels was

determined. In this way it is possible to compare the proportion of orange and purple particles in the crystallizer with the CFD-DEM simulation results. Table 2 compares the results. These first comparisons agree on the fact that orange particles strongly dominate at this location, but still show a noticeable difference between experiment and simulation. The proportion of purple pixels is higher in the experimental measurement. A reason might be that the particle-fluid porosity is higher in the experiment. If the flow rate is constant and more particles are found locally in the reactor, the cross-sectional area of the crystallizer is smaller and the local flow velocities increase (as a direct consequence of the continuity equation). Then the purple (heavy) particles reach higher speeds in the experiment and are located at a higher position in the reactor.

Table 2: Comparision of experiment and CFD-DEM simulation via pixel quantification.

	Experiment	CFD-DEM-Simulation
Proportion of orange pixels	93,49 %	99,31 %
Proportion of violet pixels	6,51 %	0.69 %

5. Conclusion

In this study a fluidized bed reactor was investigated using CFD-DEM simulations and companion experiments. For the computations, a high-resolution grid was generated. For the simulation of 100,000 particles in the crystallizer, 30 s of physical time were considered. First comparisons between experimental data and CFD-DEM results show that the product outlet nozzles lead to noticeable changes in the local flow structure due to sudden modifications of the flow cross-section, which must be avoided in future tests. Hence, the simulations were useful to identify critical regions in the crystallizer. Particle velocities, pathlines and particle discharge have been determined by CFD-DEM and are helpful for process analysis and improvement. Further comparisons between CFD-DEM simulations and camera measurements showed that the particles might reach even higher velocities in reality, which is perhaps a consequence of an underestimated porosity in the simulation. Such discrepancies have a direct influence on the bed height. The CFD-DEM simulations already provided interesting information for the process, and further model improvements are currently being implemented.

Abstract

Petrochemical and chemical complexes are so-called Systems of Systems (SoS) that consist of many subsystems that interact by exchanging energy, material and information. The individual plants or units are managed locally, by human managers and operators or by automatic algorithms, but the efficiency of the overall site depends on the coordinated use and generation of resources and on the balancing of various resource networks, e.g. for steam on different pressure levels, hydrogen, ethylene etc. Therefore global coordination is required, but the local autonomy has to be respected. Coordination of local optimization is currently an active research area. When solutions for site-wide coordination are developed, they have to be tested in faithful system-wide simulations. In this paper we present an innovative framework for modeling, simulation, and validation of large Systems of Systems that integrates physical plant models, local control and optimization algorithms, connecting networks and site-wide coordination algorithms. The framework is described and demonstrated on a coordination problem for an integrated petrochemical site.

Keywords: Site-wide management, coordination of chemical plants, modeling and simulation framework

1. Introduction

Industrial production sites consist of many production plants that are interconnected via networks for different materials and carriers of energy to enable the efficient use of material and energy, to avoid waste streams, and to achieve a cost-efficient production. While the operation of the individual plants is managed mostly locally, the optimization of global performance indicators (such as minimal energy and material consumption, or reductions in CO2 emissions) requires a site-wide strategy for demand-supply management.

Today, companies mostly rely on infrequent planning of production and consumption of the different units and interactive management of deviations in daily meetings or by phone, which leaves a significant potential for optimization due to the existence of many dynamic interactions within a site and with its environment (e.g. changes in production volumes, disturbances, start-ups, shut-downs, product changeovers, short-term variations of the cost of electricity). Automated, optimization-based site-wide management strategies are expected to significantly improve the operational efficiency of large production sites with independently operated units. This coordination has to be performed in a distributed and hierarchical fashion, making use of local automation and

optimization functionalities and respecting the management structures of the site. Such systems with local decision power and a need for global coordination are termed Systems of Systems. Model-based engineering is indispensable to guide and to validate the design of such large complex management and automation structures and requires the composition of site-wide models from modular descriptions of the different units on different levels of details and complexity.

In this paper, a new framework is presented that is tailored towards the modelling, simulation, and validation of such large Systems of Systems with decentralized management. The framework is based on the *Modelica* language for heterogeneous modelling (see e.g. Fritzson and Bunus (2002)), and aims at reducing the effort for model creation by providing standard interfaces for the connection of physical process model components of different levels of detail (both existing and newly developed models) as well as management algorithms. The plug-and-play approach facilitates the testing and validation of different management algorithms of an industrial site, and simplifies the integration of new management architectures into an existing system.

The applicability of the framework is illustrated on an example from the petrochemical industry. Petrochemical production sites are usually organized in business units which possess partial autonomy but the plants that are operated by the business units are strongly interconnected by streams of energy and material. The business units perform their local optimization of the production processes, but global coordination is needed to balance the utilization of the shared resources. The current practice for balancing of production and consumption of shared resources in petrochemical sites is through direct negotiation of the prices of the shared resources between the management of the different business units. One reason for this is the fact that different business units use different and often not compatible tools to perform the local optimization. The business units also often do not want to share sensitive information about their operation. The presented framework provides the user with the possibility to interface optimization solutions from different platforms in order to implement a cross platform coordination in an automated fashion without sharing details about plant operation. Also, the frameworks provides standard interfaces through external C functions to the most important control and optimization software tools which enables fast and easy integration.

The remainder of this paper is structured as follows: In section 2, an overview of the modelling, simulation, and validation framework is given, followed by a description of the industrial case study in section 3. Section 4 summarizes the results of the validation of the industrial case study within the framework, and finally section 5 draws conclusions and provides an outlook on future work.

2. The Modelling, Simulation, and Validation Framework

The proposed framework is based upon a modular and structured approach towards modeling, simulation and validation of large-scale complex system of systems with many interactions. The framework is implemented in the object-oriented, equation-based *Modelica* language which is specifically designed for heterogeneous modeling. *Modelica* includes libraries for a large variety of domains such as electronics, mechanics, thermodynamics, control, etc. which matches with our goal of providing a generic framework that can be applied to as many areas as possible.

However, the users of the framework are not restricted to use *Modelica* and are free to connect black box models either using co-simulation via the *Functional Mockup Interface/FMI* or using the *Modelica* option which allows calling external functions which are not written in *Modelica* but translated into C or Fortran. The external functions can be called from *Modelica* via a Dynamic Link Library of the exported functions.

As shown in figure 1, the framework represents each subsystem by four model components: the *design model* is a possibly simplified version of the subsystem model which can be used by a *local*

management and control algorithm in cases where a model-based optimization strategy is used in order to drive the subsystem towards an optimal operation with respect to a *local (optimization) problem formulation.*

After the required number of iterations with the design models, the result of the optimization algorithms can be validated using a set of *validation models*, detailed models that precisely represent the physical SoS. The black arrows on the right most part of the figure 1 represent the physical connections between the subsystems (flows of material or energy). For the implementation of such interfaces, the standard *Modelica* interfaces are used. Similar connections are realized between the design models. An optional *global coordination algorithm* is included which interacts with the local optimizers in cases where a system-wide coordination algorithm is implemented.

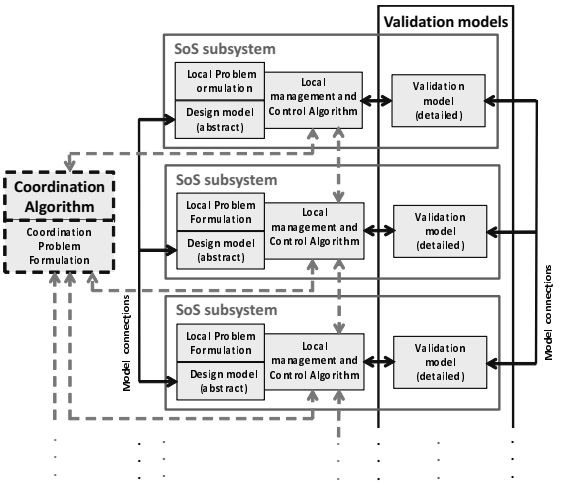

Figure 1: Structure of the modeling, simulation, and validation framework.

The framework offers generic interfaces for the implementation of interconnections between model components and validation components and optimization algorithms. All interfaces support time-discrete as well as event-driven communication. The interface between local management and optimization algorithms and validation models additionally supports time-continuous communication for situations where the local management system includes a low-level controller that is acting on the real plant.

In large-scale SoS, for which the modeling and simulation framework is designed, manual interconnection of the components requires considerable effort. Besides, full knowledge of the communicated variables is necessary. Worst of all, there is always a probability that errors are made. The framework therefore offers an automatic routine for generating the interconnections using a *Modelica* model generator. An XML configuration file which contains information on the parametrization of all the interfaces (i.e. the names, types, dimensions of the variables, the required frequency of information exchange, etc.) together with two repositories of white box and black box models are provided to the model generator. Using this information, the *Modelica* model generator verifies the structural correctness of the model components, generates the

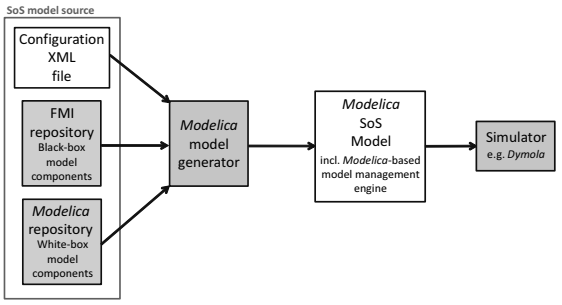

Figure 2: Workflow for the automatic generation and execution of the SoS.

required communication structure and adds the required model components. The work flow of such an automatic process is represented in figure 2.

All components must communicate via a *Modelica-based model management engine*. The model management engine requires the local management systems to define their parameters in the beginning of the simulation (i.e. either they support discrete-time or event-driven simulation, execution delays, the possibility of being triggered by other coordinators, etc.) and send data requests in order to obtain information from other management systems during the simulation. The data request contains (1) the ID of the target, (2) the ID of the requested variable, and (3) a specific index/indices of the requested variable if it is of type vector or matrix. The data request might be rejected by the model management engine in situations where triggering the operation of the target management system is not allowed according to the parameterization information which is provided to the model management engine in the beginning of the simulation. In addition, a publish/subscribe communication pattern between local and global optimizers is supported. For more details on the modeling, simulation and validation framework, please see Kampert et al. (2014).

The use of the framework is demonstrated below for the model of a petrochemical production complex where three different plants, a power plant, a cracker and an ammonia plant, are connected via networks of mass and energy.

3. Case Study: Price-based Coordination of an Integrated Petrochemical Site

We illustrate the applicability of the presented framework on a case study that was extracted from the coordination problem of a typical integrated petrochemical site. The case study comprises three plants that are interconnected by resource networks of steam of 5 and 30 bars, and hydrogen. Positive values of the utilization vector denote consumption and negative values denote production of the respective shared resource. In the example we consider four products: ethylene (*C2*) and propylene (*C3*) produced by the cracker and ammonia (*Am*) and ammonia water (*AW*) produced in the ammonia plant. A simple illustration of the case study with the shared resources streams is presented in Fig. 3.

The power plant produces electrical power, 5 and 30 bar steam and it is not connected to the hydrogen network. The manipulated variables in the power plant are the fuel gas input and the performance factor. The production of ethylene and propylene in the cracker is controlled by manipulating the naphtha feed, the severity and the 30 bar steam input. Additionally, the cracker produces hydrogen and 5 bar steam which are fed to the corresponding networks. The ammonia plant processes natural gas, hydrogen and 5 bar steam to produce ammonia, ammonia water and 30 bar steam which is fed to the network. The reader can refer to Stojanovski et al. (2015) for a detailed description of the case study.

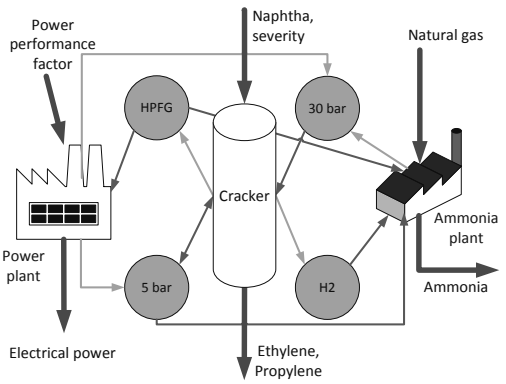

Figure 3: Example system

The coordinator initializes and updates the prices of the shared resources for all units. After the local optimizations have been performed for a given set of coordination variables (prices), the

coordinator evaluates the network balance based on the individual resource utilization vectors. If the shared resource networks are not balanced, the prices are updated by a factor proportional to the error using a weighting (gain) vector. Then, the prices are communicated to the sub-problems and the local optimization is performed again. In each iteration the prices converge towards the equilibrium prices and the difference between demand and supply decreases until the markets are cleared (Walker (1987)). The iterations are performed at each sampling time and the converged variables are then applied until the end of the next sampling interval. So the local optimizers may be queried many times at each sampling time. The formulation of the sub-problems and the price update method vary depending on the algorithm implemented, see (Stojanovski et al. (2015)).

4. Application Results

Recently, there has been much interest in the application of the coordination methods such as Alternating Direction Method of Multipliers (ADMM) on distributed problems due to their minimum communication requirements and good convergence properties (Liang (2014); Ye (2014); Kozma et al. (2014)). In this paper we use the proposed framework for the implementation of ADMM to coordinate the shared resource utilization in the integrated petrochemical site as described in Stojanovski et al. (2015). The local optimization problems for the power plant, cracker and ammonia plant are implemented in *Matlab* as stand alone optimization problems. The framework integrates the local optimization problems with the real plant simulated in *Dymola* using C-function calls through the generated DLLs and passes the necessary arguments to the coordinator. This example illustrates the ability of the framework to interface with any desired tool as long as the required dynamic/static C libraries are provided.

Figure 4 shows the changes in demands of ammonia, ethylene and propylene, the production of 5 bar and 30 bar steam, the transfer prices of the shared resources and the number of iterations needed for the coordination scheme to converge. The distributed optimization provides variable prices of the shared resources that reflect their marginal values at a given point in time due to the current product demands and prices for feedstock and energy.

A drawback of the coordination algorithms is the number of iterations needed to calculate a solution that balances the resource networks. The necessary number of iterations is strongly dependent on the tolerance, and for tight tolerances may rapidly increase. Large number of iterations require increased communication between different components in the framework which implies increased computational time. Nevertheless for this case study the computational time is sufficiently short to render a real time implementation feasible.

The proposed framework is not limited to a specific coordination approach for System of Systems and provides required interfaces and communication structure for other algorithms such as the ones presented in Ponce et al. (2014); Fele et al. (2014); Parise et al. (2015).

5. Conclusions & Outlook

The presented framework provides a plug-and-play solution to the simulation of large-scale system of systems with distributed management. The structured approach facilitates modifications of the model components which might occur due to changes in the local units, production planning, etc. Similarly, applying a new management algorithm can be done easily without having detailed knowledge about the complete SoS model. Last but not least, a less error-prone implementation of the communication structure is provided by the automatic model generation routine.

The applicability of the framework was demonstrated on a case study for price-based coordination for a subset of plants of an integrated petrochemical site. The initial results show that the proposed framework can be used to validate the incorporation of automated market mechanisms (and also

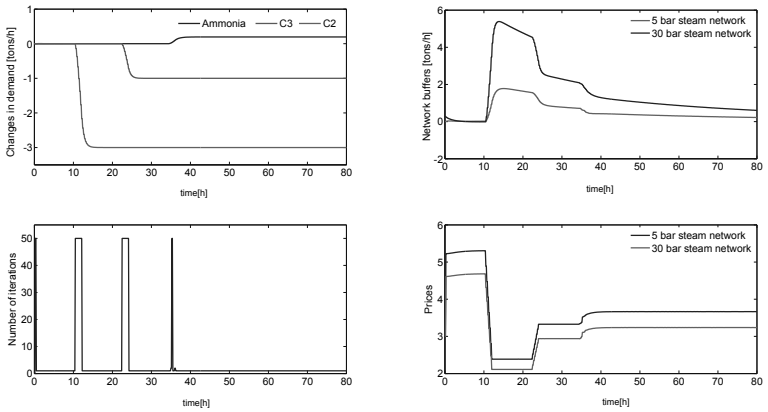

Figure 4: Changes in demands, steam network buffers, number of iterations and the transfer prices.

other coordination algorithms) in the real-time management of integrated plants. Moreover, the proposed architecture is coherent with current practice and supports the coordination of different optimization tools without revealing details of the optimization problems. The coordination algorithms can also be included as Functional Mock-up Units (FMUs) (this option is currently under development).

Abstract

Continuous increase in fuel prices driven by high energy demand and limited fossil fuel resources has been presently considered a major problem. Moreover, gas emissions from internal combustion engines lead to air pollution and global warming issues. Therefore, the development of clean, alternative energy is required in order to relieve the fossil fuel shortage and environmental impact. A biomass-to-liquid (BTL) process is recognized as a promising technology to convert biomass to liquid fuels. This study focused on the theoretical analysis of the BTL process consisting of a gasification unit for synthesis gas production and a Fischer-Tropsch (FT) unit as a downstream process for synthesis gas conversion to liquid fuels. Rice straw, one of the most biomass residuals found in Thailand, was considered a feedstock. The integrated model of the BTL process consisting of three major sections, i.e., the gasification based on the reaction kinetics of char gasification, the gas conditioning process including tar steam reforming and water gas shift reaction, and the FT synthesis was developed and used to investigate the influence of gasifying agents on the product distribution and the overall energy consumption. Two gasification systems using different gasifying agents, i.e., oxygen/steam and air/steam were considered and compared. The suitable conditions that provide the highest yield of a high-valued diesel product were identified.

Keywords: Gasification, Fischer-Tropsch process, Rice straw, Liquid fuel.

1. Introduction

Presently, an increase in fuel prices driven by high energy demand and limited fossil fuel resources has been considered a major problem. Moreover, gas emissions from combustion engines lead to air pollution and global warming issues. As the liquid transportation fuel plays an important role in human daily life. In the year 2012, around 28 % of the total world energy consumption was shared in the transportation sector (EIA, 2014). In Thailand, this sector represents about 35% of the total country energy consumption (DEDE, 2012). Therefore, the production of this fuel type from renewable energy sources in order to relieve the impact of fossil fuel shortage and environmental impact has been extensively attention.

Biomass is nowadays given closer attention due to its CO_2 neutral and environmental friendliness. In Thailand, rice is the second favorite agricultural product next to sugarcane, but it provides the highest amount of biomass residue (rice straw). In the

year 2010, 25.6 million tons of rice straw was approximately produced based on the rice production of 31.5 million tons (DEDE, 2012). As rice straw mainly contains carbon and hydrogen, therefore its conversion to energy is possible (Garivait et al., 2006). A biomass gasification and Fischer-Tropsch integrated process (BG-FT) is regarded as the promising technologies for producing green liquid fuels and this process is also known as a biomass to liquid (BTL) process (Omer, 2008).

Many previous studies on the gasification process have relied on a thermodynamic analysis (Sadhwani et al., 2013). However, the deviation between thermodynamic model-based prediction and actual behaviour of the gasification is generally observed due to its relatively low reaction rate. For the Fischer-Tropsch (FT) process, the Anderson-Schulz-Flory (ASF) distribution model (Hamelinck et al., 2004) is widely used for process design to predict a fraction of the FT product. In this study, the performance of the BG-FT process using rice straw as feedstock is investigated. The gasification model including tar formation and reaction kinetics of char reduction reactions and the FT synthesis model based on the ASF distribution are employed to analyze two gasification systems using different gasifying agents, i.e., oxygen/steam and air/steam. The syngas (H_2+CO) yield and H_2/CO of producer gas and the FT product distribution are considered. Optimal conditions giving the highest diesel production of the BG-FT process are identified.

2. Modelling of Biomass Gasification and Fischer-Tropsch Process

Model of the biomass gasification and Fischer-Tropsch process was developed using Aspen Custom Modeler V 7.1. It was divided into three parts, i.e., biomass gasification, synthesis gas cleaning and conditioning and Fischer-Tropsch synthesis as shown in Figure 1.

2.1 Biomass gasification

For simplification, the biomass gasification model was separated into two sections: the first one explains the combined pyrolysis and oxidation reactions and the second one involves the char reduction reactions.

The combined pyrolysis and oxidation section was assumed at the isothermal condition (T = 1228 K). As the pyrolysis and oxidation reactions are relatively fast, the thermodynamics equilibrium could be assumed. The overall reaction is shown in Eq.(1).

$$C_xH_yO_z + wH_2O + mO_2 + pH_2O + 3.76mN_2 = n_{CO}CO + n_{CO2}CO_2 + n_{H2}H_2 + n_{H2O}H_2O + n_{CH4}CH_4 + n_{C6H6}C_6H_6 + n_{char}Char + 3.76mN_2 \quad (1)$$

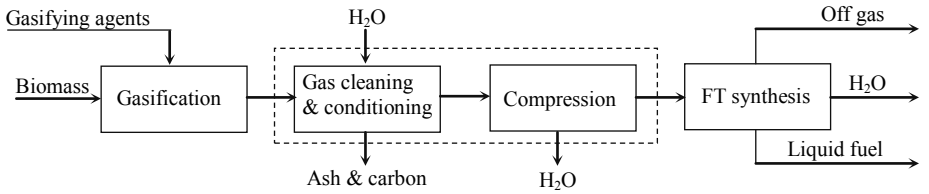

Figure 1. The schematic of the BG-FT process.

where n_{CO}, n_{CO2}, n_{H2}, n_{H2O}, n_{CH4}, n_{C6H6}, n_{Char} and n_{N2} are the number of moles of CO, CO_2, H_2, H_2O, CH_4, C_6H_6, Char and N_2, respectively, and w and m are the amount of water and oxygen per mole of biomass, respectively.

In this study, tar generated in the gasifier was represented by benzene and its concentration in the product gas was assumed to be 2 wt.% (Basu, 2010). The amount of char was obtained from the value of fixed carbon reported by the proximate analysis. Moreover, the chemical equilibrium was assumed for water gas shift and methane reactions. Eqs. (2)-(5) show the elemental balance of the reactions in this section.

Carbon balance: $x = n_{CO} + n_{CO2} + n_{CH4} + n_{C6H6}$ (2)

Hydrogen balance: $y + 2w + 2p = 2n_{H2} + 2n_{H2O} + 4n_{CH4} + 6n_{C6H6}$ (3)

Oxygen balance: $z + p + w + 2m = n_{CO} + 2n_{CO2} + n_{H2O}$ (4)

Nitrogen balance: $3.76m = n_{N2}$ (5)

The char reduction section is based on the following reactions:

R1: Boudouard reaction: $C + CO_2 = 2CO$ (6)

R2: Water gas reaction: $C + H_2O = CO + H_2$ (7)

R3: Methane reaction: $C + 2H_2 = CH_4$ (8)

R4: Methane Steam reforming reaction: $CH_4 + H_2O = CO + 3H_2$ (9)

Because the rate of the char reduction reactions is relatively low, their chemical kinetics are considered. The rate expressions of the reactions are shown in Eqs.(10)-(13).

$$r_1 = C_{RF} k_1 (x_{CO2} - \frac{x_{CO}^2}{K_{eq,1}}) \quad (10)$$

$$r_2 = C_{RF} k_2 (x_{H2O} - \frac{x_{CO} x_{H2}}{K_{eq,2}}) \quad (11)$$

$$r_3 = C_{RF} k_3 (x_{H2}^2 - \frac{x_{CH4}}{K_{eq,3}}) \quad (12)$$

$$r_4 = C_{RF} k_4 (x_{H2}^2 x_{CO} - \frac{x_{H2O} x_{CH4}}{K_{eq,4}}) \quad (13)$$

The kinetics data of such reactions were taken from Wang and Kinoshita (1993). To account for active sites on the char surface, the char reactivity factor (C_{RF}) was considered to be the constant value of 1000 (Giltrap et al., 2003). To calculate the composition of the producer gas leaving this reaction zone, the reduction section was divided into small control volumes (CV) and the mass balance of each CV was performed. The molar flow rate of species *i* leaving each CV is computed by Eq.(14)

$$n_{i,out} = n_{i,in} + V_{CV}.Rt_i \quad (14)$$

2.2 Synthesis gas cleaning and conditioning

Ash and unreacted carbon contained in the raw synthesis gas were removed in a solid separation unit. In a tar steam reforming process, benzene (tar model compound) and methane were completely converted to H_2 and CO via steam reforming reaction over Ni based catalyst at 780 ^oC, 1 atm (Basu, 2010). The chemical equilibrium was assumed for water gas shift, methane and benzene steam reforming reactions.

2.3 Compression

The clean syngas with a desired H_2/CO ratio was compressed to the FT operating pressure of 20 bar. The efficiency of compressor was assumed to be 75% (Kaneko et al., 2006).

2.4 FT reactor

The FT hydrocarbon products were assumed to be linear paraffins (Eq.(15)). The operating temperature and pressure were 220 °C and 20 bar, respectively. The product distribution was assumed to follow the ASF distribution, as shown in Eq.(16), and the chain growth probability (α) could be determined from Eqs.(17)-(18).

$$\mathrm{nCO} + (2\mathrm{n}+1)\mathrm{H}_2 \rightarrow \mathrm{C_nH_{2n+2}} + \mathrm{nH_2O} \quad (15)$$

$$M_n = \alpha^{n-1}(1-\alpha) \quad (16)$$

$$\alpha = 0.75 - 0.373\sqrt{-\log(S_{C5+})} + 0.25S_{C5+} \quad (17)$$

$$S_{C5+} = 1.7 - 0.0024T - 0.088\frac{[H_2]}{[CO]} + 0.18([H_2] + [CO]) + 0.0079P_{Total} \quad (18)$$

where S_{C5+} is the selectivity of hydrocarbon with a chain length longer than 5, $[H_2]$ and [CO] are the molar concentration of H_2 and CO in the feed gas, T and P_{Total} are the operating temperature (K) and pressure (bar), respectively.

The reaction rate used to determine the conversion of carbon monoxide during the FT synthesis was derived from the kinetic study of Yates and Satterfield (1991), as shown in Eq. (19).

$$-R_{\mathrm{CO}} = \frac{aP_{\mathrm{CO}}P_{\mathrm{H2}}}{(1+bP_{\mathrm{CO}})^2} \quad (19)$$

where R_{CO} is the CO consumption rate (mol/s $\mathrm{kg_{cat}}$), $\underline{P}_{\mathrm{CO}}$ and P_{H2} are the partial pressure of CO and H_2 (bar), and a and b are the kinetic parameters which are calculated from the correlation developed by Krishna and Sie (2000). The vapour liquid equilibrium was calculated using Raoult's law, as shown in Eq. (20).

$$y_n P_{Total} = x_n P_{vap,n} \quad (20)$$

2.5 Energy balance

The overall energy balances for each unit can be calculated by Eqs. (21)-(23).

$$H_{reactant} + Q_{in} = H_{product} + Q_{out} \quad (21)$$

$$H_{reactant} = \sum_{reactants} n_i h_{fi}^0 \quad (22)$$

$$H_{product} = \sum_{products} n_i [h_{fi}^0 + \Delta h_{Ti}] \quad (23)$$

where, h_{fi}^0 is the enthalpy of formation in kJ/kmol at the reference state (298 K, 1 atm) and Δh_{Ti} is the enthalpy difference a given state and the reference state.

3. Results and Discussions

3.1 Effect of gasifying agents (oxygen and steam) on the BG-FT process

It is found from Figure 2 that as oxygen feed rate increases; more steam is required to maintain the thermal self-sufficient condition in the gasifier. Figure 2 (a) shows that H_2/CO ratio of the produced syngas increases with oxygen content and the syngas yield shows the same effect as oxygen increases in the oxygen to biomass ratio range of 0.12 to 0.14 due to the domination of water gas shift reaction; however, the inverse effect is found as O_2 to biomass ratio is over 0.15 because the combustion reaction dominates the system. Figure 2 (b) shows the increase of diesel production with oxygen feed rate at H_2/CO ratio around 2 due to the increase in syngas production rate in gasifier. However, the diesel production sharply decreases to zero as oxygen feed rate increases since syngas feed rate dramatically decreases. The maximum diesel production is found at the oxygen and steam to biomass ratio equal to 0.14 and 0.58, respectively.

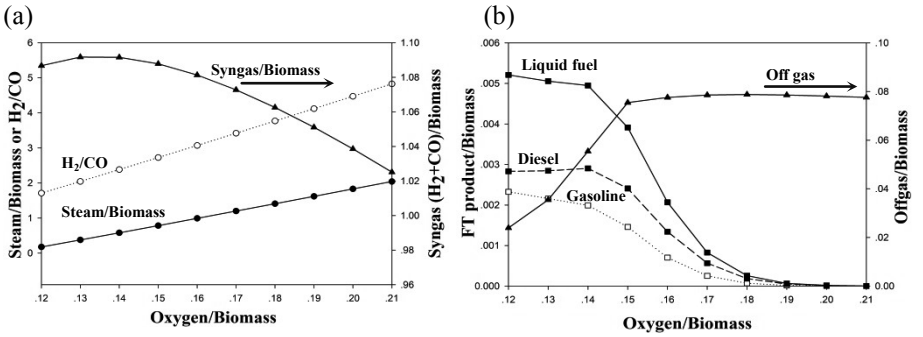

Figure 2. Effect of gasifying agents (oxygen and steam) on: (a) syngas (H_2+CO) yield and H_2/CO ratio and (b) FT product distribution.

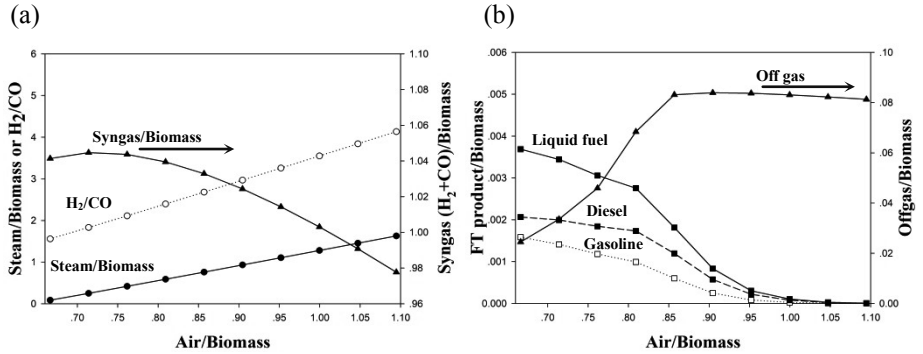

Figure 3. Effect of gasifying agents (air and steam) on: (a) syngas (H_2+CO) yield and H_2/CO ration and (b) FT product distribution.

3.2 Effect of gasifying agents (Air and steam) on the BG-FT process

The effect of air and steam feed rate on performance of BG-FT process where the gasifier is operated under thermal self-sufficient condition shows a similar trend as the system using oxygen and steam. However, a higher amount of air feed rate is required, whereas a smaller amount of syngas and diesel products are obtained due to the effect of nitrogen dilution. Figure 3 (a) shows the increase of syngas yield with air feed rate increases in the air to biomass ratio range of 0.67 to 0.70; however, the inverse effect is found as the air to biomass ratio becomes over 0.75. Figure 3 (b) shows that the relative high of diesel production is found at the H_2/CO ratio around 2 due to the increase in syngas production rate in the gasifier. However, the diesel production sharply decreases to zero as air feed rate increases because syngas feed rate dramatically decreases. The maximum diesel production is found at the air and steam to biomass ratio equal to 0.67 and 0.85, respectively.

3.3 Effect of gasifying agents on overall energy consumption of the BG-FT process

The effect of gasifying agents on overall energy consumption of the BG-FT process which the thermal self-sufficient condition is considered at gasifier is shown in Figure 4. The rate of heat release significantly increases when oxygen and air to biomass ratios are in the ranges of 0.12-0.15 and 0.67-0.85, respectively. Nevertheless, the decrease in increasing rate of heat release is observed as the oxygen and air to biomass ratios became higher than the above ranges. The released heat from air-steam system is always higher than that of the other.

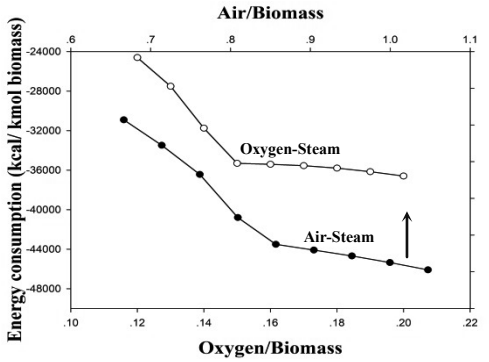

Figure 4. Effect of gasifying agents on overall energy consumption of BG-FT process.

4. Conclusions

The biomass gasification and Fischer-Tropsch (BG-FT) integrated process using rice straw as feedstock was studied. Modelling of the integrated process was performed using Aspen Custom Modeler V 7.1. Two gasification systems operated under thermal self-sufficient condition with different gasifying agents, i.e., oxygen/steam and air/steam were considered. The yield and H_2/CO ratio of the producer gas derived from the two systems as well as the diesel production show a similar trend. However, the gasifier with air/steam required a higher amount of air feed rate to achieve the thermal self-sufficient condition and the smaller amount of derived syngas and diesel products were achieved due to the effect of nitrogen dilution, whereas the higher amount of heat was released. Finally, it could be concluded that the type and amount of gasifying agent played an important role in the production of liquid fuel from rice straw using the BG-FT process. The optimum value of diesel production and overall energy consumption could be achieved via the suitable adjustment of a gasifying agent to biomass ratio.

Abstract

Multiple steady-state solutions typically exist for nonlinear chemical processes and the stability of various solutions may be different. Stability is a key component of chemical process operability and represents the tolerance for small perturbations in the process, which is related to process benefits and safety. As one of the multiple steady-state solutions, the optimal operating point may be located in the unstable branch. 1, 3-propanediol is an important chemical material, however, the optimal operating point with the highest product concentration is unstable. This paper introduced the washout filter-aided controller which was originally used for electric power system and aircraft to adjust the dynamic behavior of the anaerobic fermentation process. By selecting appropriate controller parameters, eigenvalues of an unstable point near the optimal operating point are reassigned to stabilize the high product concentration parts of the equilibrium manifold including the optimal operating point without affecting the shape of the equilibrium manifold. Finally, simulations of the closed-loop system were used to verify the effectiveness of the proposed method of adjusting dynamic behavior.

Keywords: propanediol, washout filters, stability, adjustment

1. Introduction

1, 3-propanediol is an important chemical material, mainly used in the production of polyester, e.g., polytrimethylene terephthalate (PTT), as well as the synthesis of pharmaceutical intermediates. The microbial anaerobic fermentation is an efficient and environmentally friendly process as opposed to the traditional ethylene oxidation and acrolein hydrolysis. However, the open-loop system is unstable at the optimal operating point. To overcome this problem, the method of adjusting the stability of 1, 3-propanediol fermentation process with washout filter-aided controller is studied.

Washout filter-aided controller is a kind of dynamic feedback controller with washout filters that washout(reject) steady state inputs, while passing transient inputs (Hassouneh et al., 2004). Washout filters are used commonly in control systems for power systems and aircraft (Lee and Abed, 1991). In addition, Wang and Abed (1995) studied bifurcation control of a chaotic system with washout filter, Ding and Hou (2010) studied the stabilizing control of Hopf bifurcation in the Hodgkin-Huxley model via washout filter.

The dynamics of the simplest washout filter can be written as (Lee, 1991)

$$\dot{z} = x_k - d_t z \tag{1}$$

where x_k is the kth element of the state vector, d_t is the reciprocal of the filter time constant. The output equation is

$$y = x_k - d_t z \tag{2}$$

The control law is a function of y, usually has the following form

$$\mathbf{u} = \mathbf{h}(y) = \mathbf{w}y + y^T \mathbf{Q_u} y + \mathbf{C_u}(y, y, y) \tag{3}$$

where $\mathbf{w}$ is a vector, $\mathbf{Q_u}$ is a real symmetric $n \times n$ matrix, and $\mathbf{C_u}$ is a cubic form, corresponding to linear, quadratic and cubic terms, respectively. In this paper, only the linear term is applied.

The paper is organized as follows. In Section 2, the model of 1, 3-propanediol anaerobic fermentation is presented. In Section 3, the washout filter-aided controller is introduced and implemented to stabilize the optimal operating point. In Section 4, the advantages and limitations of washout filter-aided controller are discussed. The conclusions are presented in Section 5.

2. Propanediol Anaerobic Fermentation

The mathematical model of 1,3-propanediol fermentation is as follows (Xiu et al., 1998).

$$\begin{aligned}
\frac{dx_1}{d\tau} &= x_1(p - d) \\
\frac{dx_2}{d\tau} &= d(y_0 - x_2) - x_1\varphi_1\left(\beta_1 + \gamma_1 p + \frac{x_2}{x_2 + \alpha_1}\right) \\
\frac{dx_3}{d\tau} &= x_1\varphi_2\left(\beta_2 + \gamma_2 p + \frac{x_2}{x_2 + \alpha_2}\right) - x_3 d \\
p &= \frac{x_2}{x_2 + \alpha_3}(1 - x_2)(1 - x_3)
\end{aligned} \tag{4}$$

The state variables are x_1, x_2, and x_3, which mean dimensionless biomass concentration, dimensionless substrate concentration, and dimensionless product concentration, respectively. The operating variables are dimensionless dilution rate d, dimensionless feed substrate concentration y_0 and dimensionless parameter α_3. The values of the parameters are listed in Table 1.

Table 1. Parameters of 1, 3-propanediol fermentation

Parameters	Parameters
α_1=0.01	γ_1=2.3929
α_2=0.025	γ_2=0.5583
β_1=0.0286	φ_1=0.1306
β_2=0.0083	φ_2=0.8955

The operating point is optimized to get the highest product concentration, where d=0.3, y_0=0.2744, and α_3=0.00014. Correspondingly, the optimal dimensionless product

concentration x_3 is 0.6928. The bifurcation diagram of dimensionless product concentration x_3 versus dimensionless substrate concentration is depicted in Figure 1(a), showing that the optimal operating point is unstable. The same result is also reported by Wang et al (2013). Since the optimal operating point is unstable, the steady state will drop to the lower stable point, leading to economic losses and safety problems. Therefore, a control system must be implemented. In this paper, the washout filter-aided controller is introduced to stabilize the unstable operating point.

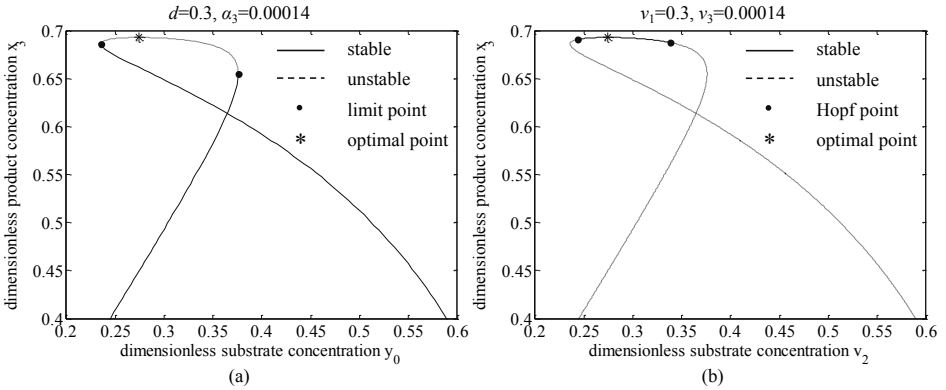

Figure 1. Bifurcation diagram of x_3 versus y_0: (a) open-loop, (b) closed-loop

3. Implementation of Washout Filter-aided Controller

Mönnigmann (2002) proposed a method to deliberately introduce Hopf bifurcations to stabilize parts of the equilibrium manifold of an ODE process model without affecting the equilibrium manifold.

Eq.(4) can be described by

$$\dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}) \tag{5}$$

where $\mathbf{x} \in \mathbf{R}^3$ is the state vector (x_1, x_2, x_3) and $\mathbf{u} \in \mathbf{R}^3$ is the input vector (d, y_0, α_3). Apply washout filter to the third state variable x_3, and only the linear term is used in the control law $\mathbf{u}=\mathbf{h}(y)$. The augmented system can be written by

$$\begin{aligned} \dot{\mathbf{x}} &= \mathbf{f}(\mathbf{x}, \mathbf{u}) \\ \dot{z} &= x_3 - d_t z \\ y &= x_3 - d_t z \\ \mathbf{u} &= \mathbf{v} + \mathbf{w} y \end{aligned} \tag{6}$$

where z is the state variable of the dynamic equation of washout filters, d_t and $\mathbf{w}$ are controller parameters, $\mathbf{v}$ is the reference input vector, corresponding to the original input vector (d, y_0, α_3) in the open-loop system. The control structure is shown in Figure 2, where G_w is the transfer function of the washout filter (Hassouneh et al., 2004).

$$G_w(s) = \frac{y(s)}{x_k(s)} = \frac{s}{s + d_t} \tag{7}$$

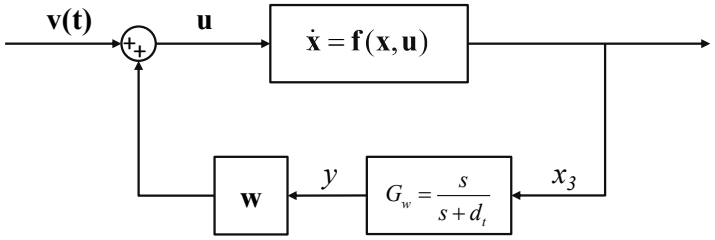

Figure 2. Control structure of washout filter-aided controller

If there is only one positive real eigenvalue at the unstable point, the positive real eigenvalue can be replaced by two arbitrarily given eigenvalues with appropriate controller parameters. Here, the key points are which point should be selected and what new eigenvalues should be assigned to make the optimal operating point locate in the stabilized parts, meanwhile, the stabilized parts should be as large as possible. Therefore, a lot of cases are evaluated and some of them are listed in Table 2.

Table 2. Some evaluated cases

Selected points	Assigned eigenvalues	Stable regions
(0.3, 0.27, 0.00014)	-0.5, -0.5	$0.2594<y_0<0.3072$
(0.3, 0.27, 0.00014)	-0.1, -0.1	$0.2620<y_0<0.3760$
(0.3, 0.25, 0.00014)	-0.5, -0.5	$0.2440<y_0<0.2676$
(0.3, 0.25, 0.00014)	-0.1, -0.1	$0.2435<y_0<0.3383$

The chosen point is

$$(d, y_0, \alpha_3) = (0.3, 0.25, 0.00014) \tag{8}$$

At the chosen point, the eigenvalues of the open-loop system is

$$(\lambda_1, \lambda_2, \lambda_3) = (-1.1083, -0.4311, 0.2349) \tag{9}$$

The single positive eigenvalue can be replaced by two given eigenvalues -0.1 and -0.1. Therefore, the eigenvalues of the augmented system become

$$(\lambda_1, \lambda_2, \lambda_3, \lambda_4) = (-1.1083, -0.4311, -0.1, -0.1) \tag{10}$$

with the following controller parameters obtained by the method proposed by Mönnigmann (2002).

$$d_t = -0.0426, w = (1.7403, -0.4586, -0.2596)^T \tag{11}$$

The bifurcation diagram of dimensionless product concentration x_3 versus the second reference input v_2 is depicted in Figure 1(b), showing that parts of the unstable equilibrium manifold is stabilized without changing the shape of the equilibrium manifold. Even though the rest of the equilibrium manifold becomes unstable, the optimal operating point is stabilized.

To verify the effectiveness of the designed washout filter-aided controller, the set-point tracking curves of the open-loop and close-loop systems are illustrated in Figure 3.

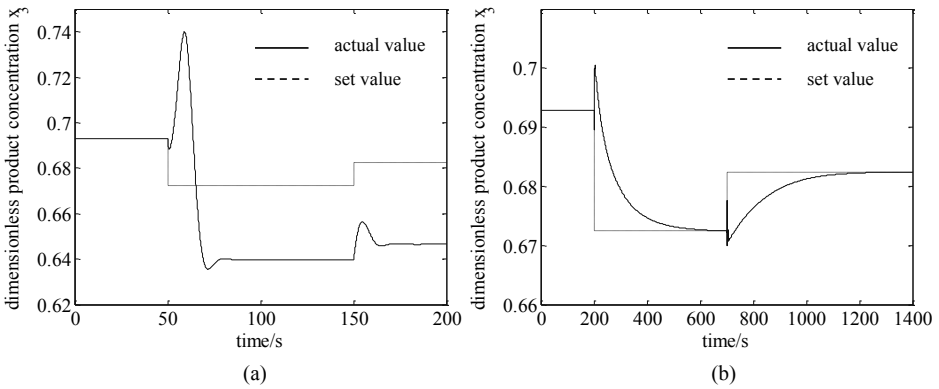

Figure 3. Set-point tracking curve. (a) open-loop, (b) closed-loop

The dashed lines mean the set values which are the same in Figure 3(a) and Figure 3(b). As shown in Figure 3(a), in the open-loop system, the steady state solution converges to the lower stable point instead of the desired higher unstable point when the operating variables vary. On the contrary, in the closed-loop system, the steady state solution converges to the stabilized optimal operating point when the operating variables vary.

4. Advantages and Limitations of Washout Filter-aided Controller

The main advantage of washout filter-aided controller is the ability to preserve all the equilibrium points of the open-loop system. In addition, washout filter-aided controller has the character of automatic equilibrium following.

Assuming that $\mathbf{x}_e$ is the steady state solution of the open-loop system in Eq.(5) when $\mathbf{u}$ is equal to $\mathbf{u}_e$. Hence

$$\mathbf{f}(\mathbf{x}_e, \mathbf{u}_e) = \mathbf{0} \tag{12}$$

Consider the closed-loop system in Eq.(6), the output y is equal to 0 when steady state is reached. Therefore, the following equation holds

$$\mathbf{u} = \mathbf{v} \tag{13}$$

The steady state solution of the closed-loop system should satisfy

$$\mathbf{f}(\mathbf{x}, \mathbf{v}) = \mathbf{0} \tag{14}$$

When $\mathbf{v}$ is equal to $\mathbf{u}_e$, $\mathbf{x}_e$ is also the solution of Eq.(14), meaning that the open-loop and closed-loop systems have the same steady state solutions. Therefore, the equilibrium manifold is preserved.

In contrast to a traditional control structure designed for a certain operating point, the washout filter-aided controller can operate in a wide range of operating conditions (Lee, 1991). In a typical direct state feedback, the control law is

$$\mathbf{u} = \mathbf{h}(\mathbf{x} - \mathbf{x}_e) \tag{15}$$

From the above control law it can be seen that the new steady state $\mathbf{x}_e$ must be computed when operating condition is changed. However, the output of washout filters can be written as Eq.(2), $\mathbf{x}_e$ is not involved in, so there is no need to do any on-line computation and adjustment.

Although the advantages of washout filter-aided controller are very attractive, there are two limitations to achieve the goal of stabilizing arbitrary unstable point without affecting the equilibrium manifold. Firstly, only one positive real eigenvalue is allowed at the unstable point we want to stabilize. Secondly, the dimension of the operating variables should be the same with the state variables. How to overcome these limitations is the future work.

5. Conclusions

In order to operate at the unstable optimal operating point, a new control structure named washout filter-aided controller is designed for the 1, 3-propanediol fermentation process. By selecting appropriate controller parameters, eigenvalues of an unstable point near the optimal operating point are reassigned to stabilize the high product concentration parts of the equilibrium manifold including the optimal operating point without affecting the shape of the equilibrium manifold, meaning that the dynamic behavior of the 1, 3-propanedoil fermentation process is adjusted.

Abstract

A modelling framework for the separation of gas mixtures using multibed Pressure Swing Adsorption (PSA) and Vacuum Swing Adsorption (VSA) flowsheets has been developed. The core of the modelling framework represents a detailed multi-scale adsorbent bed model relying on a coupled set of mixed algebraic and partial differential equations for mass, heat and momentum balance at both bulk gas and particle level, equilibrium isotherm equations and boundary conditions according to the operating steps. The proposed modelling equations have been implemented in the gPROMS™ modelling environment. The modelling framework has been applied on the capture of post-combustion carbon dioxide (CO_2) from dry flue gas by PSA/VSA process in order to validate its predictive power against experimental and simulation data available from the literature. The simulation results in terms of process performance indicators are in good agreement with data available from the literature. The results of sensitivity analysis illustrate the typical trade-offs between process performance indicators.

Keywords: pressure swing adsorption (PSA), modelling, simulation, CO_2 capture

1. Introduction

A considerable increase in the applications of adsorptive gas separation technologies, such as pressure swing adsorption (PSA), have been reported during the last few decades. A pressure swing adsorption (PSA) process is a widely used industrial unit operation process for separating gas mixtures where one or more gases are preferentially adsorbed at high pressure and then desorbed at a lower pressure. The regeneration of the adsorbent is performed by reducing the total pressure of the system, the process is termed Pressure Swing Adsorption (PSA) and the total pressure of the system changes (swings) between high pressure in feed and low pressure in regeneration. PSA like all adsorption separation processes requires the use of a fixed bed packed with a microporous-mesoporous adsorbent material that selectively adsorbs one component (or a group of related components) from a gas mixture. The effluent stream during the adsorption step that no-longer contains the preferentially adsorbed species is called the light product or “raffinate”, while the effluent stream during the desorption step that contains the strongly adsorbed species in larger proportions compared to the feed stream, is often called the heavy product or “extract”.

2. Mathematical model formulation

2.1. Problem description

Depending on the general assumptions describing the adsorbent (porous solid) – adsorbate (gas mixture) system one can employ a broad variety of mathematical models and equations to describe the PSA/VSA process. Kikkinides et al. (2011) and Nikolic et al. (2008) presented the development of a generic modelling framework for efficient simulation and optimization strategies of PSA/VSA processes with detailed adsorption and transport models. The modelling framework is coupled with a novel state transition network (STN) approach adopted from the work of Nikolic et al. (2009) to identify which state transitions are feasible and under which conditions a particular state (operating step) change occurs under a given current state in multibed PSA systems.

The following basic assumptions have been adopted in the derivation of the model equations in this study:

- An axially dispersed plug flow model is used to represent the bulk fluid flow.
- No concentration, temperature, and pressure gradients exist in the radial direction.
- The adsorbent is represented by uniform micro-porous spheres
- Thermal equilibrium between the gas and solid phase (adsorbent) is established instantaneously.
- The gas phase is described by the ideal gas law.
- Competitive adsorption behaviors are described by the dual-site Langmuir isotherm for the gas mixture.
- The mass transfer rate between adsorbent (porous solid) and adsorbate (gas mixture) is described by the linear driving force (LDF) model.
- The physical properties of the adsorbent and adsorption column void are uniform across the column and independent of the temperature.
- Pressure drop along the adsorption column is calculated by the Ergun equation.
- During the pressure-change step the interstitial velocity profile is exponential along the adsorption column and affected by the gas valve equation.

2.2. Mathematical model

The mass balance equation which describes the mass transfer in the bulk gas flow is:

$$\varepsilon_{bed}\frac{\partial(uC_i)}{\partial z}+\varepsilon_{bed}\frac{\partial C_i}{\partial t}+(1-\varepsilon_{bed})N_{g,i}=\varepsilon_{bed}\frac{\partial}{\partial z}\left(D_{z,i}\frac{\partial C_i}{\partial z}\right),\forall z\in(0,L),i=1,\dots,N_{comp} \quad (1)$$

where ε_{bed} is the porosity of the bed, u is the interstitial velocity, C_i is the molar concentration of component i in the bulk gas, $D_{z,i}$ is the mass axial dispersion coefficient and the term $N_{g,i}$ is the generation term given per unit volume of adsorbent which quantifies the mass transfer occurring between bulk flow and particles. The actual expression for the generation term $N_{g,i}$ depends on the nature of the resistances to the mass transfer and for linear driving force (LDF) mechanism is provided by the following equation (2):

$$N_{g,i}=\rho^p\frac{\partial Q_i}{\partial t},\qquad \forall z\in(0,L),i=1,\dots,N_{comp} \quad (2)$$

where Q_i is the adsorbed amount per unit mass of adsorbent and ρ^p is the density of the particle.

The heat balance equation which describes the heat transfer in the bulk gas flow is:

$$\varepsilon_{bed}\frac{\partial(\rho c_p T u)}{\partial z}+\varepsilon_{bed}\frac{\partial(\rho c_p T)}{\partial t}+(1-\varepsilon_{bed})q_g+\frac{3k_{h,wall}}{R_{bed}}(T-T_{wall})=\varepsilon_{bed}\frac{\partial}{\partial z}\left(\lambda_z\frac{\partial T}{\partial z}\right),\quad \forall z\in(0,L) \tag{3}$$

where ρ is the density of bulk gas, c_p is the specific heat capacity of bulk gas, T is the temperature of bulk gas, λ_z is the heat axial dispersion coefficient, $k_{h,wall}$ is the heat transfer coefficient between the bulk flow and the column wall, T_{wall} is the temperature of the column wall and R_{bed} is the bed radius and q_g is the generation term given per unit volume of adsorbent, which quantifies the heat transfer occurring between bulk flow and particles. The actual expression for the generation term q_g depends on the nature of the resistances to the heat transfer and for linear driving force (LDF) mechanism is provided by the following equation (4):

$$q_g=\frac{\partial(\rho^p c_p^p T)}{\partial t}+\rho^p\sum_{i=1}^{N_{comp}}\Delta H_{ads,i}\frac{\partial Q_i}{\partial t},\qquad \forall z\in(0,L) \tag{4}$$

where $\Delta H_{ads,i}$ is the isosteric heat of adsorption and c_p^p is the specific heat capacity of the particle.

The pressure drop is an important variable in the modelling of fixed adsorption columns having a high impact on the separation quality and operating cost. The hydrodynamics of flow through porous media is the most commonly described by using the following Ergun equation (non-linear, turbulent flow) for pressure drop:

$$-\frac{\partial P}{\partial z}=150\left(\frac{1-\varepsilon_{bed}}{\varepsilon_{bed}}\right)^2\frac{\mu u}{(2R_p)^2}+1.75\left(\frac{1-\varepsilon_{bed}}{\varepsilon_{bed}}\right)\frac{\rho u|u|}{2R_p},\qquad \forall z\in(0,L) \tag{5}$$

where P is the total pressure, μ is the viscosity of bulk gas and R_p is the particle radius.

An equation of state is necessary to link concentration with temperature and pressure in the gas mixture. The ideal gas law is provided by the following equation:

$$P=\sum_{i=1}^{N_{comp}}C_i RT,\qquad \forall z\in[0,L] \tag{6}$$

where R is the universal gas constant.

Physical properties (density, viscosity, thermal conductivity, specific heat capacity) of the gas mixture can be assumed constant or calculated using some of the available correlations or thermo-physical packages. In any case, physical properties are functions of temperature, pressure and composition, presented in the following general form:

$$\rho,\mu,\lambda,c_p=f\left(T,P,C_1,C_2,\dots,C_{Ncomp}\right),\qquad \forall z\in[0,L] \tag{7}$$

The mass axial dispersion coefficient $D_{z,i}$ and the heat axial dispersion coefficient λ_z can be calculated by using Wakao correlations:

$$D_{z,i}=\frac{D_{m,i}}{\varepsilon_{bed}}(20+0.5ScRe),\qquad \forall z\in[0,L], i=1,\dots,N_{comp} \tag{8}$$

$$\lambda_z=\lambda(7+0.5PrRe),\qquad \forall z\in[0,L] \tag{9}$$

where $D_{m,i}$ is the molecular diffusivity, λ is the thermal conductivity of bulk gas, Sc is the Schmidt number, Re is the Reynolds number and Pr is the Prandl number.

In linear driving force (LDF) mechanism the overall uptake rate in a particle is expressed as a function of the bulk gas flow concentration:

$$\frac{\partial Q_i}{\partial t} = \frac{15 D_{e,i}}{R_p^2}(Q_i^* - Q_i), \qquad \forall z \in [0, L], i = 1, \dots, N_{comp} \tag{10}$$

where Q_i is the adsorbed amount per unit mass of adsorbent, Q_i^* is adsorbed amount in equilibrium with the gas phase and $D_{e,i}$ is the effective diffusivity. The effective diffusivity $D_{e,i}$ can be calculated by using Bosanquet equation:

$$D_{e,i} = \frac{\varepsilon_p}{\tau_p}\frac{D_{m,i} D_{k,i}}{D_{m,i} + D_{k,i}}, \qquad \forall r \in [0, R_p], i = 1, \dots, N_{comp} \tag{11}$$

where ε_p is the porosity of the particle, τ_p is the tortuosity factor of the particle, $D_{k,i}$ is the Knudsen diffusivity and $D_{m,i}$ is the molecular diffusivity.
The Knudsen diffusivity $D_{k,i}$ can be calculated by using Kauzmann correlation:

$$D_{k,i} = 97 R_{pore}\sqrt{\frac{T^p}{MW_i}}, \qquad \forall r \in [0, R_p], i = 1, \dots, N_{comp} \tag{12}$$

where R_{pore} is the radius of the pore, T^p is the temperature of the particle and MW_i is the molecular weight of component i.
The molecular diffusivity $D_{m,i}$ is independent of the composition and for a binary mixture can be calculated by using Chapman-Enskog equation:

$$D_{m,i} = 1.8583 * 10^{-7}\frac{\sqrt{T^3\left(\frac{1}{MW_1} + \frac{1}{MW_2}\right)}}{P\sigma_{12}^2 \Omega_{12}}, \qquad \forall r \in [0, R_p], i = 1,2 \tag{13}$$

where σ_{12} is the collision diameter from the Lennard-Jones potential and Ω_{12} is the collision integral.
The following dual-site Langmuir isotherm describes the adsorption equilibrium:

$$Q_i^* = \frac{q_{mi(1)} b_{i(1)} P_i}{1 + \sum_{i=1}^{N_{comp}} b_{i(1)} P_i} + \frac{q_{mi(2)} b_{i(2)} P_i}{1 + \sum_{i=1}^{N_{comp}} b_{i(2)} P_i} \tag{14}$$

where $q_{mi(j)}$ and $b_{i(j)}$ are the isotherm parameters and P_i is the partial pressure which is a function of the molar fraction in gas phase y_i given by the following equation:

$$P_i = y_i \mathrm{P} \tag{15}$$

3. Case study

The proposed modelling framework has been applied in a PSA/VSA process concerning the separation of CO_2 from dry flue gas (15 % CO_2, 85 % N_2) using zeolite 13X as an adsorbent. The parameters of adsorption column model and the parameters of the dual-site Langmuir adsorption isotherm have been adopted from the works of Ko et al. (2004) and Ko et al. (2005).
The sequence of the operating steps for the one-adsorption column configuration is: Pressurization with the feed stream co-currently (FP), Adsorption (F), Co-current depressurization or Blowdown (CoD) to intermediate pressure and Counter-current depressurization or Evacuation (CnD) to low pressure. A 4-step PSA/VSA process with the pressure profiles adopted from the work of Haghpanah et al. (2013) is illustrated in Figure 1.

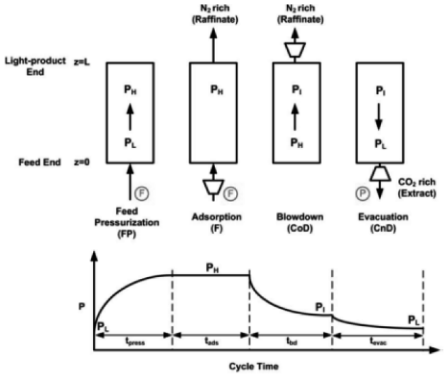

Figure 1. A 4-step PSA/VSA process with the pressure profiles.

4. Results

The modelling framework has been validated against analytical PSA models, full adsorption numerical simulations, and experiments. The simulation results in terms of process performance indicators with absolute deviations from the results of works of Ko et al. (2004) and Ko et al. (2005) are summarized in Table 1.

Furthermore, a systematic parametric analysis provides significant insight into the most critical design and operating parameters, and their effect on the process performance indicators. The parametric studies performed in this work have been carried out only in cases when it was necessary to clarify the effect of certain parameter on the process performance. Thus, once the base case parameters have been selected, only one variable at the time has been varied, and its effect analyzed. We have conducted a sensitivity study to determine which properties are most important in order to improve process performance. The results of sensitivity analysis illustrate the typical trade-offs between process performance indicators. The effect of feed pressure (P_{feed}), feed flowrate (F_{feed}), blowdown pressure (P_{blow}) and adsorption step duration (t_{ads}) on the PSA/VSA process performance indicators are presented in Figures 2,3,4,5 respectively.

Table 1. Simulation results in terms of process performance indicators with absolute deviations from the results of works of Ko et al. (2004) and Ko et al. (2005).

5. Conclusions

The core of the modelling framework represents a detailed adsorption column model relying on a coupled set of mixed partial differential and algebraic equations (PDAEs) for mass, heat and momentum balance at both bulk gas and particle level, equilibrium isotherm equations, transport and thermo-physical properties of the gas mixture and boundary conditions according to the operating steps. The modelling framework is coupled with a novel state transition network (STN) approach developed in our previous work to account for all feasible adsorption column interconnections. The modelling framework provides a comprehensive qualitative and quantitative insight into the key phenomena taking place in the process.

The proposed modelling equations have been implemented in the gPROMS™ modelling environment. The simulation results of the proposed modelling framework in terms of process performance indicators (CO_2 purity and CO_2 recovery) are in good agreement with data available from the literature. The results of sensitivity analysis illustrate the typical trade-offs between process performance indicators.

Abstract

Qualitative modeling paradigm offers process systems engineering a potential for developing effective tools for handling issues related to Process Safety. A qualitative functional modeling environment can accommodate different levels of abstraction for capturing knowledge associated with the process system functionalities as required for the intended safety applications. To provide the scientific rigor and facilitate the acceptance of qualitative modelling, this contribution focuses on developing a scientifically based validation method for functional models. The Multilevel Flow Modeling (MFM) methodology is adopted in the paper as a formalized qualitative functional modeling methodology for dynamic process systems. A functional model validation procedure is proposed to assess whether the intended modeling purpose indeed represents a relevant proposal and whether the model represents the system behavior sufficiently well. With the reasoning capability provided by the MFM syntax and semantics, the validation procedure is illustrated on a three-phase separator system of an MFM model. The MFM model reasoning results successfully compares against analysis results from API RP. 14-C.

Keywords: Functional Model; Multilevel Flow Modeling; Model Validation; Process Safety

1. Introduction

A lack of general acceptance of a qualitative modeling paradigm for process systems has limited process system engineers in developing effective tools for handling issues related to Process Safety(Stephanopoulos, Reklaitis, 2011). The most effective and economical way of dealing with hazards and risks is to address them in Conceptual and Design Steps in a design process (Manuele, 2013). However, the demands for safety through design provided by available guidelines and procedures are far beyond the existing supporting design approaches. Therefore there is a need to explicitly represent system safety features in a model-based design framework. The top-down procedure from design goals to components through functions is regarded to be of great importance in a conceptual design. A qualitative functional modeling environment can accommodate different levels of abstraction for capturing knowledge associated with the process system functionalities as required for the intended application. The intended use of the model indeed determines the necessary degree of sophistication and complexity of the model. Hence, it is necessary to check the consistency and usefulness

of a model against its end use before a model is applied. For example, a model intended for design is required to describe steady-state mass/energy balances of a system. Hence for model validation purposes, validation of a design model would require steady-state type experiments under different design/operation conditions.

In quantitative modelling, model validation concept is well established using statistical frameworks (a body of literature exists on parameter estimation, hypothesis testing via goodness of fit test, F-test, etc) that compares model predictions against experimental observations (Belia et al., 2009). However this is not the case for the field of qualitative modelling, which is the subject of this study.

The Multilevel Flow Modeling (MFM) methodology (Lind, 2013) has been shown to be applicable for the steps of goal decomposition, listing up design conditions and constraints and function assignment. MFM is selected for demonstrating the model validation of process simulation due to its powerful expression ability and a set of reference rules (Zhang et al., 2013; Lind, 2012). With the reasoning capability provided by the MFM syntax and semantics, the proposed validation procedure is illustrated on a three-phase separator system of an MFM model with the external modeling purpose of addressing the safety requirements early in the system design.

2. A scientific basis for a functional model validation

The MFM methodology builds upon a teleological-oriented view of the function to represent process plants. The elements of an MFM model constitute representation of the intentions, the process functionality and their causal relations. The use of means-end relations (Lind, 2013) is a core concept. In MFM modeling, means-end relations link the goals with a structure of flow functions. There are two validation aspects of a means-end relation, namely, a causal aspect and a teleological aspect (Lind, 2014). The causal aspect relates to the designer's experience that the means can produce or prevent the end depending upon the purpose. The teleological aspect implies that the means should be used to achieve the goals. Dealing with functional models then truth cannot be established or tested alone by physical experiments. In order to test the validity of objectives and purposes we need to test these against the consensus among a group of experts (e.g. designers and operators). In this paper, because the experiment results compare with the API standard which is agreed upon within experts of the designed system purpose, in this sense, the validity of objectives and purposes is performed.

A model validation in reality can only be carried out as a model in-validation, i.e. to determine within which range of applications a model represents the process and its functions with the required accuracy for the intended purpose, i.e. application. As claimed by Popper (1934), a theory can only be falsified.

3. Validation procedure for an MFM model

Validation of an MFM model of an artifact (the process) is here proposed as a task of performing a number of experiments using the model and testing, whether the experimental results are in agreement with knowledge, as depicted in Figure 1. The first step is to specify the modeling purpose, i.e. the intended use of the model. Therefore, the modeling is divided into two categories: internal modeling, i.e. of internal system behavior and external modeling, i.e. of system purpose. To validate external modeling is to ascertain whether the intended purpose indeed represents a relevant proposal. To

validate the internal model behavior amounts to ascertain whether the model represents the system behavior sufficiently well for the intended modeling purpose. There are a number of sources available for validation of an external model: Interviews, procedures and guidelines. To verify the internal model representation of the conceptual description of the real system, the internal MFM model behavior is investigated as the second step. It is assumed that the verification of the model implementation is handled by the MFM syntax, i.e. the modeling environment. For the internal model validation there is a realization of the system or a quantitative simulator which has been validated for some specific conditions within the operating window. Because a functional model is a conceptual model and explicitly aims at representing the tacit knowledge behind the model usage; the scope of a functional model is broader than that of a quantitative mathematical model. Thus in some cases, a validated quantitative simulator constitutes an insufficient source to validate an MFM model. Therefore, interviews, procedures and guidelines also may be important sources to complement a validated quantitative simulator for validating the internal model behavior, because these two sources implicitly contain some of the tacit knowledge. For internal model validation, a number of validation experiments should be designed to validate each of the above discussed elements of MFM model. The experiments are implemented by iteratively for i less than or equal to N(i for one design/operation condition, N for all possible design/operation conditions). If a validated quantitative simulator is chosen to be used as a source to validate an MFM model and the qualitative results derived from the MFM model include the quantitative simulation results, then the experiments are valid within the investigated range of the quantitative model; if the qualitative results are entirely consistent with the quantitative results, then the validation procedure directly proceeds to the next iteration. However if the qualitative analysis results contain more assumptions, then additional reasoning rules can be created based on either the behavior of the real system, the interviews or the quantitative simulation results. If the qualitative results derived from the MFM model follows the behavior of real system the interviews or the quantitative simulation results until i=N, then the MFM model is not invalidated which means the validation procedure ends. However, if a qualitative analysis results do not include a result derived from the behavior of real system the interviews or the quantitative simulation experiments, then that aspect of the MFM model is invalidated. Consequently that aspect of the MFM model behavior has to be further analyzed.

In this paper, because the application purpose of an MFM model is intended for the early design phase with respect to safety, quantitative model of the studied system is considered not available. Therefore, the guidelines and procedures are selected as a validation source. However, after the detailed design phase, where the quantitative information is known, and if a validated quantitative simulator is chosen to be used as a source to validate an MFM model, then the criteria for accepted discrepancy between behaviors of an MFM model and a validated quantitative simulator is related to two considerations: the difference in granularity and differences in suitable application range between a qualitative and a quantitative model. When designing validation experiments it is important to consider the difference in granularity between a qualitative and a quantitative model. The disturbance to be applied has to be sufficiently large to inflict a discernible change in the qualitative model behavior. Such a change can appear rather large in the quantitative model. On the other hand, a quantitative model has limited range of application. When the designed experiment is out of the applicable range, it is unsuitable to carry out such experiment in a quantitative simulator. Therefore validation of a functional model depends both on validation of the reasoning capability of the

functional model for "small" changes in a quantitative simulator and on determining the validity range for these predictions as indicated by the limits determined from large(-r) disturbances in the quantitative simulator.

(*Experimental result is consistent with qualitative functional model reasoning)

4. Case study

In the petroleum industry, a 3-phase separator is necessary equipment for the oil and gas production and transportation process. An MFM model of a three phase separator is shown in Figure 2. The model is built based on the goal decomposition, and functional requirements of the 3-phase separator and its control system. The mass flow structure mfs3 represents the mass flow of the heating system inside the separator. The tra 10 heating inlet mass flow mediates (me 1) the energy exchange between mixed oil, gas, water inlet flow and heating mass flow to achieve proper mixed oil, gas, water inlet temperature(obj6)as a condition for the separator to separate (sep1) the gas and water-oil liquid in desired velocity. The separated water-oil liquid produces the source (sou2) in the settling chamber of the separator separating (sep2) the oil (sto2) and the water (sto1) based on their gravity difference. The barrier (bar 1) is the function of the weir plate between the settling chamber and oil chamber. The control structures for modelling the functions of the control of the separating temperature (cfs4), the pressure control (cfs3), oil level control (cfs2), and the water level control (cfs1) are modeled.

To validate the internal modelling, the following experiments considering undesirable events for each flow structure are executed to identify causes: (1)overpressure(sto1 high), (2)underpressure(sto1 low), (3)liquid overflow(sto2 high or sto3 high), (4) gas blowby(sto2 low), (5) leak(sto1 low and sto2 low) and (6)excess temperature(tra 16 high).

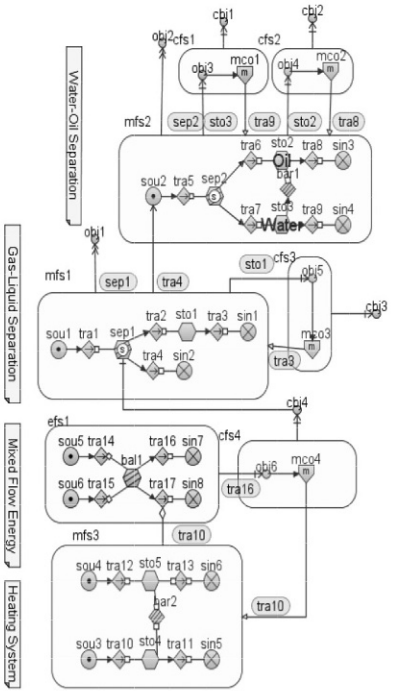

Figure 2. An MFM model of a 3-phase separator

Figure 3. Reasoning results to be compared to validation results

Table 1. Comparison experiment results with API RP 14C

Experiment No.	Causes in API RP 14C	Causes produced from the MFM model
1. Overpressure (sto1 high)	Blocked or restricted outlet	sin 1 high volume
	Inflow exceeds outflow	tra 3 low flow, tra 2 high flow
	Gas blowby(upstream component)	tra 1 high flow
	Thermal expansion	sep1 fill
	Excess heat input	obj6 fail
2. Underpressure(sto1 low)	Withdrawals exceed inflow	tra 2 low flow
	Thermal contraction	sep1 leak
	Open outlet	tra 3 high flow
	Pressure control system failure	cbj3 fails
3. Liquid overflow (sto3 high)	Inflow exceeds outflow	tra 9 low flow, tra7 high flow
	Liquid slug flow	tra 6 low flow
	Blocked or restricted liquid outlet	sin 4 high voloume
	Level control system failure	cbj 1 fail
4. Gas blowby (sto2 low)	Liquid withdrawal exceed inflow	tra 6 low flow, tra 8 high flow
	Open liquid outlet	tra 8 high flow
5. Leak (sto1 low and sto2 low)	Deterioration	
	Erosion	
	Corrosion	sep1 leak
	Impact damage	
	Vibration	
6.Excess temperature(tra 16 high)	Temperature control system failure	cbj 4 fail
	High inlet temperature	sou 5 high volume

The experimental results for each undesirable event identifying the causes are shown in Figure 3. The underlined causes are all possible root causes(">"means because of). By comparison of the results with Table A.4.1-Safety Analysis Table (SAT) Pressure

Vessels in API RP. 14-C (1998) (shown in Table 1), we find that the experiments results are in accordance with Table A 4.1. With these comparative analysis, MFM model is considered not falsified hence can be utilized as external modeling tool for safety-based design and analysis. In this way, different design of safety systems can be generated to provide primary and secondary levels of protection to prevent or minimize the effects of the failure causes identified by the MFM model.

5. Conclusions

Qualitative process knowledge is inherently used in certain PSE tasks, i.e., design and analysis of safety systems in the early project development phase using HAZID/HAZOP type structured brainstorming sessions. To facilitate the development and use of qualitative models for such ends, assessment of the validity and the validity range for qualitative models represents an important scientific challenge. Based upon the functional modeling paradigm a two layered procedure for validating functional models is proposed. The key principles of the validation procedure are demonstrated on a three phase separator system which is modeled using MFM. The causal reasoning system behind MFM is shown to be essential for demonstrating the validation procedure.

Abstract

A generalized approach for the calculation of complex chemical and phase equilibria is presented which is based on the simulation of the dynamic evolution of a mixture from arbitrary nonequilibrium initial composition towards the final equilibrium composition. The proposed method is able to deal with pure chemical or pure phase equilibria as well as with simultaneous chemical/phase equilibria. The unique advantage of our approach, compared to conventional equilibrium calculations, is the fact that the simulation algorithm always converges towards the thermodynamic equilibrium state regardless which initial composition is chosen.

Keywords: Process Simulation, Chemical Equilibria, Phase Equilibria

1. Introduction

In process simulation, a large variety of thermodynamic equilibria, such as reaction equilibria and phase equilibria between two or more phases, have to be solved in the different process units. It is common, that for different types of equilibria, different mathematical approaches are applied. For reaction equilibria, the most common approach is the direct Gibbs energy minimization which formulates the equilibrium condition in terms of an optimization problem (Gmehling et al., 2012). In the case of phase equilibria, such as vapour-liquid equilibria (VLE) or liquid-liquid equilibria (LLE), a set of algorithms is available, that solve the necessary conditions to be fulfilled at the equilibrium state, namely the equality of the chemical potentials of all species in the coexisting phases at constant pressure and temperature (Gmehling et al., 2012; Steyer et al., 2005).

In the next section, we describe the proposed method for computing thermodynamic equilibria. After that, two different types of equilibria calculations are solved.

2. Method formulation

We define a set of species $\mathscr{S}$ and a set of phases $\mathscr{P}$ that can coexist in the considered closed thermodynamic system. E. g. $\mathscr{P} = \{\mathrm{V}, \mathrm{L1}, \mathrm{L2}\}$ denotes a VLL-system, were V refer to the vapor phase and L1 and L2 refers to the two liquid phases. Without loss of generality, the presented method can also be applied to systems containing other phases like a solid phase or a third liquid phase.

In order to compute the thermodynamic phase equilibrium of a p-phase system with s species, one needs $sp(p-1)/2$ rate expressions $r_{\sigma}^{\pi,\pi'}$ that describe the mass fluxes of all species $\sigma \in \mathscr{S}$ between the phases π and π' with $\pi, \pi' \in \mathscr{P}$ and $\pi \neq \pi'$. Additionally, in each phase $\pi \in \mathscr{P}$ may occur a set of chemical reactions $\rho \in \mathscr{R}^{\pi}$.

The proposed methodological approach for solving chemical as well as phase equilibria is formulated as a set of evolution equations in the form of a set of ordinary differential equations (ODE):

$$\frac{\mathrm{d}\mathbf{n}}{\mathrm{d}\tau} = \mathbf{A}\mathbf{r} \qquad \mathbf{n}(0) = \mathbf{n}_0 \tag{1}$$

that describes the dynamics of the molar composition in all phases

$$\mathbf{n} = [\mathbf{n}^\pi]_{\pi\in\mathscr{P}} \qquad \text{with } \mathbf{n}^\pi = [n_\sigma^\pi]_{\sigma\in\mathscr{S}} \tag{2}$$

w. r. t. time τ, a stoichiometric matrix $\mathbf{A}$ and a vector of rate expressions $\mathbf{r}$ that describes the fluxes between the phases as well as the mass fluxes due to chemical reactions. The stoichiometric matrix $\mathbf{A} = \begin{bmatrix}\mathbf{A}_\mathrm{p} & \mathbf{A}_\mathrm{r}\end{bmatrix}$ can be partitioned into the sub-matrix $\mathbf{A}_\mathrm{p}$ that models the connections between the phases, and a sub-matrix $\mathbf{A}_\mathrm{r}$ that models the stoichiometry of the reactions. Correspondingly, the vector of rate expressions $\mathbf{r} = \begin{bmatrix}\mathbf{r}_\mathrm{p}^\mathrm{T} & \mathbf{r}_\mathrm{r}^\mathrm{T}\end{bmatrix}^\mathrm{T}$ consists of two sub-vectors $\mathbf{r}_\mathrm{p}$ and $\mathbf{r}_\mathrm{r}$.

All those rate expressions are to be formulated in a thermodynamically consistent way, such that (i) the steady state of the ODE system, Eq. (1), is identical to the molar composition of the system in thermodynamic equilibrium, and such that (ii) the second law is not violated, i. e. the system's entropy production must not become negative at any time along its evolution towards the final equilibrium state.

2.1. Rate expressions for the mass transfer between phases

The rate expressions for the mass transfer between coexisting phases π and π'

$$\mathbf{r}_\mathrm{p} = \left[\mathbf{r}^{\pi,\pi'}\right]_{\substack{\pi,\pi'\in\mathscr{P}\\ \pi\neq\pi'}} \qquad \text{with } \mathbf{r}^{\pi,\pi'} = \left[r_\sigma^{\pi,\pi'}\right]_{\sigma\in\mathscr{S}} \tag{3}$$

are directly derivated from the thermodynamic equilibrium condition between the two phases π and π' (using the same reference state in all phases)

$$f_\sigma^\pi = f_\sigma^{\pi'}\,. \tag{4}$$

Any derivation from the equilibrium Eq. (4), gives rise to the mass transfer from one phase to the other. The rate of mass transfer can be expressed as follows:

$$r_\sigma^{\pi,\pi'} = k_\sigma^{\pi,\pi'}\left(f_\sigma^\pi - f_\sigma^{\pi'}\right). \tag{5}$$

At thermodynamic equilibrium, the rate becomes $r_\sigma^{\pi,\pi'} = 0$. $k_\sigma^{\pi,\pi'}$ stands for the rate constant of mass transfer. Due to the fact, that we are only interested in the steady state of the ODE system (1), this constant can be set to an arbitrary positive value, to be chosen such that the stiffness of the ODE system, Eq. (1), is small, e. g. $k_\sigma^{\pi,\pi'} = 1$.

2.2. Rate expressions for chemical reactions

The rate expressions for chemical reactions

$$\mathbf{r}_\mathrm{r} = [\mathbf{r}^\pi]_{\pi\in\mathscr{P}} \qquad \text{with } \mathbf{r}^\pi = \left[r_\rho^\pi\right]_{\rho\in\mathscr{R}^\pi} \tag{6}$$

are formulated as thermodynamically consistent mass action kinetics. Starting at the equilibrium condition for a single reaction ρ (Gmehling et al., 2012, p. 532)

$$K_{\mathrm{eq},\rho}^\pi = \prod_{\sigma\in\mathscr{S}}\left(\frac{f_\sigma^\pi}{f_\sigma^{\circ\pi}}\right)^{\nu_{\sigma\rho}^\pi} = \frac{\prod_{\substack{\sigma\in\mathscr{S}\\ \nu_{\sigma\rho}^\pi>0}}\left(\frac{f_\sigma^\pi}{f_\sigma^{\circ\pi}}\right)^{\nu_{\sigma\rho}^\pi}}{\prod_{\substack{\sigma\in\mathscr{S}\\ \nu_{\sigma\rho}^\pi<0}}\left(\frac{f_\sigma^\pi}{f_\sigma^{\circ\pi}}\right)^{|\nu_{\sigma\rho}^\pi|}} \tag{7}$$

the following rate law is proposed:

$$r_\rho^\pi = k_\rho^\pi \times \left[\prod_{\substack{\sigma\in\mathscr{S} \\ \nu_{\sigma\rho}^\pi<0}} \left(\frac{f_\sigma^\pi}{f_\sigma^{\circ\pi}}\right)^{|\nu_{\sigma\rho}^\pi|} - \frac{1}{K_{\mathrm{eq},\rho}^\pi} \prod_{\substack{\sigma\in\mathscr{S} \\ \nu_{\sigma\rho}^\pi>0}} \left(\frac{f_\sigma^\pi}{f_\sigma^{\circ\pi}}\right)^{\nu_{\sigma\rho}^\pi} \right] \tag{8}$$

which becomes $r_\rho^\pi = 0$ if the chemical equilibrium is attained. k_ρ^π stands for the reaction rate constant. Again, due to the fact that we want to determine the final steady state, also this constant can be set to an arbitrary value, e. g. $k_\rho^\pi = 1$.

3. Examples

For illustration, the here proposed nonequilibrium apporach to equilibrium calculations is applied to two examples in the context of the Fischer-Tropsch (FT) synthesis which is a key process for converting syngas into liquid fuels. As first example the chemical equilibria of the synthesis of alkanes is computed. It is common, that the product spectrum can be described by a Flory-type distribution $x_{\mathrm{C}i} = (1-\alpha)\alpha^{i-1}$ (Flory, 1936), where α is the chain growth probability and i the number of carbon atoms. The subscript Ci refers to the alkane $\mathrm{C}_i\mathrm{H}_{2i+2}$. As second example, a vapour-liquid-liquid separation of the product spectrum of the Fischer-Tropsch reactor is performed.

In both examples, the resulting ODE systems were implemented in MATLAB and solved by use of the `ode15s`-solver (Shampine and Reichelt, 1997).

3.1. Fischer-Tropsch reactions

In the first example, we consider a reactive gas-phase system in which syngas is converted into n-alkanes up to C8 according to the following main FT reactions:

$$\mathrm{CO} + 3\,\mathrm{H_2} \longleftrightarrow \mathrm{CH_4} + \mathrm{H_2O}\,, \tag{9a}$$

$$\mathrm{CO} + 2\,\mathrm{H_2} + \mathrm{C}_{n-1}\mathrm{H}_{2n} \longleftrightarrow \mathrm{C}_n\mathrm{H}_{2n+2} + \mathrm{H_2O} \qquad \forall n = 2\ldots 8\,. \tag{9b}$$

In this system, we have 11 species

$$\mathscr{S} = \{\mathrm{CO}, \mathrm{H_2}, \mathrm{H_2O}, \mathrm{C}_n\mathrm{H}_{2n+2} \forall n = 1\ldots 8\}\,, \tag{10}$$

one phase $\mathscr{P} = \{\mathrm{V}\}$ and 8 chemical reactions, Eq. (9). The stoichiometric matrix $\mathbf{A}$ of this system is given by

$$\mathbf{A} = \mathbf{A}_\mathrm{r} = \begin{bmatrix} -1 & -3 & 1 & 1 & & & 0 \\ -1 & -2 & 1 & -1 & 1 & & \\ \vdots & \vdots & \vdots & & \ddots & \ddots & \\ -1 & -2 & 1 & 0 & & -1 & 1 \end{bmatrix}^\mathrm{T} \in \mathbb{R}^{11\times 8}. \tag{11}$$

Due to the fact, that we have only one phase, $\pi \equiv \mathrm{V}$, the superscript π that refers to the phase is omitted in the following equations for better readability. Expressing the species fugacity in terms of the fugacity coefficient φ_σ and the mole fraction x_σ, $f_\sigma = x_\sigma\varphi_\sigma P = (x\varphi)_\sigma P$, and setting $P^\circ = 101325\,\mathrm{Pa}$, the rate expressions applied in this case are:

$$r_1 = k_1 \times \left[(x\varphi)_\mathrm{CO}\,(x\varphi)_\mathrm{H2}^3 \left(\frac{P}{P^\circ}\right)^4 - \frac{(x\varphi)_\mathrm{C1}(x\varphi)_\mathrm{H2O}}{K_{\mathrm{eq},1}} \left(\frac{P}{P^\circ}\right)^2 \right], \tag{12a}$$

$$r_i = k_i \times \left[(x\varphi)_\mathrm{CO}\,(x\varphi)_\mathrm{H2}^2\,(x\varphi)_{\mathrm{C}(i-1)} \left(\frac{P}{P^\circ}\right)^4 - \frac{(x\varphi)_{\mathrm{C}i}(x\varphi)_\mathrm{H2O}}{K_{\mathrm{eq},i}} \left(\frac{P}{P^\circ}\right)^2 \right] \quad \forall i = 2\ldots 8\,. \tag{12b}$$

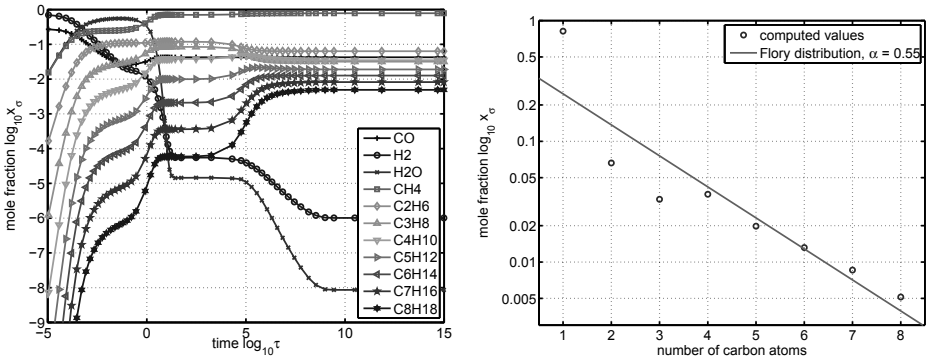

Figure 1: Evolution of the mole fractions x_σ and distribution of the alkanes at equilibrium which corresponds to the Flory distribution with $\alpha = 0.55$ (right).

Table 1: Feed composition n^0_σ and product composition n_σ of the Fischer-Tropsch reactor.

species	σ	CO	H_2	H_2O	CH_4	C_2H_6	
feed	n^0_σ/mol	1.0	2.6				
product	n_σ/mol	0.0425	0.0000	0.0000	0.7828	0.0633	
species	σ	C_3H_8	C_4H_{10}	C_5H_{12}	C_6H_{14}	C_7H_{16}	C_8H_{18}
product	n_σ/mol	0.0317	0.0349	0.0190	0.0126	0.0082	0.0049

The fugacity coefficients φ_σ are obtained from the predictive Soave-Redlich-Kwong (PSRK) Equation of State (EoS) (Holderbaum and Gmehling, 1991; Fischer and Gmehling, 1996; Soave, 1972). The rate constants k_n are used here to normalize the rate expressions by setting $k_\rho = \sqrt{K_{\mathrm{eq},\rho}}$. The equilibrium constants $K_{\mathrm{eq},\rho} = \exp(-\Delta_R g/RT)$ are defined by the Gibbs energy of reaction ρ.

The ODE system, Eq. (1), for this example was solved at $T = 530\,\mathrm{K}$ and $P = 1.5\,\mathrm{MPa}$ with a feed of $n_{\mathrm{CO}}(0) = 1\,\mathrm{mol}$ and $n_{\mathrm{H2}}(0) = 2.6\,\mathrm{mol}$. This leads to a very small yield of longer alkanes, $\alpha \approx 10^{-3}$. Therefore, a sink term for the side product H_2O was added to the ODE system

$$\frac{\mathrm{d}n_{\mathrm{H2O}}}{\mathrm{d}\tau} = \cdots - \begin{cases} (n_{\mathrm{H2O}} - n^{\mathrm{lim}}_{\mathrm{H2O}}) & : n_{\mathrm{H2O}} > n^{\mathrm{lim}}_{\mathrm{H2O}} \\ 0 & : \text{else} \end{cases} \tag{13}$$

with $n^{\mathrm{lim}}_{\mathrm{H2O}} = 10^{-5}\,\mathrm{mol}$ to shift the equilibrium to the longer alkanes. A technical approximation of this water removal can be achieved by intermediate cooling and condensation of the water or by a condensation of the water directly in the reactor at high operating pressure. This leads approximately to a Flory distribution with $\alpha = 0.55$, see Fig. 1 (right), which is in good agreement with published experimental data on this process (Stenger and Askonas, 1986). The dynamic evolution of the mole fractions x_σ in the reactor is shown in Fig. 1 (left). The feed and product compositions are also given in Tab. 1.

3.2. Separation of the Fischer-Tropsch products

In the second example, we apply our method to a phase equilibrium problem, i. e. we compute the vapour-liquid-liquid equilibrium (VLLE) of the product composition of the Fischer-Tropsch reactor as given in Table 1 at $T = 288.15\,\mathrm{K}$ and $P = 2\,\mathrm{MPa}$. In order to demonstrate the suitability

of our method for a system that forms two liquid phases, the water which was already removed in the reactor in the first example, was added to the feed of the VLL separation.

In this case, the set $\mathscr{S}$ is the same as in the first example, Eq. (10), and the set of considered phases is $\mathscr{P} = \{\mathrm{V}, \mathrm{L1}, \mathrm{L2}\}$. In this system, we have to formulate driving forces for each species across each interface. The rate expressions of the V-L mass fluxes are formulated using the φ-φ-approach for the fugacities.

$$r_\sigma^{\mathrm{V},\mathrm{L}i} = k_\sigma^{\mathrm{V},\mathrm{L}i} P \left(x_\sigma^{\mathrm{V}} \varphi_\sigma^{\mathrm{V}} - x_\sigma^{\mathrm{L}i} \varphi_\sigma^{\mathrm{L}i} \right), \qquad i \in \{1,2\} \tag{14a}$$

and the mass fluxes between the two liquid phases is described using the γ-γ-approach

$$r_\sigma^{\mathrm{L1},\mathrm{L2}} = k_\sigma^{\mathrm{L1},\mathrm{L2}} P^\circ \left(x_\sigma^{\mathrm{L1}} \gamma_\sigma^{\mathrm{L1}} - x_\sigma^{\mathrm{L2}} \gamma_\sigma^{\mathrm{L2}} \right) \tag{14b}$$

with $k_\sigma^{\pi,\pi'} = 1$. The fucacity coefficients φ_σ^π are obtained from the PSRK EoS and the activity coefficients γ_σ^π are computed from a modified UNIFAC activity coefficient model (Horstmann et al., 2005; Holderbaum and Gmehling, 1991; Fredenslund et al., 1975). The stoichiometric matrix which connects the mass balances of the species in each phase is given by

$$\mathbf{A} = \mathbf{A}_\mathrm{p} = \begin{bmatrix} -\mathbf{I} & -\mathbf{I} & \mathbf{0} \\ \mathbf{I} & \mathbf{0} & -\mathbf{I} \\ \mathbf{0} & \mathbf{I} & \mathbf{I} \end{bmatrix} \tag{15}$$

where $\mathbf{I}$ denotes the 11×11 identity matrix and $\mathbf{0}$ is a 11×11 null matrix.

The ODE system, Eq. (1), of this system was solved at $T = 288.15\,\mathrm{K}$ and $P = 2\,\mathrm{MPa}$. In order to solve systems containing more than one phase, the feed composition has to be distributed among the phases that may occur. In this example, we have chosen a random distribution of all species between the three phases as initial condition for Eq. (1). The evolution of the composition in all phases is shown in Fig. 2, as well as the final compositions at equilibrium, see also Tab. 2. As it can seen, the nonconverted carbon monoxide as well as the light alkanes (C1–C3) are dominating the vapour phase. Additionally, we get two liquid phases, one organic phase which is dominated by the heavier alkanes (C4–C8) and one aqueous phase which consists only of water that is formed as coupled by-product of the reactions.

Table 2: Molar compositions x_σ^π at equilibrium.

phase	V	L1	L2
CO	0.045	0.002	0
H_2	0	0	0
H_2O	0.001	0.003	0.999
CH_4	0.825	0.091	0.001
C_2H_6	0.064	0.040	0
C_3H_8	0.029	0.064	0
C_4H_{10}	0.025	0.193	0
C_5H_{12}	0.008	0.204	0
C_6H_{14}	0.002	0.185	0
C_7H_{16}	0	0.135	0
C_8H_{18}	0	0.084	0

4. Conclusion

We showed that our proposed method is able to reliably compute complex chemical as well as phase equilibria. In a future work, we will apply our method also to combined phase and chemical equilibria computations. Furthermore, we will demonstrate how to perform dynamic equilibrium calculations within chemical process simulations.

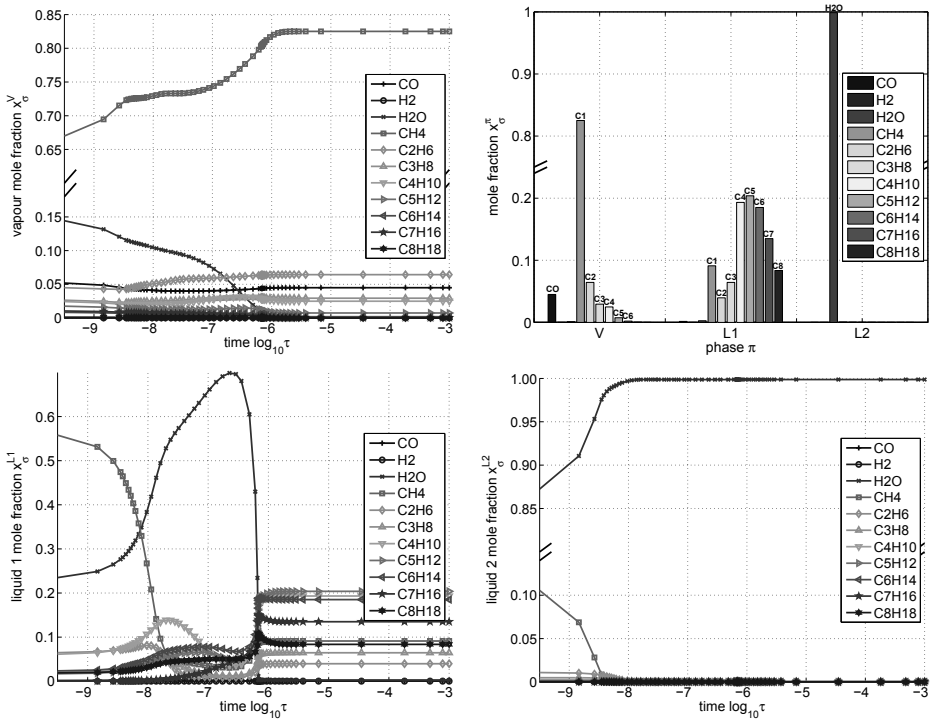

Figure 2: Evolution of the composition in the vapour phase x_σ^{V} (upper left), the evolution of the composition in the organic liquid phase x_σ^{L1} (lower left) and the evolution of the composition in the aqueous liquid phase x_σ^{L2} (lower right) w. r. t. time τ, as well as the final equilibrium composition of all phases (upper right).

Abstract

PHB (polyhydroxybutyrate) is a biodegradable polymer that is gaining importance worldwide due to their applications. In this study, the PHB fermentation process is studied using sucrose as substrate and *Azohydromonas australica* as strain. A dynamic model of the isothermal reactor fermentation is used to calculate mainly product yield and productivity. Employing modelling and simulation tools, first a sensitivity analysis is performed to determine the parameter model dependence, then the model is used to analyse the dynamic effect of operation mode (batch or fed-batch). Results show a better performance for a fed-batch reactor and will be used in the short term for economic and environmental analyses of the production process.

Keywords: fermentation, modelling, simulation.

1. Introduction

Biorefineries are mostly known for the production of energy, but the production of some biomolecules of interest and other biomaterials are also integrated. They require complex production process engineering tools for design, analysis and optimization, in order to include important factors such as low production costs, high yields and a process that is environmentally friendly. A variety of organic chemicals can be obtained from sustainably use of renewable raw materials. For instance the production of PHB (polyhydroxybutyrate), which belongs to the group of PHA (polyhydroxyalkanoate) that is a biodegradable polymer belonging to the polyesters class. This biotech product is gaining importance worldwide due to their applications such as packaging material, fibber and foam materials, medical implants, carriers for drug delivery among others.

In general, the production of PHA granules is promoted due to unfavourable conditions for the growth of bacteria. These biopolymers are produced and accumulated inside the cell as energy reserve when the bacterial cells are under stress (as limitation of phosphorus, nitrogen, oxygen, or in a non-optimal pH) and an excess of carbon source. It has been reported that it can be reached in bacteria up to 80% of its dry weight in PHA molecules (Peña et al., 2014). Currently the main problem, which limits the widespread use of PHB, is its relatively high cost compared with polypropylene. The

fermentation process, substrates and product recovery are the major cost (Madison and Huisman, 1999). Several studies have tackled this problem using different approaches, focusing mainly on the kind of microorganisms and substrates, as well as on the process configuration design and optimization. The process analysis efforts are primarily focused on the reactor because of the high value of raw materials and products, but also because of its high sensitivity to operating conditions, and risk. Hence, it is necessary to submit the process to an initial screening design prior to optimization and control.

In this study, the PHB fermentation process is studied using sucrose as substrate and *Azohydromonas australica* as strain. A dynamic model for an isothermal fermentation reactor is used to obtain mainly product yield and productivity. Employing modelling and simulation tools, first a sensitivity analysis is performed to determine the parameter model dependence, then the model is used to analyse the dynamic effect of operation mode (batch or fed-batch). The results can help the process designer to understand the fermentation process, as well as to focus experimental efforts on the parameter estimation and the determination of operating conditions with greater relevance.

2. Fermentation model

The PHB fermentation takes place in a stirred tank bioreactor. The cell growth process and PHB synthesis that is an intracellular product are shown in the Figure 1, where residual biomass (R) is the difference between total cell dry mass (X) and product PHB (P), $R = X - P$ (Dunn et al., 2008). The assumptions to develop a mathematical model are: the substrate (S_1) and nitrogen (S_2) are the only limiting substrates, the reactor contents are perfectly mixed, physicochemical properties of the mixture are constant, the level of oxygen saturation is considered constant, and the reaction is isothermal. The reactor can be either batch or fed-batch, in this latter a feed flow (F) containing substrate (S_{F1}) and nitrogen source (S_{F2}). The feed strategy is shown in Figure 2.

For the case study, the batch kinetic data were taken from Gahlawat and Srivastava (2013) for the PHB production using sucrose as substrate and *A. Australica* as strain. So that the specific growth rate (μ) of the microorganism can be expressed as a function of two limiting nutrients (S_1 and S_2), including inhibition:

$$\mu = \mu_{max}\left(\frac{S_1}{S_1 + K_{s1}}\right)\left(\frac{S_2^n}{S_2^n + K_{S2}^n}\right)\left(\frac{K_{In}}{K_{In} + S_1}\right)\left(1 - \frac{S_2^a}{S_m^a}\right) \tag{1}$$

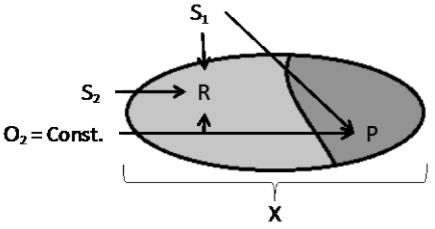

Figure 1. Cell growth and PHB synthesis.

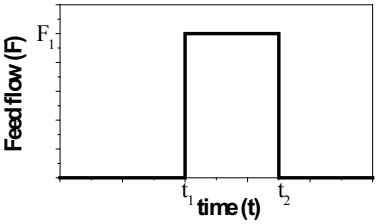

Figure 2. Feed flow for a fed-batch reactor.

The mathematical model of the PHB fermentation reactor is given by:

$$\frac{dR}{dt} = \mu R - \frac{F}{V}R, \qquad X = R + P, \qquad R(0) = R_0 \tag{2}$$

$$\frac{dS_1}{dt} = -q_{S1} R + \frac{F}{V}(S_{1F} - S_1), \qquad q_{S1} = -\left(\frac{\mu}{Y_{R/S_1}} + m_{S1}\right), \qquad S_1(0) = S_{10} \tag{3}$$

$$\frac{dS_2}{dt} = -q_{S2} R + \frac{F}{V}(S_{2F} - S_2), \qquad q_{S2} = -\left(\frac{\mu}{Y_{R/S_2}} + m_{S2}\right), \qquad S_2(0) = S_{20} \tag{4}$$

$$\frac{dP}{dt} = q_P R - \frac{F}{V}P, \qquad q_P = K_1 \cdot \mu, \qquad P(0) = 0 \tag{5}$$

$$\frac{dV}{dt} = F, \qquad V(0) = V_0 \qquad (F = 0 \text{ for a batch reactor}) \tag{6}$$

The product yield ($Y_{P/S}$) and productivity (i.e. space-time yield, Pr) are given by

$$Y_{P/S} = \frac{P \cdot V}{S_{10}V_0 + S_{1F}(V - V_0)}, \qquad Pr = \frac{P}{t} \tag{7}$$

3. Parameter sensitivity analysis

The kinetic parameters for the fermentation model (Eqs. 1-7) were adjusted from Gahlawat and Srivastava (2013) and are given in Table 1. Next a sensitivity analysis is performed for several reasons, such as the need to determine which parameters require further experimental research to enhance understanding of the process, which parameters are insignificant and can be eliminated from the model, which parameters are most highly correlated with the output; and once the model is in production use, what consequence results from changing a given input parameter (Hamby, 1994).

Table 1. Model parameters for PHB fermentation

Parameter	Value	Unit	notation
μ_{max}	0.41	h^{-1}	maximum specific growth rate
K_{s1}	10.31	g/L	sucrose affinity constant
K_{s2}	0.39	g/L	nitrogen affinity constant
K_1	3.80	g/g	growth associated product constant.
K_{In}	90.0	g/L	sucrose inhibition constant
$Y_{R/S1}$	0.099	g/g	biomass yield on sucrose
$Y_{R/S2}$	5.263	g/g	biomass yield on nitrogen
m_{S1}	0.062	g/(g.h)	maintenance coefficient respect to sucrose
m_{S2}	0.004	g/(g.h)	maintenance coefficient respect to nitrogen
S_m	13.0	g/L	critical nitrogen concentration
a	1.102	-	exponent for nitrogen inhibition
n	1.260	-	exponent for the sigmoidal relationship

A sensitivity ranking was obtained by increasing each parameter by a given percentage while leaving all others constant, and quantifying the change in model output. This sensitivity analysis was performed using the ICAS-MoT tool (Heitzig et al., 2011). Figures 3 and 4 show the corresponding results for the two main outputs (i.e. product and biomass concentrations) when varying one input parameter from its reference value of Table 1. According to these results the parameters K_1, $Y_{R/S2}$, μ_{max}, $Y_{R/S1}$ are those with more relevance (i.e. with more than 5% output difference), and they should be studied and estimated experimentally with more accurately to guaranty a satisfactory model prediction. In fact the parameters K_1, $Y_{R/S2}$, $Y_{R/S1}$ are directly related to the product and biomass yields, which depend strongly of the fermentation microorganism; while μ_{max} from the Monod Kinetics affects more the specific growth rate than K_{s1}.

4. Fermentation strategies

Batch fermentation is a popular process due to its flexibility and low operation costs, but the disadvantage is that the yield and productivity are usually low. Then, a fed-batch operation is employed to achieve high cell densities and a high concentration (Peña et al., 2014). Here both operating modes are compared by simulation to analyse their effect on the dynamics, and to achieve higher product yields and productivities.

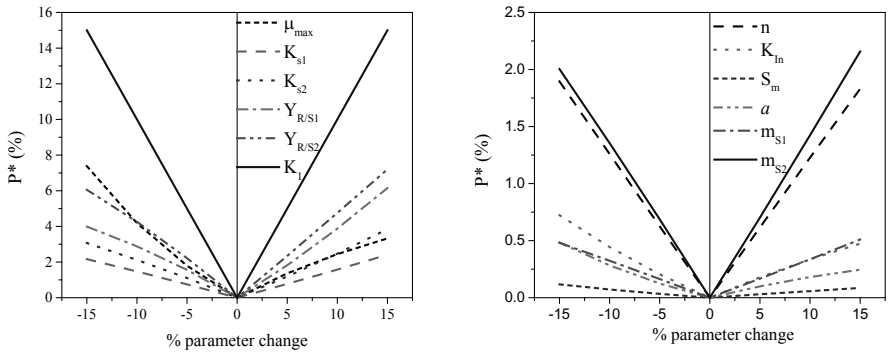

Figure 3. Parameter sensitivity analysis: product concentration difference (P^*).

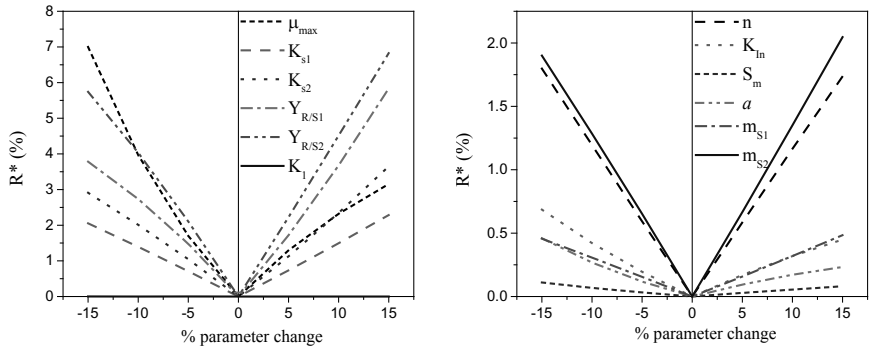

Figure 4. Parameter sensitivity analysis: residual biomass concentration difference (R^*).

All simulations consider an initial sucrose concentration of 25 g/L, as the culture growth with *A. Australica* has shown to have the maximum specific growth rate at this point; while the initial nitrogen concentration should be around 0.63 g/L to achieve the maximum specific growth rate and away from values greater than 13 g/L that corresponds to the total inhibition (Gahlawat and Srivastava, 2013). Thus, two different initial operating conditions are used for the nitrogen source to analyse its effect on the dynamic response: (a) S_{20} = 0.63 g/L, (b) S_{20} = 1.2 g/L. Simulations were performed using the ICAS-MoT tool (Heitzig et al., 2011).

4.1. Batch operation

Figure 5 shows the dynamic performance for the two different values of initial nitrogen concentration. It can be observed that the higher the nitrogen concentration almost the same product and biomass concentrations are achieved, but in shorter reaction time. The reaction time, final PHB concentration, product yield and productivity for each case are: (a) θ = 40 h, P = 8.2 g/L, $Y_{P/S}$ = 0.33 g/g, Pr = 0.21 g/(L·h); and (b) θ = 23 h, P = 8.75 g/L, $Y_{P/S}$ = 0.35 g/g, Pr = 0.35 g/(L·h). This means that the yield is not significantly improved with a slight increase in the nitrogen concentration, but productivity is increased. So that PHB production rate in multiple batches could be benefited with this finding.

4.2. Fed-batch operation

The operating conditions used for the feed strategy were: F_1 = 0.1 L/h ($16 \le t \le 31$), S_{1F} = 125 g/L and S_{2F} = 2.8 g/L. The corresponding dynamic performances are shown in Figure 6. The reaction time, final PHB concentration, product yield and productivity for each case are: (a) θ = 38 h, P = 23.4 g/L, $Y_{P/S}$ = 0.35 g/g, Pr = 0.62 g/(L·h); and (b) θ = 33 h, P = 24.0 g/L, $Y_{P/S}$ = 0.73 g/g, Pr = 0.35 g/(L·h). Comparing fed-batch reactor versus batch reactor, it can be concluded that effectively product concentrations and biomass are increased significantly in a fed-batch mode. Comparing the fed-batch reactors, it can be seen that a slight increase of the initial nitrogen concentration does not increase the PHB production, but the reaction time is reduced significantly again and thus higher productivity. Therefore, the best case found with this study corresponds to a fed-batch reactor with initial nitrogen concentration of 1.2 g/L.

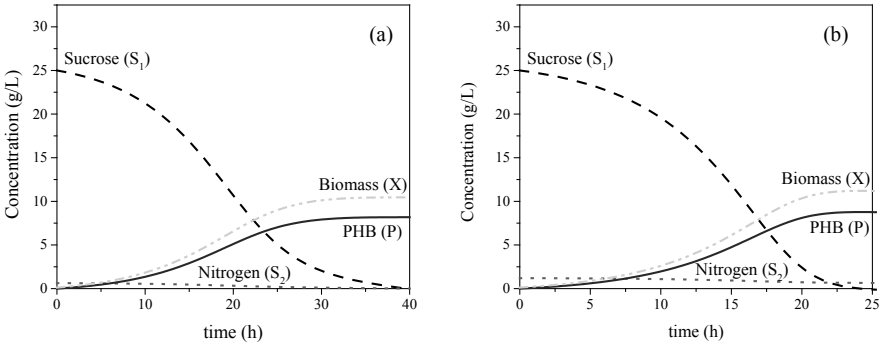

Figure 5. Dynamic response for a batch reactor: (a) S_{20} = 0.63 g/L, (b) S_{20} = 1.2 g/L.

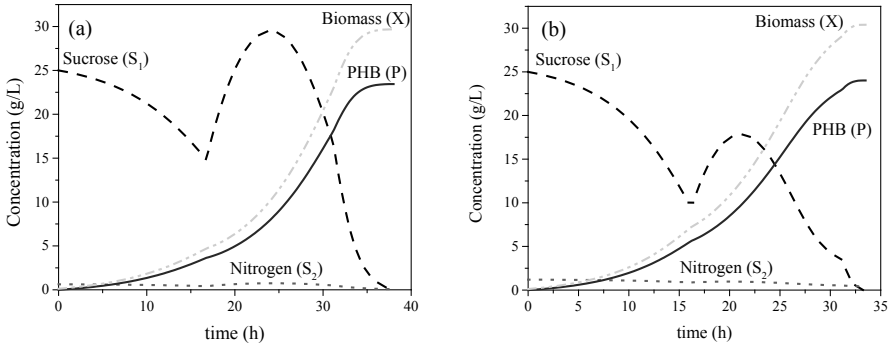

Figure 6. Dynamic response for a fed-batch reactor: (a) S_{20} = 0.63 g/L, (b) S_{20} = 1.2 g/L.

5. Conclusions

In this work, the PHB fermentation process using sucrose as substrate and *Azohydromonas australica* as strain was studied, through modelling and simulation tools. Sensitivity analysis showed that the parameters with major relevance in the fermentation model are the product and biomass yields (K_1, $Y_{R/S2}$, $Y_{R/S1}$), as well as the maximum specific growth rate (μ_{max}) used in the Monod equation. This result could help to reduce the model for control and monitoring purposes. In the other hand, relevant findings were obtained from the analysis done for the reactor operating mode. Results will be used in the short term to do optimization studies, as well as economic and environmental impact analyses, but in addition they can help the process designer to understand the process at different scales, to implement online process monitor and control, and so on.

Abstract

This work presents the use of global sensitivity analysis to retrofit mineral concentration plants. The ore that is fed to a concentration plant is heterogeneous, and it changes over time as the mine is operated. Moreover, the costs and the selling price of the concentrate can undergo significant changes. This situation forces readjustment of mineral concentration plants to new conditions. The methodology consists of three steps: 1) process modeling, 2) global sensitivity analysis to identify key variables, and 3) economic optimization of the plant. Sobol's method is used to identify the variables that most significantly affect the recovery of the species and the grade of the final concentrate. The methodology is applied to a copper and molybdenum concentrator plant of three concentration stages. The species present in the mineral correspond to chalcopyrite, chalcocite, covellite, molybdenite, pyrite, and quartz. The results show that the methodology could be helpful to improve the revenue of a flotation plant by making targeted changes to it.

Keywords: plant retrofit, global sensitivity analysis, flotation, copper, molybdenum.

1. Introduction

Flotation is a process of the physical-chemical separation of valuable species from gangue (waste material) that makes use of surface properties. The process is carried out in aerated tanks (cells or flotation columns) where the mineral particles are mixed with water and reagents that make the surface of the valuable mineral hydrophobic. When air enters the tank, the hydrophobic particles adhere to the air bubbles and form a froth, which overflows the top of the tank forming the valuable mineral concentrate. Generally, the cells are arranged in series to increase their efficiency, forming a bank of cells. To predict the metallurgical performance of a bank of cells or flotation column, a mathematical model is needed. This model should be able to relate the main operating conditions to the recovery of minerals to assist engineers in the design, monitoring and scaling of flotation devices. Many authors have proposed different models to describe the process of continuous flotation (Ek, 1992; Yianatos, 2007). Considering that the ore fed to the plant is heterogeneous and constantly changing and the costs and selling prices of the concentrate may experience significant changes, it is necessary to determine the key variables of the model, which is not easy because of the large number of equations, variables and operational aspects involved. The present work proposes a methodology for improvements in concentration plants based on the modification of key variables of the process.

2. Retrofit methodology

The retrofit methodology consists of three steps: 1) modeling of the flotation plant, 2) identification of key variables, and 3) optimization of the concentrator.

2.1 Modeling the flotation plant.

In the literature, there are several models to describe the process of flotation. The general rate equation for this type of process (Polat and Chander, 2000) involves distribution functions for the residence time and the flotation kinetics constant. The distribution function of the flotation kinetics may be rectangular, normal, or gamma, among others (Yianatos et al., 2005; Ferreira and Loveday, 2000). For residence time there are two extreme conditions, plug flow and perfect mixing (Yianatos et al., 1994). With such models, it is possible to model flotation stages that use either flotation cell banks or flotation columns.

2.2 Sensitivity analysis to identify key variables

Global sensitivity analysis (GSA) can be defined as "the study of how the uncertainty in the outcome of a model can be distributed to different sources of uncertainty in the input model" (Saltelli et al., 2008). GSA methods can be categorized into three groups (Confalonieri et al., 2010): screening methods, regression-based methods, and variance-based methods. In the last methods, the variance of the model output is expressed in terms of increasing dimensions, called partial variations, which represent the contribution of the inputs to the overall uncertainty of the model results. These methods allow the simultaneous exploration of the data space with uncertainty, which is usually performed via Monte Carlo sampling. Statistical estimators quantify the sensitivity of all input factors and groups of inputs via multidimensional integrals. The computational cost in terms of simulation models to estimate the sensitivity of higher-order interactions between the inputs can be very high. To prevent a high computational cost, Homma and Saltelli (1996) introduced the concept of a total sensitivity index. The total sensitivity index indicates the overall effect of a given input, considering all possible interactions of the corresponding entry with all other entries. It should be noted that when the value of the total sensitivity of an input variable is zero, this variable will have no influence on the model output. Examples of techniques of this group include analysis of variance (ANOVA), Fourier amplitude sensitivity test (FAST), its evolution extended FAST (S-FAST), Sobol's method (1993), and high-dimensional model representation (HDMR).

Sepulveda et al., (2013) applied global sensitivity analysis to analyze separation circuits. They concluded that Sobol's method works well in the analysis of flotation circuits. In this work, Sobol's method was used to perform the GSA. The model output was the grade and recovery of valuable metals generated by the plant. The distribution function used to represent the uncertainty of the input factors was the uniform distribution function. The software used to perform the GSA was RStudio.

2.3 Economic optimization

After identifying the key input factors, the most influential variables on the grade and recovery of concentrate, it is necessary to optimize the concentration plant from an economic point of view through revenue maximization. This optimization is performed by fixing the input factors with a sensitivity index close to zero and freeing the other input factors. Revenues will be obtained from equation (1), (Cisternas et al., 2004)

$$Revenue = \sum_k CF_k \ [p_k(g_k - \mu_k)(q_k - Rfc_k) - Trc_k]H \quad (1)$$

where k is Cu and Mo, p_k is the fraction of metal paid, g_k is the concentrate grade, Trc_k is the treatment charges, μ_k is the grade deduction, q_k is the price of metal per ton, Rfc_k is the concentrated refining charges, and H is the number of hours per year of plant operation.

3. Application: El Salvador concentration plant

3.1 Modelling of the plant

Consider the concentrator plant shown in Figure 1 (Codelco Division El Salvador, Chile), which consists of rougher, cleaner, and cleaner-scavenger stages. This plant processes 1,458.3 t/h of ore with 0.6 % Cu and 0.021 % Mo. The existing species and their feed mass flow rates are 12.64 t/h of chalcopyrite, 4.38 t/h of chalcocite, 1.32 t/h of covellite, 0.51 t/h of molybdenite, 1,223.56 t/h of pyrite, and 215.92 t/h of quartz. To model the concentrator mass balances, Eqs. (2) to (5) were used (Yianatos et al., 2005, and Yianatos and Henriquez, 2006).

$$R = R_{max}\left[1 - \frac{(1 - (1 + k_{max}\tau)^{1-N})}{(N-1)k_{max}\tau}\right] \quad (2)$$

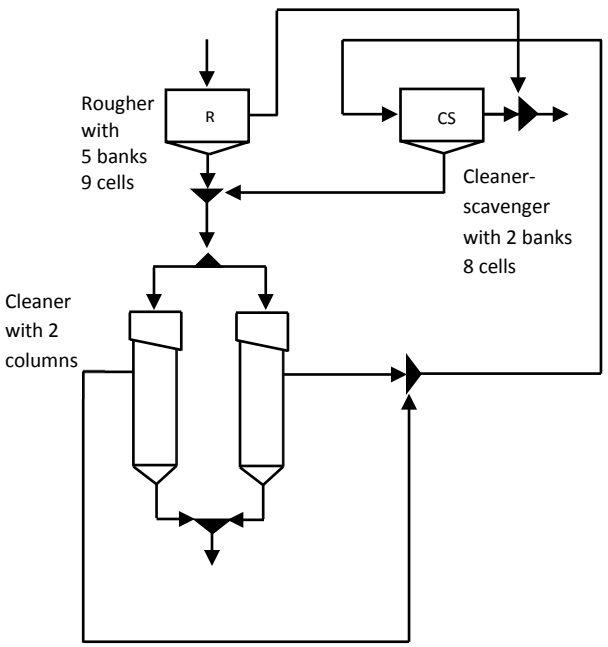

Figure 1: El Salvador (Chile) concentration plant.

$$R_C = R_{max}\left[1 - \frac{4}{3k_{max}\tau}\left(\frac{12}{k_{max}\tau + 12} - 1 + \frac{10}{9}\ln\left(\frac{10k_{max}\tau + 12}{k_{max}\tau + 12}\right)\right)\right] \quad (3)$$

$$R_F = 95exp^{\left(-0.0144\frac{H_F(1+3J_w)}{J_g^3}\right)} \quad (4)$$

$$R_G = \frac{R_C R_F}{1 - R_C + R_C R_F} \quad (5)$$

Specifically, Eq. (2) was implemented to model cell banks, and Eq. (3-5) were used to model the columns. R_{max} is the maximum recovery at infinite time, k_{max} is the maximum rate constant of the rectangular distribution function, τ is the residence time of one cell, and N is the number of cells in the bank. The maximum kinetic constants (min^{-1}) and maximum recovery included in the model are shown in Table 1.

For column flotation modelling, Eq. (5), distinguishes the collection zone recovery (R_C) and the froth zone recovery (R_F) to calculate the overall recovery R_G. The other constants involved in Equation (2-5) take the following values: 1.8 cm/s for the superficial air rate (J_g), 0.25 cm/s for superficial water rate (J_w), 100 cm for froth depth (H_F), 13.2 min for column residence time (τ_C), 3.5 min for cell rougher residence time(τ_R), and 4.8 min for cell CS residence time (τ_{CS}). The solids concentration in the R, C, and CS stages were 0.35, 0.195, and 0.22, respectively. The mathematical model used to assess the El Salvador plant gives the recoveries and grades shown in Table 2. The equipment sizes were 41 m^3 for R cells, 43 m^3 for CS cells, and 157 m^3 for columns in the C stage. The following values were used to evaluate the revenues in Eq. (1): p_k, 97 % and 98 % for Cu and Mo; Trc_k, 0.25 MUS $/t Cu and 0.1 MUS $/ t Mo; μ_k, 1.5 % and 0 % for Cu and Mo; q_k, 7 MUS $ /t Cu and 29 MUS $/t Mo; Rfc_k, 0.3 MUS $/t Cu and 0.9 MUS $/ t Mo; and H 7200 h/y. With these values, the plant revenue reaches 233 million US $/ y.

3.2. Sensitivity analysis to identify key variables

The objective of the flotation circuit used by the mining concentration plant in El Salvador is to obtain a concentrate rich in Cu and Mo. The influence of the input factors on the variability of the grade and recovery of Cu and Mo in the final concentrate is analyzed. The input factors to consider are the kinetic constants of each species in each stage, maximum recoveries of each species in each stage, residence time of the pulp in each stage, number of cells in the R and RS stages, solids concentration in each stage, froth depth height on the columns, and superficial air and water rates in the column. In total, there are 47 input factors, and uncertainty ranges were taken from Yianatos et al. (2005) and Yianatos and Henriquez (2006). Based on the current operating conditions of the El Salvador plant, variations of ∓ 15% and ∓3% for kinetic constants and maximum recoveries, respectively, were considered. In the case of the solids concentration and the froth depth, variations of ∓10% were considered. In the case of superficial air and water rates, variations of ∓11% and ∓ 12%, respectively, were considered. The variation in the number of cells in R and CS were 7-9 and 8-10, respectively. The variation of the residence time in the R and CS stages was ∓ 10%. Finally, the residence time in C varied by ∓ 7%.

Table 1. Maximum flotation kinetic constants (min^{-1}) and maximum recovery

	Chalcopyrite		Chalcocite		Covelline		Molybdenite		Pyrite		Quartz	
	R_{max}	k_{max}	R_{max}	k_{max}	R_{max}	k_{max}	R_{max}	k_{max}	R_{max}	k_{max}	R_{max}	k_{max}
R	0.85	0.65	0.82	0.54	0.82	0.45	0.81	0.47	0.19	0.17	0.13	0.10
C	0.90	0.35	0.86	0.34	0.86	0.34	0.86	0.32	0.17	0.07	0.10	0.04
CS	0.85	0.65	0.82	0.55	0.82	0.45	0.80	0.45	0.20	0.17	0.15	0.10

Table 2. Copper and Molybdenum grade and recovery, before and after plant retrofit. (chalcopyrite $CuFeS_2$, chalcocite Cu_2S, covellite CuS, molybdenite MoS_2, pyrite FeS_2, quartz SiO_2)

	Grade, %		Recovery, %		Species recovery, %					
	Cu	Mo	Cu	Mo	$CuFeS_2$	Cu_2S	CuS	MoS_2	FeS_2	SiO_2
Before	28.3	0.89	63.7	57.0	67.2	60.5	59.1	57.0	0.59	0.13
After	28.5	0.95	66.1	62.7	70.5	61.9	60.5	62.7	0.59	0.14

Figure 2 shows that input factors 10 (k_{max} molybdenite in C), 11 (k_{max} of pyrite in C), 25 (surface flow), 27 (R_{max} chalcopyrite in R), 30 (R_{max} molybdenite in R), and 42 (R_{max} molybdenite in CS) are the main sources of variability of Cu and Mo recoveries and grades. Input factor 10 affects the Mo grade and recovery, input factor 11 affects the Mo and Cu grades, input factor 25 affects both the Cu and Mo grades and recoveries, input factor 27 affects the Cu recovery, and input factors 30 and 42 affect the Mo grade and recovery. From these results, it is clear that six of the 47 input factors are the key variables for the Cu-Mo grade and recovery.

3.3. Optimization of concentrator

To optimize the plant economically, the six key variables were left free in their ranges of uncertainty, while other variables were kept fixed. The optimization was performed with the computer program using BARON-GAMS. The results indicate that the new values for the six key variables are 0.368 min^{-1} for k_{max} of molybdenite in the cleaner stage; 0.0595 min^{-1} for k_{max} of pyrite in the cleaner; 1.998 cm/s for superficial air rate; R_{max} 0.876 and 0.834 for chalcopyrite and molybdenite in R, respectively; and 0.824 for molybdenite in CS. The new metallurgical parameters for the plant are provided in Table 2.

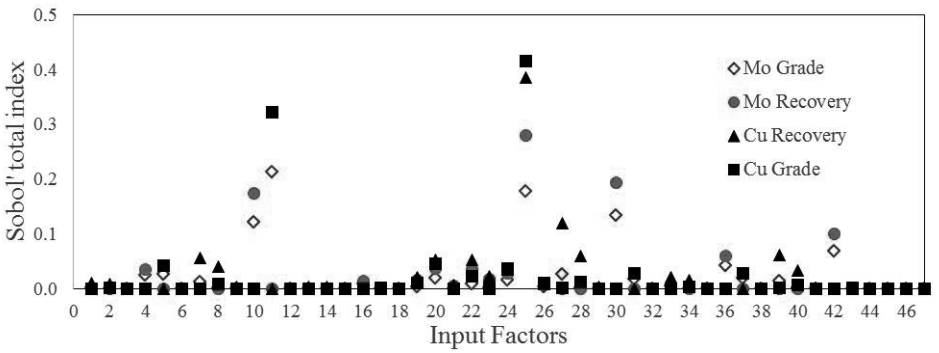

Figure 2. Sobol´s total sensitivity index.

The Cu and Mo recoveries increase from 63.7 to 66.6 % and 57.0 to 62.7 %, respectively. Moreover, the Cu and Mo grades increase from 28.3 to 28.54 % and 0.89 to 0.95 %, respectively. The revenues obtained are 244.6 million US$/y, an annual revenue increase of 11.6 million US$ with respect to the current operating conditions.

4. Conclusions

A methodology was developed for improvements in concentration plants. The methodology consists of three steps: 1) modeling of the concentrator; 2) identification of key variables, and 3) economic optimization of the plant. The contribution of this methodology is the use of Sobol's method for global sensitivity analysis to determine the variables that generate more variability on the metallurgical parameters of the concentrator. The methodology was applied to the El Salvador (Chile) concentration plant. The results indicate that GSA can significantly reduce the number of variables on which to focus when economically optimizing the plant because of the 47 input factors involved in the grade and recovery of Cu and Mo, only six factors are the most influential on these metallurgical parameters. The values obtained allowed economic optimization to increase annual revenues by almost 11.6 million US $.

Abstract

Two-phase flow in pipes occurs frequently in petroleum refineries. Simulation and design calculations for their processing units require methods for predicting void fractions and axial pressure drops, thus making it essential that precise models of the relevant thermo-fluid dynamics be combined with efficient numerical techniques. In this work, the two-phase flow with phase change problem of a refinery multicomponent naphtha (C5-C8) was modeled through the steady-state one-dimensional mixture model, which comprises continuity, momentum and energy differential equations for the mixture, in addition to an extra continuity equation for the vapor phase. Relative motions between the phases are accounted for by a constitutive expression for the one-dimensional drift velocity. Evaporation and condensation are considered via vapor-liquid equilibrium calculations, and suitable thermodynamic methods are also applied in the evaluation of physical properties. It is proposed in this work that this rigorous formulation fits in the scope of Differential-Algebraic Equations (DAE) systems and is preferably solved by proper established numerical methods rather than the customary iterative segregated semi-implicit algorithms based on finite volume approaches. Efficiency and accuracy gains are demonstrated as a result of the proposed numerical strategy, which yields higher-order numerical solutions in much less CPU time. Specific regularization functions were also developed in order to eliminate expected numerical issues of convergence failure due to discontinuities in the drift-flux parameters at flow-regime transitions.

Keywords: Two-phase flow, Drift-Flux Model, Differential-Algebraic Equations

1. Introduction

Modeling and simulation of liquid-vapor two-phase flows through pipes have motivated intense scientific research for quite a few decades now, partly due to the common occurrence of this scenario in several industrial applications. Two-phase flow plays, for instance, an important role in the thermal-hydraulics of nuclear power reactors. In the petroleum industry specifically, it can be encountered in oil and gas wells and in distillation units and boilers of petrochemical plants and refineries, as well as in pipelines for long-distance transportation of natural gas. Optimum design calculations rely on mathematical models and numerical methods for accurately predicting two-phase flow behavior in order to improve profitability and ensure that safety requirements are met.

2. Mathematical Modeling

Two-phase flow is analogous to single-phase flow in that its local instant values of densities, velocities, pressure and other field properties all exhibit random fluctuations induced by turbulence and irregular movements of liquid-vapor interfaces. Detailed predictions capturing such sudden microscopic motions would fall in the scope of *Direct Numerical Simulations* (DNS). In practice, important as though DNS may be as a research tool, its inapplicability in tackling complex engineering problems with today's available computational resources is well known. Hence, engineers resort to macroscopic formulations based on proper averaging techniques in which turbulent and interfacial fluctuations are smoothed out, with their effects being statistically accounted for. Solving these averaged equations also bears the advantage of calculating directly the mean values of most key variables, which would be the primary concern even if local instant results could be obtained (Prosperetti and Tryggvason, 2007; Yeoh and Tu, 2010).

Averaged conservation equations can be obtained for each phase or for the mixture as a whole. The latter approach lends itself more naturally than the former to the solution of many engineering problems, as they often require the response of the total mixture and not of each constituent phase. Thus, the Mixture Model is composed of four field equations, namely: the mixture continuity, momentum and energy equations, together with the vapor continuity equation (Ishii and Hibiki, 2011). A one-dimensional steady-state formulation of the model was considered in this study, as follows:

$$\frac{d\left[\rho_m v_m\right]}{dx} = 0 \tag{1}$$

$$\frac{d\left[\rho_m v_m^2\right]}{dx} = -\frac{dP}{dx} - \rho_m \frac{f_m}{2d} |v_m| v_m - \rho_m g \sin(\theta) - \frac{d}{dx}\left[\frac{\alpha_v \rho_v \rho_l}{\alpha_l \rho_m} \widehat{v}_v^{\mathrm{des}\,2}\right] \tag{2}$$

$$\frac{d\left[\rho_m v_m h_m\right]}{dx} = \frac{S\dot{Q}_w}{A} - \frac{d}{dx}\left[\frac{\alpha_v \rho_v \rho_l}{\rho_m}(h_v - h_l)\widehat{v}_v^{\mathrm{des}}\right] + \left[v_m + \frac{\alpha_v(\rho_l - \rho_v)}{\rho_m}\widehat{v}_v^{\mathrm{des}}\right]\frac{dP}{dx} \tag{3}$$

$$\frac{d\left[\alpha_v \rho_v v_m\right]}{dx} = \Gamma_v - \frac{d}{dx}\left[\frac{\alpha_v \rho_v \rho_l}{\rho_m}\widehat{v}_v^{\mathrm{des}}\right] \tag{4}$$

Talebi et al. (2012) obtained satisfactory agreement between predicted void fractions α_v and available experimental data upon solving the above model. It can be shown that these equations correspond to the Mixture Model deduced by Ishii and Hibiki (2011) when specific common assumptions are applied to the latter. These include neglecting viscous stresses, axial heat conduction, surface tension effects and covariance terms arising from area averaging.

In addition to physical properties and heat transfer, constitutive equations for the volumetric mass transfer rate Γ_v and the one-dimensional drift velocity $\widehat{v}_v^{\mathrm{des}}$ must also be provided to take into account the energy differences between phases and their relative motion, respectively. For simplicity, this study considered only the mass transfer at the wall due to the external heat transfer flux $\dot{Q}_w$ in calculating the former.

Ishii and Hibiki (2011) refer to their Mixture Model as the *Drift-Flux Model* in order to emphasize that the relative motions between both phases are taken into account by the *drift velocity* $\widehat{v}_v^{\mathrm{des}}$. The following *kinematic constitutive equation* relates this variable to the distribution parameter C_0 and the weighed mean local drift velocity $\left\langle v_v^{\mathrm{des}}\right\rangle_\alpha$:

$$\widehat{v}_v^{\mathrm{des}} = \frac{\rho_m\left[\left\langle v_v^{\mathrm{des}}\right\rangle_\alpha + (C_0 - 1)\, v_m\right]}{\rho_m - (C_0 - 1)(\rho_l - \rho_v)\,\alpha_v} \tag{5}$$

Both C_0 and $\left\langle v_v^{\mathrm{des}}\right\rangle_\alpha$ (and also the friction factor f_m) are flow-regime dependent, hence the need to establish expected flow patterns prior to selecting suitable correlations. In this study, flow regimes were predicted when necessary by means of the flow-pattern map of Mandhane et al. (1974).

3. Numerical Solution

3.1. Finite Volume Method

Standard finite volume discretization techniques have been extended to solve the general averaged equations of two-phase flows in conjunction with semi-implicit segregated algorithms such as SIMPLE and its variants. Common concepts and practices are thus retained, such as the need for staggered grids, the use of the upwind method in discretizing the advective terms or the conversion of the continuity equation into a linear system for the pressure corrections (Prosperetti and Tryggvason, 2007; Yeoh and Tu, 2010). In particular, the discretization of one-dimensional governing equations typically yields tri-diagonal algebraic systems, which Talebi et al. (2012) solved in every iteration by means of the widely used *Tri-Diagonal Matrix Algorithm* (TDMA).

Regarding the present study, a literature survey found no discussions concerning alternative numerical possibilities which exploit the model's steady one-dimensional character. Instead, predictably enough, such equations have been currently solved in the finite volume method framework as well.

3.2. Proposed Numerical Strategy

The Drift-Flux Model presents itself as an Initial-Value Problem when its equations are supplemented with known upstream conditions (at $x = 0$). Furthermore, it should be pointed out that only four of these equations are differential in x, whereas the rest are algebraic constraints comprising constitutive equations for the drift velocity and physical properties. This brief description matches the definition of *Differential-Algebraic Equations* (DAE) systems, the numerical solution of which is preferably pursued in other fields of study by available general purpose codes such as DASSL (Brenan et al., 1996). The model at hand can be readily rearranged into the most general form of DAE systems, which reads:

$$F\left[x; y(x); \frac{dy}{dx}\right] = 0 \tag{6}$$

in which y is the state vector of dependent variables and F includes both differential and algebraic equations. Many of the aforementioned general purpose integrators employ the backward differentiation formulas (BDF) with Newton's method at each integration step (Brenan et al., 1996).

There are important efficiency gains to expect from choosing this DAE approach over the Finite Volume Method in the solution of the one-dimensional steady-state Drift-Flux Model. Its capability of solving all involved equations (differential and algebraic) in a simultaneous fashion stands out next to the segregated algorithms whose iterations consist of several sub-procedures, some of which are iterative as well. Among the latter are the thermodynamic stage of updating physical properties and the successive substitution method suggested by Patankar (1980) when a tri-diagonal system is actually non-linear and thus cannot be handled by the TDMA alone. Further on, the BDF method's multistep (higher order of accuracy) nature and the adaptive (variable step-size) capability of modern computer codes also enable the latter to use very small steps only where they are really needed, thus enhancing efficiency and accuracy. Finite-volume-based solutions, on the other hand, are often based on less accurate discretization techniques. They also require testing for grid independence with successive mesh refinement between simulations until certain key results do not change above a specified tolerance (Versteeg and Malalasekera, 2007). DAE integrator codes, in turn, are capable of delivering such converged results after one simulation by estimating the truncation error and accordingly adjusting the step size throughout the solution process.

3.3. Proposed Treatment of Discontinuities

Two-phase flow models are generally known to bear numerical discontinuities which stem from switching equations at flow-regime transition boundaries. This is expected in the present study

regarding constitutive models for C_0, $\langle v_v^{\text{des}} \rangle_\alpha$ and f_m. Though this switching can be easily coded by combining IF-ELSE statements with the possible predictions of a flow-pattern map, such approach is highly inadvisable in the integration of DAE systems, for the discontinuities that are introduced in the derivatives of F (Equation 6) will cause serious problems in Newton iteration, error estimates and stepsize selection algorithms which may even lead to integration failure (Brenan et al., 1996). Proper treatment of the discontinuities is thus essential to this DAE proposal.

The standard procedure in addressing the above issue is to restart the integration after discontinuities. The present study proposes instead that the more convenient *regularization function* approach successfully used by Teixeira et al. (2014) be applied to the Drift-Flux Model. In that reference, discontinuities generically given by:

$$z(X) = \begin{cases} z_1(X), & p(X) \geq p_{max} \\ z_2(X), & p(X) < p_{max} \end{cases} \tag{7}$$

were replaced by a single continuous algebraic equation:

$$z(X) = \eta(p(X) - p_{max}; \varepsilon) z_1(X) + [1 - \eta(p(X) - p_{max}; \varepsilon)] z_2(X) \tag{8}$$

in which $\eta(arg; \varepsilon)$ is a *continuous* regularization function evaluated at scalar argument *arg* and parameter ε. In order for Equation 8 to closely reproduce 7, η was chosen as follows:

$$\eta(arg; \varepsilon) = \frac{1 + \tanh(arg/\varepsilon)}{2} = \begin{cases} 1, & arg > +\xi \\ 0, & arg < -\xi \end{cases} \tag{9}$$

in which $0 < \xi << 1$. ξ is a function of user-supplied parameter ε, which must be adjusted to each particular application so that the interval $[-\xi, \xi]$ is small enough that deviations between Equations 7 and 8 can be neglected.

In the present context, it was sought to smooth the expected discontinuities at the flow-regime boundaries of Mandhane et al. (1974). Every switch of equations in the FORTRAN code provided in that reference was continuously reproduced upon applying regularization functions exactly as discussed. This ultimately resulted in continuous functions named *elongatedBubble*, *Slug*, etc. which vary sharply but continuously between 1 and 0 as the given set of variables enter or leave the corresponding regions in the flow-pattern map. The selections of constitutive equations for C_0, $\langle v_v^{\text{des}} \rangle_\alpha$ and f_m then become three simple weighted sums of regime-specific correlations with the devised flow-pattern functions employed as weighting factors.

4. Parameters and Methods

All reported calculations considered the two-phase flow of 115000 kg/h of naphtha through a horizontal, 12-meter long carbon steel pipe segment with inner and outer diameters of 7.981 in and 8.625 in. Thermophysical and transport properties (phasic enthalpies, densities, viscosities and surface tension) were predicted through the compositional approach with constitutive methods presented by Daubert and Danner (1997) and Riazi (2005) for petroleum fractions of defined composition. Calculations of residual enthalpies and vapor-liquid equilibrium (flash) were based on the Peng-Robinson equation of state. The assumed naphtha's molar composition is very similar to that of the gas chromatography example presented by Riazi (2005).

The DAE strategy's implementation employed DASSL's extended version DASSLC, which features all desirable numerical aspects previously discussed. It minimally requires from the user an initial conditions vector and a residuals subroutine for F in Equation 6 (Secchi, 2012). Absolute and relative tolerances used were 10^{-9} and 10^{-6}. Subsequently, a finite-volume discretization of the Drift-Flux Model on a staggered grid was also carried out so as to allow a thorough assessment of the proposal's advantages. Mostly used approximations were the upwind method and the

"stepwise profile" so nicknamed by Patankar (1980). The discretized equations were sequentially and iteratively solved by the TDMA and SIMPLER algorithms. The latter, which does not require pressure underrelaxation, has been shown to be more efficient than SIMPLE and possibly as efficient as SIMPLEC or PISO (Versteeg and Malalasekera, 2007).

5. Results and Discussion

5.1. Computer Effort Assessment

The DAE strategy was first compared with the finite-volume segregated method in terms of computing times programatically measured in an average computer (2.20 GHz i7 with 8 GB of RAM). The fictional case study was a pipe exposed to 27° C and 36 km/h wind. The outer convection resistance between the pipe and its surroundings was accounted for by the forced-convection Nusselt correlation of Churchill and Bernstein (1977). Inlet conditions were 4.95 kgf/cm^2 and 163.95° C. Such values were initally chosen so that the *Elongated Bubble* flow regime prevailed through the entire range of x, and hence no discontinuity issues arose. In this flow pattern, the friction factors f_m were predicted from a single-phase correlation with the mixture's void-fraction-weighted physical properties (Hasan and Kabir, 1988). As for the drift-flux variables, the following suitable constitutive equations were used (Ishii and Hibiki, 2011; Levy, 1999):

$$C_0 = 1.2 - 0.2\sqrt{\frac{\rho_v}{\rho_l}} \tag{10}$$

$$\left\langle v_v^{\text{des}} \right\rangle_\alpha = 1.53 \left[\frac{\sigma_l g \left(\rho_l - \rho_v\right)}{\rho_l^2} \right]^{1/4} \tag{11}$$

It took DASSLC only 1.03 seconds to solve the illustrative problem, whereas the SIMPLER algorithm required 9.58 s with a 25 control-volume mesh ($NV = 25$). These measured times differ by a factor of nearly 10, which clearly demonstrates the anticipated advantages of the DAE approach regarding the one-dimensional model. A grid-independence study was also performed, with NV successively doubled up to a value of 200. After each simulation, relative errors were calculated based on DASSLC's solution, which was deemed appropriate given the latter's tight reported tolerances. Figure 1, which presents these results for the void fraction profiles, shows that only with $NV = 200$ did all relative errors fall below 0.10%. Also, the errors are shown to decrease by half when NV is doubled, which implies only first-order accuracy and thus explains the need for small steps in satisfying a given tolerance. The measured times with 50, 100 and 200 cells (27.15 s, 56.75 s and 439.0 s) also greatly exceed that required by DASSLC.

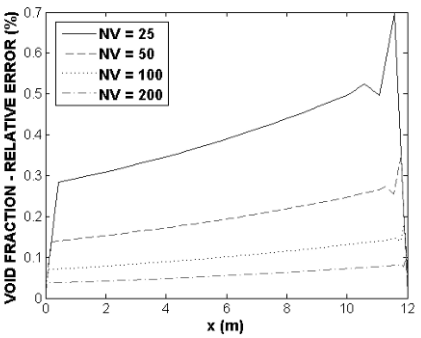

Figure 1: Vapor void fraction relative errors.

5.2. Integration of Discontinuous Equations

The effects of discontinuities on the proposed approach were investigated by replacing the assigned atmospheric conditions with a skin temperature of 215° C. Integration with DASSLC then failed at first, but succeeded when the regularization functions were applied to the flow-regime boundaries with $\varepsilon = 10^{-3}$. Figure 2 indeed shows a -6.5% discontinuity in the drift-velocity profile at $x \approx 0.78$ m, where the flow pattern was found to change from Elongated Bubble to Slug.

Calculations for the Slug regime assumed $\rho_m \approx \rho_l (1-\alpha_v)$ in predictions of f_m and also considered $C_0 = 1.2$ and $\left\langle v_v^{\text{des}} \right\rangle_\alpha = 0$ (Hasan and Kabir, 1988). Assigning $\varepsilon = 10^{-3}$ in regularization function 9 yields $\xi \approx 0.02$, which was verified to be less than 0.4% of liquid and vapor superficial velocities in the transition region and also much smaller than their variations from inlet to outlet. This successfully confined interpolations such as Equation 8 to the very vicinities of regime-transition boundaries. One side effect of such sharp variations is their need for much smaller steps, which explains the increase to 6.33 s in the measured DASSLC integration time. It seems therefore advisable to also consider a lower limit when tuning ε so as to not render the calculations too ineficient. Nevertheless, this increased time is still considerably smaller than those reported for the finite-volume method, and the regularization approach is thus shown to be an effective alternative to restarting integrations at every discontinuity.

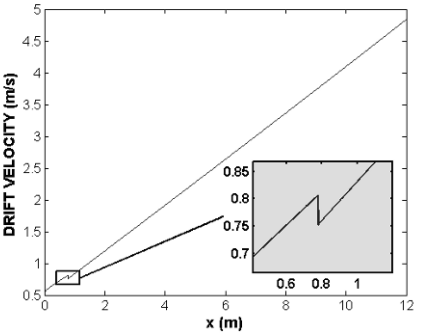

Figure 2: Discontinuous drift-velocity profile.

6. Summary and Conclusions

Modern DAE integrators have been successfully shown to be more efficient than finite-volume based iterative algorithms in numerically solving the one-dimensional steady-state equations of the Drift-Flux Model. Potential problems with the proposed strategy due to expected typical discontinuities in flow-regime boundaries were also successfully and conveniently handled by means of so-called regularization functions.

Model-based design of experiments for the identification of kinetic models in microreactor platforms

Federico Galvanin, Enhong Cao, Noor Al-Rifai, Asterios Gavriilidis, Vivek Dua*

Department of Chemical Engineering, University College London, Torrington Place, London WC1E 7JE, United Kingdom, v.dua@ucl.ac.uk

Abstract

Microreactor platforms represent advanced tools in reaction engineering for the quick development of reliable kinetic models. Experiments can be performed with a better reaction temperature control, enhanced heat and mass transfer and mixing of reactants. However, the effectiveness of the model identification procedure is strictly related to the execution of properly designed experiments, allowing elucidation of the reaction mechanisms and providing a precise estimation of the kinetic parameters. In this paper a model-based design of experiments (MBDoE) approach is proposed where experiments are designed for both discriminating among competing models and for improving the estimation of kinetic parameters. The procedure is tested on a real case study related to the identification of kinetic models of methanol oxidation on silver catalyst.

Keywords: design of experiments, model discrimination, microreactor technology.

1. Introduction

Microreactor platforms represent the ideal system for the study and determination of intrinsic reaction kinetics for strongly exothermic, endothermic, and fast catalytic reactions. These systems allow these reactions to be performed isothermally and in the absence of mass transfer limitations, ensuring the rapid manipulation of reaction conditions and the precise control of the hydrodynamic environment (Al-Rifai et al., 2013). However, the quantity, quality, and speed of information generated by these systems, due to the exploitation of small volumes and fast dynamics, are particularly affected by the experimental conditions realised during the trials. Model-based design of experiments (MBDoE) techniques (Franceschini and Macchietto, 2008) have been proposed for the purpose of designing a set of experiments yielding the most informative data to be used for model identification. Experiments can be designed for discriminating between candidate kinetic models (Schwaab et al., 2006) or, if a suitable model structure is available, to improve the precision in parameter estimation (Reizman and Jensen, 2012). Whilst the first objective is achieved based on the maximisation of the discriminating power, the second is based on the maximisation of the expected information given as a measurement function of the Fisher information matrix (FIM).

In this paper, a novel MBDoE formulation is proposed where the trade-off between Fisher information and discriminating power is computed using a *multi-objective* approach, allowing for the optimisation of the information which can be obtained from experiments in microreactor platforms. The MBDoE sequential procedure is articulated into three main steps: *i*) given a set of candidate kinetic models, a ranking of experiments is realised in order to detect both the experimental regions yielding the

maximum amount of Fisher information and the ones providing the maximum discriminating power; *ii*) information maps are detected and used for the optimal design of experiments; *iii*) the optimally designed experimental conditions are implemented in the microreactor system, providing new experimental data to be used for model identification. The iteration of steps *i*) to *iii*) lead to the detection of the best model structure representing the system, elucidating the most plausible kinetic mechanism for a given catalyst, ensuring a precise estimation of the kinetic parameters. Steps *i*)-*iii*) of the proposed procedure are tested on a real case study concerning the identification of kinetic models for the oxidative dehydrogenation of methanol to formaldehyde on silver catalyst (Andreasen et al., 2005). Experiments are carried out on a specifically designed silicon-glass microreactor fabricated by photolithography and deep reacting ion etching, and where the silver catalyst is deposited on the channel wall by sputtering (Cao and Gavriilidis, 2005). The temperature, pressure and volumetric flow rate are controlled and continuously monitored; concentrations are analyzed online at the inlet and outlet of the microreactor using gas chromatography.

2. Optimal design of experiments in microreactor platforms

As a first approximation, a microstructured reactor is modelled as a dynamic plug flow reactor (PFR) in the form:

$$\frac{\partial c_i}{\partial t} - u_z \frac{\partial c_i}{dz} = \sum_{j=1}^{N^{reaz}} \nu_{ij} r_j \tag{1}$$

where c_i is the species concentration, r_j and ν_{ij} are the reaction rate and the stoichiometric coefficient of the i-th species in the j-th reaction respectively, z is the axial coordinate, u_z is the speed of fluid flow in the z-direction and t the integration time. Equations (1), together with the reaction rate expressions, represent a system of differential and algebraic equations (DAEs) which can be written in the general form as:

$$\mathbf{f}\left(\dot{\mathbf{x}}(z,t), \mathbf{x}(z,t), \mathbf{u}(z,t), \boldsymbol{\theta}, t\right) = 0 \qquad \hat{\mathbf{y}}(z,t) = \mathbf{g}\left(\mathbf{x}(z,t)\right) \tag{2,3}$$

with the set of initial conditions $\mathbf{x}(0,0) = \mathbf{x}_0$, where $\mathbf{x}(z,t)$ is the N_x-dimensional vector of state variables (i.e. the concentrations c_i in (1)), $\mathbf{u}(z,t)$ is the N_u-dimensional vector of manipulated input variables (i.e. flow rate, temperature, pressure of the system) and $\boldsymbol{\theta}$ is the N_θ-dimensional set of unknown kinetic model parameters to be estimated. The symbol ^ is used to indicate the estimate of a variable (or of a set of variables): thus, $\mathbf{y}(z,t)$ is the vector of measured values of the outputs, while $\hat{\mathbf{y}}(z,t)$ is the vector of the corresponding values estimated by the model. Note that, in general, state variables and input variables can be characterised in both time and space.

MBDoE techniques for improving parameter estimation aim at decreasing the parameter uncertainty region predicted by model through the solution of the optimisation problem:

$$\boldsymbol{\varphi}^{\mathrm{PE}} = \arg\min_{\boldsymbol{\varphi}\in D}\left\{\psi\left[\mathbf{V}_\theta(\boldsymbol{\theta},\boldsymbol{\varphi})\right]\right\} = \arg\min_{\boldsymbol{\varphi}\in D}\left\{\psi\left[\mathbf{H}_\theta^{-1}(\boldsymbol{\theta},\boldsymbol{\varphi})\right]\right\} \tag{4}$$

The design optimisation (4) is carried out by computing the n_φ-dimensional experiment design vector $\boldsymbol{\varphi} = [\mathbf{y}_0, \mathbf{u}, \mathbf{t}^{sp}, \tau]^{\mathrm{T}}$, which includes the N_y-dimensional set of initial conditions $\mathbf{y}_0$ (subset of $\mathbf{x}_0$) on the measured variables, the set of manipulated inputs $\mathbf{u}$, the set of time instants at which the output variables are sampled ($\mathbf{t}^{sp}$) and (possibly) the experiment duration τ. Equation (4) is subject to (2,3) and to a n_φ-dimensional set of constraints on design variables, defining the design space D (i.e. the operating range of

experimental decision variables). In (4) $\mathbf{V}_\theta$ and $\mathbf{H}_\theta$ are the variance-covariance matrix of model parameters and the FIM, respectively. $\mathbf{H}_\theta$ is defined by

$$\mathbf{H}_\theta(\boldsymbol{\theta},\boldsymbol{\varphi}) = \mathbf{H}_\theta^0 + \sum_{k=1}^{n_{sp}} \sum_{i=1}^{N_y} \sum_{j=1}^{N_y} s_{ij} \left[\frac{\partial \hat{y}_i(z_k,t_k)}{\partial \theta_l} \frac{\partial \hat{y}_j(z_k,t_k)}{\partial \theta_m}^T \right]_{l,m=1\ldots N_\theta} . \quad (5)$$

In (5) s_{ij} is the *ij*-th element of the $N_y \times N_y$ inverse matrix of measurements error and $\mathbf{H}_\theta^0$ is the prior dynamic information matrix, taking into account preliminary statistical information about the parametric system before each trial is carried out. According to (4), the experiment is designed so as to minimise a measurement function ψ of $\mathbf{V}_\theta$, representing the design criterion. The most common design criteria are the A-, D-, E-optimal criteria, minimising the trace, the determinant and the maximum eigenvalue of $\mathbf{V}_\theta$ respectively (Pukelsheim, 1993), or its singular values (Galvanin et al., 2007).

2.1 MBDoE for model discrimination: multi-objective formulation

In order to evaluate the relative amount of information which can be obtained for the estimation of the *j*-th model parameters from the *i*-th experiment the following Relative Fisher Information (RFI) index can be computed:

$$RFI_{ij} = \frac{\left\|\mathbf{H}_{ij}\right\|}{\sum_{i=1}^{N_{exp}} \left\|\mathbf{H}_{ij}\right\|} = \frac{\left\|\mathbf{H}_{ij}\right\|}{\left\|\mathbf{H}_j\right\|} \quad (6)$$

where $\left\|\mathbf{H}_{ij}\right\|$ is the FIM related to the *i*-th experiment for the *j*-th competitive model evaluated from (5) and $\left\|\mathbf{H}_j\right\|$ is the global information obtained from the N_{exp} experiments for the identification of the *j*-th model according to a norm $\| \cdot \|$. In this study, the trace has been used as a suitable matrix norm. The utility of (6) is that it allows for a ranking of the available experiments, underlining the most informative regions of the design space *D* to be exploited for parameter identification.

A multi-objective MBDoE is formulated with the purpose of discriminating between N_M competing models ensuring at the same time the best possible estimation of kinetic parameters:

$$\boldsymbol{\varphi}^{\mathrm{MD}} = \arg\max_{\boldsymbol{\varphi}\in D} \left\{ \psi^{\mathrm{MD}} \right\} = \arg\max_{\boldsymbol{\varphi}\in D} \left\{ \sum_{M,N=1}^{N_M} P_M P_N \left[\sum_{i=1}^{N_y} \frac{\left(\hat{y}_{M,i} - \hat{y}_{N,i}\right)^2}{\sigma_{y,i}^2} \right]_{M,N} \right\} \quad (7)$$

$$\text{s.t.} \qquad \psi^{\mathrm{PE}} = \sum_{j=1}^{N_M} \left\|\mathbf{H}_j\right\| / N_M \le \varepsilon \qquad \varepsilon^{MIN} \le \varepsilon \le \varepsilon^{MAX} \quad (8)$$

In (7) ψ^{MD} is the discriminating power, ψ^{PE} is the design optimality criterion, $\hat{y}_{M,i}$ and $\hat{y}_{N,i}$ are the *i*-th predicted responses of model *M* and *N*, while P_i is the relative probability of the i-th model to be the "true" model computed after parameter estimation (Schwaab et al., 2006). The optimisation (7-8) is carried out for a number of values of ε, ranging from the minimum value ($\varepsilon = \varepsilon^{\mathrm{MIN}}$, MBDoE for model discrimination) to the maximum value ($\varepsilon = \varepsilon^{\mathrm{MAX}}$, MBDoE for improving parameter estimation).

3. Case study: methanol oxidation on silver catalyst

3.1 Reaction mechanisms

In the identification study the simplified model proposed by Andreasen et al. (2005) was used as a reference model (Model 1). According to Model 1, the following reactions constitute the base (global) mechanism:

$$CH_3OH + 1/4\ O_2 \rightleftharpoons CH_2O + 1/2\ O_2 + 1/2\ H_2O \quad (9)$$

$$CH_2O + 1/2\ O_2 \rightleftharpoons H_2 + CO_2 \quad . \quad (10)$$

Two additional simplified kinetic models of increasing level of complexity were considered:

1. Model 2: including the following combustion reactions for both CH_3OH and CH_2O:

$$CH_3OH + 3/2\ O_2 \rightarrow 2H_2O + CO_2 \quad (11)$$

$$CH_2O + O_2 \rightarrow H_2O + CO_2; \quad (12)$$

2. Model 3: including combustion reactions (11,12) for CH_3OH and CH_2O; the global methanol oxidation reaction (9) was split into a dehydrogenation reaction ($CH_3OH \rightleftharpoons CH_2O + H_2$) and a selective oxidation reaction ($CH_3OH + 1/2O_2 \rightleftharpoons CH_2O + H_2O$).

The hydrogen oxidation reaction ($H_2 + 1/2O_2 \rightarrow H_2O$) has also been included in each reaction mechanism. Although this reaction is known to occur only at higher temperatures (Schubert et al., 1998), it has been considered to account for the low hydrogen concentrations observed in the experiments. The reaction rate expressions for (9,10) are the ones proposed by Andreasen et al. (2005), while power law kinetic expressions have been used for the other reactions in the proposed mechanisms.

3.2 Model discrimination and ranking of experiments

In this case study the elements of the design vector $\boldsymbol{\varphi}$ which can be optimised are:

1. Composition of reactants in terms of molar fractions: methanol (0.07-0.14), oxygen (0.03-0.10) and water (0.02-0.22) modelled as initial conditions $\mathbf{y}_0$;
2. Temperature T (725 K < T < 826 K) modelled as input $\mathbf{u}$;
3. Pressure P (1.6-1.7 atm) modelled as input $\mathbf{u}$;
4. Flow rate F (25-27 mL/min) modelled as input $\mathbf{u}$.

The ranges of operability shown in parenthesis in the above represent the investigated design space D, where P and F have been basically kept constant during the trials. Concentration measurements are available as molar fractions of CH_3OH, O_2, CH_2O, H_2, H_2O and CO_2 at the inlet ($z = 0$) and outlet ($z = l$, where l is the reaction channel length [mm]) of the reactor and they are assumed corrupted by Gaussian noise with zero mean and a standard deviation of 1% on the reading. Preliminary data from N_{exp}= 21 experiments from the microreactor system were available in order to discriminate among the rival models (Model 1-3) where the effect of temperature (T) and feed composition (CH_3OH, O_2 and H_2O molar fraction, $\mathbf{y}_0 = [y_{CH3OH}\ y_{O2}\ y_{H2O}]^T$) on final products ($CH_3OH$, O_2, H_2O, CH_2O, H_2, CO_2) was investigated:

1. Experiments E1-5: T varied from 725 to 826 K (y_{CH3OH}=0.10, y_{O2}=0.04, y_{H2O}=0.07);
2. Experiments E6-9: T varied from 725 to 826 K (y_{CH3OH}=0.15, y_{O2}=0.06, y_{H2O}=0.11);
3. Experiments E10-21: T kept at 733 K, variable y_{CH3OH} (range 0.07-0.14, E10-E14), y_{O2} (range 0.03-0.10, E15-E17) and y_{H2O} (range 0.02-0.21, E18-E21).

In all these performed experiments He was used as an inert, the volumetric flow rate was kept at F = 26.5 mL/min and the pressure at P = 1.6 atm. The reaction channel length containing the catalyst was 12.5 mm long, 0.12 mm high and 0.6 mm wide. A

model discrimination was carried out from experimental data by assessing for each proposed model: *i*) the lack-of-fit in terms of χ^2 obtained after parameter estimation is carried out; *ii*) the Akaike information criterion (AIC) investigating the trade-off between fitting capability and model complexity (i.e. N_θ); *iii*) the probability P_i. Results after model discrimination are shown in Figure 1. Model 3 provides the most satisfactory results in terms of lack-of-fit, underlined by the lower χ^2, and turns out to be the most probable "true" model (P_3 = 39%). However, it also represents the most complex model in terms of number of model parameters, as clearly indicated by the relatively high AIC value, which tends to promote the use of Model 1.

	Model		
	Model 1	*Model 2*	*Model 3*
χ^2	9762	7721	6874
N_θ	6	10	12
AIC	-6.4	2.1	6.3
P_i	27%	34%	39%

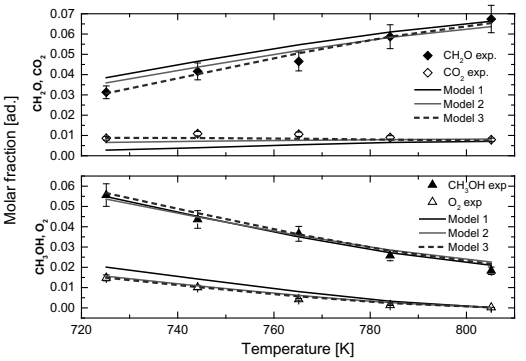

Figure 1. Relative performance of candidate kinetic models after model identification in terms of molar fractions as a function of temperature for selected species. Model discrimination results are given in the table on the left hand side.

Model 1 (solid line) is ineffective in representing oxygen, formaldehyde and CO_2 molar fractions, while methanol profiles are always represented in a satisfactory way by all the proposed models. Interestingly, the representation of oxygen and methanol concentration as a function of the investigated temperature was significantly improved by including the combustion reactions in the model formulation (Model 2 and 3) as compared to the original model formulation (Model 1). Furthermore, a better representation of both CO_2 and CH_2O can be realised if competitive dehydrogenation and selective oxidation steps are included (Model 3). The model availability allows the definition of the best experimental conditions in order to estimate the model parameters with the greatest precision. Figure 2a shows the RFI evaluated from (6) for a ranking of experiments E1-E21. Each proposed model shows a different RFI response to a change in experimental conditions. In particular: *i*) an increment in temperature *T* would be beneficial for Model 2, but would be unhelpful for the estimation of Model 1 and Model 3 kinetic parameters; *ii*) an increment on oxygen concentration in the feed is beneficial for the identification of all the proposed models; *iii*) higher methanol concentration in the feed is beneficial for the identification of Model 2 and 3, while a maximum in the information level is realised for Model 1; *iv*) water concentration increases the information for Model 1 and 2, while does not particularly affect Model 3 identification.

3.2 Multi-objective design of experiments for model discrimination

Results in terms of solutions of the multiobjective problem (7-8) are given in Figure 2b. Points 1-4 in the figure represent the solutions of the optimization problem (7-8) in terms of trade-off between discriminating power (ψ^{MD}) and design optimality (ψ^{PE}). Interestingly, the temperature *T* turns out to be the most influential design variable to be considered. In fact, points 1-4 in the plot are all identified by $\mathbf{y}_0 = [y_{CH3OH}\ y_{O2}\ y_{H2O}]^T$ = [0.14 0.10 0.22] ^{T}, F = 26.0 mL/min, P = 1.6 atm (same inlet conditions) but totally

different reaction temperatures (T^1 = 826 K , T^2 = 796 K, T^3 = 765 K, T^4 = 732 K). Low temperatures are beneficial for the precise estimation of the model parameters, while high temperatures allow for a higher difference between the model responses.

Figure 2. (a) Ranking of experiments based on Relative Fisher Information (RFI). (b) Multi-objective MBDoE solution points as results of optimisation (7-8).

4. Conclusions

A new MBDoE approach has been proposed and applied for a ranking of the experiments in microreactor platforms showing the best experimental conditions to be used for a precise estimation of the set of kinetic parameters of candidate kinetic models. A discrimination of simplified kinetic models of methanol oxidation on silver has been carried out, underlining a better representation of experimental results when dehydrogenation and a selective oxidation step are included in the model formulation, paving the way to new (possible) model formulations. Furthermore, a multi-objective MBDoE underlined the important role of temperature in the model discrimination task.

Abstract

The online or real time optimization system required an on-line monitoring for important state variables and parameters in order to provide feedback to the algorithm implemented. The unmeasured states and unknown parameters can be determined by estimator. The estimator used must be feasible and has several functionalities such as bias-free parameter and state estimates, high speed of convergence from initialization errors, perfect tracking and short computational time. To address those issues, the derivative free stochastic observer is applied in this work. Different derivative-free techniques implemented which are based on the Gaussian approximation are scaled Unscented Kalman Filter technique (sUKF), Divided Difference Kalman filter (DDKF) and Cubature Kalman filter (CKF). Here, an autocatalytic esterification of Propionic Anhydride with 2-Butanol is considered as a case study. The performance of estimator which is indicated by the accuracy, speed convergence and robustness, is represented by the root mean squared error (RMSE). While, the efficiency of the estimator's computation are evaluated by CPU time consumed. The derivative free-estimators are then evaluated within two case studies which are normal condition and effect of uncertainty of initialization parameter. The results of overall state and parameter estimator study show that the CKF outperform the sUKF and DDKF for both cases. Moreover, computational load consumed for the CKF is feasible for online practice However, in term of CPU time DDKF results to the shortest among all techniques implemented.

Keywords: Nonlinear estimation, sUKF, DDKF, CKF, semi batch processes, auto catalytic esterification.

1 Introduction

Online optimization and control strategy which are based on the key state variables cannot be implemented unless those required variables can be measured on-line. Despite the advent of process analytical technology in the recent years, online measurement of all process variables is not often viable due to various technological and economical limitations. Thus, there is an urgent need to provide the estimator for estimating those

state variables from other state variables which are relatively simple and easy to measure (Hartikainen et al., 2011).

The best estimator must have several functionalities such as bias-free state estimates, high speed of convergence from initialization errors, perfect tracking and short computation time. The most common way of applying the estimator to a nonlinear batch system is in the form of the extended Kalman filter (EKF). Nevertheless, EKF contains several flaws that may seriously affect its performance. One of the flaws is the computation of the state transition matrix which calls for calculation of the Jacobian matrix and its matrix exponential, which, in turn, requires linearization of the system model (van der Merwe, 2004).

In this work the derivative free stochastic estimator is applied. The different derivative-free techniques which is based on the Gaussian approximation namely; scaled Unscented Kalman Filter technique (sUKF), Divided Difference Kalman filter (DDKF) and Cubature Kalman filter (CKF) (Hartikainen et al., 2011) are implemented. To the best authors' knowledge, there is no work reported in application of CKF on batch chemical processes. Therefore a comparison study between CKF and other derivative-free estimators (sUKF and DDKF) is required in order to select the best estimator applied in this study. The process considered is Catalyzed Esterification of Propionic Anhydride with 2-Butanol in semi batch reactor. The derivative free- estimators are then evaluated based on two case studies which are normal condition and effect of uncertainty of initialization parameter.

2. Modeling of autocatalytic esterification process

Esterification of propionic anhydride with 2-butanol is producing sec-butyl propionate and propionic acid. It exhibits a kind of autocatalytic behaviour when sulphuric acid is introduced. The reaction kinetics of this esterification has been investigated and the data of parameters is depicted from Zaldivar et al. (1993) and the parameter involved in heat transfer is depicted from Ubrich (2000). The semi batch reactor model which the mass and energy balances are represented by following equations, are considered as the process plant.

$$\frac{dC_B}{dt} = -((k_1 + k_2 C_{cat1}) C_A C_B + k_3 C_{cat2} C_B) + \frac{F_o}{V}(C_{B0} - C_B) \tag{1}$$

$$\frac{dC_C}{dt} = \frac{dC_D}{dt} = ((k_1 + k_2 C_{cat1}) C_A C_B + k_3 C_{cat2} C_B) - \frac{F_0 C_C}{V} \tag{2}$$

$$\frac{dC_{cat1}}{dt} = -\frac{dC_{cat2}}{dt} = -(k_4 10^{-H} C_{cat1} C_A) - \frac{F_0 C_{cat1}}{V} \tag{3}$$

$$\frac{dT}{dt} = \frac{-\Delta Hr_{total}}{\rho C_p} + \frac{UA}{\rho C_p V}(T_j - T) + \frac{F_O}{V}(T_{feed} - T) \tag{4}$$

$$\frac{dT_j}{dt} = \frac{F_j}{V_j}(T_{jin} - T_j) + \frac{UA}{\rho_j V_j C_j}(T - T_j) \tag{5}$$

$$\frac{dV}{dt} = F_o \tag{6}$$

where C_A, C_B,C_C, C_{Cat1}, and C_{cat2} are concentration of 2-butanol, propionic anhydride; propionic acid, sulphuric acid and mono-butyl sulphuric acid, respectively. F_o, V are the feed rate and the volume of solution within reactor. F_j is the jacket flowrate, T_j is the jacket temperature; T_{jin} is the inlet jacket temperature; T_{feed} is the feed temperature; A is the heat exchange area; V_j is volume of the jacket; U is the heat exchange coefficient; C_p, C_j is heat capacity of solution in the reactor and the jacket, respectively; H is the acidity function; ΔHr is the heat of reaction; ρ is density of solution in the reactor; ρ_j is density of the jacket solution. The initial value of C_A, C_B, C_C, C_D, C_{cat1}, C_{cat2}, V, T and T_j is 3.4M, 0M, 0M, 0M, 1.02x 10^{-2}M, 0M, 1L, 303K, and 303K, respectively.

3. Estimation method

The estimator problem is concerned with the estimation of the state vector of a dynamic system which is governed by the non-linear stochastic differential equations approximated in discrete time as:

$$x_k = f(x_{k-1}, k-1) + q_{k-1}$$
$$y_k = h(x_k, k) + r_k \quad (7)$$

where $x_k \in R^n$ is the state on the step time k, **f** is the dynamic model function, $q_{k-1} \sim N(0, Q_{k-1})$ is the process noise on the step time k−1, Q is process noise covariance. The prior distribution for the state is $x_0 \sim N(m_0, P_0)$, where parameters m_0 and P_0 are initial mean and covariance of the states which are set using the known information from the system under consideration. $y_k \in R^m$ is the measurement on the step time k, **h** is the measurement model function, $r_k \sim N(0, R_k)$ is the measurement noise of step time k, R is the measurement noise covariance (van der Merwe, 2004). In this study, the sUKF, DDKF and CKF have been used to develop nonlinear state observers for the esterification process.

Scaled Unscented Kalman Filter (sUKF) uses deterministically chosen sigma points to approximate the nonlinearities. The unscented transformation (UT) is a method for calculating the statistics of a random variable which undergoes a nonlinear transformation and builds on the principle that it is easier to approximate a probability distribution than an arbitrary nonlinear function (van der Merwe, 2004). The computer code *KalmTool* was used for sUKF which was developed by Nørgaard et al. (2003).

Divided Difference Kalman filter (DDKF) uses Sterling's polynomial interpolation to approximate the distribution (Nørgaard et al., 2000). The divided difference filters (DDFs) are similar to the extended Kalman filter (EKF). At the propagation step, the DDKF also involve a local expansion of a nonlinear function, not via a Taylor series expansion as in the EKF, but through Stirling's interpolation formula. The computer code *KalmTool* was also used for DDKF which was developed by Nørgaard et al. (2003).

Cubature Kalman filter (CKF) uses a third-degree cubature approximation to solve the Gaussian integrals (Arasaratnam and Haykin, 2009). Specifically, a third- degree spherical-radial cubature rule provides a set of cubature points scaling linearly with the state-vector dimension. The CKF may therefore provide a systematic solution for high-dimensional nonlinear filtering problems. CKF method was implemented using package code developed by Hartikainen et al (2011).

4 Simulation of the derivative-free estimators

The derivative free-estimators were evaluated based on two case studies which were normal condition and effect of uncertainty of state initialization. The normal condition case evaluates the accuracy of the estimators where there were no noises, disturbance and uncertainties. The estimators were also performed to check of their nominal character included the efficiency of estimator. The efficiency of the estimator's computation is determined by CPU time consumed. The uncertainty of state initialization case examines the speed convergence of the estimators. They were initialized with the initial estimates which are varied far from the true values i.e. different initial value of concentration of 2-butanol, +30% of C_{A0}.

The states x and measurements y of the autocatalytic esterification semi batch reactor considered were:

$$x = [C_A \; C_B \; C_c \; C_D \; C_{cat1} \; C_{cat2} \; T \; T_j]; y = [C_A \; T \; T_j]$$

The initial condition of the state estimation which is the same as the initial model is:

$x_0 = [3.4\text{M } 0\ 0\ 0\ 1.02\text{x } 10^{-2}\text{M } 1\ 303\text{ K } 303\text{ K}]$

Measurement noise has been considered on concentration of 2-butanol, the reactor and jacket temperatures. State noise was added to the system dynamic equations. The noises involved in the cases was maintained at low level where their values set as process noise covariance (Q matrix) = diag [0 2.4 x 10^{-14} 2.4 x 10^{-10} 1x 10^{-12} 1 x 10^{-14} 1x 10^{-14} 0 0] and measurement noise covariance (R matrix) = diag [5x 10^{-1} 5 x 10^{-1} 5x 10^{-1}] (Ramkhelawan, 2000).

5 Results and discussion

All the cases were simulated in MATLAB environment and were conducted by using IntelRCoreTM i3 CPU 530 with 2.93GHz and 3.17GB of RAM. In this simulation, the process time considered is 100 min which is the time required to achieve more than 90% conversion as reported by Zaldivar et al. (1993).

5.1 Estimator performance in a normal condition.

The RMSE results and CPU time for all estimators obtained are tabulated in Table 1. From the table, for under the normal condition, it can be seen that all the estimators provide a good estimation of ester (sec- butyl propionate) with very small RMSE. Among those three estimators, CKF has the highest accuracy due to the lowest RMSE obtained, followed by sUKF's and DDKF. The DDKF suffers to the lowest accuracy because the posterior mean and covariance obtained is only covered accurately to the first order with all higher order moments truncated (Nørgaard et al., 2000, van der Merwe, 2004). Meanwhile, the sUKF is able to encompass the posterior mean and covariance accurately to the 2nd order for any nonlinearity choosing by the weights and sigma-point locations such that the first and second order terms matched exactly. Under this scheme, errors are only introduced in the 3rd and higher orders (Luo, 2009). Therefore, sUKF has a higher accuracy than DDKF. On the other hand, CKF produced highest accuracy since it considers the third-degree spherical-radial rule which is accurate for polynomials of all odd degrees even beyond three (Arasaratnam and Haykin, 2009). Meanwhile, the computation time requested to complete a single run by DDKF is the shortest, followed by CKF and sUKF. The CPU time of estimators is depending on the numerical complexity as indicated by the number of points inherited for function evaluations.

Table.1: RMSE of sec- butyl propionate under normal condition and CPU obtained

Case study	sUKF	DDKF	CKF
1. Normal condition:			
- RMSE $x10^{-2}$	0.83	0.94	0.61
- CPU time (s)	3.26s	1.16s	1.33 s
2 Uncertain initial condition			
- RMSE $x10^{-2}$	166	162	173

The DDKF was the fastest among filters due to the simplest algorithm constructed which requires a single point and 2n+1 sample in the probabilistic state space to propagate the mean and covariance, respectively (Wu *et al.*, 2006). Meanwhile, the cubature rule in CKF entails 2n cubature points to calculate both mean and covariance (Arasaratnam and Haykin, 2009). In contrast, the sUKF needs 2n+1 point to capture correctly both mean and covariance which can be considered as the most complex algorithm and thus the longest computation time is consumed (Wu *et al.*, 2006).

5.2 Effect of initial condition uncertainty

In this study, the deviation in C_{A0} was considered as initial state uncertainty, which effected directly on concentration C_A behavior. Figure 1 show the profile of C_A when +30% uncertainty in C_{A0} is introduced. From the Figure, it can be observed that all the estimators are still able to converge to the true states. It is also indicate that the convergence speed of the state estimators from initialization deviation is quite fast. It can be found that both DDKF and sUKF have almost the same speed convergence. Meanwhile, the CKF is converged to true state slower than both DDKF and sUKF.

From Table 1, it can be observed that the amount of RMSE can be link to the speed of convergences. Higher error the estimates signify slower convergence to the correct state. The RMSE of CKF is found to be the highest among the others since it is the slowest to converge. It was assumed that the error obtained in CKF incurred in computing the integral of nonlinear function with respect to a Gaussian weight function. The information loss in some integration points for capturing the true evolving posterior density is afforded from the cubature rule which some of its points outside the integration region. This occurrence yields round off errors and then degrades covariance accuracy (Wu *et al*., 2006, Arasaratnam and Haykin, 2009).

6. Conclusion

The performance of CKF, UKF and DDKF on normal condition and uncertain initial state condition that is occurred in semi batch autocatalytic esterification reactor has been evaluated. In the normal condition, CKF produced highest accuracy and comparable CPU time. Meanwhile, DDKF suffered worst accuracy but had the shortest CPU time. In the presence of uncertain initial of C_{A0}, the DDKF showed the fastest speed convergence. Meanwhile, the CKF obtained the slowest one. To conclude, CKF outperformed the sUKF and DDKF for both cases. Therefore, CKF is preferred to be implemented in online system since the RMSE obtained from CKF, sUKF and DDKF is almost similar in the two case studies. In order to determine the best performance of estimators, the performance evaluation in the presence disturbance and uncertainty is required which will be considered as future study.

Abstract

A two dimensional, heterogeneous model was developed for the simulation of a coked catalyst regeneration fixed-bed reactor in a green acrylics process. A kinetic model which consists of combustion of coke containing carbon, hydrogen and oxygen was derived. The unknown parameters (including the kinetic parameters, initial composition and concentration of coke, heat transfer parameters and catalyst pore diameter) were identified using the results of regeneration experiments with the coke formed in a glycerol dehydration process. Good agreements between the model predictions and experimental results were obtained.

Keywords: Fixed-bed reactor modeling; Catalyst regeneration; Coke combustion kinetics; Parameter identification

1. Introduction

Chemistry as it is perceived today has largely developed from oil, natural gas and coal, i.e. non-renewable fossil resources. This is particularly the case of acrylic acid production that uses propylene as the raw material. However, the expected exhaustion of oil and current environmental requirements lead chemical industries to seek new raw materials from biomass to meet the needs of the population. An interesting alternative resource to propylene in acrylic acid industry is glycerol (Katryniok et al., 2010) that is renewable, sustainable, available and abundant, particularly as a major by-product in the biodiesel production process. However, during the selective catalytic dehydration of glycerol to acrolein, coke (or heavy products) is formed and thus deactivates the catalyst. Substantial coke formation means that the catalyst regeneration step is an essential part of the industrial process that is normally carried out by combustion of the coke with a small amount of oxygen in an inert gas stream. As the reaction is highly exothermic, either thermal runaway or catalyst sintering may happen. In order to investigate the influence of different process parameters, to identify the conditions leading to runaway, and finally to develop a method to maximize the effectiveness of the oxidation of coke while maintaining a moderate level of temperature in the bed, a predictive model of the process is necessary. The aim of this work is to develop the most predictive possible model (including reactor and kinetic model) for a coked catalyst regeneration process. The needed experimental measurements for the model identification and validation were carried out and provided by Arkema Company.

2. Experimental rig and measurements

The process considered here is a gas-solid fixed-bed tubular reactor which is schematically presented on figure 1. This figure shows the location of temperature probes, which are actually placed

in a thermowell of radius R_{in} at the center of the reactor. Catalyst particles fit in the annular space left between the thermowell and the inner wall of the reactor. A coolant fluid is used to remove the heat generated by the reactions. A set of five experiments where either the coolant temperature

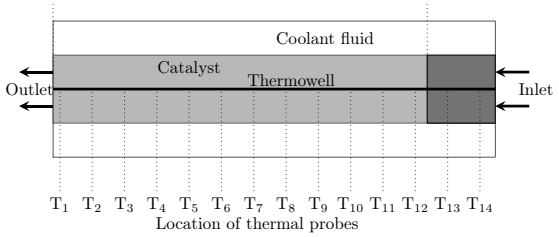

Figure 1: Experimental rig

or inlet gas composition were varied is available. Experimental measurements consist mainly of temperatures along the thermowell, inlet and outlet pressure, inlet oxygen flow rate, outlet gas flow rate and its composition in terms of CO, CO_2 and O_2. It is noteworthy that other components are present in the outlet gas stream, but their concentration was not measured. These measurements will be used for the development of the kinetic and reactor models in the next section.

3. Reactor and kinetic modelling

In order to develop a comprehensive reactor model, the knowledge of kinetics of the coke combustion is required. These kinetics are widely investigated in literature (Kanervo et al., 2001; Sierra et al., 2010), but most of the studies ignore the reaction of hydrogen contained in the coke. Indeed, the oxygen mass balance in the reactor is not satisfied and this is clearly shown on figure 2. This figure compares the equivalent oxygen flow rate at outlet computed by considering its presence in all measured components to its inlet flow rate. The lack of oxygen for times below 0.5 advocates for the creation of an oxygenated product that is not measured at outlet. With the possible presence of hydrogen in the coke, this product is considered to be water only.

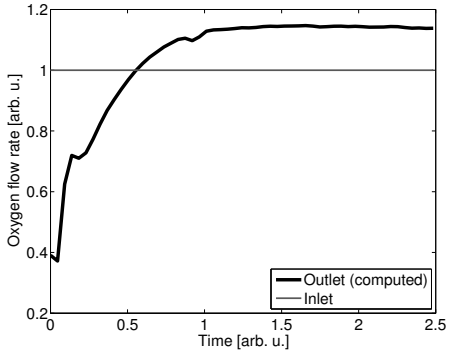

Figure 2: Oxygen flow rate in feed, and calculated from O2, CO2 and CO measurements at outlet

However, after t=0.5 and even with the additional consumption due to water formation, the oxygen balance shows a generation of oxygen in the system. This oxygen is assumed to be present in the coke. This is coherent with experimental studies (Suprun et al., 2009) which have shown that coke is formed through condensation of oxygenated compounds such as aldehydes.

We can now state that coke is made of carbon, hydrogen and oxygen in unknown proportions, i.e. CH_xO_y. Taking into account this information, the initial composition of the coke will then be identified from experimental measurements through a reactor model. To our knowledge, the determination of coke composition through measurements of temperature profiles and gas composition has not been investigated so far in literature.

The kinetic scheme used to model the coke combustion should take into account its specific composition. In particular, it has been postulated that a carbon atom bonded to an oxygen has different reactivity than one which is not. We thus considered two kinds of carbon atoms in the coke, one noted [C] which is not bonded to oxygen, and the other noted [CO], which represents both carbon and oxygen atoms. These two carbons can be oxidized to CO_2, whereas [C] can also be oxidized into CO. This leads to the following kinetic scheme:

$$\begin{array}{lcl} [C]+\frac{1}{2}O_2 & \longrightarrow & CO \\ [C]+O_2 & \longrightarrow & CO_2 \\ [CO]+\frac{1}{2}O_2 & \longrightarrow & CO_2 \\ [H]+\frac{1}{4}O_2 & \longrightarrow & H_2O \end{array} \tag{1}$$

The reaction rates are assumed to be of first order with respect to coke (Keskitalo et al., 2006; Sierra et al., 2010) and an unknown order with respect to oxygen. The unknown orders for the four reactions should thus be identified.

3.1. Coke spatial profile

From the evolution of the temperature profiles measured during the regeneration step (not represented, temperature peaks move slowly near the entrance and faster close to the exit) and the measurement of the coke concentrations in a laboratory scale reactor (figure 3), we assumed that the initial concentration of the coke is not uniform along the reactor and is modelled by the following linear expression where C_1 and C_2 are constants :

$$(\mathrm{CH}_x\mathrm{O}_y)_0 = C_1 - C_2 z \tag{2}$$

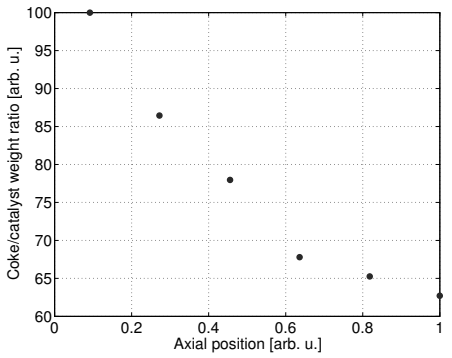

Figure 3: Coke concentration profile in a laboratory reactor (arbitrary units)

As the coked catalyst for each regeneration experiment was not obtained with exactly the same operating conditions, its initial concentrations and compositions might be different. The initial concentration (i.e. C_1 and C_2) of coke and its composition (i.e. x and y) will thus be identified for each experiment.

Now, the kinetic model as well as initial profile of coke composition will be included in a reactor model developed in the next section.

3.2. Reactor model

The catalyst regeneration step involves both chemical reactions and transport of reactants and products. Some studies (e.g. Müller et al. (2010)) show that the diffusion resistance of oxygen into the pores strongly influences the actual speed of coke combustion . In addition, the concentration profile of the coke in a catalyst particle during the combustion may be non-uniform (Tang et al. (2004)). This leads to the use of a two-phase model, where the mass balance is considered in the catalyst and in the surrounding gas phase. The process model developed is also based on the following additional assumptions: (i) the ideal gas law can be used, (ii) the internal temperature gradients in the catalyst particles are neglected owing to high thermal conductivity of the catalyst material, (iii) the heat and mass transfer resistances between solid and gas are neglected.

Based on the above assumptions, and taking into account the possible presence of intraparticle diffusion resistance, and as the radial temperature gradient in the reactor is not negligible (according to the Mears criterion (Mears, 1971)), a two-dimensional heterogeneous model was thus considered. The model equations include mass balances on both solid and gas phases for each component, heat balance on a pseudo-homogeneous phase and momentum balance on gas phase. As the pore diameters are small, the effective mass diffusion coefficient in the catalyst is given as :

$$D_e = \frac{\varepsilon_p}{\tau_p} \frac{1}{\frac{1}{D_k} + \frac{1}{D_m}} \tag{3}$$

where $\varepsilon_p = 0.571$ and $\tau_p = 2.5$ are respectively the catalyst porosity and tortuosity, $D_m = 1.114 \times 10^{-9} T^{1.726}$ is the molecular diffusion and Knudsen diffusivity D_k is given by the relation:

$$D_k = \frac{1}{3} d_{\text{pore}} \sqrt{\frac{8RT}{\pi M}} \tag{4}$$

The mass balance of component i in the solid phase (noted with subscript s) is derived as:

$$N_{s,T}\varepsilon_p \frac{\partial x_{s,i}}{\partial r_p} + c_{T,s}\varepsilon_p \frac{\partial x_{s,i}}{\partial t} = \varepsilon_p \frac{1}{r_p^2} \frac{\partial}{\partial r_p} \left(D_e c_{T,s} r_p^2 \frac{\partial x_{s,i}}{\partial r_p} \right) + \rho_s \sum_{j=1}^{NR} \left[R_j \left(\nu_{ij} - x_{s,i} \sum_{i=1}^{NC} \nu_{ij} \right) \right] \tag{5}$$

where r_p is the radial coordinate in pellet, ρ_s the catalyst density, c_T the overall gas concentration, N_T is the total mole flux, R_j the rate of reaction j, ν_{ij} the stoichiometric coefficient of component i in reaction j, and x_i the component i mole fraction.

In the reactor, the mass balance per component is:

$$uc_T \frac{\partial x_i}{\partial z} + vc_T \frac{\partial x_i}{\partial r} + c_T \varepsilon \frac{\partial x_i}{\partial t} = \nabla (D_e c_T \nabla x_i) + \varepsilon_p (1-\varepsilon) a_v \left(N_i|_{r_p=R_p} - x_i N_T|_{r_p=R_p} \right) \tag{6}$$

where r and z are the radial and axial coordinates, u the gas superficial velocity, ε the porous bed void fraction, a_v the specific area of catalyst pellet and N_i the mole flux of component i.

The overall mass balance can be deduced by summing the previous equations :

$$\frac{\partial (uc_T)}{\partial z} + \frac{\partial (vc_T)}{\partial r} + \varepsilon \frac{\partial c_T}{\partial t} = \varepsilon_p (1-\varepsilon) a_v N_T|_{r_p=R_p} \tag{7}$$

The heat balance equation can be written as:

$$\begin{aligned} c_T \sum_{i=1}^{NC} \left(u x_i C_{p,i} \frac{\partial T}{\partial z} \right) + \left[\varepsilon c_T \sum_{i=1}^{NC} (x_i C_{p,i}) + (1-\varepsilon) \rho_s C_{p,s} \right] \frac{\partial T}{\partial t} \\ = \nabla (\lambda_{\text{bed}} \nabla T) - \varepsilon_p (1-\varepsilon) a_v \sum_{i=1}^{NC} \left[\left(\Delta_f H_i^0 + H_i - H_i^0 \right) N_i|_{r_p=R_p} \right] \end{aligned} \tag{8}$$

where $C_{p,i}$ and $C_{p,s}$ are the heat capacity of component i and solid respectively, λ_{bed} the heat conductivity of homogeneous phase, H_i the enthalpy of component i (exponent ^{0} denotes standard conditions) and $\Delta_f H_i$ the standard enthalpy of formation of coke.

Finally, the pressure drop is computed using Ergun equation as:

$$\frac{dP}{dz} = \alpha u + \beta u^2 \tag{9}$$

The coefficients α and β are assumed to be unknown, mainly since the wall effect are by far not negligible in our case, and will be identified from experimental measurements.

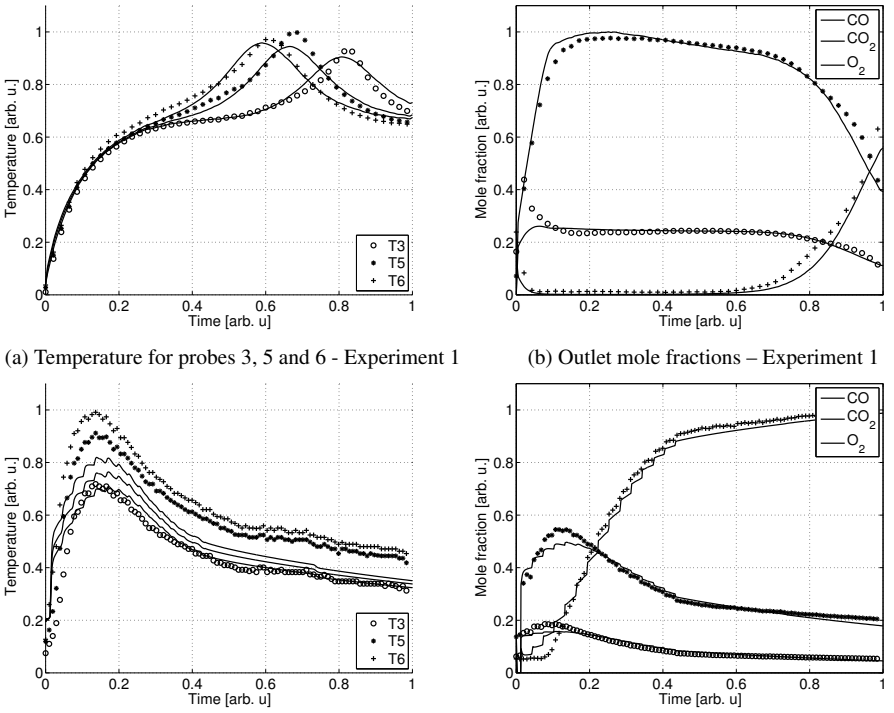
For all these equations, initial and boundary conditions are classical and are not be presented here, except for the heat balance. Heat transfer at the wall depends on an overall coefficient h_t, given by correlations (Green and Perry, 2008). The resulting conditions are given in equation 10.

4. Results and discussion

The model equations were implemented within gProms software (Process Systems Enterprise, 2012), which uses the Method of Lines to solve the PDEs. These PDEs were discretized using a centered finite difference scheme. The modelling software does not allow different discretization schemes for advective and diffusive terms. In order to avoid a bias in second order terms, a centered scheme was chosen. This required a grid Péclet number lower than 2, and thus a large number (100) of discretization intervals on axial coordinate. On radial coordinates (both in the reactor and particles), a non uniform grid was used and the number of intervals was chosen to ensure an acceptable precision.

It is important to mention that an index problem was encountered during the simulations. In order to cope with this issue, a time derivative had to be added to both sides of the boundary conditions on temperature, that is:

$$\left.\frac{\partial T}{\partial r}\right|_{r=R_{in}} + \frac{\partial T}{\partial t} = \frac{\partial T}{\partial t} \quad \text{and} \quad -\lambda \left.\frac{\partial T}{\partial r}\right|_{r=R} + \frac{\partial T}{\partial t} = h_t \left(T_{cool} - T|_{r=R}\right) + \frac{\partial T}{\partial t} \tag{10}$$



(a) Temperature for probes 3, 5 and 6 - Experiment 1

(b) Outlet mole fractions – Experiment 1

(c) Temperature for probes 3, 5 and 6 - Experiment 3

(d) Outlet mole fractions – Experiment 3

Figure 4: Comparison of experimental results (dots) and model prediction (lines)

Finally, the resulting number of parameters to be identified is 19. They include pressure drop equation coefficients α and β, pre-exponential factor, activation energy and oxygen reaction order per reaction, catalyst pore diameter d_p, coke composition in terms of hydrogen (x) and oxygen (y) for each experiment and coke distribution coefficients C_1 and C_2 for each experiment.

The parameter identification is carried out using the maximum-likelihood method, implemented within the Parameter estimation tool of gProms. One very interesting result of this identification is related to the values of hydrogen and oxygen fraction in the coke, which are different from one experiment to another but have an average value of 0.47 and 0.43 respectively. This shows that the coke cannot be considered to be consituted of carbon only, and can give hints on the kinetic scheme of coke formation.

Simulations are then carried out using the identified model, which is common to all experiments, and the coke composition and distribution, which is calculated for each experiment. Some results are presented in figure 4, for two types of operating conditions: either the oxygen feed is constant and coolant temperature increases with time (figure 4a and 4b) or its flow rate increases with time for a constant coolant temperature (figure 4c and 4d). In both cases, the predictions are quite accurate. The mole fractions of measured products are in very good agreement with the predictions. This is a major difference with the results obtained when the coke initial profile was considered uniform, as shown by Lei (2014): in this case, the model highly underestimated the CO_2 fraction. In terms of temperature, although a difference in temperature value might exist (figure 4c), the peak positions are always well predicted.

5. Conclusions

A predictive model for coke combustion in a glycerol dehydration reactor is proposed. The unknown parameters were identified using several experiments, and the simulated results showed that the model is reliable. Identification also allowed to determine the coke composition and spatial distribution. More specifically, it was shown that hydrogen and oxygen are present in the coke in substantial amounts (average ratio to carbon of respectively 0.47 and 0.43). These data will be useful for the study of glycerol dehydration kinetics. The resulting model is considered accurate enough to be used for process design and optimization.

Abstract

Waste such as contaminated biomass, which contain potentially high level of heavy metals, are widely available resources. One of the drawbacks of using this biomass in gasification processes is that some heavy metals might be transferred in the produced syngas, and requires then specific further cleaning steps. Thermodynamic equilibrium calculations are a relevant tool to estimate the behavior of those heavy metals to manage the syngas treatment. The calculations were made with the commercial software FactSage. Due to the several thousands of produced compounds, a specific methodology was set up to choose the stable compounds of the database for the simulations. As an illustrative example, the results of the thermodynamic equilibrium calculations of lead are presented in this paper.

Keywords: Biomass, Heavy metals, Thermodynamic equilibrium, Simulation, Gasification.

1. Introduction

Biomass is considered to be the only natural and renewable carbon resource that can effectively be a substitute to fossil fuels. This is why current researches focus on the development of the use of this alternative renewable fuel in many processes in order to produce energy. Gasification has recently been receiving increasing attention thanks to the success of the first plants for the production of electricity from biomass. In fact, gasification is the partial oxidation of biomass, which transforms the organic matter into energy carrier gas. The synthesis gas (CO and H_2) allows a wide range of application: power production or biofuel. Most of research works in literature are focused on process using clean biomass as opposed to contaminated biomass which is available in significant quantities. However it is used to a much smaller extent as a source of energy due to their potentially high level of heavy metals.

An example of such biomass is phytoextraction plants which are used to extract contaminants from polluted soils. Heavy metals are then accumulated inside the roots, stems and leaves of these plants (Gupta and Sinha 2007). Following the thermochemical process of biomass gasification, these metals are found in the ash, gas and tar products which make them difficult to use and may increase risks to human health and the environment (Nzihou and Stanmore, 2013). Recent works have shown that heavy metals can have a significant influence on reaction kinetics and on thermodynamics equilibrium. The aim of this work is to contribute in understanding the behavior of heavy metals during the gasification process of contaminated biomass by modeling the

thermodynamic equilibrium. This study aims at predicting the partitioning of heavy metals in the gasification products (gas, tar or ash fractions) (Al Chami et al. 2014). This is an important scientific challenge for optimizing the thermochemical conversion processes applied to the contaminated biomass.

2. Materials and method

2.1. Biomass characterization

The biomass considered in this study is willow, which is the most used plant in phytoextraction thanks to its high absorption capacity of heavy metals. Willow is composed of 55% cellulose, 28% hemicellulose and 17% lignin (Phyllis Database, 2012). The elementary composition of willow is indicated in Table1 (Phyllis Database, 2012).

Table 1

Elementary composition of dry contaminated willow.

Element	mol/kg	Element	mol/kg	Element	mol/kg
C	41.25	S	0.012	Pb	$6.51\ 10^{-4}$
H	58.40	F	$5.30\ 10^{-3}$	Ti	$1.87\ 10^{-4}$
O	27.56	Na	$5.20\ 10^{-3}$	Sr	$1.59\ 10^{-4}$
N	0.300	Al	$3.70\ 10^{-3}$	Mn	$1.46\ 10^{-4}$
Ca	0.090	Fe	$1.97\ 10^{-3}$	Cu	$1.10\ 10^{-4}$
Si	0.060	Ni	$1.32\ 10^{-3}$	Ba	$2.91\ 10^{-5}$
K	0.050	Zn	$9.48\ 10^{-4}$	Cd	$1.51\ 10^{-5}$
P	0.020	Cr	$8.65\ 10^{-4}$	V	$3.92\ 10^{-6}$
Mg	0.014	B	$8.18\ 10^{-4}$	Sn	2.5210^{-6}

2.2. Calculations methodology

The aim of the thermodynamic modeling is to determine the nature, the state (gas, liquid or solid), speciation the amount of gasification products in given operating conditions considering that all chemical reactions reach their equilibrium. Thermodynamic models can be developed using two approaches (Basu, 2010):

- Stoichiometric Equilibrium Models, based on equilibrium constants of each reaction.
- Non-Stoichiometric Equilibrium Models, where the only inputs needed are the elemental compositions of the feeds.

The non-stoichiometric method which is often referred to as “Gibbs free energy minimization approach” is the usual approach since no chemical reaction needs to be assumed (Basu, 2010). It may be calculated using modern software provided the thermodynamic data for all compounds (reactants and products) under consideration exist. In a reacting system, a stable equilibrium condition is reached when the Gibbs free energy of the system is at the minimum. Since the thermodynamic properties of the willow components are unconventional in most software, willow has to be split into its constituent elements/molecules as input data to the software. The operating conditions chosen as initial data for the calculations are:

- initial quantity of biomass: 7 mol (biomass chemical formulae: $C_6H_9O_4$),
- reactor pressure: 1 or 10 bar,
- reactor temperature: from 500 to 1000 °C (step value: 25 °C),
- gasification agent: 41 mol of H_2O (Froment et al. 2013).

Calculations were performed with FactSage 6.3 commercial software (Bale C.W. et al. 2009), which has already found applications in the field of biomass gasification modelling (Fraissler et al. 2009) (Froment et al. 2013) and includes a large database on heavy metals. FactSage uses the Gibbs free energy minimization method. For each compound, the structure of the database is as follow: available thermochemical data (standard enthalpy of formation ΔH° at 298 K, absolute entropy S° at 298 K) and heat capacity polynomial dependence on temperature Cp(T)) are provided for a given state (solid, liquid and gas) and a given temperature range.

As thousands of compounds and phases exist in the multicomponent system consisting of contaminated willow, a preliminary selection of the compounds which might form in gasification conditions was required: software limitations and computing time impose to take into account a maximum of 1500 compounds, while the commercial SGPS database includes more than 256 liquids, 813 solids and 894 gases. The selection procedure, based on the systematic calculation of predominance diagrams for gaseous compounds, leads to the definition of a new specific database containing a few hundreds compounds. The following methodology was applied:

1. Selection of the major elementary compounds of the main organic components of wood: C, H, N, O and S.
2. Removal of gas, liquid and solid C_nH_m compounds with n > 3.
3. Selection of all gaseous compounds existing in the contaminated willow system.
4. Removal of unstable gaseous compounds, based on predominance diagram calculations (this step is developed below).
5. Removal of gaseous compounds whose Cp(T) range validity is outside the range [500 °C-1000 °C].

Predominance diagrams were computed in order to identify the most stable compounds over specific partial pressure ranges of gaseous master species: O_2, S_2, F_2, C_2 and H_2. By combination with a metal element, these master species allow to account for the formation of oxides, sulfides, fluorides, carbides, hydrides and their combinations (e.g. hydroxydes, oxyfluorides, etc.). The predominance diagrams are plotted for a given fixed temperature and a total pressure. In this work, two extreme conditions of gasification process were taken into account: 500 °C/1 bar and 1000 °C/10 bar. For compounds involving O, S, H and C, all compounds shown stable on the predominance diagram were selected. Fig. 1 shows as illustrative example, the Cr-H-O predominance diagram at 500 °C and 1 bar. All those compounds were selected.

Furthermore, due to the high number of existing fluoride compounds, it has been decided to eliminate the compounds that are unlikely to form in gasification conditions

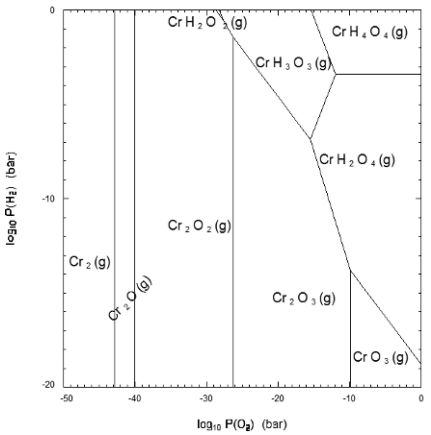

Figure 1. Cr-H-O predominance diagram (500 °C - 1 bar).

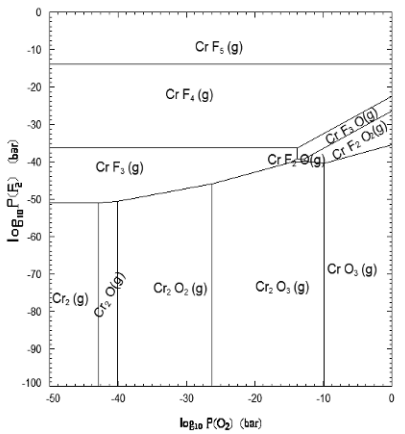

Figure 2. Cr-F-O predominance diagram (500 °C - 1 bar).

due to the low partial pressure of F_2(g).
Preliminary calculations using a simplified biomass mixture showed that at 500 °C and 1 bar the fluoride partial pressure $P(F_2)$ is below 10^{-39} bar and below 10^{-21} bar at 1000 °C and 10 bar. So all stable compounds which appeared in the predominance diagrams at a $P(F_2)$ above those two values were eliminated from the database. For instance, CrF_5(g) and CrF_4(g) which are present in the Cr-F-O diagram (Fig.2) were not selected in the database.

3. Results

After the calculation and examination of 163 predominance diagrams for 20 elements (Al, B, P, Na, K, Mg, Ca, Ti, V, Mn, Cr, Fe, Ni, Cu, Zn, Cd, Pb, Si, Sr et Sn), 271 gaseous compounds were selected amongst 894 and grouped in a specific user database. Hence, the thermodynamic equilibrium calculations were performed, with the elemental composition of willow (Table 1), with the user database for the gases and the SGPS database for the liquid and solid compounds.

3.1. Partial Pressure of gaseous master species and total volume of gas

The equilibrium calculations allow determining the total gas volume and the partial pressure of all the gaseous compounds. Fig. 3 shows the variation of partial pressure of gaseous master species (O_2, S_2, F_2, H_2) at two total pressures 1 and 10 bar. These pressures are related to the predominance diagrams so we can exactly determine the stable compounds and their fate at the real partial pressure of this system. The calculations confirm that the fluoride partial pressure at 500 °C/1 bar is less than 10^{-39} bar and 10^{-21} bar at 1000 °C/10 bar. Hence, the hypothesis regarding the selection of fluoride compounds is validated. Hence, the hypothesis regarding the selection of fluoride compounds is validated. And as expected from thermodynamic point of view, the total volume of gas increases with the temperature and the total pressure (Fig. 4).

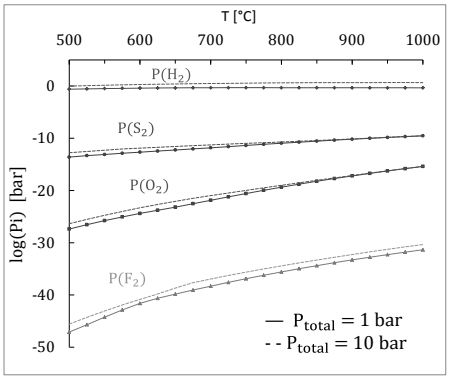

Figure 3. Partial pressure of gaseous master species at 1 and 10 bar.

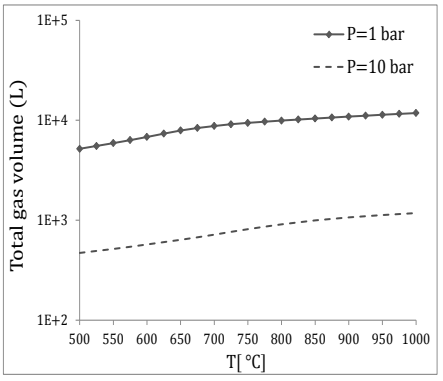

Figure 4. Total volume gas variation at 1 and 10 bar.

3.2. Speciation of Pb species

As an example of heavy metals, the behavior of lead is discussed in this work, because of its high volatility.

The thermodynamic calculations are used to identify the speciation of all biomass elements. Fig. 5 presents the speciation of the lead at a total pressure of 1 bar. Above 700 °C, liquid Pb vaporizes to form mainly Pb(g) and PbS(g), as well as small quantities of PbO(g). The calculations also show that, even if the PbO(g) amount notably increases at high temperature, this compound remains a minor component of the gas phase in the whole temperature range.

3.3. Pressure effect

The total pressure effect from 1 to 10 bar is reported in Fig. 6. As expected from thermodynamic stand point, increasing the total pressure delays volatilization of most Pb species. At 1 bar the whole amount of lead volatizes at 700 °C, while for a total pressure of 10 bar it volatizes at 800 °C. A comparison of the speciation of lead at 1bar and 10 bar (Fig. 5 and Fig. 6), evidences the presence of PbS in the condensed phase at high pressure and low temperature.

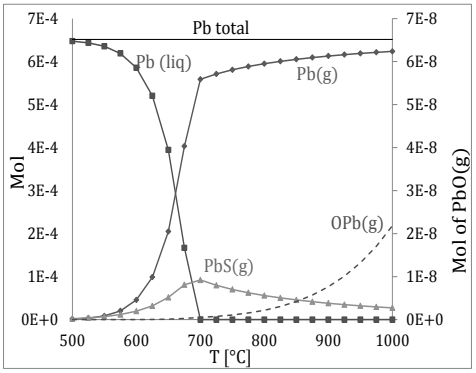

Figure 5. Speciation of Pb calculated at 1 bar.

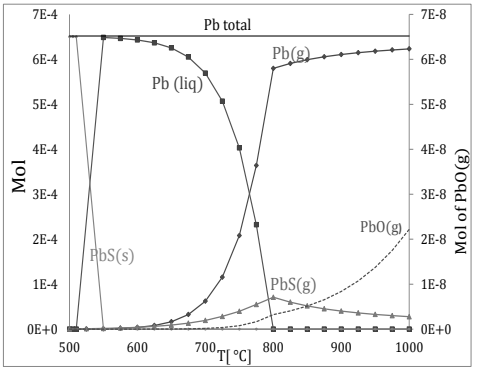

Figure 6. Speciation of Pb calculated at 10 bar.

3.4. Concentration effect

As willow is a plant which has a high potential to accumulate heavy metals, the concentration of Pb can vary for a plant to other depending in the soil contamination. The initial lead concentration in the willow used in this work is 135 $mg.kg^{-1}$. Nzihou et al. (2013) summarized the different limits concentration of heavy metals in phytoextraction plants: the concentration of Pb can vary between 55 and 300 $mg.kg^{-1}$.

Fig. 7 shows that doubling the initial concentration of Pb increases the temperature at which the whole amount of Pb volatilizes by 30 °C. Conversely, a speciation of inorganics during wood gasification realized by Froment et al. (2013) using a lower lead concentration (1 ppm) shows that the whole amount of Pb volatilizes at 500 °C. This is linked with the increase of the total volume of gas with temperature (Fig. 4): a higher volume of gas is required to evaporate a higher amount of Pb. No other concentration effect was evidenced.

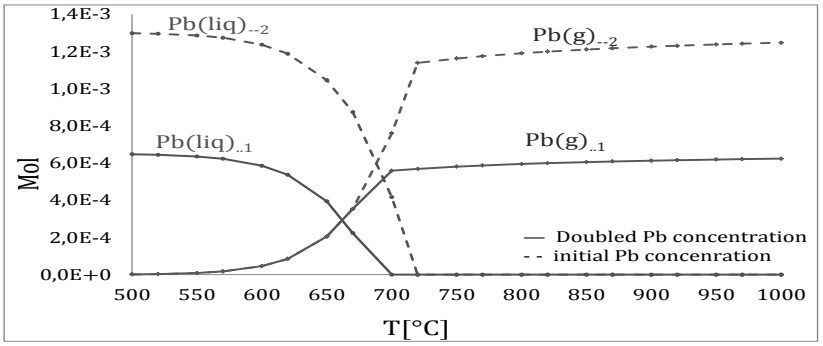

Figure 7. Effect of lead concentration (135 and 270 mg.kg^{-1})

4. Conclusions

Equilibrium calculations using a compound thermodynamic database were carried out to simulate contaminated biomass gasification. Due to the high number of compounds related to biomass composition, a selective methodology was applied in order to focus on the most relevant gaseous compounds.

An example dealing with the behavior of lead during gasification is provided. It shows that, at concentration of about 135 mg/kg in a contaminated willow biomass, lead is mostly found in the gaseous phase under its metal form, and in smaller quantity as sulfur and oxide.

Ongoing work is considering the behavior of other metal species (Transitions metals, Alkali and alkaline earth metals).

Multi-objective optimization for the production of fructose in a simulated moving bed reactor

Edwin Zondervan,[a], Bram van Duin,[a], Nikola Nikacevic,[b], Jan Meuldijk, [a]

[a]*Eindhoven University of Technology, Eindhoven, the Netherlands*
[b]*Belgrade University, Belgrade, Serbia*

Abstract

In this work we develop a simulated moving bed reactor model for the parallel isomerization and separation of fructose and glucose. The model consists of component balances and equilibrium relations. The appropriate computation of the cyclic steady state forms the core of the model. The resulting partial differential equation system is discretized and solved using a continuous prediction method. After testing the model, an optimization strategy is implemented that can be used to optimize the performance of the simulated moving bed reactor. First single objectives are optimized; the purity and the throughput. Secondly we use a multi-objective optimization approach to optimize for both systems parallel, the result is a pareto-front.

Keywords:

1. Introduction

The isomerization of glucose into fructose is an important reaction for the food industry. Fructose based syrups compete with sucrose (from cane sugar) in many food applications as sweetener. Fructose is 2-3 times sweeter than sucrose - which means basically that less raw material is required to give taste to for example soft drinks and that makes the production cheaper. As a result the change in world prices of cane sugar dropped and basically crippled sugar economies.

However, more recently the isomerization reaction of glucose into fructose was also proposed as a new means towards the bio based economy. Fructose is the starting material for the synthesis of furanic precursors which can be used to produce non-petroleum derived polymers. In addition, glucose is a monomer unit of the abundantly available polysaccharide cellulose. Glucose has the potential to become the most important organic raw material for a society depending on biomass recourses.

The big challenge exists in the separation of the formed product from the reaction mixture. The separation of isomers and other similar components is generally performed in a chromatographic/adsorption separation system.

These systems are operated in a non-continuous fashion. The isomerization reaction can be combined with the adsorption reaction into a simulated moving bed reactor. The introduction of the simulated moving bed reactor makes it possible to perform reactions and chromatographic separations quasi-continuously.

Moreover, since the reaction is reversible, the combination of reaction and separation intensifies the process by shifting the equilibrium. It is, however, difficult to optimize the design and operation of a simulated moving bed reactor due to the many variables and the cyclic nature of the process. A schematic representation of a simulated moving bed system is depicted in Figure 1.

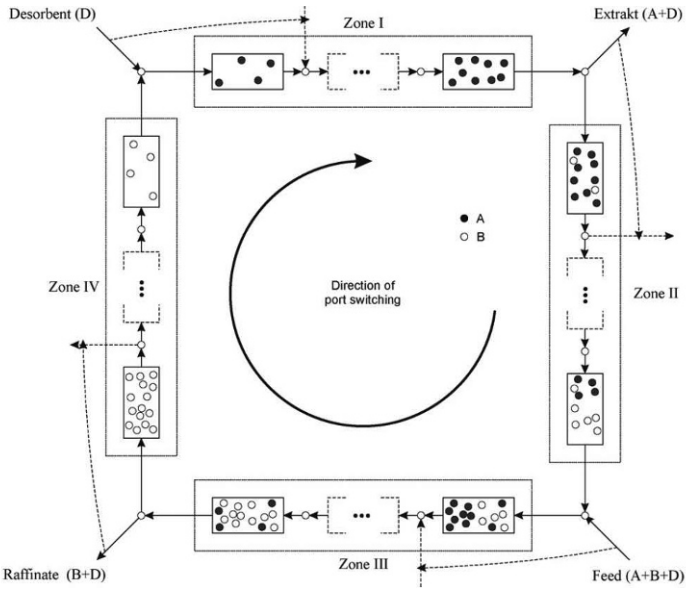

Figure 1: Principle of a Simulated Moving Bed system (Toumi *et al.* 2007)

2. Model development

In earlier work (Zondervan *et al.* 2012) we have endeavoured to develop a mathematical model in GProms for the SMBR. The resulting partial differential algebraic equation system was complex and gave computational issues when we build an optimization shell around it. We now propose a new model that neglects diffusion and we implement the model in MATLAB. The overall performance seems much better.

Given the zone velocities and the concentration of glucose and fructose in the inlet streams, our model will predict the concentration of both components as a function of time and space. It is assumed that no radial concentration distribution is present in the system and that the axial dispersion of the components is negligible. Typical liquid velocities for SMB systems are around 5 $m.h^{-1}$ (Menacho *et al.* 2013). For velocities of this magnitude, the Peclet number is in the range of 10^3, indicating that the influence of the diffusion terms are minimal. For this reason the diffusion term is not implemented in the model. We further assume that thermal and pressure effects on the separation are very small.

We now define the component balance in the liquid phase:

$$\varepsilon_b \frac{\partial C_{n,i}(x,t)}{\partial t} + (1-\varepsilon_b)\frac{\partial q_{n,i}(x,t)}{\partial t} + u_m(t)\frac{\partial C_{n,i}(x,t)}{\partial x} = 0 \qquad (1)$$

The component balance over the adsorbent:

$$\frac{\partial q_{n,i}(x,t)}{\partial t} = K_{abs,i} k_{eff,i} (q^*_{n,i} - q_{n,i}) \quad (2)$$

For the isomerization reaction rate a simple relation is used:

$$\frac{\partial C_{n,i}(x,t)}{\partial t} = K_i C_{n,i} \quad (3)$$

For this system (Eq. 1-3), the following boundary conditions hold:

$$C_{n,i}(0,t) = C^{in}_{n,i}(t) \quad (4)$$

$C_{n,i}(x,t)$ is the concentration of component i (i = fructose, glucose) in the liquid phase of column n (n=1,…,N). $q_{n,i}(x,t)$ is the concentration in the solid phase. $C^{in}{}_{,n,i}(t)$ is the inlet concentration to the n^{th} column, $u_m(t)$ is the superficial liquid velocity in zone m (m = I,II,III,IV) $q^*_{n,i}$ is the equilibrium concentration in the solid phase, $K_{abs,i}$ is the component mass-transfer coefficient and $k_{eff,i}$ denotes the component adsorption coefficient.

In addition, we have mass balances over the entrance- and exit nodes of each column. We follow an approach similar as in (Strube *et al*., 1998) We define a desorbent node (or eluent node) as:

$$C^{in}_{i,I} Q_I = C^{out}_{i,IV} Q_{IV} + C_{i,D} Q_D \;\; ; \;\; Q_I = Q_{IV} + Q_D \quad (5)$$

We define the extract draw-off node balance as:

$$C_{i,E} Q_E + C^{in}_{i,II} Q_{II} = C^{out}_{i,I} Q_I \;\; ; \;\; Q_{II} = Q_I + Q_E \quad (6)$$

The feed node:

$$C^{in}_{i,III} Q_{III} = C^{out}_{i,II} Q_{II} + C_{i,F} Q_F \;\; ; \;\; Q_{III} = Q_{II} + Q_F \quad (7)$$

The raffinate draw-off node:

$$C_{i,R} Q_R + C^{in}_{i,IV} Q_{IV} = C^{out}_{i,III} Q_{III} \;\; ; \;\; Q_{IV} = Q_{III} + Q_R \quad (8)$$

Where Q_D, Q_E, Q_F and Q_R are the flow velocities (flow rate divided by cross sectional area) of the desorbent, extract, feed and raffinate respectively.

Since the SMBR repeats the same operation for the number of columns, the profiles at the beginning of a step are identical to those of the downstream adjacent column at the end of each step. To ensure this the following equations are introduced:

$$C_{n,i}(x,0) = C_{n+1,i}(x, t_{step}) \quad (9)$$

$$q_{n,i}(x,0) = q_{n+1,i}(x, t_{step}) \quad (10)$$

$$C_{N,i}(x,0) = C_{I,i}(x,t_{step}) \quad (11)$$

$$q_{N,i}(x,0) = q_{I,i}(x,t_{step}) \quad (12)$$

With n = 1,..,N-1. The model parameters used in the model are listed in Table 1. To reach the CSS fast a continuous prediction (CPM) method is used. The method used in this work is described by Yao *et al*. (Yao *et al*. 2010) and Lubke *et al*.(Lubke *et al*. 2007) and does not depend on a good initial estimation for the CSS operation parameters. This calculation scheme computes new initial values for the next cycle based on the end state of the last switch.

Parameter	Value	Glucose	Fructose
ε_b (-)	0.389	-	-
L (cm)	52.07	-	-
$q^*_{n,i}$ (g/l)	-	$0.32C_{gluc} + 0.000457C_{fruc}C_{gluc}$	$0.675C_{fruc}$
$K_{eff,}i$ (1/min)	-	0.90	0.72
$k_{abs,i}$ (1/s)	-	$6.84.10^{-3}$	$6.84.10^{-3}$
K_i (1/h)	-	0.743	0.518
$C^{in}_{n,i}$ (g/l)	-	322	363

Table 1: Parameters for the glucose/fructose isomerization and separation

The partial differential equations were discretized and the MATLAB ODE solvers were used to compute the concentration profiles for fructose and glucose over the column lengths and time. As an illustration a typical concentration profile is shown in Figure 2.

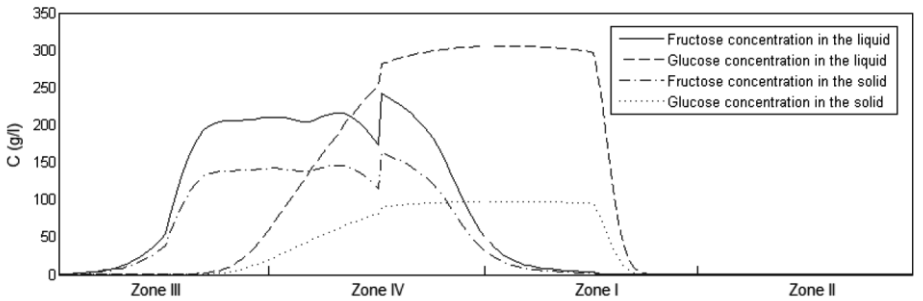

Figure 2: Concentration profiles for the isomerization and separation of fructose and glucose for an 8 column system, operated over 4 zones.

3. Optimization

Given the SMBR model as described under Eq. 1-12, the objective is to find the entrance- and exit node velocities that maximize the throughput while the purity requirements for the product in the extract and raffinate are satisfied. This problem translates into a nonlinear programming (NLP) problem that is solved with a gradient based solver in MATLAB (the built-in *fmincon* function). Mathematically the objective function of the optimization problem can be expressed as followed:

$$\max \bar{u}_F = \sum_n^N u_F^n \quad (12)$$

This objective is subject to the model equation proposed in Eq. 1-12. Furthermore the following constraints for the extract purity (EP) and raffinate purity (RP) hold:

$$EP = \frac{\int_0^{t_{step}} u_E(t) C_{E,k}(t) dt}{\sum_i^N \int_0^{t_{step}} u_E(t) C_{E,i}(t) dt} \geq EP^{min} \quad (13)$$

$$RP = \frac{\int_0^{t_{step}} u_R(t) C_{R,k}(t) dt}{\sum_i^N \int_0^{t_{step}} u_R(t) C_{R,i}(t) dt} \geq RP^{min} \quad (14)$$

the index k refers to the desired product. In this work we will use the same specifications for the minimum extract- and raffinate purities, i.e. $EP^{min} = RP^{min}$. In addition, there are limits on the zone velocities:

$$u_L \leq u_m(t) \leq u_U \quad (15)$$

We have solved the optimization model for different target purities. Table 2 shows the purity requirements versus the maximized throughput and the optimized values for the velocities and the step times.

PUR (%)	50	60	70	80	90	100
u_F(m/h)	11,91	10,62	9,69	8,58	7,71	5,62
u_{II} (m/h)	11,85	9,37	7,5	6,79	5,27	2,9
u_{III} (m/h)	18,57	19,42	18,57	19,94	20,34	22,23
u_{IV} (m/h)	7,89	7,78	7,63	8,33	8,33	9,1
t_{step}	4740	4740	4740	4740	4800	4740
PUR FRUCT (%)	81,3	86,9	96,4	92,9	96,5	99,4
PUR GLUC (%)	50	60	70	80	90	97,9
THROUGHPUT FRUC (g/h)	3570	3340	2840	2480	2100	1350
THROUGHPUT GLUC (g/h)	2460	2750	2660	2780	2340	1060

Table 2: Optimal solutions for the isomerization and separation with various purity requirements

If we now compare the maximized throughputs with the targeted purity we obtain a pareto-front as shown in Figure 3.

Figure 3 shows that for fructose as well as glucose the throughput decreases as product purity increases. We can obtain a maximum purity of fructose and glucose of 99.4% and 97.9%, respectively. At these purities the throughputs are 1350 g/h for fructose and 1060 g/h for glucose. If we maximize for throughput we obtain maximum throughput of fructose at 3570 g/h At this throughput the purity requirements are 81.3% for fructose and 50% for glucose. If we maximize for glucose, we obtain a value of 2780 g/h where the purity requirements are 92.9% and 80% for fructose and glucose respectively.

Each of the solutions on the front are pareto optimal. utopian point analysis can be used to select one of the outcomes as best trade-off. In utopian point analysis an utopian point is identified; the maximum throughput and the maximum product purity. Subsequently the point on the pareto front that has the shortest measurable distance to the utopian point is selected as the best trade-off. In this case the utopian point is located

at a fructose purity of 92.9%, a glucose purity of 80%, a fructose throughput of 2480 g/h and a glucose throughput of 2780 g/h.

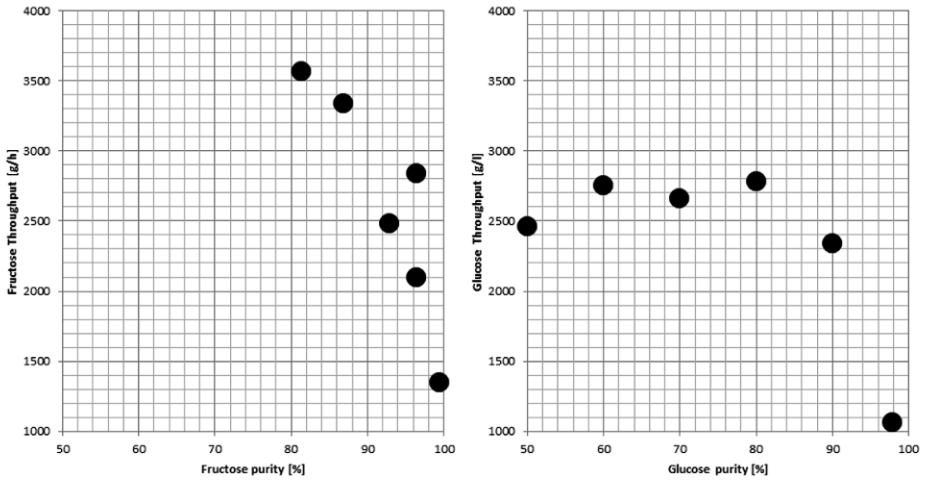

Figure 3: Fructose (left) and glucose (right) purity versus throughput.

4. Conclusions

In this work we have developed a model that can be used to compute the concentration of fructose and glucose over time and column length in a simulated moving bed reactor. The model contains component balances and equilibrium relation. The resulting partial differential equation is discretized and solved in MATLAB with a continuous prediction method. Next we use the model to optimize the entrance- and exit velocities of each of the columns in such way that the overall throughput is maximized. We then balance the throughput with the product purity by determining the pareto front and measuring the solution that is closest to the utopian point.

A Modeling Framework for Optimal Design of Renewable Energy Processes Under Market Uncertainty

Aryan Geraili, Jose A. Romagnoli*

Department of Chemical Engineering, Louisiana State University, Baton Rouge, LA, USA, 70803
Jose@lsu.edu

Abstract

A distributed optimization strategy for development of a reliable framework to address optimal design of renewable energy systems under uncertainty is presented. A structural approach is utilized for production capacity design, simulation of the process in detail, and optimizing the operating condition of the plant. To demonstrate the effectiveness of the proposed approach, a hypothetical multiproduct lignocellulosic biorefinery is considered as a case study. The results prove the efficiency of the proposed approach, and provide a quantitative analysis to determine the optimal design in the face of uncertainty.

Keywords: Decision support framework; Integrated biorefinery; Stochastic programming; Risk management.

1. Introduction

In recent years there has been a marked surge in the search for alternative sources of energy that wean the world off of dependence on fossil fuels and reduce the carbon foot-print. As the world has recognized the importance of diversifying its energy resource portfolio away from fossil resources and more towards renewable resources such as biomass, there arises a need for developing strategies which can design renewable sustainable value chains that can be scaled up efficiently and provide tangible net environmental benefits from energy utilization. Second generation biofuels are examples of such fuels that are extremely attractive owing to the fact that the raw materials can be composed completely of “left-over” wastes of food crops and forest harvests that don't interfere with the human food chain and the natural ecosystem. It also can provide new income and employment opportunities in rural areas.

Several contributions have appeared over the last few years in order to manage the complexity of decision making process for designing profitable renewable energy production systems. Many of the proposed studies in the literature use deterministic modeling approaches which assume that all the parameters are known in advance. However, common to early stages of process design is the lack of certain information that will introduce variability into the decision-making problem.

In this study we present the development and implementation of a multi-layered decision support tool for the optimal design of renewable energy systems under the presence of uncertainties. We apply a distributed, systematic approach which is composed of different layers including strategic, tactical, and operational tasks. Market

uncertainty is incorporated to the decision support framework through stochastic programming in strategic model. To demonstrate the effectiveness of the proposed methodology, a multiproduct lignocellulosic biorefinery is considered as a case study.

2. Optimization framework

A major component of any decision support system is a forecasting module which estimates the future parameters that will impact the enterprise performance. In our study, product supplies, demands, and prices are considered as uncertain parameters. Once the requisite parameters are forecasted over desired time scales, these parameters are inputted into the decision analysis framework. The process is formulated as a stochastic mixed integer linear programming (MILP) model which incorporates a stepwise capacity expansion strategy by defining binary variables for capacity increments at each time period in the planning horizon instead of establishing the whole capacity during the first planning year. These mass and energy balances that dictate core technologies in the energy production system are integrated with cost and revenue functions through a techno-economic model. The output of the model includes optimal design of production capacity of the plant for the planning horizon by maximizing the expected net present value (NPV).

To overcome the mismatch between nonlinear process mechanisms and LP-based strategic optimization, a decomposition strategy is proposed that combines net present value (NPV) optimization for long term planning with rigorous non-linear process simulation and process-level optimization. The second stage, which optimizes the operating conditions of the plant, consists of two main steps including simulation of the process in the simulation software (nonlinear modeling), and employing stochastic optimization methodologies to optimize the operating condition of the plant. Process simulation and optimization will be performed iteratively until the convergence criteria are met. A general schematic structure of the proposed iterative hybrid optimization framework is presented in Figure 1. Each component of the proposed algorithm (Figure 1) is described in more detail in section 4.

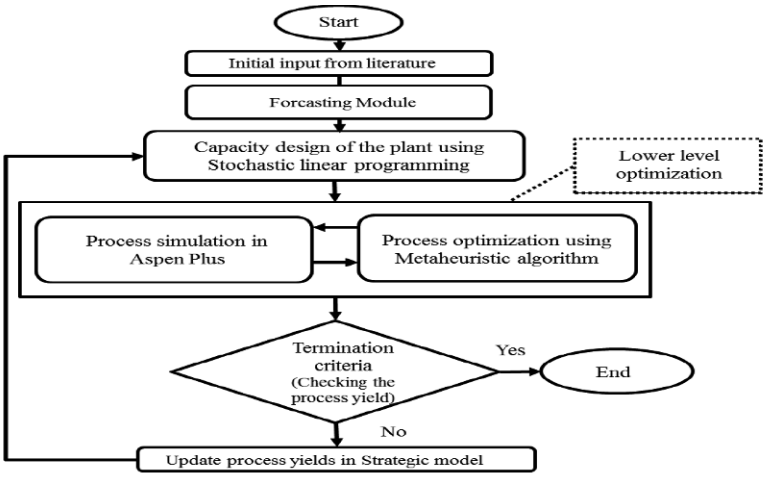

Figure 1. Proposed hybrid optimization framework

3. Process description

The lignocellulosic biorefinery, used in this study to demonstrate the capabilities of the proposed decision support framework, is a multiproduct plant that uses a fermentation-based sugar conversion platform, with 3 products: cellulosic ethanol, biosuccinic acid, and bioelectricity. Switchgrass serves as the selected feedstock for the biorefining process. The production chain comprises of 6 major systems: feedstock pretreatment, sugar hydrolysis, sugar fermentation, product purification, heat and power generation, and wastewater treatment. The systems superstructure is shown in Figure 2.

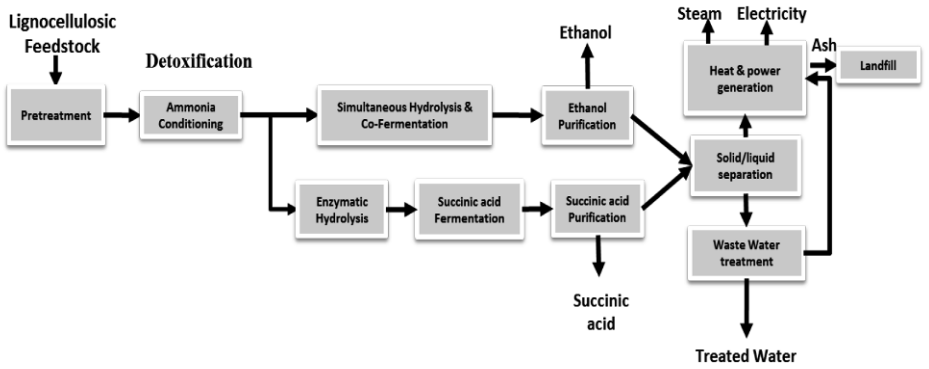

Figure 2. Block diagram for the multiproduct biorefinery plant

Technological configurations along with capital and operational cost, yield, and energy data for bioethanol production are obtained from Humbird et al. (2011) and Kazi et al. (2010). For succinic acid production, operational and economic data are obtained from Vlysidis et al. (2011); these are used as starting estimates to begin the iterative optimization process.

4. Framework details

In this section each component of the proposed framework (Figure 1) is described in some detail. While the description of the framework is based on the design of the case study presented in Section 3, each component, and the framework, can readily be adapted to other energy value chains. Due to space limitations, all model equations used for optimization cannot be listed. A description of model constraints is provided for each layer of the proposed optimization model.

4.1. Strategic layer

In the first layer, strategic planning is formulated as a mixed integer based linear program (MILP) with a 14-year planning horizon and bi-annual time steps. The mathematical formulation is broken into sub-models for ease of description which include a production model, financial model and risk management model. In production model, all major process systems are represented as linear black boxes. Major equations include linearly approximated mass and energy balances for each node in the value chain.

Financial model is broken into 2 salient aspects including market model and calculation of capital costs, operating expenses and revenues. In market model, price and demand evolution of bioproducts are described by considering that crude oil is represented as a stochastic input following Geometric Brownian Motion (GBM) and assuming that

market of bioproducts are impacted primarily by the price of crude oil. Binomial lattice generation approach is utilized to discretize the continuous stochastic model of oil price yielding Markov chain decision tree. Each node in the decision tree is represented as a price scenario for crude oil (and consequently for bioproduct markets). Calculation of the price and the demand of products (ethanol and succinic acid) is derived from the hypothetical market model proposed in the previously published journal paper Sharma et al. (2013). Additionally, to reflect and control the variability of performances associated with each specific scenario, a risk metric based on the downside risk management approach is utilized.

4.2. Operational layer

Then results from strategic layer (optimal capacity plan) are utilized to simulate the technological configuration in Aspen Plus. By simulating the entire model in Aspen Plus, the implicit correlations between upstream and downstream stages of the process are taken into consideration. One of the characteristics of our approach is the incorporation of the complex kinetics of bio-reactions in the simulation model. An iterative dynamic data exchange between process simulation model in Aspen Plus and developed kinetic models in Matlab is embedded as part of the process simulation (Geraili et al., 2014b). Developed mathematical formulations for the kinetics are based on the validated models by (Kadam et al., 2004; Morales-Rodriguez et al., 2011; Song et al., 2008). Differential evolution (DE) algorithm, which is a metaheuristic approach, was selected as an efficient optimization method for biorefinery processes in the previously published paper (Geraili et al., 2014a). This algorithm is utilized here to optimize operating conditions of the plant. Enzyme loading, pretreated biomass allocation between ethanol and succinic acid production, and hydrolysis temperature are selected as operating conditions to be optimized to maximize the annual cash flow.

5. Results and discussion

In this section, the results for the optimal design of the multiproduct biorefinery are discussed. The decision variables considered in the framework are composed of the optimal capacity plan for long term production in biorefinery, optimal temperature for enzymatic hydrolysis, optimal enzyme amount utilized in hydrolysis reaction and optimal allocation of pretreated biomass for production of final products. Plant life time considered in this study is 14 years with an annual discount rate of 10%.

Base on the results of the MILP model for the strategic optimization which is implemented in the modeling system GAMS and solved with a CPLEX linear solver, the distribution of the NPVs for two different scenarios are calculated as shown in Figure 3. First layer (strategic planning model) is solved in one scenario by utilizing stochastic approach and for the other scenario strategic model is reformulated by incorporating risk management model (multiobjective model) to demonstrate the effectiveness of controlling the variability of parameters. The optimal expected NPV of the enterprise for the first scenario (single objective model) is 62.8 $MM which indicates that value is created through the corporate activities and it is a profitable project investment. Figure 3 shows a wide range of values for calculated NPVs which represent the influence of market variability in the optimization model. In the calculation of the downside risk, the target level π is set to 51 $MM. The optimal expected NPV for this scenario (multiobjective model) is 60.0 $MM and we can see that the risk of occurrence of NPV in low cost area has been reduced (from 10% to 3%). Therefore, results show that reduction of the risk of occurrence of unfavorable scenarios

can be attained in the expense of a reduction in the expected value of the economic objective. It is also shown in the Figure how the risk management approach reconstructed the NPV distribution to reduce the risk of occurrence of unfavorable scenarios while maintaining acceptable expected revenue.

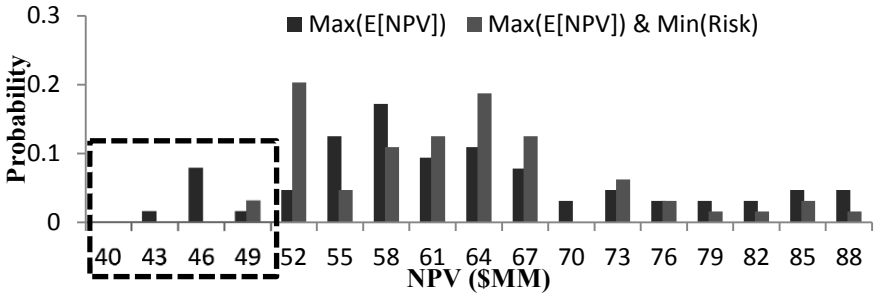

Figure 3. Block diagram for the multiproduct biorefinery plant

Iterative results of the hybrid optimization methodology are presented in Table 1 which shows that in two iterations the model is converged. Initial process yields are obtained from literature (step1); then these yields are utilized in strategic model to calculate the production capacity plan (step2); the optimal values for the capacity are passed to the process level simulation and optimization to find the optimal process conditions and calculate the process yields based on the results of simulation (step3). These calculated yields are compared with the initial values used in the strategic model to check the convergence. Since the difference between calculated yields and initial yields is greater than the threshold, this hybrid optimization needs to be carried out again based on the new yield values. Optimal values of the decision are shown in Table 2.

Table 1: Iteration results in hybrid optimization strategy

Parameters and Variables		Iteration1			Iteration2	
		Step 1	Step 2	Step 3	Step 1	Step 2
Capacity Constraints	Feedstock (1000 ton/yr)	--	222.2	--	218.0	--
	Ethanol (MM gal/yr)	--	15.3	--	11.4	--
	Succinic Acid (1000 ton/yr)	--	6.0	--	5.9	--
Yield Parameters	Sugar (kg / kg)	0.87	--	0.65	--	0.65
	Ethanol Fermentation	0.85	--	0.98	--	0.98
	Succinic Acid Fermentation	0.25	--	0.45	--	0.45
	Ethanol Purification	0.99	--	0.98	--	0.98
	Succinic Acid Purification	0.78	--	0.78	--	0.78

Table 2: Optimal values for decision variables and objective function

Temperature	33.55 °C
Sugar allocation	0.62 (ethanol), 0.38 (succinic acid)
Enzyme loading ratio	34.8 (g enzyme/ Kg Cellulose)
Cash flow	$71 million per year

6. Conclusions

In this paper a procedure was proposed to develop optimal design of renewable energy systems by utilizing a hybrid optimization algorithm. The proposed approach has the advantage of integrating long term planning with operational level decisions in the face of uncertainty. The analysis of the results reveals that considering uncertainty will provide an optimal design that reflects the variation of market parameters. In the second layer of the optimization model, results show a deviation from the values obtained from literature. This is attributed to the nonlinear modeling of our proposed framework to impart a greater degree of realism to the actual representation of the value chain.

Abstract

A light petroleum cuts hydrotreating model was developed comprising a molecular reconstruction approach based on the entropy maximization criteria to characterize the feed and to develop a kinetic mechanisms as follow: Langmuir-Hinshelwood, direct first order power law and reversible first order power law approaches to hydrodesulfurization, hydrodenitrogenation and aromatic hydrogenation reactions, respectively, on a trickled bed reactor. Only liquid phase reactions were considered, assuming a complete wetting of the catalyst surface. Rigorous phase equilibrium calculations were used in order to calculate the component concentrations in the gas-liquid interphase along the reactor length. The model was tuned using data generated under pilot plant test conditions for different temperatures at constant pressure, LHSV and hydrogen/feed. In addition, it was implemented as an interoperable software component based on the CAPE-OPEN standard, where a dedicated thermodynamic package was used to calculate the properties and phase equilibria required for the reactor model calculations. Results for the reconstruction step and model prediction were found in good agreement with experimental data.

Keywords: Molecular reconstruction, hydrotreatment, trickle bed reactor, CAPE-OPEN

1. Introduction

Hydrotreating is a process widely used in the petroleum industry for producing high quality fuels and as part of a scheme for upgrading heavy crude oil by reducing sulfur, nitrogen and/or metal content (Chen et al., 2011). Frequently, detailed studies are required in order to operate at optimal conditions and/or to design new plants, where a rigorous steady state reactor model becomes an imperative tool to face these process engineering tasks (Korsten and Hoffmann, 1996; Chen et al., 2011; Murali et al., 2007).

In the case of refinery reactors such as light-medium cuts hydrotreating reactors, since the feed is a mixture of hundreds (or even thousand) of compounds, not all compounds can be considered explicitly. Instead, pseudo or hypothetical compounds are defined, which are taken as a basis to represent the feed. A feed characterization step is required to obtain a representative feed composition in terms of these pseudo-components.

A traditional approach to face this task is by defining a set of pseudo-compounds generated from a true boiling point distillation curve as described in (Kaes, 2000). Another approach used by many

authors, is the "lumping" of species, where different species are grouped by families (Chen et al., 2011; Korsten and Hoffmann, 1996).

Since hydrotreating of light-medium petroleum cuts is based on three phase heterogeneous catalysis, the model must consider a proper way to formulate the kinetics that govern the reactions with the re-characterization as a starting point, then estimation kinetic parameters with data generated at bench or pilot plant scale, and finally scaling up for cases of commercial units performance predictions (Kaes, 2000; Korsten and Hoffmann, 1996; Muñoz et al., 2007; Murali et al., 2007). A drawback that could arise when using "pseudo-compounds" or "lumps" with the purpose of refinery reactor modeling is that new compounds, in terms of their properties, are generated for each new feed, which prevents from formulating a fixed reaction set.

In order to overcome this problem, many proposals have been made in the last years to have a detailed representation of hydrocarbon mixtures starting from the feedstock properties, where the molecular reconstruction technique has given adequate results (Alvarez et al., 2014; Pyl et al., 2010; Hudebine et al., 2011).

With the purpose of developing a tool for modeling hydrotreating reactors for light to medium petroleum cuts, this work used the molecular reconstruction approach to have a molecular representation of the feedstock as explained in Section 2. In Section 3 the reactor model formulation is explained, the kinetics of which are based on elementary reaction steps derived from the feedstock re-characterization. Finally, Section 4 explains the software architecture used for this model in order to assure its availability in different simulation platforms.

2. Feed characterization

2.1. Molecular reconstruction approach

The "Shannon entropy" is a concept introduced by Shannon (1948), where a measure of the uncertainty of occurrence of certain event, given partial information about the system, is proposed.

In the context of molecular reconstruction, the Shannon entropy is defined as $\mathscr{H} = -\sum_{i=1}^{n} x_i \cdot \log x_i$, and solving the reconstruction is posed as an optimization problem,

$$\max(\mathscr{H}) = \max(-\sum_{i=1}^{n} x_i \cdot \log x_i) \qquad \text{subject to} \qquad \sum_{i=1}^{n} x_i = 1 \tag{1}$$

where x_i is the mass fraction for each compound that constitute the mixture (Hudebine et al., 2011). In this work, a fixed selection of compounds, whose presence in light to medium hydrocarbon mixtures is well described in literature (Hudebine et al., 2011), is taken as the set of compounds for all cases studied.

2.2. Properties estimation

The solution of the equation 1 gives as a result the same mass fraction for each compound, where the function $\mathscr{H}$ is maximized. According to the conceptual meaning of the Shannon entropy, this results would be interpreted as, if there is no more information available about the system, there is an equal probability of each compound to be present. The reconstruction is fully defined when adding restrictions of the form $p_k = f_k(x)$, and equation 1 becomes,

$$\max(\mathscr{H}) = \max(-\sum_{i=1}^{n} x_i \cdot \log x_i) \qquad \text{subject to} \qquad \sum_{i=1}^{n} x_i = 1, \quad |p_k - f_k(x)| \leq \varepsilon \tag{2}$$

where p_k is the k^{th} experimental property available of the sample, f_k is the k^{th} function that estimates the property p_k as a function of the composition vector x and ε is the uncertainty of the experimental value.

Properties (p_k) considered in this study are shown in the column *Properties* of Table 1 and are essentially bulk properties that provide information about the molecular nature of feeds and products. The column *Estimation Function* shows the functions used to estimate each property p as a function of x. In Table 1, for each compound i sg_i is specific gravity, mw_i molecular weight, $^{\circ}S_i$ and $^{\circ}N_i$ the number of sulfur and nitrogen atoms respectively while mw_i^S and mw_i^N are the atomic mass for a nitrogen and sulfur atom.

Properties, p	**Estimation function,** $f(x)$
API Gravity (°API)	$141.5 \cdot \sum_{i=1}^{n} \frac{x_i}{sg_i} - 131.5$
TBP (K)	*see text*
Saturates (sT) (%wt)	$\sum_{i=1}^{n} x_i \; \forall \; i \in \{sT\}$
mono-Aromatics (mA) (%wt)	$\sum_{i=1}^{n} x_i \; \forall \; i \in \{mA\}$
di-Aromatics (dA) (%wt)	$\sum_{i=1}^{n} x_i \; \forall \; i \in \{tA\}$
tri-Aromatics (tA) (%wt)	$\sum_{i=1}^{n} x_i \; \forall \; i \in \{dA\}$
Sulfur (ppm)	$\sum_{i=1}^{n} \frac{x_i \cdot {}^{\circ}S_i \cdot mw_S}{mw_i} \cdot 10^6$
Nitrogen (ppm)	$\sum_{i=1}^{n} \frac{x_i \cdot {}^{\circ}N_i \cdot mw_N}{mw_i} \cdot 10^6$

Table 1: Properties considered as restrictions in the reconstruction formulation

The calculated TBP curve is composed by normal boiling points for each compound $\mathrm{nbp_i}$, sorted in ascending, in combination with the accumulative mass fraction, so an assumption of a perfect compound separation in the TBP distillation is made. In addition, a regression function is required in order to estimate TBP temperature at standard points for this curve such as 10%wt or 90%wt.

2.3. Composition estimation

Once equation 2 is set, the reconstruction problem is ready to be solved where the weight fraction of each compound is estimated. In this work, a general non-linear optimization method with an augmented Lagrange multiplier method was used, available as an open source package *"RSolnp"* in R (R core team, 2013).

3. Reactor model

3.1. Reaction network

Different reactions including hydrodesulphurization (HDS), hydrodenitrogenation (HDN), aromatic hydrogenation (HDA), olefins hydrogenation (HDO) and hydrocracking (HCK) occur during hydrotreatment. In the studied cases, because of the low olefin content and low severity process conditions HDO and HCK reactions were not taken into account, as shown in Figure 1.

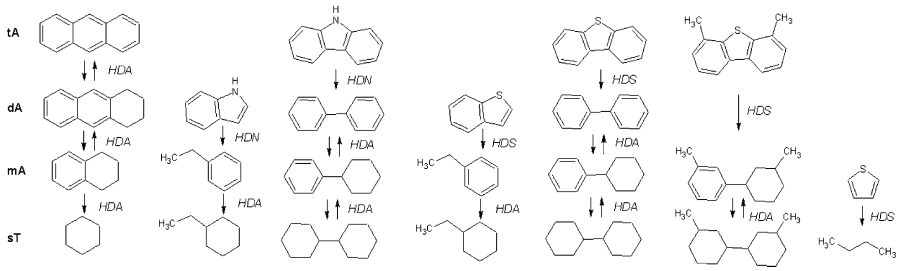

Figure 1: Reaction network

3.2. Assumptions and mathematical formulation

The following assumptions were made in order to pose the mathematical formulation of the reactor model: ideal plug flow reactor (Eq. 3), no mass transfer limitations, total catalyst wetting, liquid-vapor equilibrium (LVE) along the reactor lenght, isothermal temperature, Langmuir-Hinshelwood mechanism for hydrodesulphurization (HDS) (Eq. 4), direct reaction for nitrogenated compounds (HDN) (Eq. 5) and kinetic reversible reaction for aromatic (de)hydrogenation (HDA) (Eq. 6).

The reactor was modeled using equations 3, 4, 5 and 6, where F is molar flux, V is volume, r is the reaction rate, k_0 is the preexponential factor, E_a is the activation energy, C is the concentration in the liquid phase and K is the adsortion factor. Concentrations were taken from phase equilibrium calculations at each reaction step, values for K were taken from literature (Macías and Ancheyta, 2004) while E_a and k_0 where determined by error minimization of experimental and calculated data, using the BFGS algorithm. R is the universal gas constant and T is the absolute temperature.

$$\frac{dF}{dV} = -r_i \tag{3}$$

$$r_{HDS} = \frac{k_0^S \exp(-\frac{E_a^S}{RT}) C_s C_{H_2}^m}{(1 + K_{H_2S} C_{H_2S})^2} \tag{4}$$

$$r_{HDN} = k_0^N \exp(-\frac{E_a^N}{RT}) C_N C_{H_2}^m \tag{5}$$

$$r_{HDA} = k_0^A \exp(-\frac{E_a^A}{RT}) C_A C_{H_2}^m - k_0^{HA} \exp(-\frac{E_a^{HA}}{RT}) C_{HA} \tag{6}$$

4. Implementation architecture

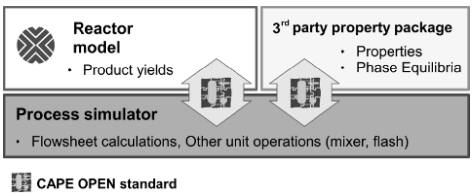

Figure 2: Conceptual approach

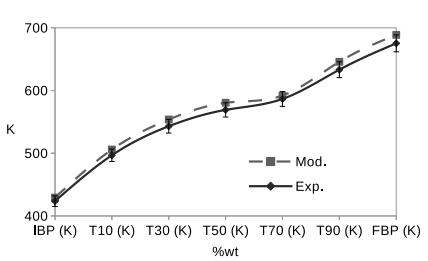
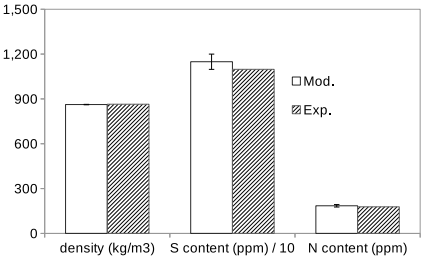
Most process simulators offer flexibility to model different kinds of unit operations. However, models that require experimental data to be set up, such as refinery reactor models, are typically developed as "in-house" software. In this work, the 1.1 version of the CAPE OPEN standard was used as the basis of the architecture. Since we envision use the combination of thermodynamics and unit operation in other process simulators, CAPE-OPEN has been used as the implementation platform.

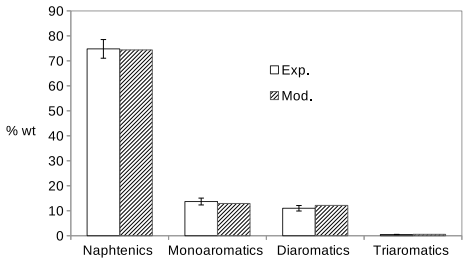
Figure 2 shows the conceptual integration of the model developed, a third party property package and the process simulator, using the CAPE-OPEN standard. While the reactor model calculates the product yield of each compound, the property package performs thermophysical property calculations and phase equilibrium calculations and the simulator defined stream objects store calculation conditions and thermophysical property values. The reactor model requests thermophysical property calculations and phase equilibrium calculations from the simulator, that are performed by the third party property package. All this information is communicated through the process simulator using CAPE-OPEN. Major commercial and non-commercial process simulators allow for using external unit operations and property packages via CAPE OPEN which ensure the possibility of using the developed model in a wide range of simulators (Van Baten and Pons, 2014). It is important to remark that the using of a dedicated property package ensures the availability of the compounds used for the reconstruction step in any simulator selected.



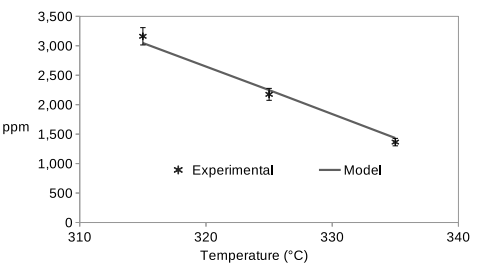
(a) TBP curve.



(b) Density, sulfur and nitrogen content in the feed.



(c) Naphtenics and aromatics distribution in the feed.



(d) Sulfur content in the liquid product.

Figure 3: Case A, P = 476 *psig*, LHSV = 2.9 h^{-1} and H2/oil = 99 Nm^3/m^3.

5. Results

The model was adjusted with experimental data generated in pilot plant conditions. Case A shows a process with low conversion for sulfur compounds while Case B is about a process where an ultra-low sulfur product is produced. With the aim of testing the extrapolative capability of the model, in both cases the two lower temperatures where used for kinetic parameter optimization and a prediction was made for the higher one. . Results for the molecular reconstruction step and reactor HDS model performance for both cases are shown in Figures 3 and 4.

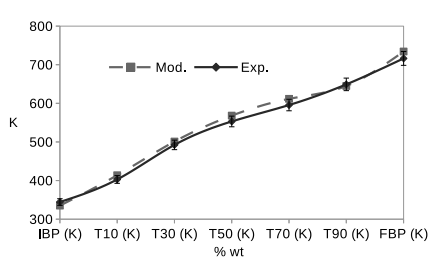
Figures 3 and 4 shows a succesful reconstruction of the feed in terms of the reproduction of the properties within the uncertainty limits for the experimental properties values. The sulfur content prediction for the product in both cases followed the experimental trend with an accuraccy into the experimental value uncertainty.

6. Conclusions

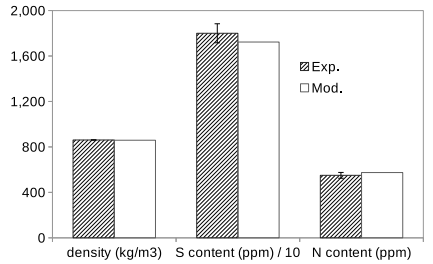
A molecular reconstruction strategy was succesfully applied for two light petroleum cuts, where TBP distillation, density, sulfur content, nitrogen content, naphtenic content and aromatic distribution were taken as the variables to be reproduced by the reconstructed feed.

Since the molecular reconstruction was based on a fixed set of compounds, it served as a basis to propose a fixed reaction network and a kinetic formulation with the aim of modeling the hydrotreating process for each of the feeds.

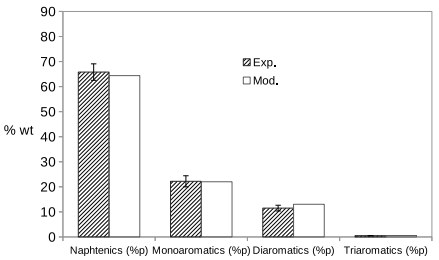
The adoption of CAPE-OPEN as the basis architecture will allow running along the model, with the required thermodynamics server, in a variety of process simulators, without modifying the reactor model or the thermodynamic server. Due to the choice of a fixed reaction set, no refinery-reactor specific requirements were present on the used CAPE-OPEN interfaces.



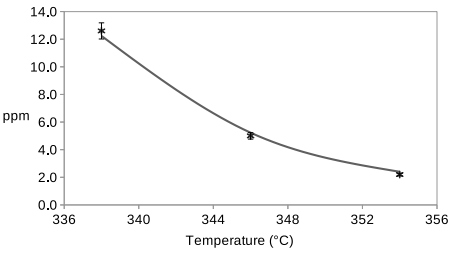
(a) TBP curve in the feed.



(b) Density, sulfur and nitrogen content in the feed.



(c) Naphtenics and aromatics distribution in the feed.



(d) Sulfur content in the liquid product.

Figure 4: Case B, P = 1598 *psig*, LHSV = 0.81 h^{-1} and H2/oil = 1472 Nm^3/m^3.

Finally, in the cases studied the developed model reproduces adequately the trend of the sulfur content in the liquid product at different reactor temperatures and is able to extrapolate for a higher temperature.

Abstract

The economic and technical feasibility of a hybrid distillation-membrane system applied to the separation of ethanol from water in traditional dry-grind corn ethanol facilities was studied. The current distillation technology was modeled in Aspen Plus and the proposed membrane unit in gPROMS. A system with the membrane placed after the distillation column with the membrane retentate recycled to the column feed was determined to be the most suitable for the separation requirements of this industry. Sensitivity analyses were performed to assess the effect of key membrane performance parameters such as flux, selectivity and cost on the economic feasibility of this system. These allowed for appropriate technical and economic performance targets for the membrane to be determined.

Keywords: Hybrid Separation Systems, Membranes, Techno-Economic Analysis

1. Introduction

The separation of ethanol from water is a crucial, energy intensive, step in the refining of corn ethanol. This separation step is particularly energy intensive because of the azeotrope formed between ethanol and water. Membrane technologies are not limited by this azeotropic behaviour and have been shown to be a promising alternative to traditional distillation technologies (O'Brien et al. (2000); Vane and Alvarez (2008)). The objective of this work is to investigate the technical and economic feasibility of one such technology based on an ethanol selective membrane and to ultimately develop a target set of membrane performance criteria which would render the system technically and economically feasible.

A simulation study of the current technology, which is based on a three distillation column configuration, is first performed to establish performance benchmarks that the membrane technology must meet or exceed in order to be considered technically and economically attractive. A hybrid configuration with a membrane system replacing two of the distillation columns is proposed that can achieve the desired separation targets.

The economics of this configuration are then studied. Performance targets for membrane parameters such as flux, selectivity and cost are established to ensure the economic feasibility of the proposed hybrid system.

2. Base Case: Distillation Modelling Results

The current state of the art technology used to separate ethanol produced by fermentation of corn sugars from water is a series of three distillation columns whose configuration is shown in fig-

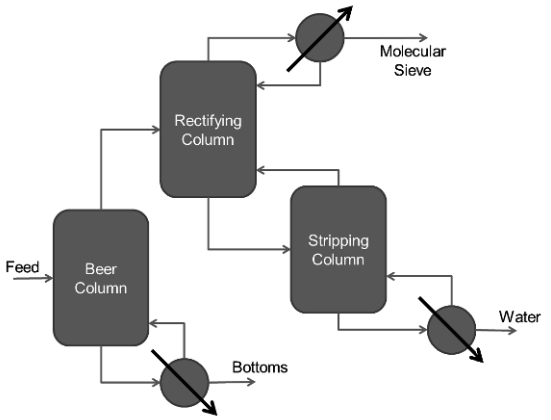

Figure 1: Process Flowsheet for Ethanol Distillation Base Case

ure 1 (Kwiatkowski et al. (2006)).

The first column, known as the beer column, has 22 trays, a reboiler but no condenser. The column produces a vapour top product that contains the feed ethanol and approximately equal amount of water. The reboiler steam flowrate is chosen such that almost all the ethanol is recovered in the top product. The bottom product contains all the fermentation solids (corn kernels, yeast cells and corn oils) and water which, once dried, are sold as dry distillers grains with solubles (DDGS) to be used as animal feed. The revenues from DDGS contribute significantly towards the total revenue of these facilities.

The second column, the rectifying column, has 22 trays, a condenser but no reboiler. This column produces a top liquid product at the azeotropic ethanol concentration of 95wt%. The bottom liquid effluent is fed to the third column, the stripping column.

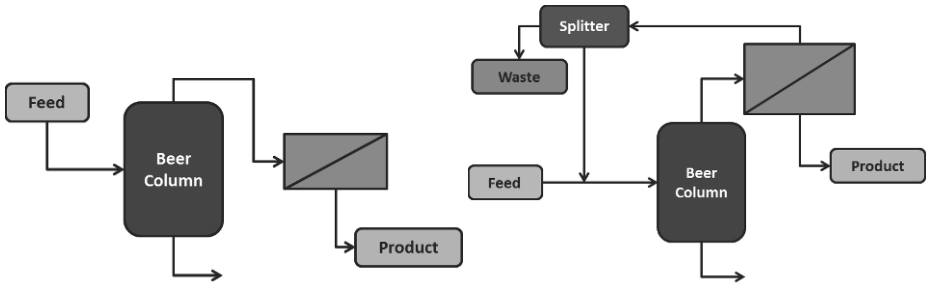
The stripping column has 35 trays, a reboiler but no condenser. It produces a top vapour product which is fed to the bottom of the rectifying column. Again, the reboiler steam flowrate is chosen to recover almost all the ethanol in the top product.

The three columns have been simulated in Aspen Plus. The overall recovery achieved is 99% and the top product purity is 95wt% ethanol. The reboiler energy costs are the largest operating expenses of these columns and far outweigh the capital costs (Kwiatkowski et al. (2006)). The Aspen Plus results show that the beer column uses 9.50MW and the stripping column uses 4.20MW of steam which costs $1.66MM and $0.74MM, respectively, assuming natural gas boilers operating at 80% efficiency and $5.00/MMBTU natural gas price.

This base case is capable of recovering 99% of the ethanol produced during fermentation and produces a 95wt% product. These two values become the performance targets that a membrane system must meet or exceed in order to outperform the existing technology.

3. Membrane Modelling

The membrane unit considered was modeled as a plug-flow counter-current hollow-fiber membrane module where the feed enters the hollow fibers (retentate side), ethanol permeates through the membrane and leaves in the product stream exiting the shell side (permeate side). Nitrogen is used as a sweep gas on the permeate side and assumed not to permeate through the membrane. The system of equations was solved in gPROMS v3.6 by discretization of the length of the membrane. The key parameters of the membrane system are the total membrane area, nominal flux and



(a) Single Pass (b) Recycle Scheme

Figure 2: Process Schematic for Single Pass and Recycle Schemes

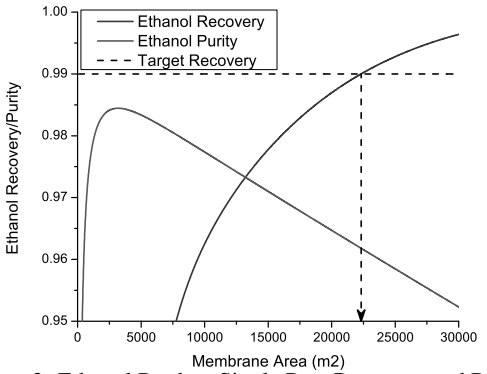


Figure 3: Ethanol Product Single Pass Recovery and Purity vs Membrane Area for Selectivity 250

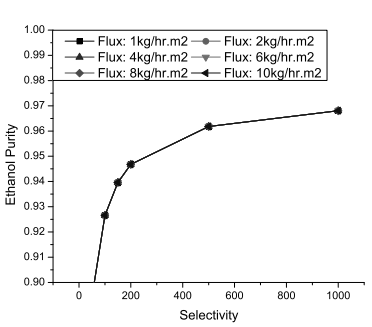
selectivity. The selectivity is defined as the ratio of ethanol to water permeability. The nominal flux is defined in units of kg/hr.m^2 assuming a fixed driving force of 1atm. This reported nominal flux is not the same as the modelled flux of ethanol or water through the membrane which will vary according to the partial pressure difference across the membrane.

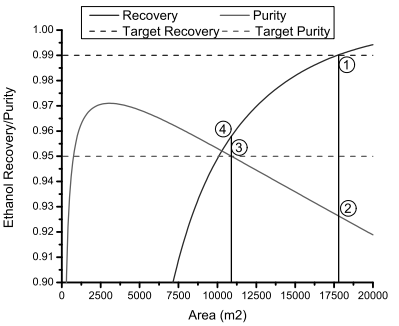
4. Results and Discussion

Three possible configurations were studied: a membrane system in place of all distillation columns, a membrane placed before the distillation series, and a membrane placed after the beer distillation column. Based on an energy analysis, the latter is the most attractive option and will be analyzed further in the rest of the paper.

We begin with the configuration shown in figure 2a which must achieve the required separation in a single pass. As an example of the type of results that we have generated, we present figure 3 which shows the ethanol purity and recovery as a function of membrane area for a fixed flux of 6kg/hr.m^2 and a selectivity of 250. We see that purity initially increases as more ethanol is permeated through the membrane and dilutes the nitrogen sweep gas. At approximately 4,000m^2, the trend is reversed as increasing amounts of water permeates through the membrane and dilutes the ethanol product stream. The required membrane area is chosen as the area required to meet the 99% recovery target as shown by the black arrow in the figure. Once the required membrane area is found, the corresponding product purity can be read from the graph which in this case is just above 95%.



(a) Ethanol Product Purity vs Membrane Selectivity for Different Values of Flux



(b) Ethanol Product Purity and Recovery vs Membrane Area - Selectivity: 100, Flux: 6kg/hr.m^2

Figure 4: Membrane Simulation Results

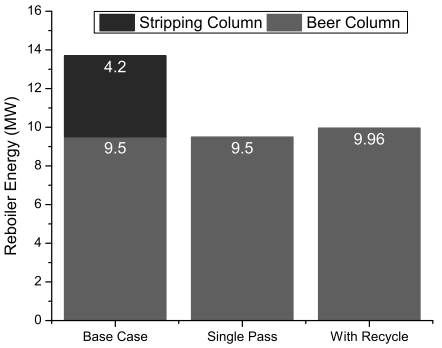


Figure 5: Column Energy Requirements for Three Scenarios

We can repeat the analysis for a range of fluxes and selectivities and produce figure 4a which shows the final ethanol product purity achieved at the 99% recovery target for different values of flux. The figure shows that the achieved product purity is a very weak function of flux and that in order to achieve the desired 95wt% purity target a membrane with selectivity of at least 250 is required. Since such a value can be considered unrealistic given the current state of membrane technology (Zhang et al. (2013)) a more reasonable upper bound of 100 should be used, however, as shown in figure 4a the required purity and recovery cannot both be met in a single-pass membrane configuration with this selectivity.

Figure 4b shows ethanol product purity and recovery as a function of membrane area for a membrane with selectivity 100 and a flux of 6kg/hr.m^2. The single pass membrane configuration must be operated at point 1 (17,800m^2) for the required recovery to be achieved; however, this means that the achieved product purity (point 2, $\sim$93wt%) does not meet the 95wt% target. A smaller membrane can be used which achieves the required product purity at point 3 (10,900m^2) but does not achieve the required recovery at point 4 ($\sim$96%).

In order to increase the overall recovery, we introduce a recycle loop as shown in figure 2b with a purge stream to avoid material accumulation. In this configuration both the target purity and target recovery can be achieved with a membrane with selectivity 100.

The split fraction between the purge and recycled streams is set such that exactly 1% of the feed

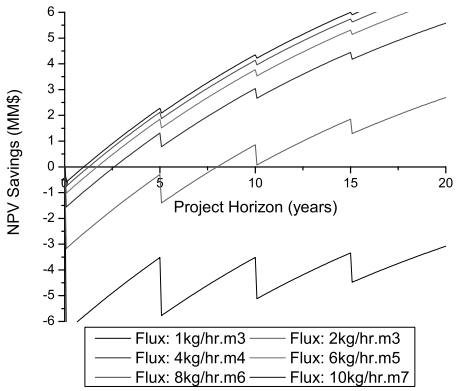

Figure 6: NPV Savings Projections for Different Flux Values - Membrane Cost: $100/m2

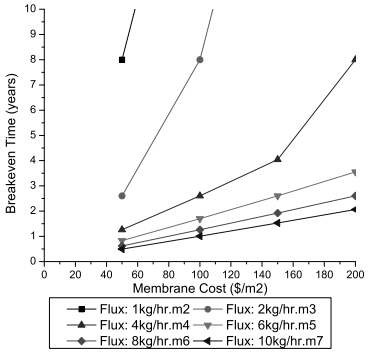
ethanol is in the purge stream and therefore the overall recovery target of 99% is achieved. As expected the recycle stream will cause the beer column feed stream to increase in flow rate and decrease in ethanol concentration, and this is expected to increase the energy required in the beer column reboiler. The column(s) is modeled for the three scenarios considered in Aspen Plus and the energy requirements are shown in figure 5. The results show that as expected the beer column in the recycle scenario uses slightly more energy than in the single pass case, however, significant energy is saved compared to the base case. It was found that 3.77MW are saved which corresponds to a savings of $656,000/year.

5. Membrane Economics

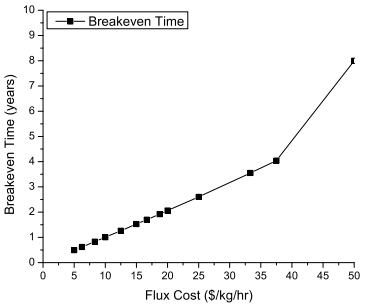
The Net Present Value (NPV) savings that can be achieved over the current best practice are calculated assuming a discount rate of 7%. The NPV savings projections over the course of an assumed 20 year project lifetime for a membrane cost of $100/m^2 are shown in figure 6 for the same set of fluxes studied above. In the figure, we see that each set of points follows a similar pattern. The initial investment in the membrane unit results in a negative NPV. The total energy cost savings of $656,000/year is in place for the next four years. The membrane tubes are assumed to have a lifetime of five years and cost half the initial investment to replace. This pattern is repeated for the next 15 years. Overall, we see that as the flux increases, the system's economics improve because the required membrane area decreases.

Obviously, the results in figure 6 will change according to the assumed membrane cost. The process economics will improve with decreasing membrane costs. In order to understand the trade-offs between increasing flux or decreasing costs, we plot the breakeven time, defined as the time in years needed to reach an NPV of zero, against membrane costs for a set of fluxes. These results are shown in figure 7a. To further improve the clarity and usefulness of our results we suggest a new parameter termed "flow cost" which is calculated as the membrane cost ($/m^2) divided by the membrane flux (kg/hr.m^2) and therefore has units of $/kg/hr. The flow cost can be thought of as the cost of ethanol flow rate through the membrane.

When the results shown in figure 7a are recast using this new parameter, the results shown in figure 7b are obtained. In this figure, all the points lie on a single line as long as the breakeven time is less than the lifetime of the membrane (assumed to be 5 years here). Results with a breakeven times higher than 5 years correspond to scenarios that require at least one membrane replacement thus increasing the slope of the breakeven time vs flow cost curve. The five year



(a) Breakeven Time vs Membrane Cost for Different Flux Values



(b) Breakeven Time vs Flow Cost

Figure 7: Breakeven Time Graphs

membrane lifetime assumption provides a reasonable upper bound on the required breakeven time. This breakeven upper bound, therefore, sets a limit on the flow cost of $42/kg/hr. Any membrane with a combination of membrane flux and cost that achieves this upper flow cost limit will be economically attractive given the assumptions used.

6. Conclusions

We have designed a novel hybrid system that combines a distillation column with a membrane unit to be used to separate corn ethanol from water. The distillation column is fed the fermentation effluent stream and produces a vapour product with an ethanol concentration of 56wt%. This is fed to a membrane unit with enriches the ethanol to the required 95wt% purity target. The overall ethanol recovery target of 99% is achieved by the use of a recycle stream. The required membrane performance targets are a selectivity of 100 and a flow cost less than $42/kg/hr. An energy savings of approximately 3.74MW is achievable which corresponds to 24.6% of the total energy currently used in corn ethanol water distillation.

Abstract

Multi-stream heat exchanger (MHEX) is an important equipment to recover cold energy in air separation units (ASU). Multiple streams are designed to exchange heat simultaneously in this equipment. Modelling and simulation of MHEX is an essential step for operational optimization for an air separation process. In the MHEX of an ASU, some streams are designed to enter or leave from a certain layer in the middle section, which increases the complexity of modeling the MHEX. In this paper, an equation oriented (EO) modelling method for complex MHEX is proposed. By considering the structural feature, the complex MHEX is decomposed into several bundles. In each bundle, all streams leave and enter from two ends. A regression model is used to describe the relation among the flowrates, inlet temperatures, and outlet temperatures of the stream in a bundle. The overall model can be solved in an EO mode by lumping the multi-bundle models together. The proposed modelling method is demonstrated with a large number of plant data from a commercial 20000Nm^3/h internal compressed ASU. The results show that the developed model can well predict the operation of the MHEX without knowing the detailed information of the internal structure.

Keywords: equation-oriented model, multi-stream heat exchanger, air separation unit.

1. Introduction

MHEX is a single process unit in which multiple hot and cold streams exchange heat simultaneously with high flexibility and efficiency(Wang et al., 2001; Boehme et al., 2003). It has been widely used in cryogenic systems to recover the huge amount of cold energy at very small temperature approach such as 1-3 K(Hasan et al., 2009). Therefore, the performance of the MHEXs plays an important role in the control and optimization of load change process of an ASU (Zhu et al., 2009; Xu et al., 2011). It is necessary to establish a robust and efficient MHEX model under various operation points. However, first principle model of an industrial MHEX is difficult to be established due to the complex structure of the proprietary(Khan et al., 2012). Moreover, some streams enter or leave an MHEX from a certain layer in the middle section with phase changing. In this project, a model for complex MHEX of ASU is developed based on data regression. The proposed method decomposed the complex MHEX into several bundles to prevent streams from entering or leaving a bundle in the middle layer. A regression model is used to correlate the outlet temperatures with the inlet temperatures and flowrates for each bundle and then lumped into the whole MHEX model. The regression model for the whole unit is no longer an explicit function of input variables due to the existence of variables at the intermediate layers. Both the parameter estimation and process

simulation require solving simultaneously in an EO mode. The performance of the proposed method will be demonstrated with real plant data obtained from a commercial 20000Nm^3/h internal compressed ASU.

2. Multiple Bundle EO Model of MHEX

The schematic of an MHEX is illustrated in Fig. 1. It is a typical MHEX equipment designed for a commercial 20000Nm^3/h internal compressed ASU. In this equipment, three hot streams (H1 to H3) and four cold streams (C1 to C4) exchange heat together. Among the streams, H1 and C3 leave the equipment from middle layers while H3 enters at another layer. Flowmeters and temperature transducers are mounted on each stream to obtain the flowrate and inlet/outlet temperatures.

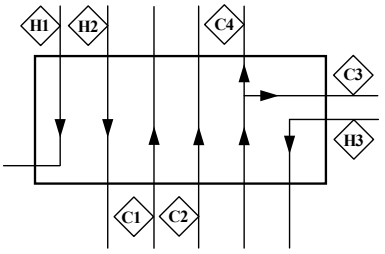

Figure 1. Schematic of an ASU MHEX

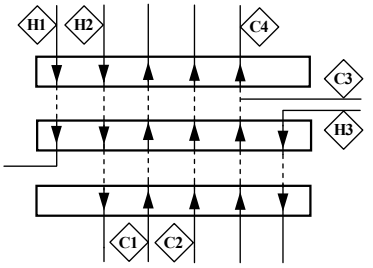

Figure 2. Multiple Bundle Structure of the Model

Instead of treating the regression as a pure black-box model, a multiple bundle structure is proposed as illustrated in Fig. 2. The MHEX is decomposed at every intermediate inlet and outlet section. A three bundle structure is then developed for the original MHEX in Fig. 1. In each bundle, streams are no longer entering or leaving the bundle in the middle layer but from the two ends of the bundle. To further simplify the modelling work for each bundle, the following assumptions are made.

(1) Ignore the heat loss from streams to equipment, and from equipment to environment;
(2) Fouling and other thermal resistance are negligible;
(3) Ignore the impact on heat transfer from small pressure drop;
(4) No heat transfer between hot streams or cold streams.

For each bundle, an explicit polynomial model can be built by choosing flowrates and inlet temperatures as input and outlet temperatures as output. To depict the nonlinear feature, a quadratic regression is the simplest approach:

$$y = \beta_0 + \sum_{p=1}^{n} \beta_p x_p + \sum_{p=1}^{n} \sum_{q>p}^{n} \beta_{pq} x_p x_q + \sum_{p=1}^{n} \beta_{pp} x_p^2 + \varepsilon \quad (1)$$

where x denotes the input variables, y denotes the output variables, β denotes the parameters to be estimated, and ε is the residual error. It consists of constant, linear, interactive, and pure-quadratic terms. With enough data, the least square regression can be used to obtain the parameters. However, even with a medium scale like in the case, the total number of the parameters to be estimated in a full quadratic regression is very large, which in turn requires a large number of data under different operating conditions for a proper regression. Therefore, rules based on process analysis are concluded to reduce the polynomial terms and the estimated parameters.

For a traditional heat exchanger with only one hot stream and one cold stream, the outlet temperature of a stream can be correlated as a function of the flowrates and inlet temperatures of both streams as:

$$T_{out,s}=f\ (F_i, F_j, T_{in,i}, T_{in,j})\ s \in i \cap j \tag{2}$$

where *i* and *j* represent the indexes of the hot stream and cold stream, respectively. The analysis of the heat transfer equation and the heat balance equation for a heat exchanger shows that the flowrate and temperature of a stream always appears in a pair as a product term. Therefore, rather than building a relation for outlet temperature, we choose the product of the flowrate and temperature of a stream as the output. Still keeping the description form in Eq. (2), the regressed model for the hot and cold streams are changed to the following formulations by multiplying the flowrate to both the input and output variables in Eq. (2).

$$F_i T_{out,i}=f(F_i^2, F_i F_j, F_i T_{in,i}, F_i T_{in,j}) \tag{3}$$

$$F_j T_{out,j}=f(F_i F_j, F_j^2, F_j T_{in,i}, F_j T_{in,j}) \tag{4}$$

By extending the description to a multi-stream case and unify the input variables for prediction of both the hot and cold streams in one formulation, the following description is eventually determined for a bundle section of the MHEX:

$$\begin{aligned} F_s T_{out,s} = f(&F_{H,1}^2,..,F_{H,N_I}^2,F_{C,1}^2,...,F_{C,N_J}^2,\\ &F_{H,1}F_{C,1},...,F_{H,1}F_{C,N_J}F_{H,2}F_{C,1},...,F_{H,N_I}F_{C,N_J},\\ &F_{H,1}T_{in,H,1},...,F_{H,N_I}T_{in,H,N_I},F_{C,1}T_{in,C,1},...,F_{C,N_J}T_{in,C,N_J},\\ &F_{H,1}T_{in,C,1},...,F_{H,1}T_{in,C,N_J},F_{H,2}T_{in,C,1},...,F_{H,N_I}T_{in,C,N_J},\\ &F_{C,1}T_{in,H,1},...,F_{C,1}T_{in,H,N_I},F_{C,2}T_{in,H,N_I},...,F_{C,N_J}T_{in,H,N_I})\quad s \in S = I \cap J \end{aligned} \tag{5}$$

where *I* represents the index set of the hot streams, *J* represents the index set of the cold streams, and *S* represents the union of two stream sets, N_I represents the total number of hot streams, N_J represents the total number of cold streams. Function *f* is chosen as a quadratic expression as shown in Eq. (1). Therefore, the coefficients of each term consist of the parameter set to be estimated. As a summary, the eventual description is composed by (a) constant term; (b) the square term of the flowrate of the hot stream *i*; (c) the square term of the flowrate of the cold stream *j*; (d) the interactive flowrate term between hot stream *i* and cold stream *j*; (e) the product term of flowrate and inlet temperature of hot stream *i*; (f) the product term of flowrate and inlet temperature of cold stream *j*; (g) interactive product term of flowrate of hot stream *i* multiplied by inlet temperature of cold stream *j*; (h) interactive product term of flowrate of cold stream *j* multiplied by inlet temperature of hot stream *i*. By following this description, the total term number is greatly reduced from $\sum_1^{2(N_I+N_J)} n + 2(N_I+N_J)$ of the full quadratic regression to $2(N_I+N_J)+3N_I N_J$. For this specific case, it is reduced from 119 to 50. As the measurement of the plant data is only available for variables at the inlet and outlet of the MHEX and no measurement is available for the variables at middle layers, the parameter estimation of this multi-bundle model cannot be formulated as a linear least-squares problem. Instead, by lumping the three-bundle models together, the modelling work can be converted to a nonlinear programing as described below.

$$Min \sum (T_{out,s,b}^{predict} - T_{out,s,b}^{measure})^2 + \delta \sum (T_{intermediate,s,b}^{predict} - T_{intermediate,s,b}^{measure})^2 \tag{6a}$$

$$s.t.\ F_{s,b} T_{out,s,b}^{predict} = f(F_{s,b}^{measure}, T_{in,s,b}^{measure}, T_{in,s,b}^{predict}, \beta) \quad \forall b \in 1,2,3 \tag{6b}$$

$$T_{out,i,b}^{predict} = T_{in,i,b+1}^{predict} \tag{6c}$$

$$T_{out,j,b+1}^{predict} = T_{in,j,b}^{predict} \tag{6d}$$

$$T_{out,i,b}^{predict} \geq T_{in,j,b}^{predict} + 1 \tag{6e}$$

$$T_{in,i,b}^{predict} \geq T_{out,j,b}^{predict} + 1 \tag{6f}$$

$$\frac{\partial f(F_{s,b}^{measure}, T_{in,s,b}^{measure}, T_{in,s,b}^{predict}, \beta)}{\partial F_{i,b}^{measure}} > 0 \tag{6g}$$

Eq. (6a) is the objective function which contains two terms. The first term denotes the error between prediction and measurement, which relates to the variables at the two ends of the equipment. The second term relates to temperature approach at intermediate layers, where only the stream leaving or enter the equipment there has the measurement. An optimal structure should not only predict as close as the measurement but also ensures that the intermediate temperature not vary far from the side stream. To constrain the temperatures of the streams, the temperature approaches at these points are also anticipated as described by the second term. Eq. (6b) represents the regression model of each bundle b, where β represents the parameter set to be estimated. Function f follows the description in Eq. (5). Eqs. (6c) & (6d) are connection equations for outlet stream and inlet stream at two bundle junction. Eqs. (6e) & (6f) constrain that hot stream should always be hotter than the cold streams at least 1K at the same level, which assumes the minimum temperature difference constraint is 1K according to the design. At last, Eq. (6g) states that the structural coefficients should satisfy certain physical law, e.g., if the flowrate of a hot stream increases, the outlet temperature should also increase.

3. Results and discussion

Applying the aforementioned modeling method, a three-bundle regression model is developed to capture the structural nature of the process. Real operational data is collected from the DCS system from the ASU plant. The operational data include flowrate, inlet temperature, outlet temperature of each stream. Note that the raw data contains measurement noise. In addition, the cyclic switch of the molecular sieves is a large disturbance for the operation which causes the large fluctuation in temperatures and flowrates. Therefore the raw operational data is pre-processed by averaging data for every 15 min and eliminating invalid data that is outside the normal range. After the pre-processing, 2500 data points are collected as the full data set. The first 1500 points are used for training and the other 1000 points are selected for validation. Figs. 3a & 3b plot the flowrate and inlet temperature in time sequence, respectively. The vertical dotted line in the figures represents the division of the training and checking samples. As shown in Fig. 3a, we can see that all flowrates change collectively. When one flow rate increases, other flowrates will also increase. This is mainly because the load change of ASU affects all the flowrates of the MHEX in the same direction. Fig. 3b plots all the inlet temperatures. To better illustrate them under the large temperature range of the streams, two vertical axes are used. Hot streams in Fig. 3b correspond to the vertical axis on the left and cold streams correspond to the vertical axis on the right. We can observe the cyclic feature with sudden changes for every 200 to 300 points. It is due to the cyclic operation for switching the molecular sieves as mentioned earlier. Basically, the flowrate and temperature varies within a certain range in all time. This means that a regression model based on part of these data should also apply to the other part.

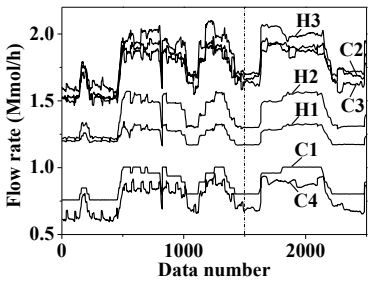

Figure 3a. Variation of flowrate

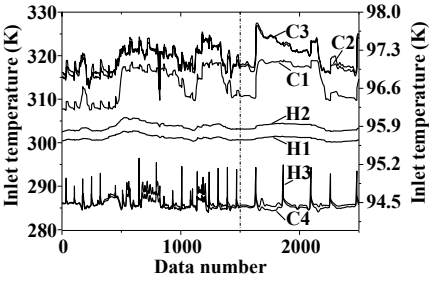

Figure 3b. Variation of inlet temperature

We build our MHEX model on the General Algebraic Modeling System (GAMS). The regression problem is constructed as a quadratic optimization problem which tries to find the optimal structural coefficients that minimize the error between the predicted temperature and real measurement. The final regression model includes 39,423 and 100,501 constraints (including 37,500 equality constraints). CONOPT solver is applied to solve the model which takes about 253 minutes to obtain the optimal solution. Fig. 4 shows the prediction error of the regressed model with both the training and checking data. The curves at the upper part of the figure denote the error of the outlet temperature and the curve at the bottom is the inlet temperature of stream H3 (denoted as TMinH3), which corresponds to the right vertical axis. From Fig. 4, the maximum error of outlet stream temperature of the training data is within 3K. The error distributes along the zero horizon line, indicating that the regression model is well trained. Also we can find out through the dotted curve of TMinH3 that relatively large error happens when the inlet temperature of stream H3 changes abruptly. This may be either due to the model mismatch when the temperature deviates from the normal operating condition or dynamic features of the MHEX system that is not taken account in our model.

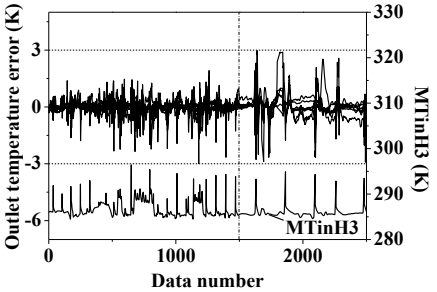

Figure 4. Outlet temperature error for simulation data

For the checking data, the optimal structural coefficients are imported to the simulation model to test the error between the predicted and real outlet temperature. As the structural coefficients are fixed in the validation model, the validation problem degenerates to a linear simulation problem with zero degree of freedom. CPLEX is used to solve this problem in a few seconds. The detailed information of the model accuracy in terms of the mean and max absolute errors is listed in Table 1. The mean errors for both the training and checking data are quite small. The max errors of the checking data are also within 3K. The comparison with the bottom curve of TMinH3 shows that the relatively large error occurs around the cyclic changes of the inlet temperature, corresponding to the cyclic switch operation. Apart from these points, the model predicts accurately. This indicates that the regression model is able to perform well

under most cases. Therefore the multi-bundle model can be used for outlet temperature prediction.

Table 1 Error of training and testing data of the multiple bundle model

		H1	H2	H3	C1	C2	C3	C4
Training data	Mean*	0.291	0.090	0.133	0.135	0.147	0.368	0.135
	Max*	1.922	0.548	0.723	0.946	0.936	2.985	1.199
Checking data	Mean	0.499	0.155	0.218	0.145	0.141	0.587	0.172
	Max	2.525	0.528	0.633	1.147	0.918	2.972	1.502

* In table 1, "Mean" refers to mean absolute error, "Max" refers to max absolute error.

4. Conclusions

An EO model of a complex MHEX is built by considering the equipment structure. Industrial plant data are collected to regress the multiple bundle model through EO optimization. Without using detailed structure information of the MHEX, the regressed model can correlate the equipment operation in good performance. This model is applicable for simulation of MHEX and air separation process.

Abstract

The use of fertilizers for microalgae growth is one of the major constraints for energetically feasible and sustainable production of fuel from microalgae at commercial scale. In a recent biological study, a distinct species of microalgae, *Botryococcus braunii*, which can produce long chain hydrocarbons and excrete them outside of the cell wall, has been tested for repetitive extraction of its hydrocarbons - termed as milking. The determination of the ability of the *Botryococcus braunii* to produce the hydrocarbons repeatedly without any extra supply of nutrients is expected to be an important step towards the sustainable production of fuels and chemicals from microalgae. In this study, the newly proposed method has been compared with the conventional method for the growth of microalgae to produce similar amount of microalgal oil. The mathematical models consisting of mass balance equations were developed using Aspen Custom Modeler for both the conventional microalgal growth system and the process of repetitive production of hydrocarbons from *Botryococcus braunii*. The results show that compared to the conventional system, the fertilizer requirement, water consumption and energy inputs in the milking process can be decreased by 90 %, 30 % and 70 %, respectively. This shows that the milking system has the potential to reduce the overall energy input to the process of production of fuel from microalgae. Also, high heating value of hydrocarbon contents of *Botryococcus braunii* gives the higher energy output resulting in higher output to input energy ratio of the process, making it energetically more feasible than the conventional system.

Keywords: Energy, Fuel, Microalgae, Repetitive Hydrocarbon Production, Milking

1. Introduction

High use of fossil resources due to increase in energy demand is causing the climate change and depletion of fossil resources. Renewable energy sources other than biomass are the alternate for fossil resources for electricity generation. Biomass is the only alternate of fossil fuels for liquid fuel and fossil derived industrial chemicals production. Microalgae are the source having tremendous potential for contributing to the energy crisis and greenhouse gas emissions solutions. Microalgae are the single cell organisms living in colonies or individually. They utilize sunlight, carbon dioxide, water and fertilizers (nitrogen and phosphorus) to produce organic compounds by photosynthesis. The major compounds present in microalgae are proteins, carbohydrates, nucleic acids and lipids. Microalgal oil (lipids) has high heating value of average 38 MJ/Kg

(Williams and Laurens 2010) which is very close to the heating value of petroleum crude oil (45 MJ/Kg).

Algal fuel production pathway follows the cultivation (growth), harvesting (dewatering), extraction of oil and upgradation steps (Pragya et al. 2013). The process of algal fuel production is not commercial yet. The main constraints are high energy consumption and high cost of the process. The cultivation of microalgae on commercial scale for the production of fuel or fuel based chemicals needs large amount of CO_2, water, nitrogen and phosphorus fertilizers and energy associated with them (Borowitzka and Moheimani 2013). Nitrogen and phosphorus fertilizers are used as the nutrient source for the growth of microalgae. Production of nitrogen fertilizers consumes vast amount of energy from fossil resources and generates greenhouse gas emissions. Phosphorus is obtained from finite natural phosphorus rocks. The use of these fertilizers is one of the major energy consuming and cost contributing factors and sustainability constraints for microalgal fuel production (Borowitzka and Moheimani 2013). Furthermore, the supply of nitrogen and phosphorus fertilizers for microalgal growth for commercial scale fuel production will affect the supply of these fertilizers for the agriculture sector (Chisti 2013).

In a recent biological study, a distinct species of microalgae, *Botryococcus braunii*, has been tested for non-destructive repetitive extraction of its hydrocarbons - termed as milking. *Botryococcus braunii* has two unique properties: a) produces long chain hydrocarbons and b) stores most of the hydrocarbons in extracellular matrix, outside of the cell walls (Weiss et al. 2012). This is in contrast to all other microalgal species which produce lipids instead of hydrocarbons and store them inside the cells (Hirose et al. 2013). Based on the produced hydrocarbons, *Botryococcus braunii* is divided to four races A, B, L and S. Race A produces straight odd numbered from C23 to C33 alkadienes and alkatrienes, race B produces triterpenoids from C30 to C37 also called botryococcenes and race L produces tetraterpenoids (Metzger and Largeau 2005). Race S produces n-alkanes and epoxy n-alkanes ranging from C18 to C20 (Kawachi et al. 2012). *Botryococcus braunii* has high oil contents ranging from 25 % to 75 % of dry weight biomass, most of which are the hydrocarbons (Mata et al. 2010). The energy contents of *Botryococcus braunii* hydrocarbons (49 MJ/Kg) (Dote et al. 1994) are higher than average energy contents of lipids of other microalgal species. These hydrocarbons can be hydrocracked to produce gasoline, aviation fuels and diesel (Hillen et al. 1982). But *Botryococcus braunii* is not considered suitable for conventional microalgal fuel production process due to its very low productivity (biomass growth rate).

In milking, some biocompatible solvents (usually alkanes) are used to extract the lipids from microalgae without damaging it (Frenz et al. 1989). In two recent studies (Moheimani et al. 2013, Moheimani et al. 2013), it was found that the same biomass of *Botryococcus braunii* after milking, produces similar amount of hydrocarbons again without any extra nutrients supply and extraction can be repeated many times. *Botryococcus braunii* BOT-22 (Race B) can be milked after every 5 days up to 15 times with 1 % CO_2 aeration to the culture, without extra supply of nutrients (Moheimani et al. 2013). This repetitive hydrocarbon production process omits the requirement of growing the new algal biomass for each extraction as in the case of conventional process. After extracting hydrocarbons, the algal biomass is recycled back to the ponds and kept under the same growth conditions (sunlight, water, CO_2) to let it reproduce the

hydrocarbons between two consecutive extractions. The repetitive extraction will not only decrease the fertilizer requirement but it will also decrease the water losses in the downstream process. Both of these parameters will affect the energy requirements of the process. In this study, the growth ponds have been modeled for the repetitive production of hydrocarbons from the same microalgae culture to determine the material and energy requirements of the growth phase. The conventional system (new microalgae growth for each extraction) has also been modeled to compare the two systems.

2. Methodology

Open ponds were considered for the growth of algae in both systems and for the phase of repetitive production of hydrocarbons by microalgae in milking system. The mathematical models consisting of mass balance equations were developed using Aspen Custom Modeler for both systems. The amount of microalgal oil/hydrocarbons to be produced was taken as the basis. The biological parameters such as productivity and oil contents of microalgae, concentration of algal biomass in culture media, number of days required for repeated production of hydrocarbons and number of repetitions up to which *Botryococcus braunii* is able to produce the hydrocarbons are the inputs to the model. Nitrogen and phosphorus fertilizer, water and CO_2 requirements have been calculated for both the conventional and repetitive hydrocarbon production systems. The area of open ponds required for the growth of algae in both systems has also been calculated using the model. Using the outputs from material balance equations together with the assumptions taken from literature for energy consumption, the direct and indirect energy requirements for the paddle wheel mixing, the fresh water pumping, the culture pumping to and from the ponds, the CO_2 supply and the indirect energy associated with the fertilizer production have also been calculated. Important growth phase assumptions and energy input assumptions for base case scenarios are shown in Table 1. Sensitivity analysis was performed to quantify the effect of important input assumptions for the range of their values reported in the literature on the ratio of the energy requirements of the two processes.

Table 1: Productivity, lipid contents and energy input assumptions for base case analysis

Parameter	Value	Reference
Biomass productivity (conventional)	20 g/m^2 day	(Borowitzka and Moheimani 2013)
Lipid contents (conventional)	40 %	(Borowitzka and Moheimani 2013)
Biomass productivity (milking)	9 g/m^2 day	(Zhang 2014)
Hydrocarbon contents (milking)	40 %	(Banerjee et al. 2002)
Fresh water supply energy	0.443 MJ/m^3	(Davis et al. 2011)
Harvest and recycle pump energy	0.09 MJ/m^3	(Davis et al. 2011)
Paddle wheel mixing energy	173 MJ/ha day	(Frank et al. 2011)
CO_2 transfer to ponds energy	0.076 MJ/Kg	(Frank et al. 2011)
Nitrogen fertilizer energy	35 MJ/Kg N	(Jonker and Faaij 2013)
Phosphorus fertilizer energy	17 MJ/Kg P	(Jonker and Faaij 2013)
Heat rate for electricity	32%	(EIA 2014)

3. Results and Discussion

The results of the material balance analysis for the conventional system and the repetitive hydrocarbon production system with different no. of repetitions (n) for hydrocarbon production are shown in Table 2. The results show that both nitrogen and phosphorus fertilizer consumption was reduced by 80 %, 90 % and 94 % for 5, 10 and 15 repetitions, respectively when repetitive hydrocarbon production system was considered. CO_2 consumption was the same in all cases as we considered the same CO_2 aeration for the recycled culture for repetitive production of hydrocarbons. Water consumption was reduced to 8 giga litres per year in the repetitive production system in contrast to 26 giga litres per year in the conventional system showing 70 % reduction. This is because the whole culture is recycled back in milking which reduces the downstream water losses. The open pond area required to grow the microalgae and reproduce the hydrocarbons in the repetitive hydrocarbon production system is 11 % higher than the open pond area required in the conventional system. It is because the productivity of the *Botryococcus braunii* is very low as compared to the average productivity of other microalgal species used in conventional system, increasing the growth pond area.

Table 2: Material consumption and area requirements for open ponds for microalgae cultivation in conventional system and in milking system with 5, 10 and 15 repetitions for hydrocarbon production from same *Botryococcus braunii* culture to produce 100,000 bbl of oil per year

Parameter	Conventional	Milking (n=5)	Milking (n=10)	Milking (n=15)
Nitrogen consumption (t/y)	2,253	450	225	150
Phosphorus consumption (t/y)	312	62	31	20
CO_2 consumption (t/y)	84,600	84,600	84,600	84,600
Water consumption (GL/y)	26	8	8	8
Open pond area (ha)	490	544	544	544

The total energy (onsite and indirect) requirements of the process are shown in Figure 1. The energy required for the paddle wheel mixing in open ponds and the energy required for pumping culture to the downstream harvesting unit and then back to the ponds is higher for the repetitive production system. On the other hand, the energy required for pumping fresh water to the ponds and the indirect energy associated with the production and transport of fertilizer are lower for the repetitive production system. Overall, the repetitive production system consumes 10 %, 30 % and 37 % less energy than the conventional system for 5, 10 and 15 repetitions, respectively.

For the sensitivity analysis (Figure 2), the ratio of the energy requirements of the two systems (energy requirement of the repetitive hydrocarbon production system/energy requirement of the conventional system) was defined as the parameter to compare the two systems. 10 repetitions for the hydrocarbon production system give an energy ratio of 0.7 indicating 30 % reduction in the energy consumption. This was considered as the base case for sensitivity analysis. The results of the sensitivity analysis show that energy ratio of the two systems is less than unity in all cases except one indicating less energy consumption in the repetitive production system. The hydrocarbon contents for the repetitive production system and the lipid contents in the conventional system are the

most influencing parameters for the energy consumption. 50 % decrease in hydrocarbon contents relative to the base case value in the repetitive hydrocarbon production system makes this system relatively more energy consuming.

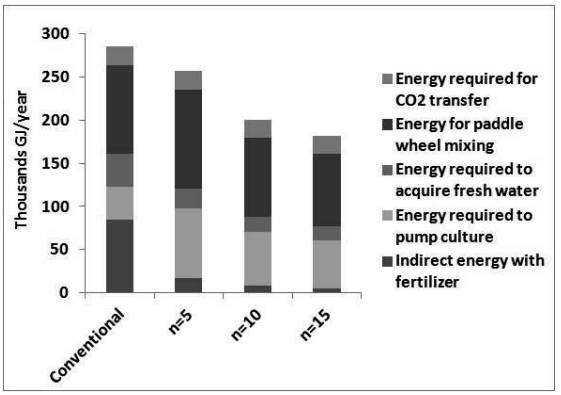

Figure 1: Energy consumption of conventional and repetitive hydrocarbon production systems with 5, 10 and 15 repetitions

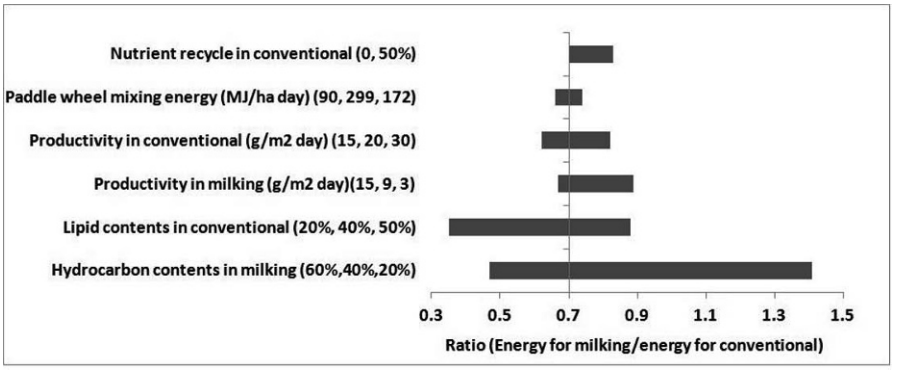

Figure 2: Sensitivity analysis on the ratio of energy requirements of the repetitive hydrocarbon production and the conventional systems. The ratio was found to be 0.7 for base case scenarios indicating that milking has 30 % less energy requirements.

4. Future Work

The next step in this project is the techno economic analysis of the fuel production using milking process in order to determine the energetic and economic feasibility of the process.

5. Conclusions

The production of fuel from microalgae is a highly energy consuming process. *Botryococcus braunii* is a hydrocarbon producing alga but the extraction of hydrocarbons from it by the conventional pathway is not feasible. The newly proposed milking process has the potential of reducing the energy requirements of extracting the hydrocarbons from *Botryococcus braunii* by decreasing the fertilizer consumption, water consumption and energy requirements. Lower energy consumption for hydrocarbon production and higher energy contents of the hydrocarbon produced from *Botryococcus braunii* will result in higher energy output/input ratio of the repetitive

hydrocarbon production process compared to the conventional process of microalgal oil production from other species.

Abstract

In this paper, Multistage Flash (MSF), Reverse Osmosis (RO) and hybrid MSF/ RO systems are modelled and simulated in Aspen Custom Modeler (ACM) V.8.4. Both steady state models include material balances; but RO focusses more on pressure differences, while MSF relies on energy balances. The model of a hybrid superstructure is developed by combining individual models of MSF and RO systems. The hybrid superstructure is developed in an optimization framework to analyse and optimize various process configurations. Operating conditions such as temperatures, pressures and process design variables such as the number of membrane elements in a pressure vessel and the number of stages in an MSF system are used as optimization variables to minimise the economic objective function. Primary results show that the hybrid MSF/ RO systems sharing common intake-outfall facilities have lower annual intake cost and can be considered in the areas where high overall product recovery and high product quality is required.

Keywords: hybrid MSF/RO, superstructure, simulation, optimization, minimum energy

1. Introduction

The overtaking demand of freshwater all around the world can be fulfilled by innovative and adaptive technologies such as desalination. Multistage Flash desalination (MSF) system is based on thermal technologies. Despite the high cost it is the first choice of the consumer because of its proven reliability and large production capacity especially in the areas where fuel prices are low (El-Dessouky and Ettouney, 2002). On the other hand, Reverse Osmosis (RO) is a pressure driven membrane process. Its low energy consumption, simple automation and control, easy scale up and high product recovery and quality makes it the second choice of the consumer (El-Dessouky andEttouney, 2002). A lot of efforts have been made in the past three decades to reduce the cost of MSF plant. Considering the advantages of RO plant, it is believed that one possible way to reduce the cost of MSF plant is to hybridize MSF and RO systems (Helal et al., 2003). Another significant advantage of using MSF/RO hybrid plant is that the fresh water produced from both systems is mixed and the concentration of the final product is the average between the concentrations of both systems. In this manner the RO plant can work for lower product quality requirements.

The research work around modelling and optimization of hybrid MSF/RO plant is limited. Al-Sofi et al. (1984) performed an optimization study to maximize overall plant

recovery. Helal et al. (2003) reported an optimization study based on minimum water cost to compare the configurations suggested by Al Sofi et al. (1984) along with two additional hybrid plant configurations. All of these efforts were based on individual flow sheets for different configurations and simple models were developed by using average values of the physical properties. Moreover the model of the RO plant does not consider design parameters. Helal et al. (2003) suggested in the results of their study that among all configurations RO plant and MSF plant operating individually and sharing the same intake-outfall facilities is worth consideration for future desalination plants.Considering the efforts of researchers and the gap analysis in hybrid desalination system modelling and optimization, this work presents an optimization study based on minimum energy cost of MF/RO hybrid systems with common intake-outfall facilities. For this purpose a superstructure is developed using Aspen Custom Modeler (ACM) V.8.4. The superstructure provides a flexible way of analyzing various configurations using one flow sheet.

2. Process Model

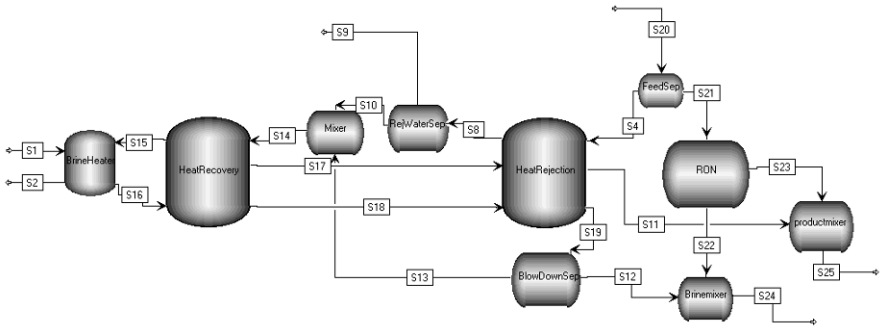

Figure.1 Schematic diagram of superstructure

The schematic diagram of the superstructure is presented in Figure. 1. The process model developed for MSF plant is based on the mass balance, enthalpy balance and heat transfer models. The thermo-physical properties functions used for water, steam and brine solutions are taken from Rosso et al. (1997). These functions contribute to the non-linearity and complexity of the equations. The RO process model is developed for a single stage RO module with spiral wound membrane by combining the widely accepted and most commonly used solution-diffusion transport model (Sassi and. Mujtaba, 2013) with the film theory approach (Wijmans, 2007) and with the hydraulic design model(Lu et al., 2007). Film theory approach is used to predict the wall concentration and the hydraulic design model takes into account the pressure drop and the concentration changes in the membrane channel (Lu et al., 2007).In this manner a detailed description of the MSF and RO processes is achieved by characterizing all process streams in a good manner. The development time for the model is reduced because the solution algorithm is specified in ACM instead of writing it. The developed model can be used to perform multiple simulation and optimization studies by just changing the input specifications.

MSF Process Model

The model for the MSF plant is based on the following assumptions:

- The distillate produced is salt free.

- Heat of mixing for brine solutions is negligible.
- There is no subcooling of condensate produced in the brine heater.

RO Process Model

The model for the RO plant is developed according to the following assumptions:

- The feed concentration varies linearly along the feed side channel.
- The feed channels of spiral wound membrane are flat.
- The pressure drop along the permeate channel is neglected.

The model equations for the MSF and RO systems are presented in Figure. 2 and Figure. 3.

Overall balance: $Fm = D + BD$; Overall salt balance: $Fm.CF = BD.CBN$; Brine heater balance: $W = BO$; Brine heater salt balance: $CR = CBO$; Mixer balance: $W = R + Fm$; Mixer salt balance: $W.CR = R.CBN + FmCF$; Blow down splitter balance: $BD = BN - R$; Reject water splitter balance: $CW = Fsea - Fm$; Balance for any stage:$B_{j_{-1}} + D_{j_{-1}} = B_j + D_j$; Salt balance for any stage: $B_{j_{-1}}.C_{B,j-1} = B_j.C_{B,j}$; Equilibrium equation: $TD_j = TB_j - (BPE_j + NEA_j + \Delta_j)$; Brine heater enthalpy balance: $Ws.\lambda s = W.S_{bh}.(TBO - TF1)$; Brine heater heat transfer model: $Ubh.Abh = \frac{Ws.\lambda s}{(LMTD)bh}$; Mixer enthalpy balance: $W.hw = R.hR + Fm.hm$; Overall enthalpy balance for any stage:

$W.Src_j.(TF_j - TF_{j+1}) = D_{j-1}.SD_{j-1}.(TD_{j-1} - Tref) + B_{j-1}.SB_{j-1}.(TB_{j-1} - Tref) - D_j.SD_j.(TD_j - Tref - Bj.SBj.(TBj - Tref)$; Bottom enthalpy equation: $Bj - 1.hj - 1 = Bj.hj + Bj - 1 - Bj.hvj$; Heat Transfer Model at the condenser for heat recovery section: $W.Sr_j.(TF_j - TF_{j+1}) = U_j.Ar_j.(LMTD)_j$; Note: For heat rejection section $W = Fsea$

3. Optimization Problem formulation

The performance of the MSF plant is highly dependent on the evaporation range. The evaporation range can be elongated by using high top brine temperature which requires significant amount of energy. Similarly, the RO process performance is based on mass transfer driving force. The performance of the RO process can be maximized by managing the temperature and pressure of the feed stream which also needs notable amount of energy. Thus appropriate optimization approaches should be used to determine optimum values of design and operating conditions of both MSF and RO plants while managing the cost of energy. The optimization problem incorporates process models of the MSF, RO and any additional equipment (separator, mixer) for the hybrid system. Operating variables (steam temperature, steam flow rate, feed pressure, feed flow per membrane element) and design variables (number of stages, number of elements in a pressure vessel) are optimized to minimize the economic objective

function. The energy cost per kg of feed is minimized based on 1 hour of operation. The cost of steam in MSF process and the energy cost of high pressure pump in RO process are considered as these are the major contributors to the total energy cost. The cost functions used to evaluate energy cost are taken from (Helal et al., 2003) for MSF plant and from (Marcovecchio et al., 2005) for RO plant and are presented in Figure. 4. For comparison basis, overall plant recovery, annual intake cost and product quality of MSF, RO and hybrid plants are also evaluated. The cost functions for the intake cost are taken from Helal et al., (2003). The optimization strategy employed in this research work which looks at both design and operating parameters is presented in Figure. 4.

MSF optimization formulation:
Given: Feed water conditions, condenser and stage design specifications
Determine: Optimal steam flow rate, steam temperature, no of recovery stages
Objective Function: Minimize energy cost per unit of feed
Subject to: Equality constraints: Process model, product demand and specification
Inequality constraints: Linear bounds on optimization variables and other parameters
RO optimization formulation:
Given: Feed water conditions, membrane properties and specifications
Determine: The optimal feed pressure, feed flow per membrane, number of elements in a pressure vessel
Objective Function: Minimize energy cost per unit of feed
Subject to: Equality constraints: Process model, product demand and specification
Inequality constraints: Linear bounds on process and design variables
Steam cost for MSF: $8000.Ws.\frac{T_s-40}{85}.0.00415$, Energy Cost for RO: $\frac{Pf.\ Qf}{\eta_{pump}}.D_{energy}.f_c$, Energy charge rate, D_{energy} = 0.08 $/kWh (Lu et al., 2007)
Where Ts is steam temperature, η_{pump} is pump efficiency and f_c is plant load factor

Figure. 4 Optimization formulation

4. Case Study

The process models for the MSF, RO and hybrid systems are simulated using Aspen Custom Modeler V.8.4. The hybrid system consists of independent MSF and RO systems with common intake-outfall facilities. The MSF plant considered in this work has fixed number of stages (3 stages) in the heat rejection section for the independent MSF plant and the MSF plant section in the hybrid plant. For both plants the number of stages in the heat recovery section can vary from 13 to 16. Single stage RO system with spiral wound RO membrane element SW30XLE-400 is considered for the independent RO plant and the RO section in the hybrid plant. The number of elements per pressure vessel varies from 2 to 8 for both plants. The input data used to solve the models is taken from Wahab et al., (2012) and Lu et al., (2007). The three processes are compared on the basis of the same plant capacity. For this purpose the ratio of MSF plant capacity to RO plant capacity in hybrid plant is taken equal to 1:2. To achieve this capacity in the independent MSF plant, three MSF plants operating in parallel are considered with common intake-outfall facilities.

5. Results and Conclusions

The optimum design of a hybrid MSF/ RO system with common intake-outfall facilities was studied in this work. Detailed process models for MSF and RO plant based on thermo-physical properties functions, solution-diffusion model and hydraulic design model were developed in ACM. The optimization variables consist of steam temperature, steam flow rate, number of recovery stages, feed pressure and number of membrane elements in a pressure vessel. The proposed design was compared with conventional MSF and RO systems on the basis of energy cost per kg of feed, annual intake cost, product quality and overall plant recovery. The design and optimization results are presented in Table 1. The minimum energy cost per kg of feed, annual intake cost, overall plant recovery and plant capacity are presented in Table 2.
Note: The design and operating variables for the independent MSF plant belong to one of the three identical MSF plants.

Table 1 Optimal design characteristics of MSF, RO and hybrid plant

MSF plant section:	Independent MSF plant	Hybrid MSF/RO
Number of recovery stages	13	13
Steam Temperature, °C	105	105
Steam flow rate, kg/ h	23724	23724
RO plant section:	Independent RO plant	Hybrid MSF/RO
Feed Pressure, kPa	7000	7000
Feed flow per module, kg/h	14688	11016
Number of elements per pressure vessel	7	7
Number of pressure vessels	90	66
Product concentration, g/L	0.12	0.07

Table 2 Minimum energy cost, annual intake cost, overall plant recovery and plant capacity of the optimal designs

MSF plant	RO plant	Hybrid plant	
Energy cost, $/kg	0.18	0.000162	0.04
Annual intake cost, $	5500000	5400000	3700000
Overall plant recovery	13%	45%	24%
Plant capacity, m^3/d	89394	89394	89394

The results show that the hybrid MSF/RO has higher overall system recovery than MSF system, higher product quality than RO system, low annual intake cost compared to MSF and RO systems and 77% decrease in energy cost per kg of feed compared to independent MSF plant. This suggests that while having higher energy cost per kg of feed compared to independent RO plant such systems should be used in the areas where high overall system recovery and high product quality is required. The number of stages touched the lower bound for both independent MSF and hybrid MSF section. This shows that the defined decision variables have no pronounced effect on heat recovery section. In the future work, the superstructure will be used for multiple optimization studies and will also be extended to perform sensitivity analysis and control studies of the hybrid systems.

Nomenclature

Ws, Fm, D, BD, W, BO, R, BN, CW, Fsea, B_j, B_{j-1}, D_j and D_{j-1} are flow rates of steam, makeup seawater, distillate, brine blow down, cooling brine in heat recovery section, flashing brine entering first stage, recycle brine, flashing brine leaving last stage, reject

seawater, feed seawater, flashing brine leaving stage j, flashing brine entering stage j, distillate leaving stage j and distillate entering stage j respectively, CF, CBN, CR, CBO, $C_{B,j}$ and $C_{B,j-1}$ are salt concentrations of feed, flashing brine leaving last stage, recycle brine, flashing brine entering first stage, flashing brine leaving stage j and flashing brine entering stage j respectively, TB_j, TB_{j-1}, TBO, TF1, TF_j, TF_{j+1}, TD_j and TD_{j-1} are temperatures of flashing brine leaving stage j, flashing brine entering stage j, flashing brine leaving brine heater, cooling brine leaving stage 1, cooling brine leaving stage j, respectively, λs is the latent heat of vaporization of water in brine heater, Ubh and U_j are overall heat transfer coefficients at the brine heater and at stage j respectively, Abh and Arj are total heat transfer areas of brine heater and stage j respectively, $(LMTD)bh$ and $(LMTD)_j$ are log mean temperature differences for brine heater and stage j respectively, BPEj, NEAj and Δj are boiling point elevation, non-equilibrium allowance in temperature for flashing brine and temperature drop in demister in stage j, Tref is reference temperature, Qf, Qp and Qr are the feed, permeate and reject flow rates respectively, Cf, Cp, Cr, Cw and Cb are the feed, permeate, reject, wall and bulk concentrations respectively, Pf and Pp are the feed and permeate pressures respectively, μ is brine viscosity, d is diameter of element, C is concentration, T is temperature, Aw is water permeability, Δπ is osmotic pressure drop, As is salt permeability constant, ρ is brine density, Ds is solute diffusivity, df is feed spacer thickness, m is no of membrane element in a pressure vessel, Lm is length of membrane element, Amem is area of membrane, N1 is number of leaves in a membrane element, hsp is height of spacer channel, ε is feed spacer void fraction

Abstract

Simulation of growth rate and cells size distribution is important in order to predict and improve productions from microalgae. Aim of this paper is to use a modified breakage equation model to calculate the growth rate, the "breakage rate" and the particle size distribution of microalgae, which are changing over the time. Differently from previous mathematical models, various stages of the life cycle of Chlorella Vulgaris have been considered. According to the experimental data, the proposed method is able to predict the growth and, similarly, it can be extended to other kind of microalgae. This wants to be a new starting point for future development of microalgae growth kinetic.

Keywords: microalgae, growth model, breakage equation, size distribution.

1. Introduction

Global warming is a topic of great concern in many countries and this situation led to the development of new international emissions regulations. For that reason, investments on renewable energy production have gained great importance in the past few years. For instance, microalgae can be a very good choice and give a double benefit: CO_2 emission reduction and biofuel production. For example, Van den Hende et al. (2010) illustrated that these microorganisms can subtract carbon dioxide and other pollutants directly from the flue gas emitted by power plants. On the other hand, since there is a continuous increment in energy demand, electricity generation and biofuels production from microalgae have been studied by numerous research groups around the world in the past years (Mata et al., 2010). Also, deserves to be noted that the production of fine chemicals for pharmaceutical and cosmetic industries and proteins for human and animal consumption has been taken under consideration in a number of life cycle assessment studies (Williams and Laurens, 2010) (Slade and Bauen, 2013).

In order to increase the production of useful chemicals, the conditions must be set in order to improve the microalgae productivity. Indeed, microalgae growth is influenced by several factors: temperature, pH, light intensity, CO_2 and nutrients concentrations. Most of the studies, trying to reproduce the growth using mathematical models, do not consider all of the mentioned factors; for example Mayo (1997) has considered in his paper temperature and pH, while in other works (Goldman and Carpenter, 1974) the model is temperature-nutrients based. Moreover, seems that the life cycle of cells has been generally neglected by many authors even though the concentration of useful substances inside the cells do vary depending on its size (Morimura, 1959). The size and contents of microalgae are varied by the growing conditions (de-Bashan et al.

2002). Microalgae with the same size may carry different contents. As discussed, size distribution and population growth provide us additional information such as breakage, growth and even death rates. Knowing these information may help us to improve the cultivation as well as the harvesting system.

The model we are going to propose has many analogies with the breakage equation (Vanni, 1999) used for calculating the number/mass of particles in various processes, such as crushing, grinding and for modelling crystallizers performance. Main purpose and contribution of this work is to build a correlation between the total number of microalgae and its PSD (population size distribution). The model depends strongly on the growing conditions and, as it will be explained, the parameters are functions of the environmental factors.

2. Model

Before going to present our model, it is good to provide some information related to the traditional breakage equation. The number-based breakage equation (Hill and Ng, 1995) can be written as shown in Eq. (1).

$$\frac{dn(v)}{dt} = \int_v^\infty b(v,w)S(w)n(w)dw - S(v)n(v) \tag{1}$$

where $n(v)$ is the number of particles between volume v and $v+dv$. $S(w)$, which is commonly called specific rate of breakage, is the fraction of particles at size w that will break into smaller sizes. Finally, $b(v,w)$ is the breakage function and it represents the fraction of particles at size w that break into the $[v, v+dv]$. The integral is expressed from v to ∞ because any particle bigger than v might be broken into v. After discretization, Eq. (1) can be rewritten as Eq. (2).

$$\frac{d}{dt}N_i(t) = \sum_{j=i+1}^{\infty} b_{ij}S_jN_j(t) - S_iN_i(t) \tag{2}$$

where $N_i(t)$ is the number of particles in interval i, between volumes v_{i-1} and v_i. Similarly, as described in Eq. (1), particles included into a generic interval j (with $j > i$) break into smaller particles and, some, will end up into interval i.

It can be interesting to see that a good discretization plays a very important role in the solution of the problem. Indeed, as shown in an example presented by Hill and Ng (1995), a particle situated inside interval j can break into two particles of smaller intervals; anyway there is the possibility for one of the particles to remain inside interval j itself.

The modified breakage equation we would like to suggest for the determination of microalgae growth works similarly. Anyway, there are several differences between them! In primis, a microalgae can't be considered as a solid particle, such as those we use for grinding problems, and, even more important, in microorganisms the growth factor shall be taken under consideration. This actually means that the cells can break into smaller parts, but they can also grow in size inside the same interval or they might "jump" on an interval which contains larger particles.

Equation (3) below introduced a new breakage function *B(v,w)* that represents the breakage and/or growth from size *w* to size *v*. The discretization form of equation (3) is written as Equation (4).

$$\frac{dn(v)}{dt} = \int_{v_{min}}^{v_{max}} B(v,w)n(w)\,dw \tag{3}$$

$$\frac{d}{dt}N_i(t) = \sum_{v_{min}}^{v_{max}} B_{ij}N_j(t) \tag{4}$$

The total growth and breakage are represented by the B_{ij} (i and j have the same meaning of the traditional model) in Eq. (3) and Eq. (4). In other words, the B_{ij} includes b_{ij} and S present in the traditional breakage equation. Another difference that can be noticed with the previous model is that in this case, *j* can be any interval included between the minimum and maximum volume since both growth and breakage may occur. v_{min} and v_{max} are the minimum and maximum volume that microalgae can achieve (note that in Eq. (4) v_{min} and v_{max} are intervals).

Since microalgae grow in a cycle, unlike equation (2), *w* can be either larger or smaller or even equal to *v*. For instance, if the size is divided from 1 (smallest) to 10 (largest) intervals, the smallest microalgae (i.e. size 1) may grow into larger intervals (e.g. 3, 4 or 5) without breaking during a measurement period. In this case, the summation of *B(v,'1')* or B_{v1} equals to one. At the largest intervals (i.e.10), it may likely break into small intervals (e.g. 1, 2 or 3). In this case, the summation of *B(v,'10')* or B_{v10} can be any number smaller than b_{max} (the maximum possible breakage). For Chlorella Vulgaris, b_{max} is around 4. With these consideration, equation (5) below limits the summation of breakage (B_{ij}).

$$\sum_{v_{min}}^{v_{max}} B_{ij} \leq \sum_{j}^{v_{max}} B_{ij} + \left[1 - \sum_{j}^{v_{max}} B_{ij}\right] b_{max} \tag{5}$$

The first term on the right hand side of equation (5) is the number of microalgae that grow without breaking. The second term on the right hand side is the number microalgae that grow and break into smaller sizes. In this model, we assume that the time interval between two measurements is shorter than a growing cycle of microalgae. Although the model is not limited by this but if the measurement interval is too long, the number of b_{max} can be a number larger than the number of the physical breakage of a matured cell.

3. Results

3.1. Experiment

The model was verified on Chlorella Vulgaris UTEX 2714 which was used in the experiment. Microalgae were grown inside a 2-liter transparent plastic bottle and the experiment was run for 15 days. Light intensity was maintained constant at about 1.1 klux and temperature and pH were kept at 26 C and 7.8 respectively. For counting microalgae, a drop of solution positioned on a hemocytometer was observed at the

microscope. The particle size distribution was measured using a particle size analyser. Main objective of the experiment was to prove the possibility to use this model.

Figure 1 shows the size distribution at day 1 and 15. Data from day 1 are used as initial conditions in the model.

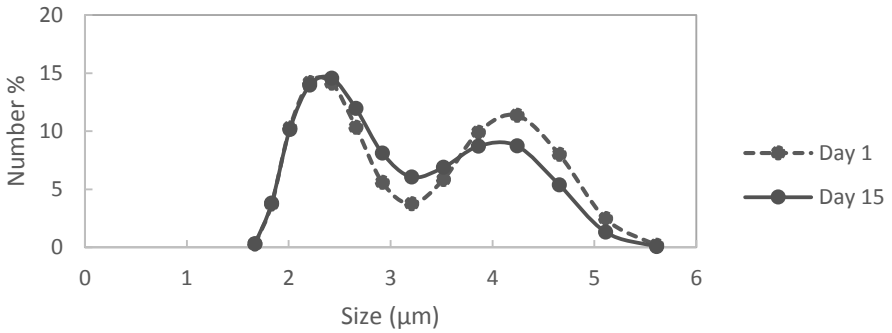

Figure 1 Size distribution of microalgae - day 1 and day 15.

3.2. Simulation

The model was developed using Microsoft® Excel 2013. The cells were divided into 14 intervals (same number of intervals get from the particle size analyser) and the following results will show how the model can be used to fit the experimental data. In Figure 2 and Figure 3 are illustrated the good similarity between the model and the experimental data. In particular, Figure 2 shows the total number of cells over the time, while Figure 3 shows the particle size distribution after 15 days (the initial distribution is not illustrated since it is an initial condition). To be noticed is the stiffness of the problem. Indeed when we try to minimize the gap between the experiment and the simulation, it is possible to note that there are different orders of magnitude (overall population number >> fraction number); therefore some weight factor were necessary in order to balance the objective functions for curve fitting.

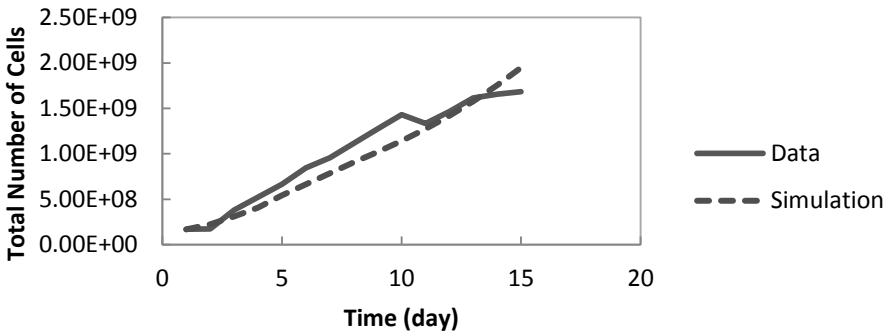

Figure 2 Comparison between experimental data and breakage equation model.

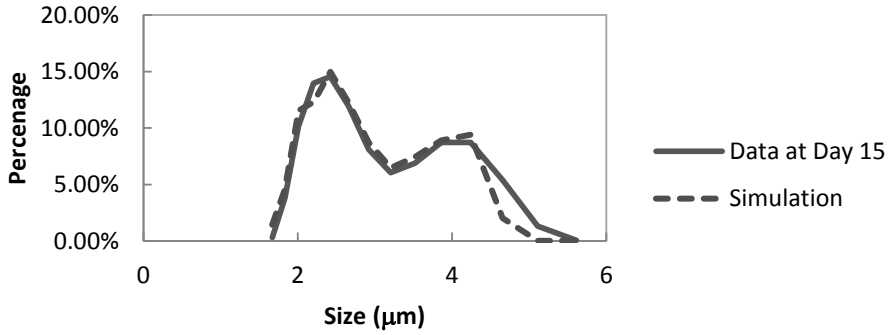

Figure 3 Comparison between size distribution in experimental data and the model.

An example of the parameters B_{ij} present in the model are shown in Table 1. Notice that the sizes (1.669, 1.832, …, 5.611) are all expressed in μm. Also consider that the growth/breakage happens from *j* to *i* and not vice versa.

5.111	8.23E-04	8.27E-04	2.36E-05	3.95E-04	3.64E-04	1.48E-05	1.30E-04	1.01E-03	5.19E-04	4.16E-04	9.47E-04	4.41E-05	9.05E-04	9.98E-01
5.611	5.97E-04	2.83E-03	1.68E-04	3.99E+00	5.35E-04	6.46E-04	6.71E-04	6.24E-04	3.57E-04	2.76E-03	5.93E-04	4.80E-05	1.36E-05	4.42E-05

As mentioned already, the parameters shown in Table 1 are related to both growth and breakage. To read the table, consider that the particles can break into the same interval. If we consider the first column, the first cell is the *B* value of cells breaking into the same interval; going down we will find the cells breaking from second to first interval and so on. Moving on the second column, the first cell (top) is the one representing the growth from the first interval while the rest represent the breakage from bigger particles. The diagonal represent the parameter of the particles remaining in the same interval. Practically there is growth over it and breakage below.

Looking at the values above it is not easy to find a physical meaning for these values. Indeed, all these parameters are related to the environmental conditions: light intensity, pH, temperature, CO_2 and nutrients concentrations. To understand the kind of correlation additional experimental data will be necessary in future.

4. Conclusions

A new microalgae growth model has been derived from breakage equation and, according to the results, the model works and can be applied for the designed experiment. The model takes into account the growth cycle of microalgae, its growth rate and its breakage from microalgae of size *j* to microalgae of size *i*. Since just one case study has been developed so far, the proposed model can be applied only for the proposed environmental conditions and, very important, for Chlorella Vulgaris. Further studies and additional experiments (in different conditions) would lead to better understand the physical meaning of the parameters, obtained adapting the proposed model.

Abstract

Pipeline network plays a very important role in chemical plant, refinery, oil and gas gathering. Design, optimization and scheduling of pipeline network are based on the simulation of pipeline network. With the increase of the number of pipe segments, pipeline network model becomes more difficult to be solved. Traditionally, nonlinear equations of pipeline network need to be calculated by equation oriented method. However, this method has large computational complexity and it highly depends on initial values. When there are more unknown variables, it is harder to assign appropriate initial values and also harder to get convergence. In this work, a new strategy for the simulation of gas pipeline network is introduced. A pipeline network model suitable for compressible gas is built. Pipeline network is identified and simplified by adjacent matrix searching. After adjacent matrix searching, the number of equations is reduced and pipeline network model becomes easier to solve. This solution is applied to a case study for verifying the proposed model and strategy.

Keywords: pipeline network, adjacent matrix, nonlinear equations

1. Introduction

Gas pipeline network is widely presented in chemical plants and natural gas gathering. Design and optimization of gas pipeline network are usually based on the simulation of gas pipeline network. Flow and pressure for each pipe segment need to be calculated first in simulation. Gas pipeline network has been studied by many workers. Kiuchi (1994) analyzed unsteady gas networks at isothermal conditions by an implicit method. Ke and Ti (1999) studied isothermal transient gas flow by using electrical models. Behbahani-Nejad and Bagheri (2010) proposed and developed a MATLAB-Simulink library for the transient flow simulation of gas pipeline network. Alamian et al. (2012) proposed a transient flow simulation for gas pipeline network based on the state space equations. Gonzales et al. (2009) simulated a gas distribution pipeline network by MATLAB-Simulink component library, which is built based on S-functions philosophy. Nonlinear equations are usually calculated by equation oriented method in steady state simulation. But this method has large computational complexity and it highly depends on initial values. In this paper, a gas pipe segment model is proposed together with a new strategy for the simulation of gas pipeline network, in order to reduce the computational complexity.

2. Mathematical model

2.1. Pipe segment model

In pipeline network, one pipe with fixed length, diameter and material is defined as one pipe segment. Pipeline network can be considered as an assembly of pipe segments. The gas flows in a pipe segment, as shown in Fig. 1, can be described by Bernoulli's equation. The following equations describe pipe segment model.

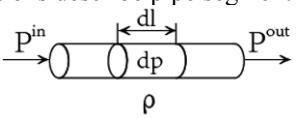

Figure 1. A pipe segment

$$g\Delta z + \Delta\frac{u^2}{2} + \frac{\Delta P}{\rho} = w_e - h_f \tag{1}$$

where h_f is flow resistance loss, can be calculated as $h_f = \lambda \cdot \frac{l}{d} \cdot \frac{u^2}{2} = \lambda \cdot \frac{l}{d} \cdot \frac{(FM/\rho A)^2}{2} = \lambda \cdot \frac{l}{d} \cdot \frac{(FM/\rho(\pi d^2/4))^2}{2}$; g is the acceleration of gravity; Δz is height difference; u is velocity; ΔP is pressure drop; ρ is gas density; w_e is external work; λ is Fanning factor; l is pipe length; d is pipe diameter; F is molar flow rate; and M is the molecular weight of gas in the pipe.

2.2. Model simplification

In order to study pipeline network topology conveniently, it is possible to simplify model calculation by assuming (1) the height difference of pipe segments are negligible, then $g\Delta z=0$; (2) gas is in steady flow state, then $\Delta u2/2=0$; (3) there is no external work in pipe segment, i.e., $w_e=0$; (4) gas flow under isothermal condition; (5) gas physical properties can be described by ideal gas state equation, i.e., $\rho=PM/RT$. According to above assumptions, pipe segment equation can be derived as following:

$$\Delta P = \frac{8}{\pi^2} \cdot \lambda \cdot \frac{l}{d^5} \cdot \frac{M^2}{\rho} \cdot F^2 \tag{2}$$

$$dP = \frac{8}{\pi^2} \cdot \lambda \cdot \frac{dl}{d^5} \cdot \frac{MRT}{P} \cdot F^2 \tag{3}$$

$$\Delta P = P^{in} - P^{out} = \frac{8}{\pi^2} \cdot \lambda \cdot \frac{l}{d^5} \cdot \frac{MRT}{(P^{in} + P^{out})/2} \cdot F^2 \tag{4}$$

$$\Delta P = rF^2 \tag{5}$$

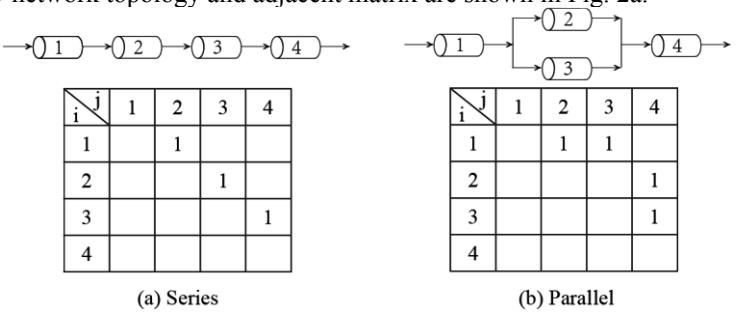
For liquid pipe segment, density is constant, but gas density is not. In Fig. 1, when pipe segment length is dl and pressure drop is dP, gas density can be considered as constant. Thus, Eq.(2) can be rewritten as Eq.(3). Integrating Eq.(3) obtains Eq.(4), which is the model equation for a pipe segment. As it can be seen in Eq.(4), λ, l, d are pipe segment parameters. M and T are gas physical properties. $(P^{in}+P^{out})/2$ is average pressure of pipe segment. For a given pipe segment and gas, these parameters will remain constants. So a pipe segment resistance coefficient r can be designated to replace these parameters. Eq.(4) is rewritten as Eq.(5).

3. Pipeline network topology identification

Pipeline network topology is described by adjacent matrix *A*. *A* is an n-dimensional matrix, where *n* is pipe segment number. When the element of row *i*, column *j* is equal to 1 in the adjacent matrix, i.e. A_{ij}=1, there is a path from pipe segment *i* to *j*; when A_{ij}=0, no path from pipe segment *i* to *j*. There are many similar sub-networks in a pipeline network. Typical sub-networks can be roughly classified as series and parallel structures.

3.1. Series sub-network and its identification

Series sub-network is defined as two pipe segments connected one after the other. Series sub-network topology and adjacent matrix are shown in Fig. 2a.



i \ j	1	2	3	4
1		1		
2			1	
3				1
4				

i \ j	1	2	3	4
1		1	1	
2				1
3				1
4				

Figure 2. Series and parallel sub-network topology and corresponding adjacent matrixes

It can be seen in Fig. 2a, $A_{23} = \sum_{j=1}^{4} A_{2j} = \sum_{i=1}^{4} A_{i3} = 1$. It means pipe segment 2 connects to pipe segment 3. Thus, if pipe segment *k* connects pipe segment *l* in the adjacent matrix, it can be identified by Eq.(6).

$$A_{kl} = \sum_{j=1}^{n} A_{kj} = \sum_{i=1}^{n} A_{il} = 1 \tag{6}$$

3.2. Parallel sub-network and its identification

Two pipe segments are defined as a parallel sub-network, when they share the same upstream pipe segment and downstream pipe segment. Parallel sub-network topology and its adjacent matrix are shown in Fig. 2b. When $A_{12} = A_{13} = 1$ and $A_{24} = A_{34} = 1$, it means pipe segment 2 parallels with pipe 3. Thus, if pipe segment *k* is parallel with pipe segment *l* in the adjacent matrix, it can be identified by Eq.(7).

$$\begin{cases} A_{ik} = A_{il} = 1 \\ A_{kj} = A_{lj} = 1 \end{cases} \tag{7}$$

4. Pipeline network topology simplification

Pipeline network model includes a large number of equations. The simultaneous solution of equations is challenging. So pipeline network topology needs to be simplified. Series sub-network and parallel sub-network can be simplified as equivalent pipe segments.

4.1. Series sub-network simplification

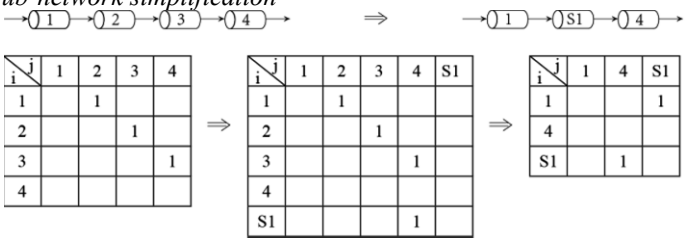


Figure 3. Simplification of series sub-network

In Fig. 3, Eq.(6) is employed to identify series sub-network (pipe segment 2 and 3). Adjacent matrix A needs to be added row S1 and column S1. Let $A_{i,S1} = A_{i2}(i = 1 \cdots 4)$, $A_{S1,j} = A_{3j}(j = 1 \cdots 4)$, $A_{S1,S1} = 0$. Delete row 2, 3 and column 2, 3. The new adjacent matrix is shown in Fig. 3. Pipe segment S1 can be represented by Eq.(8). It is known that the resistance coefficient of pipe segment S1 is equal to the sum of the resistance coefficient of pipe segment 2 and 3 shown in Eq.(9). When n pipe segments are in series, $r_s = \sum_{i=1}^{n} r_i$. The relationship between series sub-network and its equivalent pipe segment is described by Eq. (10).

$$\Delta P_S = P_2^{in} - P_3^{out} = r_S F_S^2 \tag{8}$$

$$r_S = r_2 + r_3 \tag{9}$$

$$\begin{cases} \Delta P_2 = P_2^{in} - P_2^{out} = \dfrac{r_2}{r_S}\Delta P_S \\ \Delta P_3 = P_3^{in} - P_3^{out} = \dfrac{r_3}{r_S}\Delta P_S \\ F_S = F_2 = F_3 \end{cases} \tag{10}$$

4.2. Parallel sub- network simplification

In Fig. 4, pipe segment 2 is parallel with pipe segment 3. Equivalent pipe segment P1 is used to represent parallel sub-network. Pipe segment P1 is described by Eq.(11). The resistance coefficient of pipe segment P1 can be calculated by Eq.(12). When n pipe segments are in parallel, $\sqrt{\dfrac{1}{r_P}} = \sum_{i=1}^{n} \sqrt{\dfrac{1}{r_i}}$. The relationship between parallel sub-network and its equivalent pipe segment is described by Eq. (13).

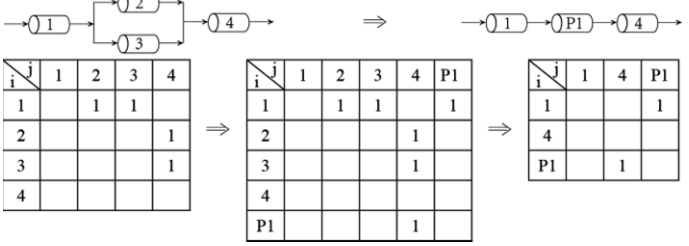

Figure 4. Simplification of parallel sub-network

$$\Delta P_P = P_2^{in} - P_2^{out} = r_P F_P^2 \text{ or } \Delta P_P = P_3^{in} - P_3^{out} = r_P F_P^2 \tag{11}$$

$$\sqrt{\frac{1}{r_P}} = \sqrt{\frac{1}{r_2}} + \sqrt{\frac{1}{r_3}} \tag{12}$$

$$\begin{cases} F_2^2 = \dfrac{r_P}{r_2} F_P^2 \\ F_3^2 = \dfrac{r_P}{r_3} F_P^2 \\ F_P = F_2 + F_3 \end{cases} \tag{13}$$

(c) Simplification of series sub-network

Figure 5. Pipeline network topology and adjacent matrix

$$\begin{cases} \Delta P_i = P_i^{in} - P_i^{out} = r_i F_i^2 (i = 1 \cdots 4) \\ P_1^{out} = P_2^{in} \\ P_1^{out} = P_3^{in} \\ P_2^{out} = P_4^{in} \\ P_3^{out} = P_4^{in} \\ F_1 = F_2 + F_3 \\ F_2 + F_3 = F_4 \end{cases} \tag{14}$$

$$\Delta P_{S1} = P_1^{in} - P_4^{out} = r_{S1} F_{S1}^2 \tag{15}$$

A pipeline network topology is shown in Fig. 5a. It includes a series sub-network and a parallel sub-network. There are 4 pipe segments, and each pipe segment is described by 4 variables. Initially, boundary values are given before simulation. Inlet pressure of pipe segment 1 is 300,000Pa; outlet pressure of pipe segment 4 is 100,000Pa. In order to facilitate calculation, all resistance coefficients are $10Pa \cdot s^2 \cdot kmol^{-2}$. Parallel sub-network is simplified in Fig. 5b and Series sub-network is simplified in Fig. 5c. Pipeline network

model is described by Eq.(14). After identification and simplification, original pipeline network becomes an equivalent network shown in Fig. 5c. In the equivalent network, there are 1 pipe segment and 4 variables. Equivalent network model is described by Eq.(15). Compared with Eq.(14), it is easier to calculate Eq.(15) obviously.

6. Results and discussion

After simplification, resistance coefficients of equivalent pipe segments are calculated by Eq.(9) and Eq.(12). Before simplification, the pressure and flow of original pipeline network are calculated by Eq.(10) and Eq.(13). The calculated results, which are simulated by this new strategy, are listed in Table 1. Eq.(14) is also solved by equation oriented method using MATLAB. The results agree with that in Table 1. When initial values are 1, it converges at iteration 68. When initial values and calculated results are at the same order of magnitude, the number of iterations converged is 21. By using adjacent matrix searching strategy proposed in this paper, computational complexity is significantly reduced.

Table 1. Calculated results for pressure and flow

Pipe segment No.	Boundary of inlet pressure, Pa	Boundary of outlet pressure, Pa	Inlet pressure of pipe segment, Pa	Outlet pressure of pipe segment, Pa	Flow rate, kmol/s
1	300,000	-	300,000	211,111.11	94.28
2	-	-	211,111.11	188,888.89	47.14
3	-	-	211,111.11	188,888.89	47.14
4	-	100,000	188,888.89	100,000	94.28

7. Conclusions

In this work, a new strategy for the simulation of gas pipeline network has been presented. By adjacent matrix operations, a complex pipeline network is simplified hierarchically. In fact, adjacent matrix simplification is equation simplification. After identification and simplification, the numbers of equations and variables are significantly reduced. The simulation of pipeline network becomes easier. The results of case study prove that the proposed strategy is effective in the simulation of gas pipeline network.

Modelling and optimization of a heat integrated gasification process

Yi Zhu, Adetoyese Olajire Oyedun, Maojian Wang, Ergys Pahija, Chi Wai Hui

Department of Chemical and Biomolecular Engineering, The Hong Kong University of Science and Technology, Clear Water Bay, Kowloon, Hong Kong

Abstract

In this study, an iteration optimization is performed based on the Gibbs free energy minimization approach. Further, simultaneous optimization of a heat integrated gasification process is presented. The study shows how heat integration can improve the overall efficiency of a gasification process. We formulated a mathematical model which simultaneously optimizes the operating parameters and its interaction via heat integration among the hot syngas, steam generation and the feed preheat. This allows the model to simultaneously maximize the cold gas efficiency and also minimize the Gibbs free energy. The model also combined gasification model with an energy targeting model that is able to handle processes with variable stream temperatures and flow rates.

Keywords: gasification, heat integration, simultaneous optimization.

1. Introduction

The threats of global warming and energy crises urge the need of cleaner conversion technologies for fossil fuels such as coal. Due to the ability to mitigate the pollutions to the environment and greenhouse gas emissions, gasification becomes a promising conversion technology and receives increasing attention worldwide (Clayton et al., 2007). The production of syngas from gasification, however, is a complex process that is strongly affected by the composition of feedstock, the gasification temperature and pressure, the amount of gasification feed water (GFW) and oxygen, etc. (Abuadala et al., 2010).

To evaluate how these parameters would influence the gasification performance, several equilibrium models based on Gibbs free energy have been developed to effectively study the process in measurement of cold gas efficiency (CGE). However, most of efforts are placed on the parametric studies through control variant methods rather than find the optimum operating condition considering feed flow rates along with gasification temperature. Additionally, in gasification, quite a lot of feedstock is fully or partly oxidized to provide heat for raising the reaction temperature to a very high level, often over one thousand degree Celsius. The recovery of the sensible heat from the hot syngas plays a key factor in the overall energy efficiency and has seldom been taken into account in previous studies.

In this work, the iteration algorithm is first utilized to identify the operating condition of a gasification process corresponding to the highest CGE. Further, a heat integrated gasification model is developed that maximizes CGE of a gasification process with considerations of the amount of feed as well as heat integration simultaneously. A heat integration model is established to ensure the feasibility of heat exchange among the hot

syngas, feed streams and steam boiler. The model will be illustrated through case studies of carbon gasification.

2. Equilibrium modelling

The gasification modelling approach is based on the theory that chemical equilibrium is achieved when the total Gibbs free energy for a set of considered gasification products is minimized. The total Gibbs free energy is calculated as:

$$G_{sys} = \sum_{i=prod}^{N} n_i \Delta G_{f,i}^{0} + \sum_{i=prod}^{N} n_i RT \ ln \ P + \sum_{i=prod}^{N} n_i RT \ ln \ y_i \quad (1)$$

Besides, the function, G_{sys}, also needs to satisfy the elemental and heat balance. The energy balance for the gasification process is calculated using Eq. (9).

$$nH_{f,fuel} + H_p(T_{in}) + \sum_{i=react}^{N} n_i H_{f,i}(T_0) = \sum_{i=prod}^{N} n_i H_{fa,i}\,(T_{out}) \quad (2)$$

As suggested by de Souza-Santos, the enthalpy of formation for the solid fuel reactant can be calculated as shown in Eq. (10) (de Souza-Santos, 2004).

$$H_{f,fuel} = LHV + \sum_{i=prod}^{N} H_{f,i}\,(T_0) \quad (3)$$

where LHV is the lower heat value in kJ/kmol and $H_{f,i}$ is the enthalpy of formation of *i*th gas under complete combustion of the solid fuel. In the calculation, the outlet temperature of syngas is taken as the gasification temperature. The initial temperature of reactants (T_0) is assumed to be 298.15 K. Thus, preheating heat represents the enthalpy change from 298.15 K of all reactants.

In addition, the minimization of Gibbs free energy is subject to elemental balance by:

$$\sum_{k=react}^{N} n_k \, a_k = \sum_{k=prod}^{N} n_k \, a_k \quad (4)$$

The constrain now is to find a set of n_i and a gasification temperature (T) in Eq. (1) which can minimize the total Gibbs free energy of the system while satisfying heat balance (Eq. (2)) and elemental balance (Eq. (4)). The direct minimization is accomplished by generalized reduced gradient nonlinear method. The reaction pressure is pre-specified. Providing initial values, the minimization of Gibbs free energy generates a set of n_i and determines the reaction temperature simultaneously.

3. Optimization through iteration

Based on the developed equilibrium model based on Gibbs free energy minimization, the iteration algorithm is utilized to identify the optimum operating condition. The details of calculation procedure are illustrated in Figure 1.

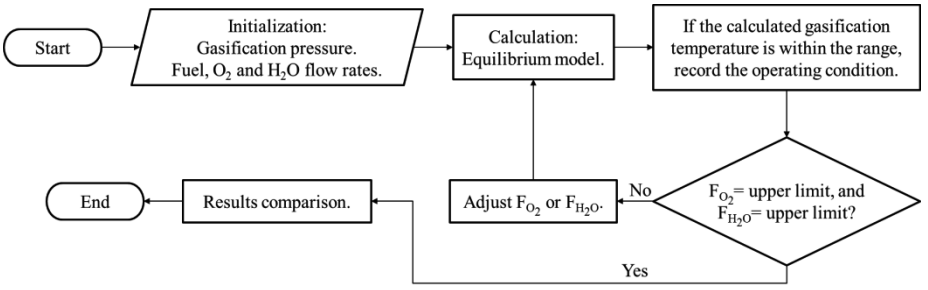

Figure 1. Calculation procedure of iteration

The upper limit of O_2 feed can be set as the stoichiometric amount for complete combustion. The value of O_{H2O}/C at 1 is considered as the upper limit for GFW feed. Although the approach is direct, we should also notice that the iteration process will be exponentially increased if the heat integration is also included or the high fidelity is required.

4. Simultaneous optimization of a heat integrated gasification process

To improve the optimization process, an approximation model which can consider the heat integration along with the gasification process parameters is developed.

Assuming that coal contains only carbon, gasification of coal consists of several major reactions (Li et al., 2001): partial and complete combustion, carbon-steam, boudouard, methanation and water-gas shift reactions.

Table 1. The major reactions and equilibrium constants at different temperatures

	1,000 K	1,200 K	1,400 K	1,600 K
$C + 0.5O_2 = CO$	2.89E+10	3.04E+09	5.94E+08	1.72E+08
$CO + 0.5O_2 = CO_2$	1.65E+10	57,535,774	1,023,261	50,350
$C + H_2O = CO + H_2$	2.52	38.43	267.56	1,141.03
$C + CO_2 = 2CO$	1.75	52.75	580.46	3,423.81
$C + 2H_2 = CH_4$	0.10	0.02	0.00	0.00
$CO + H_2O = CO_2 + H_2$	1.44	0.73	0.46	0.33

As shown in Table 1, the calculated equilibrium constants indicate that:

(1) Gasification is in favour of high temperature to promote complete conversion of carbon. High temperature facilitates the production of H_2 and CO instead of CO_2.
(2) With sufficient supply of oxygen, the reactions tend to produce more CO than CO_2. The CO_2 formation is only subject to the energy balance.
(3) At reaction temperature above 1,200K, CH_4 production can be eliminated.

Based on the above analysis, the question is whether the Gibbs free energy of the product gas can be simultaneously minimized while maximizing CGE. In order to ascertain this, Eq. (1) is removed from the developed equilibrium model to form a "simultaneous model". The simultaneous model is used to maximize CGE at a specific reaction temperature between 1,000K to 1,800K by varying oxygen and steam feed at 1 bar pressure. The reaction pressure is fixed since it should not have a strong influence to the product yield or composition. The elevated pressure in commercial gasifiers was mainly for reducing equipment size (Phillips, 2006).

At each reaction temperature, the optimized feed rates from the simultaneous model are used as inputs to the equilibrium model that minimizes Gibbs free energy. Reaction temperature is recalculated from the equilibrium model and compared to that from the simultaneous model. As shown in Figure 2, results (reaction temperature) from both models are identical when reaction temperature above 1,400K. These results are verified by Aspen Plus Gibbs reaction model.

The tests indicate that when the reaction temperature is above 1,400K, maximizing CGE will simultaneously minimize the Gibbs free energy of the product gas. This observation greatly simplifys the solution procedure. Having the reaction temperature at above

1,400K also coincide with the latest commercial entrained-flow coal gasifiers that are operated at 1,473 K-1,873 K (Collot, 2006).

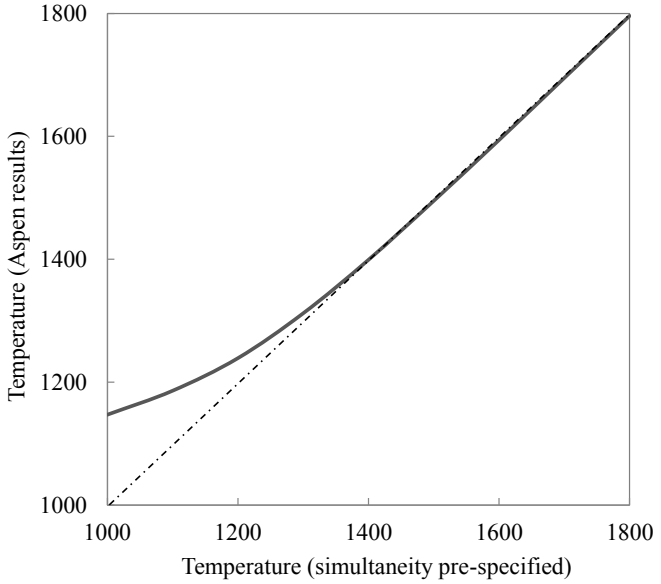

Figure 2. Temperature profile of simultaneous model and equilibrium model.

On the other hand, sensible heat utilization is evaluated between feed preheating and steam generation. Ensuring feasible heat integration imposed new constraints to the problem. The model of heat integration ensures the feasibility of heat transfer. In this work, the simultaneous optimization model proposed by Duran and Grossmann (Duran and Grossmann, 1986) is applied to simultaneously optimize the gasification process and the amount of energy recovery. The model is modified to accommodate process streams with phase change.

5. Case study

The feeding rate of coal (with 100% carbon) is fixed at 10,000 kg/h and reacts with oxygen and GFW at 1 bar. HP steam is produced at (832 K, 125 bar) for export and the cooled syngas is utilized for electricity generation in combined cycle. Minimum approach temperature of heat exchange is set at 10K. Two cases are presented in the following sections. Case 1 shows the approach to identify optimum feed flow rates and reaction temperature by iteration. In Case 2, flow rates as well as stream temperatures are optimized simultaneously with consideration of heat integration. The heat integration model is considered in Case 2 to ensure the feasible heat recovery.

5.1. Case 1

In this case, the optimization is conducted with gasification temperature ranging from 1,273 K to 1,873 K. An iterative approach is applied to maximize CGE by varying the feed flow rates while Gibbs free energy is minimized. Reaction temperature is converged at 1,273 K with feeding 3,909 kg/h GFW and 10,009 kg/h O_2. The highest CGE reaches 87.11%. Since require iteration, the solution process is slow and easily trapped at local optimum.

To further study the gasification, O_{H2O}/C vs CGE in two typical temperatures are plotted in the Figure 3. As shown in it, the highest CGE for each operating temperature appears at the carbon conversion turning point where the carbon happens to be completely converted. Before or after it, CGE has a lower value due to the negative effects brought by the wasted carbon residue or the excessive GFW respectively. Because in the equilibrium model, the higher operating temperature means the more energy is wasted on raising the temperature. Therefore, the optimizations converged at the allowed lowest temperature, 1,273 K, which saves the most heat.

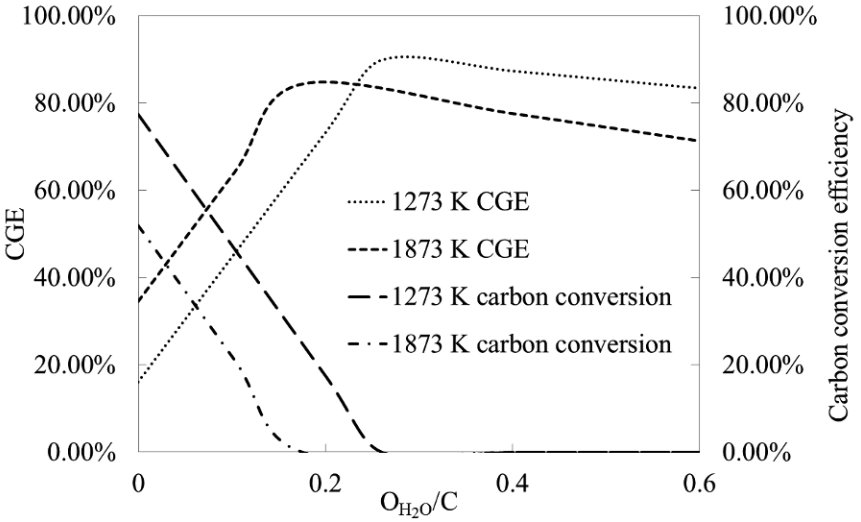

Figure 3. CGE and carbon conversion efficiency at 1,273 K and 1,873 K

5.2. Case 2

The flow rates of gasification process are optimized directly through simultaneous model while the sensible heat recovery through feed preheating as well as HP steam generation is also considered. The gasification temperature is allowed to be varied between 1,673 K and 1,873 K. Considering reasonable endurance of heat exchanger (Gupta et al., 1999), we set the related temperature limits as shown in Table 2.

Table 2. Parameters of the heat integrated gasification process.

Parameters	Lower temperature limit (K)	Upper temperature limit (K)
O_2	298	700
GFW	298	700
Gasification temperature	1673	1873

Optimum solution of Case 2 is shown in Figure 4 where 9,863.73 kg/h O_2 and 3,903.29 kg/h GFW are fed and preheated to 700 K. Reaction temperature is converged to 1,673 K with CGE reaches 87.95%. The difference comes from the higher feed temperatures which are both optimized at 700 K. As a result, O_2 supply is reduced dramatically to 9,863.73 kg/h. Meanwhile, due to the lower oxygen feed, more GFW is fed that resulted in more H_2.

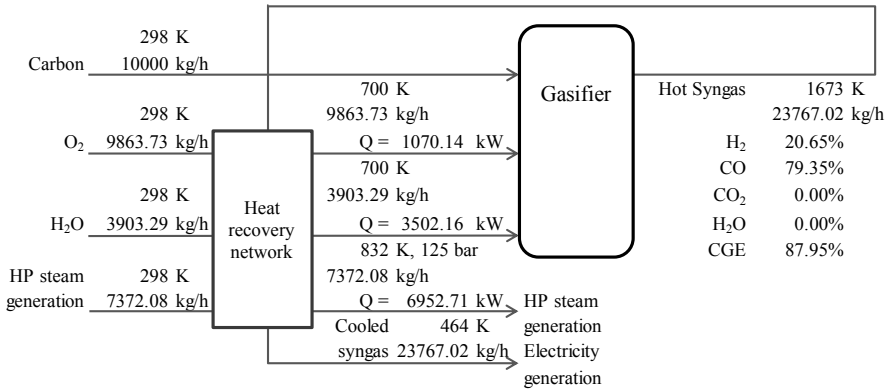

Figure 4. Process flowsheet of Case 2.

6. Conclusion

Effectively utilize the sensible heat from the syngas for feed preheating or steam generation can reduce oxygen demand and improve the overall gasification performance. In this study, a novel model is formulated to simultaneously optimize the gasification conditions, flow rates and preheating levels of the feeds and the utilization of the hot syngas. When reaction is at temperatures above 1,400K, maximizing CGE automatically results gas products with minimum Gibbs free energy. This observation reduces the complexity in solving the bi-level optimization problem and reduces the chances of being trapped at local optimum. The gasification model is integrated with a heat integration model that guarantee feasible reaction on one hand and optimize the feed flow rates and preheating levels on the other. Case studies have demonstrated the effectiveness of the integrated model.

Abstract

This paper focus on understanding the ethylene cracking reaction (ECR) networks with complex networks approach to polish up the accuracy of the product prediction. Though the radical reaction model (Ranzi, 2005) has been widely used in industrial simulations of pyrolysis process by SPYRO for years, analysis of the reaction scheme is still one of the important subjects the scholars concerned. According to the radical kinetic scheme, a simulation system of the ethylene cracking process has been developed include the feedstock reconstruction model, detailed kinetic schemes generator, and the reactor simulation model. As the complex networks research has grown steadily for its potential to represent, characterize and model a wide range of intricate natural systems and phenomena, a modified PageRank algorithm is applied to represent the topological structure and dynamic system characteristic of ECR networks. As a result, the hubs and authorities in reaction networks are illustrated by the algorithm and correction coefficients derived from these hubs is applied in detailed kinetic schemes generator. The product yield the adjusted model predicted is verified in an industrial case of naphtha pyrolysis process which shows a reasonable match with the industrial data. Furthermore, the simplification of kinetic scheme by PageRank algorithm has also shown in this case.

Keywords: Complex network, Reaction model, PageRank algorithm, Naphtha pyrolysis

1. Introduction

The accurate mathematic model applied in simulation of ethylene cracking process is appreciated in the industry. Though the molecular reaction model (Kumar, 1985) and lumped reaction model are introduced for the petrochemical industry, these crude models can't afford the description of the real kinetic mechanism. Recently, the radical reaction model (Dente et al., 2007) has made great progress in the pyrolysis reaction simulation and the SPYRO software adopting the reaction network generated by the radical model is applied in practical industrial process. Unfortunately, the complexity and scale of the reaction scheme built by detailed reaction mechanism still impede the calculate speed of the whole simulation with different reactor geometry and the operating condition. The lumping procedures and the automatic generation (Dente et al., 2010) are used in the radical kinetic schemes created by the SPYRO. Apart from the lumping methods derived from the chemical mechanism, the mathematic analysis methods such as the sensitivity analysis, principal component analysis (PCA), asymptotic theories, and computational singular perturbation (CSP) are applied in reaction scheme simplification. To sum up, the major difficulties in kinetic schemes generation not only lie in the large amount of reactions and parameters it contained but also in the complexity of the corresponding dynamic system. The main focus of this paper is to analyse the characteristics of the detailed kinetic schemes by transforming

the reaction networks into visualized graph and apply the graph algorithm to assist the generation and simplification of the detailed kinetic schemes. Besides the analysis, a whole simulation model of the naphtha pyrolysis with three function modules is also developed in this work.

2. Simulation Model

To establish the simulation model of the pyrolysis process, this paper builds the feedstock reconstruction model, detailed kinetic schemes generator with both reaction networks and corresponding kinetic parameters, and the reactor simulation model. The flow chart of the whole simulate model is shown in Figure 1.

2.1. Feedstock reconstruction model

The feedstock reconstruction approach discussed in this work uses the probability distribution function (Steven P. Pyl et al, 2011) to model the composition of the complex oil fractions. The molecular composition of petroleum fractions is calculated by Shannon entropy optimization with the bulk property of the feedstock including average molecular weight, H/C ratio, density, true boiling point distillation curve, and PINA group number as Figure 1 shows.

2.2. Detailed kinetic schemes generator

The radical reaction mechanism plays the most important role in the thermal degradation of the hydrocarbon. For pyrolysis process, radical chain propagation mechanism can be classified as 5 types of reaction: Initiation, H-Abstraction, Isomerization, Beta-scission, and Termination reactions. Therefore, the reaction kinetic parameters used in this paper are referenced from the literature (Dente 2007, Ranzi 2005). As the manual generation of the whole set of reactions becomes intractable, especially when the hydrocarbon molecular weight is increased, an automatic generator of the reaction scheme is introduced in structuring the radical reaction networks with the estimated kinetic parameters.

2.3. Reactor simulation model

Considering the geometry of tubular cracking furnace, the one-dimension reactor model is established to simulate transfer and reaction process. Then the ordinary differential equations (ODEs) is solved by GEAR Methods. In addition, the zone method (Vercammen, 1980) combined with the Monte-Carlo Integral method is utilized in calculating the radiative transfer heat of the tubular reactor furnace. This set of ordinary differential equations (ODEs) are given by

$$\frac{dN_m}{dL} = \frac{S}{V}\sum_i v_{im} r_i = f_N\left(T, P, N_m\right) \tag{1}$$

$$\frac{dT}{dL} = \frac{Q - \sum_m \Delta H^0_{fm} \frac{dN_m}{dL}}{\sum_m C_{pm} N_m + C_{pH_2O} N_{H_2O}} = f_T\left(Q, P, N_m\right) \tag{2}$$

$$\frac{dP}{dL} = f \frac{W_g G^2 \times 10^{-4}}{19.62 \times D_i \rho} = f_P\left(T, P, N_m\right) \tag{3}$$

Where L is the length of the reaction tube; N_m is the concentration of substance m in reaction tube; S is the flow area of reaction tube; V is the volume flow rate of the gas in reaction tube; v_{im} is the stoichiometric coefficient of substance m in reaction i; r_i is the

reaction rate of reaction i; T is the temperature in the reaction tube; Q is heat transfer by the furnaces; ΔH^0_{fm} is the standard enthalpy of formation of substance m; C_{pm} is the heat capacity at constant pressure; P is the pressure in reaction tube; f is the frictional factor; W_g is the equivalent length of reaction tube; G is the mass flow rate of the gas in reaction tube; D_i is the inner diameter of reaction tube; ρ is the density of the gas in reaction tube.

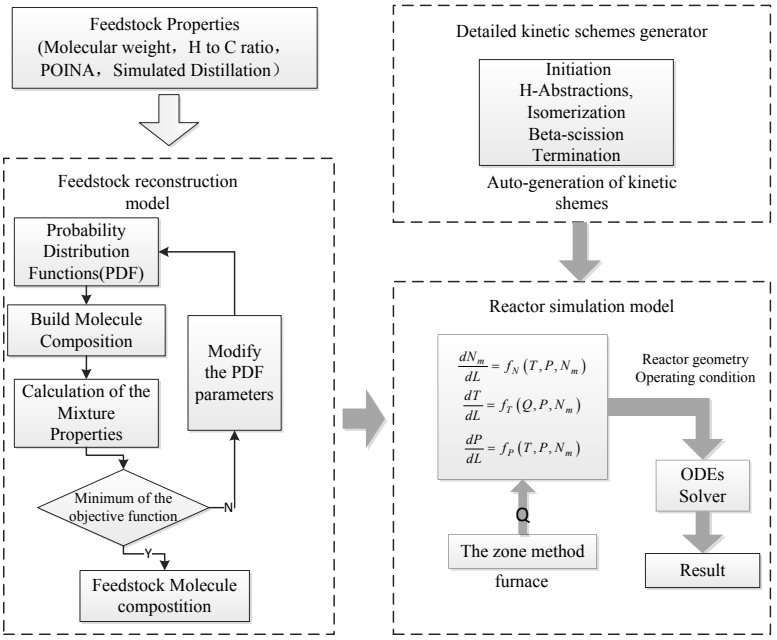

Figure 1 Flow chart of cracking process simulation

3. Reactions Networks Analysis

Most goals of reaction network analysis (both mathematic and chemical approaches) are to clarify the nature of intermediates and correlative reactivity principle. However within a kinetic schemes (reaction networks), the topological and chemical components are logically interrelated and can't be considered separately. Therefore, it is necessary that graph theory takes a view of the chemical mechanism as a graph-like structure.

First, the reaction networks are transformed into the petri-net which links the places (the set of substances) with the transitions (the set of reactions).With the petri-net model, the kinetic schemes can be written as a graph matrix as well. The kinetic parameters are calculated into the weight of the edge as the element in the matrix (Figure 2).

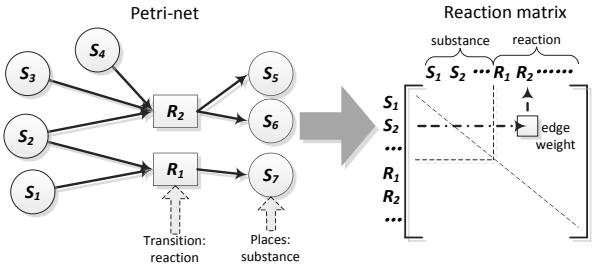

Figure 2 Petri-net model and the reaction matrix

Recently, facing the intricacy of the complex networks, most algorithms are focus on the topology of the undirected graph which can't express the dynamic system feature. The PageRank algorithm (L. Page, 1998) is widely used in the analysis of the direct graph and PageRank works by counting the number and quality of links to a nodes to determine an estimate of how important the nodes is. The nodes with high PageRank (PR) value could be the hubs or authorities in the graph. The core idea in PageRank is present the probability distribution of a random walk on the graph. Intuitively, this can be thought of as modeling the behaviour of a "random surfer". Because of the directed driving force in the ethylene cracking dynamic system is different from "random surfer", we improve the PageRank algorithm by adding the Markov process of reaction rate into the edge weight of graph and calculates the transfer matrix of PageRank with the edge weight. Moreover, for the reactions begin with the feedstock, the initial values of PR vector should correspond to the feedstock fractions. To sum up, the modified PageRank may be computed as follows:

S1: Set the initial value of the Page Rank vector $\bar{P}_0$:

$$\bar{P}_0(S_i) = \frac{C(S_i)}{\sum_{S_i} C(S_i)} \tag{4}$$

Where S_i is the composition of the feedstock; $C(S_i)$ is concentration of S_i;

Loop:

S2: Calculate the transfer Matrix A of the reaction system:

$$A(reactant, reaction) = r_{reactant} \cdot V_{reaction} \tag{5}$$

$$A(reaction, resultant) = r_{resultant} \cdot V_{reaction} \tag{6}$$

$$V_{reaction} = \frac{\sum_i rate_{\Delta L_i} \cdot \Delta L_i}{\sum_i \Delta L_i} \tag{7}$$

Where $r_{reactant}$ is the stoichiometric number of the reactant; $r_{resultant}$ is the stoichiometric number of the resultant; $V_{reaction}$ is reaction rate of the reaction, calculated by Eq.(7); $rate_{\Delta Li}$ is reaction rate in the infinitesimal section ΔL_i of reactor;

S3: Calculate the PageRank vector $\bar{P}_{k+1}$:

$$\bar{P}_{k+1} = \alpha A \cdot \bar{P}_k + \frac{1-\alpha}{N} \tag{8}$$

S4: Calculate the error δ

$$\delta = \left\| \bar{P}_{k+1} - \bar{P}_k \right\|_1 \tag{9}$$

While: $\delta > \varepsilon$

After every simulate process, the PR value is calculated to state the importance of the nodes including both reactions and substances. Though the PR values has already revealed the character of the reaction networks and information of the simulate process, these values can be applied to adjust the kinetic networks as well. In the yield data the model simulated, some errors will inescapably occur compared with the data from the industry. To fix these errors, the algorithm establishes a reaction queue for each product.

Within the queue, the reactions related to the product are chosen and sorts the queue by the PR value. Two type of the reactions can be in the queue as Figure 3 shows:
1-degree reaction: the reactions link to the object product.
2-degree reaction: the reactions link to the resultant or reactant of the 1-degree reaction
The corrected coefficients $\bar{A}_i$ of the reaction i is calculate with the error between the industrial data and the simulate result following the queue to adjust the kinetic schemes.

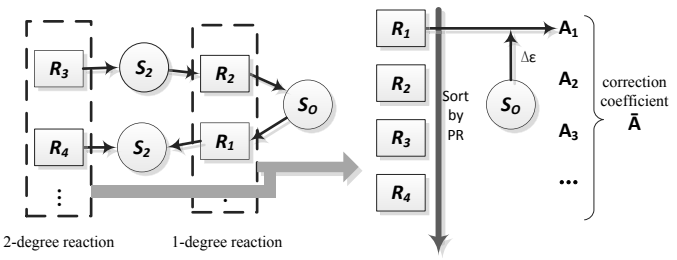

Figure 3 Calculation of correction coefficient $\bar{A}_i$

4. Case result

An industrial cases of naphtha pyrolysis from a petrochemical plant is used to testify this model. The generator establishes the original kinetic schemes with 4694 reactions and 142 substances. Then, these substances and reactions in the networks has been sorted by the modified PageRank algorithm as Figure 4 shows. The radical molecule and the cracking product are chosen as the vital nodes of the networks by the algorithm and the reactions contain these the hubs are considered positive in the react process.

C_2H_6(0.0273) C_3H_6(0.0213) C_2H_3·(0.0188)

Figure 4 The PageRank value graph and the PR values

The correction coefficients derived from model are applied in the kinetic scheme generation which polishes up the accuracy of the product prediction. The product yields of the adjusted kinetic scheme obtained by reactor simulation model are shown in Table 1. To test the reduced function of the algorithm, a kinetic scheme with 4622 reactions is also simulated in the industrial process. The reduced scheme is simplified by picking off the reactions with lower PageRank value on the basis of the adjusted scheme. The product yields are also shown in Table 1. Furthermore, the average relative error of the product yield of adjusted kinetic and the reduced scheme is 6.05%. The error is acceptable considering the scale of the original networks which has been reduced by pseudo steady state assumption (PSSA).

Table 1 Product yields with the different reaction kinetic

product yield	original kinetic scheme	adjusted kinetic scheme	reduced kinetic scheme	industrial data
H_2	1.68	1.39	1.3612	1.04
CH_4	13.02	15.42	14.3669	16.22

n-C_4H_8	2.36	1.76	1.6143	1.46
i-C_4H_8	4.69	3.19	3.1095	2.69
i-C_4H_{10}	0.30	1.08	0.9948	1.01

5. Conclusions

In this paper, the simulate model for pyrolysis process was established, including feedstock composition reconstruction model, detailed kinetic schemes generator and reactor simulation model. As the literature referenced kinetic schemes is inappropriate in some specific cases, the modified PageRank algorithm has been applied to adjust the kinetic scheme. The result of this algorithm demonstrates that the hubs and authorities in the networks contribute significantly to the simplification of the reaction networks. To modify the networks, these hubs and authorities are treated preferentially and the kinetic scheme with corrected coefficients has more accurate prediction of product yield compared with industrial data. The method to adjust model could be expected to be applied in future simulation of industrial ethylene cracking furnace. In addition, the simplification of the kinetic scheme could be assist by the algorithm as well.

Abstract

Biofuels are an attractive source of renewable energy as they can easily replace liquid fuels used in transportation and other machinery. The present study considers typical feed of ethanol-water-CO_2 from which ethanol is recovered and purified using two popular techniques: pressure swing adsorption with molecular sieves and extractive distillation using ethylene glycol. Heat integration in both processes is performed to ensure a fair basis for evaluation. Optimal separation cost is found to be US$0.1394/kg and US$0.1185/kg for the extractive distillation and pressure swing adsorption process, respectively. Hence, fuel-grade ethanol production via pressure swing adsorption with 15% lower separation cost is better than extractive distillation using ethylene glycol.

Keywords: Bioethanol; Cost of manufacture; Extractive distillation; Optimization; Pressure swing adsorption

1. Introduction

Fossil fuel reservoirs are depleting rapidly and are unsustainable in the long run. Rising environmental concerns have also motivated the search for cleaner fuel alternatives. Among the different types of renewable energies, bioenergy is interesting since biofuels can directly substitute liquid fuels used in transportation and other machinery (Sunggyu, 2006). Production of bioethanol in the world, with more than half of it in US and Brazil (Chum et al., 2013), still relies on 1st generation biofuel crops since technologies to produce from 2nd and 3rd generation crops are relatively immature and difficult to control (McAloon et al., 2000).

Bioethanol concentration in the fermentation broth is about 10 wt% whereas fuel grade ethanol can be up to 99.8 wt% pure. Atmospheric distillation is used for preliminary recovery of bioethanol to various degrees of concentration depending on the process design. Ethanol and water form an azeotrope mixture of 95.6 wt% of ethanol at 1atm and 78.15°C. Hence, to further purify bioethanol, the industry employs either of the common techniques: pressure swing adsorption (PSA) using molecular sieves and extractive distillation (ED) using ethylene glycol (EG). Publications in the last decade have focused mainly on evaluating the amount of energy consumed for recovery and separation of ethanol without regards to economic feasibility. Recently, Kiss and Ignat

(2012) studied and optimized ED and extractive dividing-wall column (E-DWC) processes by minimizing the total heat duty of the distillation sequence. For this, they have simulated the processes using a binary feed of ethanol-water, which does not accurately reflect separation cost of a multi-component feed. Roth et al. (2013) made an economic evaluation of hybrid processes involving distillation, molecular sieve adsorption and membrane separation, but their work focused on purification starting from ethanol concentration of 45, 80 and 92 wt%, without optimization.

In this paper, ED and PSA processes are designed and compared, on a consistent basis, for recovery and purification of bioethanol from a typical mixture of ethanol-water-CO2 from the fermenter. Unit separation cost derived from the cost of manufacture (COM) is used as the objective function, to determine the competitive process. Heat integration is taken into account through feed pre-heating and use of mechanical vapor recompression (MVR), if applicable.

2. Literature Review

After pre-concentration of bioethanol by distillation, further purification can be achieved through adsorption using molecular sieves of pore diameter 3Å (3A zeolites) since water molecules are roughly 2.5Å in diameter (Kumar et al., 2010). Molecular sieve properties from ZEOCHEM are used for modelling in this study. Strength of adsorption of target molecules in molecular sieves depend strongly on temperature and pressure; water molecules are adsorbed at high pressures and low temperatures, and regenerated at low pressures and high temperatures (Sowerby and Crittenden, 1988). Alternatively, ED can be used for purification after pre-concentration. A relatively non-volatile liquid solvent is fed into the column to alter the volatility of one of the components in order to improve separation and overcome azeotrope point. The solvent, which accumulates in the column bottoms, is recovered and recycled using an additional column. Among the commonly used liquid solvents as extractive agents for ethanol-water system are EG, diethyl ether, toluene and furfural (Kumar et al., 2010). ED using EG has favorable features such as high product quality, suitability for large scale production and relatively low volatilization amount. However, large amount of solvent is required to achieve the purity requirement of fuel-grade ethanol, resulting in high energy consumption for the recovery process (Kumar et al., 2010).

3. Process Specifications and Simulation Methodology

More than 15 components are present in the bioethanol-water solution produced by sugar fermentation. Many of these components exist in very small quantities, and can be neglected as they would not have substantial impact on distillation/separation. For simplicity, only 3 major components are considered in the feed for this simulation: CO_2, ethanol and water. According to Moncada et al. (2013), “beer” formed in a sugarcane biorefinery contains 7-10 wt% ethanol. After considering future improvements to fermentation, feed composition used in this work is 10 wt% ethanol, 0.1 wt% CO_2 and 89.9 wt% water. Assuming overall recovery of at least 0.99 of ethanol in the feed and plant operation of 8,250 hours/year, the required feed mass flow rate can be calculated.

For bioethanol to be used as fuel, its moisture content is subjected to a maximum limit to prevent corrosion of the machinery interior. The maximum allowable water is 0.2 vol% in Europe (CSN EN 15376, 2011), 2.0 vol% in Brazil (Resolucao ANP No. 7, 2011) and 1.0 vol% in USA (ASTM D4806-11, 2011). Considering these standards,

purity of ethanol is taken to be 99 wt%. At the same time, CO_2 concentration in the product is reduced to less than or equal to 100 ppm. Production capacity is based on the sizes of bioethanol plants that can be found in the industry. In the 2012 industry outlook report, the Renewable Fuels Association (RFA, 2012) listed the production capacities of all fuel ethanol plants in USA; these data show that annual production volumes are concentrated around 2 values: 50 (medium scale) or 100 (large scale) million gallons (equivalent to 189,270m^3 and 378,541m^3). Rounding up, the production volume used in this work is 200,000 m^3. The final product is depressurized to 1 atm and cooled to 40^{o}C.

In this study, Aspen HYSYS v8.2 is used for simulating and optimizing the two separation processes. Aspen Properties NRTL-RK model is chosen to describe ethanol-water-CO_2 system since it gives better estimates for important intensive properties of the components involved. For ED, presence of EG requires additional validation of this model, and it is checked against the recently published experimental isobaric VLE data of the ternary system. The binary interaction parameters (BIPs) have been refitted with values as correlated by Pla-Franco et al. (2013). The form of equation used to describe the temperature-dependency of dimensionless asymmetric interaction parameter, τ_{ij} in Aspen Properties is different from the form used by Pla-Franco et al. (2013).

Form of equation used by Pla-Franco et al.: $\tau_{ij} = \frac{A_{ij}+B_{ij}T}{RT}$ (1)

Form of equation used by Aspen Properties: $\tau_{ij} = a_{ij} + \frac{b_{ij}}{T}$ (2)

In Eq.(1), R is the gas constant (= 8.314J/mol-K), and A_{ij} has units of J/mol while B_{ij} has units of J/mol-K. In Eq.(2), a_{ij} is dimensionless, while b_{ij} has unit of K. By comparing Equations 1 and 2, $a_{ij} = \frac{B_{ij}}{R}$ while $b_{ij} = \frac{A_{ij}}{R}$. The adjusted values closely agree with the experimental data with very low average absolute deviation for both vapor mole fractions and temperature.

Although many unit operations are readily available in HYSYS, PSA module is not one of them because this simulator does not normally deal with pseudo-continuous processes. However, it is possible to treat PSA separation as a fully continuous process by using a component splitter for PSA unit in the simulation model. The component splitter allows the user to define pressure and temperature of each outlet, thus it is possible to simulate column pressure drop, vacuum conditions needed to regenerate the molecular sieves, as well as temperature changes due to heat of adsorption. As recommended by ZEOCHEM, a 2-bed PSA system is used in this study. Each bed has a 16 min cycle split equally for adsorption and regeneration. The adsorption and desorption pressures and temperatures are decision variables for optimization. Using Excel and defining constraints in the optimizer, the simulator interacts with the spreadsheet containing molecular sieve isotherm data, allowing the PSA system to be fully defined. An excess of molecular sieves is used to provide processing margin, considering the mass transfer zone (breakthrough curve) in the PSA column.

4. Results and Discussion

The objective function is to minimize the separation cost per unit of fuel ethanol produced, subject to the product purity constraint. It is dependent on decision variables such as pre-concentrator feed temperature, CO_2 concentration level after pre-concentration, feed/recycle/side-draw stages, number of trays, and distillate and bottoms

purity of each distillation column. Feasible boundaries are defined for each variable to avoid non-convergence of simulation and lengthy computational time. The choice between the use of a vapour or liquid side draw is also investigated to understand its impact on separation cost. The in-built optimizer of Aspen HYSYS v8.2 is used to optimize the separation process, using sequential quadratic programming method as the solver since it can handle both equality and inequality constraints.

The model layouts for each system simulated are shown in Figures 1 and 2. Preliminary analysis indicated having only one pre-concentrator column (PDC) is better for EG process; followed by an extractive distillation column (EDC) and solvent recovery column (SRC). On the other hand, PSA process requires two columns (DC1 and DC2) for concentration; this is related to the choice of liquid or vapour side-draw from column, which affects overall energy demand. All equipment in each of the processes is sized according to established design practices, simulation data and results. COM can be determined using Eq.(3) after estimating the following costs: fixed capital investment (FCI), cost of operating labor (C_{OL}), cost of utilities (C_{UT}), cost of waste treatment (C_{WT}) and cost of raw materials (C_{RM}) (Turton et al., 2013).

$$\text{COM (US\$/year)} = 0.280\ \text{FCI} + 2.73\ C_{OL} + 1.23\ (C_{UT} + C_{WT} + C_{RM}) \quad (3)$$

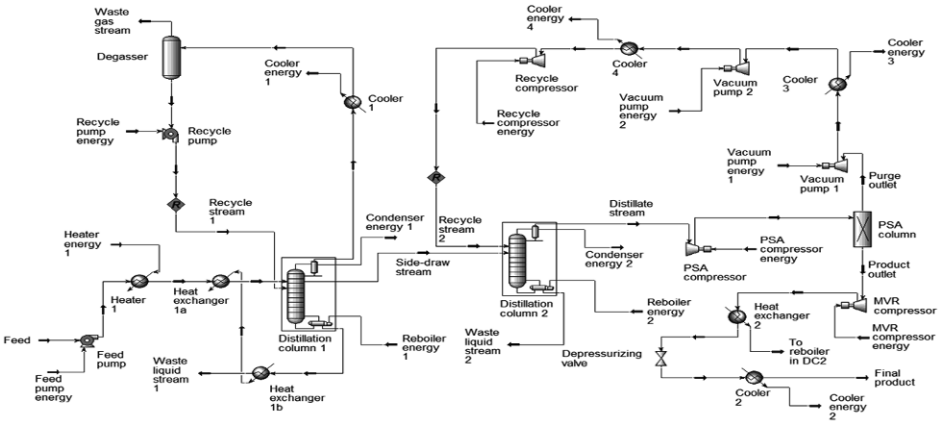

Figure 1: Aspen HYSYS model layout for PSA process

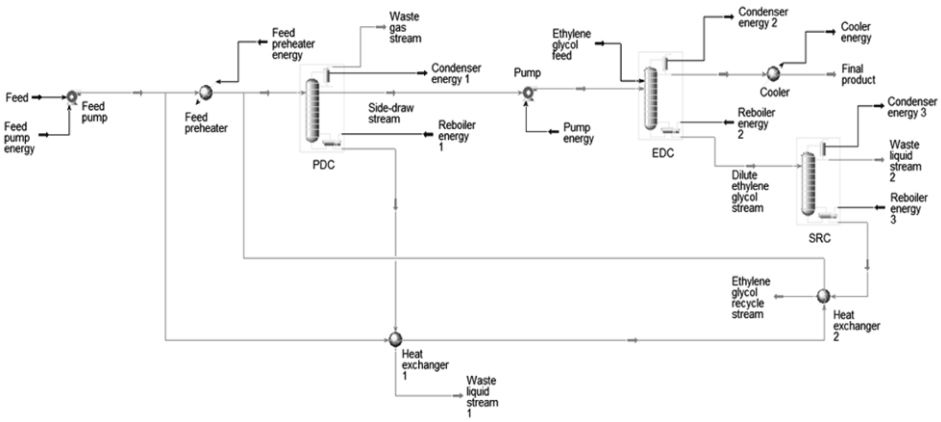

Figure 2: Aspen HYSYS model layout for ED using EG process

Here, depreciation allowance of 0.10 FCI is taken into account but waste treatment and raw materials costs are not considered in this work. Unit separation cost is calculated by dividing COM by ethanol produced (kg/year), for minimization. Optimal separation cost obtained for PSA process is US$0.11854 with ethanol recovery rate of 99.7%, whereas that for E*D using EG process is US$0.13938* with ethanol recovery rate of 99.6%. Clearly, recovery and purification using the PSA proc*ess is more advantageous at 15*% lower cost and slightly higher recovery rate. This is *more* significant *at higher production capacities; that which is considered in this work is* of a medium-size fuel ethanol plant, and so the difference in unit separation cost is likely to increase for large plants. Optimal values of parameters of both processes are shown in Table 1.

Table 1: Optimal values of process parameters of PSE and ED processes

Process parameters	**PSA**		**ED using EG**		
	DC1	**DC2**	**PDC**	**EDC**	**SRC**
Number of stages	35	38	50	57	23
Feed stage	4	16	18	32	6
Recycle stage	1	15	-	-	-
Side-draw stage	7	-	2	-	-
Distillate purity (wt%)	54.7	92.6	90.9	99.8	0.14
Bottoms purity (wt%)	0.01	0.01	0.02	0.02	0.00
Feed temperature (^oC)	90.0	-	98.71	-	-
CO_2 concentration (ppm)	-	100	-	50	-
Heat energy demand (GJ/h)	106	17	111	34	17

4.1. Cost Savings from Lower Energy Demand and MVR

Thermal energy demand for the PSA process is 122.7 GJ/h, which is 24.3% lower than that for the ED using EG process which requires 162.1 GJ/h. One reason for this is the lower distillate purity required in the PSA process since it is cheaper to use molecular sieves for purification from 92.6 wt% to 99 wt%. In addition, ED process requires energy to recover EG. Another factor that lowered the separation cost of the PSA process is the use of MVR for additional heat integration. As shown in Table 2, although capital cost has risen by US$1 million because of the additional compressor, operating cost has dropped by US$1.2 million/y. Annualizing capital cost over 10 years (10% depreciation), net cost savings from MVR is US$1.1 million/y or 2.4% of COM. However, cost savings from MVR depends on the relative cost of steam and electricity; locations with high electricity cost will not reap any benefits. Further, compressor operation is challenging in most plants. Nevertheless, even without MVR, separation cost using PSA process is 12.6% lower than that for ED using EG.

Table 2: Summary of cost savings from MVR

Capital cost			
Additional equipment		**Removed equipment**	
MVR compressor	US$2,050,700	**Heat exchangers**	US$1,041,300
Total increase in capital cost		US$1,009,400	
Operating cost			
	LP steam	**Cooling water**	**Electricity**
Cost per unit (Turton et al., 2013)	US$29.29/1000 kg	US$14.80/1000 m^3	US$0.06/kWh
Quantity required	-	-	921.8 kWh
Quantity reduced	6,855 kg	89.8 m^3	-
Total reduction in operating costs		US$1,211,100/yr	

5. Conclusions

In this paper, separation cost to produce fuel-grade ethanol by two common industrial processes is studied and compared on a consistent basis. It is found that, for a ternary system of ethanol-water-CO_2, it is less costly to produce fuel-grade ethanol with PSA rather than ED using EG. The optimal separation cost of fuel-grade ethanol is 15% lower at US$0.11854/kg for the PSA process. This is because the PSA process requires 24.3% lower energy demand, partly due to the additional energy required to recover EG in the ED process. Furthermore, the integration of MVR in the PSA process contributed to additional savings of about 2.4% of COM. Therefore, in order for ED to become competitive against PSA, the use of a dividing-wall column can be considered for reducing energy demand in the overall process.

Abstract

Concentrations measured during the course of a chemical reaction are corrupted with noise, which reduces the quality of information. When these measurements are used for identifying kinetic models, the noise impairs the ability to identify accurate models. The noise in concentration measurements can be reduced using data reconciliation, exploiting for example the material balances as constraints. However, additional constraints can be obtained via the transformation of concentrations into extents and invariants. This paper uses the transformation to extents and invariants and formulates the data reconciliation problem accordingly. This formulation has the advantage that non-negativity and monotonicity constraints can be imposed on selected extents. A simulated example is used to demonstrate that reconciled measurements lead to the identification of more accurate kinetic models.

Keywords: Kinetic identification, Data reconciliation, Model discrimination, Vessel extents

1. Introduction

Chemical reactions are used in the chemical, biotechnological and pharmaceutical industries to convert feed materials into manufactured products. Measurements of concentrations made during the course of the reaction are vital for efficient reactor operation. Process monitoring, control and optimization can be carried out using measurements by either building first-principles (kinetic) models or using data-driven models, or by combining these two approaches.

Kinetic modeling of chemical reaction systems is generally performed via simultaneous identification, Bardow and Marquardt (2004). This identification path suffers from combinatorial complexity and is therefore computationally intensive. As an alternative, the extent-based incremental identification introduced by Amrhein et al. (2010) can be used to build first-principles kinetic models incrementally. The procedure involves a transformation of the measured numbers of moles to extents. This transformation decouples the modeling task into a set of sub-problems, thereby reducing the combinatorial complexity when there are several candidate models for each reaction. Since measurements are corrupted by noise, the performance of the modeling/identification task, and thus also of the subsequent monitoring, control and optimization steps, depends highly on the accuracy of the measurements.

To reduce noise and improve the accuracy of the measured information, data reconciliation (DR) techniques are often used as a pre-processing step, see Narasimhan and Jordache (1999). Data reconciliation exploits process constraints derived from conservation equations to reconcile measurements, that is, to correct the measured data so as to satisfy constraints that are valid at all times. This paper describes a reconciliation approach that is based on extents instead of concentrations. This novel problem formulation allows using additional constraints such as the non-negativity and

monotonicity of extents, which improves significantly the accuracy of the reconciled concentrations and of the identified kinetic models, as illustrated through a simulated example.

2. Preliminaries

2.1. Mole Balance Equations

The mole balance equations for an homogeneous reaction system involving S species, R independent reactions, p inlet streams, and one outlet stream can be written as follows:

$$\dot{\mathbf{n}}(t) = \mathbf{N}^{\mathrm{T}}\mathbf{r}_v(t) + \mathbf{W}_{in}\,\mathbf{u}_{in}(t) - \omega(t)\mathbf{n}(t), \qquad \mathbf{n}(0) = \mathbf{n}_0, \tag{1}$$

where $\mathbf{n}$ is the S-dimensional vector of the numbers of moles, $\mathbf{r}_v := V\,\mathbf{r}$ with V the volume and $\mathbf{r}$ the R-dimensional vector of reaction rates, $\mathbf{u}_{in}$ the p-dimensional vector of inlet mass flowrates, $\omega := \frac{u_{out}}{m}$ the inverse of the residence time with m the mass of the reaction mixture and u_{out} the outlet mass flowrate, $\mathbf{N}$ the $R \times S$ stoichiometric matrix, $\mathbf{W}_{in} = \mathbf{M}_w^{-1}\check{\mathbf{W}}_{in}$ the $S \times p$ matrix of inlet compositions, $\mathbf{M}_w$ the S-dimensional diagonal matrix of molecular weights, $\check{\mathbf{W}}_{in} = [\check{\mathbf{w}}_{in}^1 \cdots \check{\mathbf{w}}_{in}^p]$ with $\check{\mathbf{w}}_{in}^j$ being the S-dimensional vector of weight fractions of the jth inlet flow, and $\mathbf{n}_0$ the S-dimensional vector of initial numbers of moles. If needed, the concentration are computed from the numbers of moles as $\mathbf{c}(t) = \frac{\mathbf{n}(t)}{V(t)}$.

2.2. Conservation Equations

The S dynamic equations (1) are often redundant, as the variability in the system is determined by the number of independent reactions and inlet/outlet streams, and not by the number of chemical species. These redundancies can usually be expressed in terms of algebraic constraints. The number and nature of these constraints depend on the operating mode of the reactor. Table 1 lists the number of constraints q and the procedure for deriving them from structural elements of (1), in particular $\mathbf{N}$, $\mathbf{W}_{in}$ and $\mathbf{n}_0$, for three different operating modes. The matrix $\mathbf{P}$ represents the null space of the corresponding structural matrix.

Table 1: Algebraic constraints under different operating modes.

Operation	# constraints	Constraint derivation	Constraints
Batch	$q = S - R$	$\mathbf{P}^{\mathrm{T}}[\mathbf{N}^{\mathrm{T}}] = \mathbf{0}_{q\times R}$	$\mathbf{P}^{\mathrm{T}}\mathbf{n}(t) = \mathbf{P}^{\mathrm{T}}\mathbf{n}_0$
Fed-batch	$q = S - R - p$	$\mathbf{P}^{\mathrm{T}}[\mathbf{N}^{\mathrm{T}}\ \mathbf{W}_{in}] = \mathbf{0}_{q\times(R+p)}$	$\mathbf{P}^{\mathrm{T}}\mathbf{n}(t) = \mathbf{P}^{\mathrm{T}}\mathbf{n}_0$
Open	$q = S - R - p - 1$	$\mathbf{P}^{\mathrm{T}}[\mathbf{N}^{\mathrm{T}}\ \mathbf{W}_{in}\ \mathbf{n}_0] = \mathbf{0}_{q\times(R+p+1)}$	$\mathbf{P}^{\mathrm{T}}\mathbf{n}(t) = \mathbf{0}_q$

2.3. From numbers of moles to vessel extents

Amrhein et al. (2010) and Rodrigues et al. (2015) have developed a linear transformation for open reaction systems that transforms the numbers of moles $\mathbf{n}$ into four contributions, namely, the R extents of reaction $\mathbf{x}_r$, the p extents of inlet $\mathbf{x}_{in}$, a dimensionless extent of initial conditions x_{ic}, and the $q = S - R - p - 1$ invariants $\mathbf{x}_{iv}$ that are identically zero. The linear transformation $\mathscr{T}$ reads:

$$\begin{bmatrix} \mathbf{x}_r(t) \\ \mathbf{x}_{in}(t) \\ x_{ic}(t) \\ \mathbf{x}_{iv}(t) \end{bmatrix} = \mathscr{T}\,\mathbf{n}(t) := \begin{bmatrix} \mathbf{R} \\ \mathbf{F} \\ \mathbf{i}^{\mathrm{T}} \\ \mathbf{Q} \end{bmatrix} \mathbf{n}(t), \tag{2}$$

The transformation matrix $\mathscr{T}$ is given by $\left[\mathbf{N}^{\mathrm{T}}\ \mathbf{W}_{in}\ \mathbf{n}_0\ \mathbf{P}\right]^{-1}$, where $\mathbf{P}$ represents the null space of $\left[\mathbf{N}^{\mathrm{T}}\ \mathbf{W}_{in}\ \mathbf{n}_0\right]$, and brings the dynamic model (1) to the following decoupled form:

$$\dot{\mathbf{x}}_r(t) = \mathbf{r}_v(t) - \omega(t)\,\mathbf{x}_r(t) \qquad \mathbf{x}_r(0) = \mathbf{0}_R \tag{3a}$$

$$\dot{\mathbf{x}}_{in}(t) = \mathbf{u}_{in}(t) - \omega(t)\,\mathbf{x}_{in}(t) \qquad \mathbf{x}_{in}(0) = \mathbf{0}_p \tag{3b}$$

$$\dot{x}_{ic}(t) = -\omega(t)\,x_{ic}(t) \qquad x_{ic}(0) = 1 \tag{3c}$$

$$\mathbf{x}_{iv}(t) = \mathbf{0}_q\,, \tag{3d}$$

where $\mathbf{R}$, $\mathbf{F}$ and $\mathbf{Q} = \mathbf{P}^+$ are matrices of dimensions $R \times S$, $p \times S$ and $q \times S$, respectively, and $\mathbf{i}$ is a S-dimensional vector. Each individual extent $x_{r,i}$ or $x_{in,j}$ defined in (3) is in fact a vessel extent expressing the amount of material (due to a reaction or an inlet) that is still in the reactor, the negative terms on the right-hand side accounting for what has left the reactor. Similarly, the extent $x_{ic}(t)$ in (3c) indicates the fraction of the initial conditions that is still in the reactor at time t.

The vector of numbers of moles $\mathbf{n}(t)$ can be reconstructed from the various extents by pre-multipliying (2) by $\mathscr{T}^{-1} = \begin{bmatrix}\mathbf{N}^{\mathrm{T}} & \mathbf{W}_{in} & \mathbf{n}_0 & \mathbf{P}\end{bmatrix}$ and considering that $\mathbf{x}_{iv} = \mathbf{0}_q$, which yields:

$$\mathbf{n}(t) = \mathbf{N}^{\mathrm{T}}\mathbf{x}_r(t) + \mathbf{W}_{in}\mathbf{x}_{in}(t) + \mathbf{n}_0 x_{ic}(t). \tag{4}$$

Remark 1 (Fed-batch reactor)
For fed-batch reactors, the transformation (2) *transforms the* $\mathbf{n}$ *into the* R *extents of reactions* $\mathbf{x}_r$*, the* p *extents of inlets* $\mathbf{x}_{in}$ *and the* $q = S - R - p$ *invariants* $\mathbf{x}_{iv}$*.*

Remark 2 (Batch reactor)
For batch reactors, the transformation (2) *transforms* $\mathbf{n}$ *into the* R *extents of reactions* $\mathbf{x}_r$ *and the* $q = S - R$ *invariants* $\mathbf{x}_{iv}$*.*

Proposition 1 (Monotonicity of x_{ic})
The extent $x_{ic}(t)$ *is strictly positive and monotonically decreasing over time in an open reactor.*

Proof: The solution to (3c) is $x_{ic}(t) = e^{-\int_0^t \omega(\tau)d\tau}$ with $\omega(t) = \frac{u_{out}(t)}{m(t)}$. Since $\omega(t) \geq 0$, $x_{ic}(t)$ varies as a negative exponential function and hence is monotonically decreasing.

Proposition 2 (Monotonicity of $\mathbf{x}_r$ and $\mathbf{x}_{in}$ in batch and fed-batch modes)
The extents $\mathbf{x}_r$ *for reactions with net positive rates and the extents* $\mathbf{x}_{in}$ *are strictly increasing in batch and semi-batch modes.*

Proof: In absence of outlet, that is for $u_{out} = 0$, (3a) reduces to $\dot{\mathbf{x}}_r(t) = \mathbf{r}_v(t)$ and (3b) to $\dot{\mathbf{x}}_{in}(t) = \mathbf{u}_{in}(t)$. It follows from $\mathbf{r}_v(t) \geq \mathbf{0}_R$ and $\mathbf{u}_{in}(t) \geq \mathbf{0}_p$ that both extents are strictly positive and increasing.

3. Data Reconciliation

Data reconciliation applied to reaction systems uses redundancy expressed as algebraic constraints, such as those provided in Table 1, to improve the accuracy of measured concentrations. The following assumptions are made in this study:

A1. the concentrations of all S species are measured and available,

A2. the volume is measured accurately without noise, and

A3. the initial conditions are known perfectly.

Let $\tilde{\mathbf{c}}(t_h) = \mathbf{c}(t_h) + \boldsymbol{\varepsilon}_c$ denote the S-dimensional vector of noisy concentrations measured at H time instants, $t_h \in [t_1, t_H]$ with $t_1 = 0$, where $\boldsymbol{\varepsilon}_c$ is an S-dimensional vector of zero-mean Gaussian noise with the constant variance-covariance matrix $\boldsymbol{\Sigma}_c$. The noise in the numbers of moles $\tilde{\mathbf{n}}(t_h) = V(t_h)\tilde{\mathbf{c}}(t_h)$ also follows a zero-mean normal distribution with the time-varying variance-covariance matrix $\boldsymbol{\Sigma}_n(t_h) = V(t_h)^2\boldsymbol{\Sigma}_c$.

3.1. Data reconciliation in terms of numbers of moles

For all operating modes, the reconciliation of the measured numbers of moles $\tilde{\mathbf{n}}$ can be formulated as an optimization problem constrained by algebraic relationships:

$$\begin{aligned} \min_{\hat{\mathbf{n}}(t_i)} \quad & \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right)^{\mathrm{T}} \mathbf{W}(t_i) \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right) \\ \text{s.t.} \quad & \mathbf{P}^{\mathrm{T}}\hat{\mathbf{n}}(t_i)=\mathbf{0}_q, \quad \hat{\mathbf{n}}(t_i)\geq \mathbf{0}_S \end{aligned} \tag{5}$$

where $\hat{\mathbf{n}}$ is the vector of reconciled numbers of moles and $\mathbf{W}(t_i)=\boldsymbol{\Sigma}_n^{-1}(t_i)$ is the weighting matrix. Note that, due to the presence of inequality constraints, Problem (5) does not have an analytical solution and hence must be solved numerically. In this formulation, the DR problem for different time instants are decoupled, that is, the reconciled number of moles can be estimated independently at each time instant.

3.2. Data reconciliation in terms of extents

An alternative consists in defining the DR problem directly in terms of extents. The formulation of this problem depends on whether the reactor has an outlet (open reactors) or not (batch and fed-batch reactors). In this formulation, the reconciliation in terms of extents at instant t_i involves reconciling all the previous measurements as well.

3.2.1. Open reactors

In the presence of an outlet, there is a monotonicity constraint only for x_{ic}. The reconciliation problem for reactions with net positive rates reads:

$$\begin{aligned} \min_{\substack{\hat{\mathbf{x}}_r(t_1),\ldots,\hat{\mathbf{x}}_r(t_H)\\ \hat{\mathbf{x}}_{in}(t_1),\ldots,\hat{\mathbf{x}}_{in}(t_H)\\ \hat{x}_{ic}(t_1),\ldots,\hat{x}_{ic}(t_H)}} \quad & \sum_{i=1}^{t_H} \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right)^{\mathrm{T}} \mathbf{W}(t_i) \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right) \\ \text{s.t.} \quad & \hat{x}_{ic}(t_i)-\hat{x}_{ic}(t_{i-1})\leq 0 \quad \forall i>1, \\ & \hat{\mathbf{n}}(t_i)\geq 0, \quad \hat{\mathbf{x}}_r(t_i)\geq 0, \quad \hat{\mathbf{x}}_{in}(t_i)\geq 0, \quad \hat{x}_{ic}(t_i)\geq 0 \end{aligned} \tag{6}$$

with $\hat{\mathbf{n}}(t_i)=\mathbf{N}\hat{\mathbf{x}}_r(t_i)+\mathbf{W}_{in}\hat{\mathbf{x}}_{in}(t_i)+\mathbf{n}_0\hat{x}_{ic}(t_i)$ from (4).

3.2.2. Batch and fed-batch reactors

In the absence of outlet, monotonicity constraints can be imposed on $\mathbf{x}_r$ in batch mode, and on $\mathbf{x}_r$ and $\mathbf{x}_{in}$ in fed-batch mode. For a fed-batch reactor, the reconciliation problem for reactions with net positive rates then reads:

$$\begin{aligned} \min_{\substack{\hat{\mathbf{x}}_r(t_1),\ldots,\hat{\mathbf{x}}_r(t_H)\\ \hat{\mathbf{x}}_{in}(t_1),\ldots,\hat{\mathbf{x}}_{in}(t_H)}} \quad & \sum_{i=1}^{t_H} \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right)^{\mathrm{T}} \mathbf{W}(t_i) \left(\tilde{\mathbf{n}}(t_i)-\hat{\mathbf{n}}(t_i)\right) \\ \text{s.t.} \quad & \hat{\mathbf{x}}_r(t_i)-\hat{\mathbf{x}}_r(t_{i-1})\geq \mathbf{0}_R \quad \forall i>1, \qquad \hat{\mathbf{x}}_{in}(t_i)-\hat{\mathbf{x}}_{in}(t_{i-1})\geq \mathbf{0}_p \quad \forall i>1, \\ & \hat{\mathbf{n}}(t_i)\geq 0, \qquad \hat{\mathbf{x}}_r(t_i)\geq \mathbf{0}_R, \qquad \hat{\mathbf{x}}_{in}(t_i)\geq \mathbf{0}_p \end{aligned} \tag{7}$$

with $\hat{\mathbf{n}}(t_i)=\mathbf{N}\hat{\mathbf{x}}_r(t_i)+\mathbf{W}_{in}\hat{\mathbf{x}}_{in}(t_i)+\mathbf{n}_0$ from (4) with $x_{ic}(t_i)=1$. The constraint $\mathbf{P}^{\mathrm{T}}\hat{\mathbf{n}}(t_i)=\mathbf{0}_q$ is implicitly satisfied in (6) and (7) since the invariants $\mathbf{x}_{iv}$ are zero.

4. Application to Model Identification

The different formulations of the reconciliation problem are compared via a simulated example. The chosen reaction system is the catalyzed acetoacetylation of pyrrole, which consists of $R = 4$ reactions and $S = 6$ species (plus the catalyst), Ruppen et al. (1998). The reaction scheme and the kinetic models used to generate the data are:

$$\begin{array}{llllll} \text{R1:} & \text{A} + \text{B} & \rightarrow & \text{C} & r_1 = k_1 c_A c_B c_K \\ \text{R2:} & \text{B} + \text{B} & \rightarrow & \text{D} & r_2 = k_2 c_B^2 c_K \\ \text{R3:} & \text{B} & \rightarrow & \text{E} & r_3 = k_3 c_B \\ \text{R4:} & \text{C} + \text{B} & \rightarrow & \text{F} & r_4 = k_4 c_C c_B c_K \end{array}$$

This reaction system is simulated in an isothermal batch reactor. The values of the rate constants are $k_1 = 0.0530$, $k_2 = 0.1280$, $k_3 = 0.0280$ s^{-1} and $k_4 = 0.003$ L^2 mol^{-2} s^{-1}. The initial volume is 1 L with the concentrations $\mathbf{c}_0 = \begin{bmatrix} 1.25 & 1 & 0 & 0 & 0 & 0 \end{bmatrix}^{\mathrm{T}}$ mol L^{-1} and $c_{K0} = 0.5$ mol L^{-1} for the catalyst K. Since the density is assumed constant, the volume is also constant.

According to Table 1, this batch reaction system has $q = S - R = 2$ invariant relationships:

$$\begin{aligned} -2c_A(t) + c_B(t) - c_C(t) + 2c_D(t) + c_E(t) &= -2c_{A,0} + c_{B,0} - c_{C,0} + 2c_{D,0} + c_{E,0} \\ c_A(t) + c_C(t) + c_F(t) &= c_{A,0} + c_{C,0} + c_{F,0}. \end{aligned} \tag{8}$$

Each concentration is corrupted with additive independent zero-mean Gaussian noise of standard deviation corresponding to 10% of its maximum concentration. Catalyst K and species F are assumed to be noise free. The variance-covariance matrix $\mathbf{\Sigma}_n$ is constant (batch conditions) and is assumed to be known. Measurements are taken every 0.5 min for 30 min.

The measured numbers of moles $\tilde{\mathbf{n}}$ are reconciled in two ways. First, in terms of numbers of moles, according to the problem formulation (5) using constraints given by the invariant relationships (8). Second, in terms of extents, according to the formulation (7) (with $\hat{\mathbf{x}}_{in} = \mathbf{0}$) with constraints on the positivity and monotonicity of the extents of reaction $\hat{\mathbf{x}}_r$. The performance of the different approaches is assessed using the residual sum of squares (RSS) calculated as the difference between the *true* simulated data and the measured/reconciled data. Table 2 shows that the formulation (7) improves significantly the accuracy of the reconciled data compared to the unreconciled (original) measurements and the data reconciled according to the formulation (5). Figure 1 shows the simulated, measured and extent-based reconciled concentrations of species A to E.

Table 2: Residual sum of squares between the *true* simulated numbers of moles and the numbers of moles obtained without reconciliation ($\tilde{\mathbf{n}}$) and with reconciliation according to (5) and (7).

Species	Measurements	Data reconciliation	
	via $\tilde{\mathbf{n}}$	via $\hat{\mathbf{n}}$ (5)	via $\hat{\mathbf{x}}$ (7)
A	0.9164	0.0332	0.0108
B	0.4615	0.1317	0.0355
C	0.0316	0.0332	0.0109
D	0.0392	0.0268	0.0062
E	0.0162	0.0155	0.0115

Note that incremental model identification can be performed independently for each reaction, as discussed in Srinivasan et al. (2012) and Billeter et al. (2013). For each rate law, kinetic identification is performed using the measured data ($\tilde{\mathbf{n}}$) and the data reconciled according to (5) and (7). For each set of data (measurements, reconciled estimates via $\hat{\mathbf{n}}$ and reconciled estimates via $\hat{\mathbf{x}}$), the capability of discriminating between correct and incorrect kinetic laws is assessed by comparing the RSS of each candidate rate law to that of the correct law. Table 3 shows drastic improvement when measurements are reconciled with (7), that is, using constraints on extents. In all cases, the least RSS is obtained for the correct kinetic model, which implies that the correct model is identified. However, the use of the raw measurements (without reconciliation) makes it difficult to discriminate between models 1 and 3 for R1 and models 1 and 4 for R2. In contrast, the use of reconciled estimates based on the formulation (7) enables unambiguous identification of the correct kinetic model.

Table 3: Ratios of RSS (with respect to the correct model, thus giving 1 for the correct model) for different kinetic models for reactions R1 and R2 using the measured numbers of moles $\tilde{\mathbf{n}}$ and the numbers of moles reconciled according to 5 ($\hat{\mathbf{n}}$) and 7 ($\hat{\mathbf{x}}$).

R1	Measurements via $\tilde{\mathbf{n}}$	Reconciled estimates via $\hat{\mathbf{n}}$ (5)	Reconciled estimates via $\hat{\mathbf{x}}$ (7)	R2	Measurements via $\tilde{\mathbf{n}}$	Reconciled estimates via $\hat{\mathbf{n}}$ (5)	Reconciled estimates via $\hat{\mathbf{x}}$ (7)

5. Conclusion

This paper has shown that data reconciliation using invariant relationships helps reduce the effect of measurement noise. Furthermore, formulating the reconciliation problem in terms of extents allows exploiting additional monotonicity constraints. It has also been shown through a simulated example that the use of reconciled estimates together with the extent-based incremental approach leads to improved model discrimination. Future work will focus on developing monotonicity constraints for the extents of reaction and mass transfer in the context of open heterogeneous reaction systems.

Abstract

A mathematical first-principle model (FPM) of a ruthenium reactor was developed, implemented and successfully validated against a set of measurements of the real reactor of a precious metal refinery (PMR). The model describes the dynamic behavior of a process involving two exothermic reactions, occurring simultaneously in a semi-batch reactor equipped with a jacket. The reactions describe the dissolution of solid ruthenium (Ru) to produce liquid ruthenium trichloride ($RuCl_3$), which is then evaporated into ruthenium tetroxide gas (RuO_4). This paper presents a lumped model of the process whose main objective was to achieve satisfactory tracking of temperature and pressure data sets of the real reactor. The model was written as an explicit system of ordinary differential equations (ODEs), and has demonstrated satisfactory predictions of temperature and pressure dynamics. However, more work aiming at achieving better validation of the model is still in progress. This involves using nonlinear optimization techniques to find optimum parameter estimates of reaction kinetics constants, together with some heat and mass transfer coefficients, only obtained by trial-and-error at this point.

Keywords: FPM, ODE, Estimation, Semi-batch Reactors, Model Validation.

1. Introduction

Mathematical models can be built to describe various dynamic behaviors taking place in systems of continuous, batch or semi-batch processes. A ruthenium semi-batch reactor is such a system for which a mathematical model can be developed. Ruthenium is a precious metal, an element of the platinum group metals (PGMs). It is regarded as a specialty product and often processed in batch or semi-batch reactors, operating sequentially through the phases of heating, reaction, cooling and filtering. Modeling the ruthenium reactor involves capturing such reaction dynamics that are descriptive of the operation of a semi-batch reactor.
Two types of models are commonly developed and used. They are empirical models (EM) and first-principles models (FPM). The former are generated by fitting a polynomial algorithm to a set of data, using model identification techniques provided by commercial software packages. The latter are developed by capturing dynamic behaviors describing their systems. This is done by applying the principles of conservation laws of mass and energy balances in the mathematical formulations of either ODEs or DAEs. Those models are built and solved in numerical platforms, their formulation, development and numerical integration can become more difficult with large and complex systems (Pantelides and Renfro (2013)).

Although first-principles modeling of batch and semi-batch reactors have been well addressed in the scientific literature, there is still little work that has been published on PGMs related processes. However, all dynamic FPMs of batch and semi-batch reactors are based on the same mathematical principles regardless of the process recipe. Nyström (2007) has reported that processes are mod-

eled using DAEs or ODEs, consisting of differential equations that describe the dynamic behavior of the system, as mass and energy balances, and algebraic equations that ensure physical and thermodynamic relations. The same mathematical principles have been reported on by Prokopová and Prokop (2009). FPMs have been developed and validated to predict temperature behaviour of an industrial, semi-batch, emulsion polymerization reactor (Hvala and Kukanja (2013), Hvala et al. (2011)).

2. System Description

The system is a jacketed semi-batch reactor (see Figure 1), in which two exothermic reactions take place simultaneously, according to the following chemical equations of reactions.

$$Ru(s) + Cl_2(g) \rightarrow 2RuCl_3(l) \quad (1)$$

$$2H_2O(l) + 2RuCl_3(l) + 2NaClO_3(l) \rightarrow 4HCl(l) + 2RuO_4(g) + Cl2(g) + 2NaCl(l) \quad (2)$$

Steam and cooling water are the hot and cold utilities used to regulate the temperature conditions of the reactor during the process. The first reaction (Eq.1), describes the dissolution of solid ruthenium (Ru) in the presence of chlorine ($Cl_{2(g)}$) to produce ruthenium tri-chloride ($RuCl_{3(l)}$). The second reaction (Eq.2) describes the evaporation of $RuCl_{3(l)}$ in the presence of sodium chlorate ($NaClO_{3(l)}$), used as the oxidizing agent, to produce ruthenium tetroxide ($RuO_{4(g)}$) as the main product, sodium chloride ($NaCl_{(l)}$) and Hydrochloric acid ($HCl_{(l)}$) as by-products.

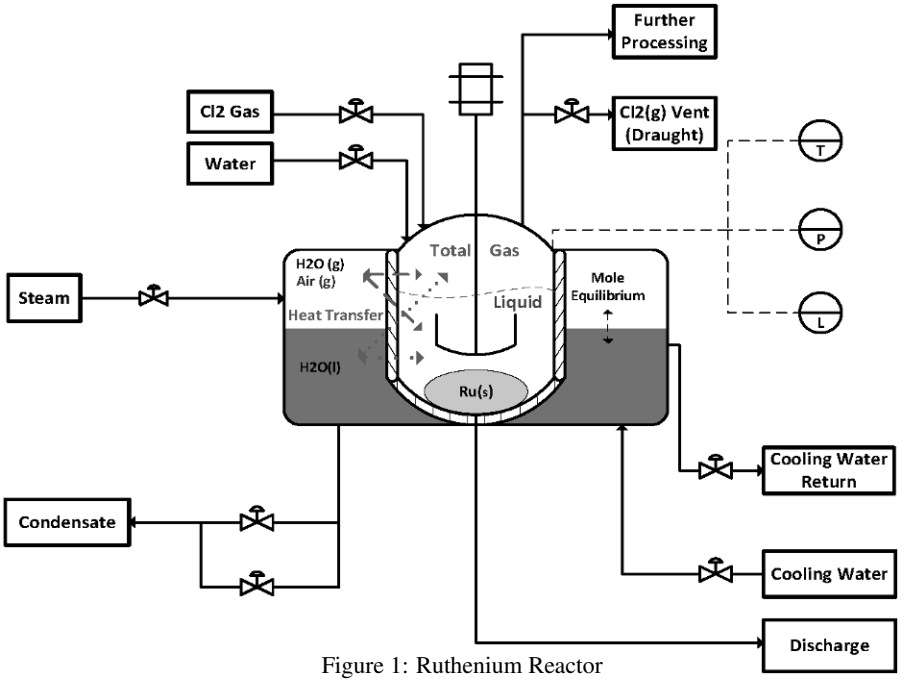

Figure 1: Ruthenium Reactor

The process takes place in five phases. The first phase involves loading the reactor with $H_2O_{(l)}$, $Ru_{(s)}$ and catalyst $NaClO_{3(l)}$. The second phase involves heating the reactor up to a temperature of about 40 $^{\circ}C$ by introducing steam into the jacket. The third phase is the chlorination, where $Cl_{2(g)}$ is added into the reactor and dissolves into water to react with $Ru_{(s)}$. $Cl_{2(g)}$ is also used to maintain the reaction pressure condition to the required operational level of $\pm$ 400 kPa. At this point the reaction phase starts, steam is cut off and the exothermic reactions proceeds. The last phase involves cooling the reactor by pumping cooling water into the jacket at the end of the batch. The phases of heating, cooling and chlorination take place simultaneously with the reaction phase. Utilities are pumped alternately into the jacket to regulate the reaction temperature such that there be no temperature runaways, leading to potentially dangerous situations.

3. Model Development

The mathematical model of the reactor was developed with respect to the chemical reactions of Eq.1 and Eq.2. Those reactions were modeled primarily to lump the reaction heat to be handled and the transport dynamics between the jacket and reactor compartments. In the system, temperature and pressure are the most important variables for the initial control situation.The model was developed and implemented in the "Matlab" computational environment.

3.1. Explicit ODE Model

The equations were written as an explicit system of ODEs, with a total of 115 equations describing the system, of which, 18 are differential equations and 97 algebraic equations. They were written for the solid, liquid, and gas phases. Ru is the solid specie. H_2O, Cl_2, $RuCl_3$, HCl, $NaClO_3$ and NaCl are in the liquid phase, and H_2O, Cl_2, RuO_4 are in the gas phase. Matlab solver "Ode15s" was used for numerical integration.The model was subject to the following assumptions:

- The reactor solution is perfectly mixed.
- There is negligible heat loss to the surroundings.
- The solutions are ideal (i.e molar concentrations considered instead of activity coefficients).
- Ionic species do not contribute to volume but do contribute to density.
- There is a mixed phase (liquid and gas) into the jacket compartment at all times.
- The dynamics of the reactor wall are neglected, to enhance direct heat transfer.

The model parameters of heat and mass transfers coefficients, as well as reaction kinetic constants were estimated by trial-and-error, as no experimental values of those were available, and no generic method of tuning them has been developed at this point.

3.2. Model Differential Equations

Due to the size of the model, with 115 equations, which cannot all be presented in this document, the equations are mostly presented in the liquid phase, and give the general formulation used to derive the model dynamics, in both compartments, for all species and phases involved.

Moles in Reactor:

$$\frac{dN_{Ru_{(s)}}}{dt} = F^{In}_{Ru_{(s)}} - F^{Out}_{Ru_{(s)}} - r_1 V_{rx_{(g)}} \tag{3}$$

$$\frac{dN_{i_{(l)}}}{dt} = F^{In}_{i_{(l)}} - F^{Out}_{i_{(l)}} \pm F_{i_{(l-g)}} \pm x^{r1}_i \cdot r_1 V_{rx_{(g)}} \pm x^{r2}_i \cdot r_2 V_{rx_{(l)}} \tag{4}$$

Temperatures in Reactor:

$$\frac{dT_{rx_{(l)}}}{dt} = \frac{1}{Cp^{rx}_l \cdot N^{tot}_{rx_{(l)}}} \times \left(\sum_{Reaction,\, i} \left((-r_1 V_{rx_{(g)}} + r_2 V_{rx_{(l)}}) \times Cp^{i_{(l)}} \Big|_{T_{rx_{(l)}}} \dots \right. \right. \tag{5}$$

$$\left. \left. \times (T_{rx_{(l)}} - T_{ref}) \right) + H_{rx_{(l-l)}} + H_{rx_{(g-l)}} \right)$$

$$\frac{dT_{rx_{(g)}}}{dt} = \frac{1}{Cp^{rx}_g \cdot N^{tot}_{rx_{(g)}}} \times \left(F^{In}_{Cl_{2(g)}} \cdot Cp^{Cl_{2(g)}} \Big|_{T^{In}_{rx_{(g)}}} \times (T^{In}_{rx_{(g)}} - T_{ref}) \dots \right. \tag{6}$$

$$\left. - \sum_{\substack{Outlet \\ streams,\, i}} \left(F^{Out}_{i_{(g)}} \cdot Cp^{i_{(g)}} \Big|_{T_{rx_{(g)}}} \times (T_{rx_{(g)}} - T_{ref}) \right) + H_{rx_{(g-g)}} + H_{rx_{(l-g)}} \right)$$

Moles in Jacket:

$$\frac{dN_{H_2O_{(l)}}}{dt} = F^{In}_{CW} - F^{Out}_{CW} - F_{H_2O_{(l-g)}} \tag{7}$$

$$\frac{dN_{H_2O_{(g)}}}{dt} = F^{In}_{Steam} - F^{Out}_{Steam} + F_{H_2O_{(l-g)}} \tag{8}$$

Temperatures in Jacket:

$$\frac{dT_{hx_{(l)}}}{dt} = \frac{1}{Cp_l^{hx} \cdot N_{hx_{(l)}}^{tot}} \times \Bigg((F_{CW}^{In} + F_{Steam}^{In}) \cdot Cp^{H_2O_{(l)}} (T_{hx_{(utility)}}^{In}) \times \ \ldots \tag{9}$$

$$(T_{hx_{(utility)}}^{In} - T_{ref}) - (F_{CW}^{Out} + F_{Steam}^{Out}) \cdot Cp_l^{hx} \times (T_{hx_{(l)}} - T_{ref}) \ \ldots$$

$$+ F_{H_2O_{(l-g)}} \cdot H_v^{H_2O}(T_{hx_{(l)}}) - H_{rx_{(l-l)}} \Bigg)$$

3.3. Model Algebraic Equations

A total of 97 algebraic equations were solved simultaneously with the 18 differential equations. The general formulation of the key algebraic equations are presented for the reactor compartment of the system only. The corresponding equations, in the jacket, were derived similarly.

3.3.1. Reactor Side

Total Moles:

$$N_{rx_{(l)}}^{tot} = \sum_{Species,\, i} N_{i_{(l)}} \tag{10}$$

Volumes:

$$V_{rx_{(l)}}^{tot} = \sum_{Species,\, i} \frac{N_{i_{(l)}}}{\rho_{i_{(l)}}\big|_{T_{rx_{(l)}}}} \tag{11}$$

Pressures:

$$P_{rx_{(g)}}^{tot} = \frac{N_{rx_{(g)}}^{tot} \times R \times T_{rx_{(g)}}}{V_{rx_{(g)}}^{tot}} \tag{12}$$

$$P_{rx_{(l)}}^{tot} = \rho_{rx_{(l)}} \times \mathrm{g} \times h_{rx_{(l)}}^{eq} + P_{rx_{(g)}}^{tot} \tag{13}$$

Flow rates of Phase Changes in H_2O & Cl_2: (14)

$$F_{i_{(l-g)}} = k_i \times (P_{i_{(l)}} - P_{i_{(g)}}) \tag{15}$$

Rates of Reactions:

$$r_1 = k_{r1} \times C_{Cl_{2(g)}} \tag{16}$$

$$r_2 = k_{r2} \times C_{RuCl_{3(l)}} \times C_{NaClO_{3(l)}} \tag{17}$$

Heat Transfers from Liquid in Jacket to Liquid in Reactor:

$$H_{rx_{(l-l)}} = (h_{rx_{(s)}} + h_{rx_{(l)}}) \times (2 \cdot \pi) \times (r_{rx} + w_{rx}) \times U_{l-l} \times (T_{hx_{(l)}} - T_{rx_{(l)}}) \tag{18}$$

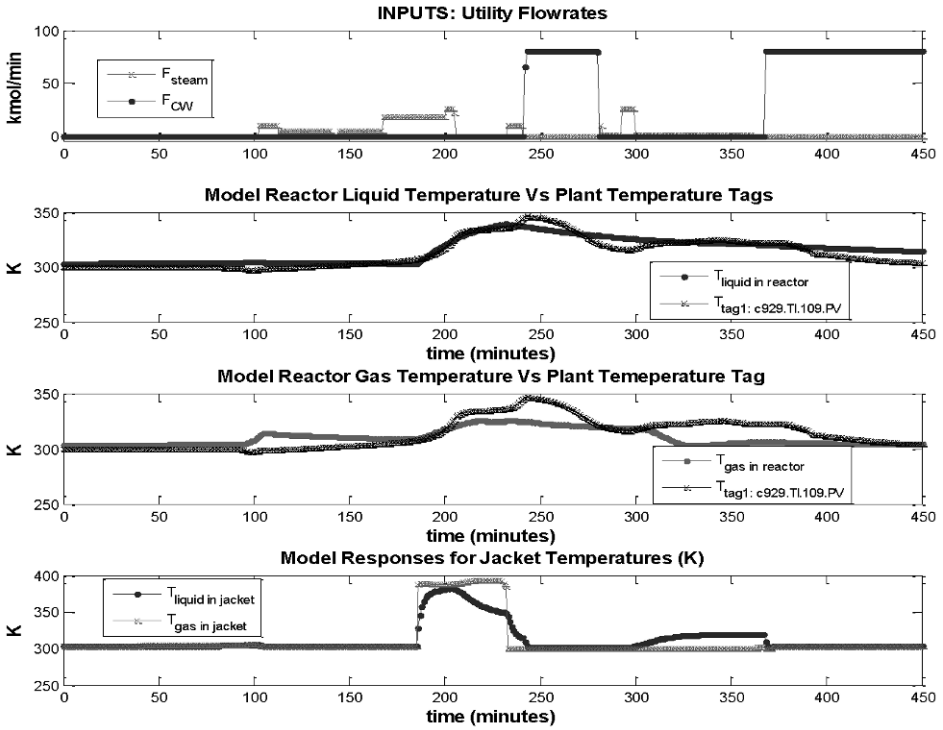
A total of four additional relations, similar to Equation 18, are calculated to account for the cross-phase heat transfer between the two compartments. From liquid in jacket to solid and gas in reactor, then from gas in jacket to liquid and gas in reactor.

4. Results and Discussion

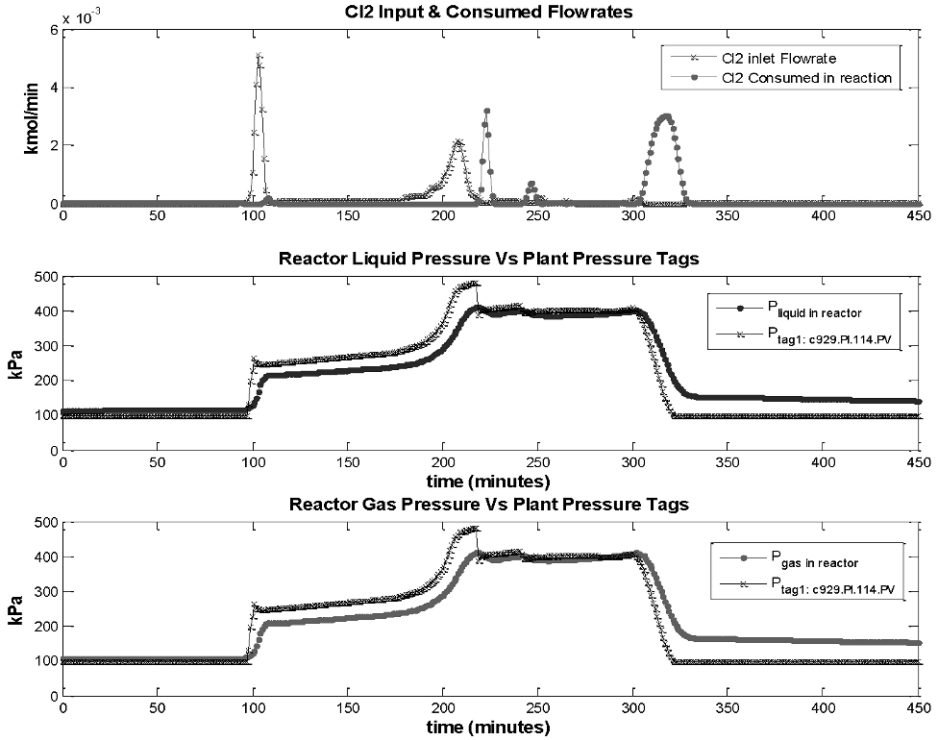
Simulating the model, the generated responses of temperature and pressure showed some good tracking of the batch data set they were compared to (see Figure 2). The model parameters were tuned by trial-and-error with a single batch run. A total of 28 different batches were simulated with those same parameters as the estimation could not be repeated for all batches.

4.1. Explicit Model Simulations

Figure 2a shows the model temperatures responses against the temperature data of a selected batch. In this simulation, steam and cooling water were supplied at the temperatures of 115 $^{\circ}C$ and 27 $^{\circ}C$, respectively. The reactor model was set at a steady state temperature of 30 $^{\circ}C$. The first subplot (top graph), shows the molar flow rates of the utilities pumped into the jacket. The second and third subplots (counting from top), demonstrate good tracking of batch data by the simulated temperatures responses. The bottom figure shows the dynamics of temperatures in the jacket of the reactor model, when subjected to the utility inputs.



(a) Model Temperatures against Temperature Data



(b) Model Pressures against Pressure data

Figure 2: Temperature and Pressure responses

Figure 2b shows the model pressure responses against the pressure data of the same batch. During the reaction, the required pressure condition inside the reactor is achieved and maintained by pumping Cl_2 gas into the reactor, at variable time intervals. The top graph of Figure 2b shows the Cl_2 (g) flow rate into to the reactor model and the amount of Cl_2 (g) consumed as the reaction proceeds. The second and third graphs, from the top, show the liquid and gas pressures of the reactor model, respectively. The model responses show a similar trend to that of the pressure data set ($P_{tag1:\ c929.PI.114.PV}$), although the pressure simulated responses do not track the pressure data very closely as some offset can be seen between the two.

5. Conclusions

We have developed a first-principle mathematical model of a ruthenium reactor. The aim of this work was to develop a model that could achieve good predictions of temperature and pressure dynamics of the real reactor. The parameters of heat and mass transfer coefficients, together with the reaction kinetic constants were estimated by trial-and-error. However, a more systematic method of parameterization is being developed, such that optimum parameters could be computed repeatedly as the model is run with various batches. The validation work, for better responses, is still in progress.

Nomenclature

C = Molar concentration
C_p = Specific heat capacity at constant pressure
CW = Cooling Water
H = Enthalpy
H_v = Heat of vaporization
hx = Jacket compartment
h_{rx} = Height of reactor vessel
i = A given specie
k_i = Mass transfer coefficient of a given specie
k_{r1} = Kinetic constants of reaction 1
$N_{Ru_{(s)}}$ = Moles of ruthenium solid
$N_{i_{(l)}}$ = Moles of specie in liquid phase
r1 = Reaction 1
r_1 = Rate of reaction1
rx = Reactor compartment
r_{rx} = Radius of reactor vessel
T_{ref} = Reference temperature
U = Heat transfer coefficient
w_{rx} = Thickness of reactor wall
x_i^{r1} = Stoichiometric constant of specie (i) in reaction 1

Abstract

This work focuses on the dynamic modelling of a Pilot-scale Tubular Reactor (PTR) for the pre-treatment of lignocellulosic materials (LCM), with three main process stages: extrusion, autohydrolysis and steam explosion. The reactor was modelled as an arrangement of Continuous Stirred Tank Reactors (CSTR), in order to have the residence time (τ) as an explicit variable, to be used as input variable in the associated control scheme. This dynamic model also takes into account the production of intermediate oligosaccharides as well as of acetyl-compounds in the reaction rates. The model performance was validated with experimental data, consisting of concentration profiles of hemicellulose, cellulose, glucose and xylose in the PTR outlet stream, as well as temperature and acidity profiles. The proposed model is able to describe the dynamic behaviour of the PTR at 160 ºC and 75 psig, within reasonable tolerances.

Keywords: lignocellulosic material, autohydrolysis, pilot-scale reactor.

1. Introduction

The production of ethanol and other products from lignocellulosic materials (LCMs) is attracting great interest due to their low cost and vast availability. These raw materials represent an attractive source of fermentable sugars; nonetheless, their complex chemical structure makes it difficult to extract them from the lignocellulosic matrix. Traditionally, the ethanol production process from LCMs using biochemical platforms consists of four stages; pretreatment, enzymatic hydrolysis, fermentation and separation. The overall performance of this process depends highly on the pretreatment stage, due to its effect on the cellulose and hemicellulose accessibility in the LCM matrix for the enzymatic hydrolysis. This accessibility directly impacts on the process yields and costs (Mosier, et al., 2005).

There are several LCMs pretreatment alternatives consisting on physical, chemical and biological treatments aiming to improve the performance of the enzymatic hydrolysis stage of the ethanol production process. Physical treatment includes size reduction techniques and extrusion, which have been studied in order to improve the carbohydrates release from the biomass (Karunanithy, et al., 2008). Chemical treatments

consist mainly on the addition of alkalis or acids that perform a partial LCM hydrolysis. However, fermentation inhibiting products may be formed, and reactor corrosion may be a serious issue in the case of acid treatment (Saha, et al., 2005). Another physico-chemical treatment that greatly improves the process overall performances is the steam explosion. In steam explosion, LCM undergoes a treatment with high pressure steam, followed by a violent depressurization. The high temperatures promote acetic acid formation, which partially hydrolyses the biomass, and the depressurization process manages to separate its fibres (Pan, et al., 2005). Aiming to optimize the LCM pre-treatment performance without adding acids or alkalis under a continuos operation strategy, a pilot-scale tubular reactor for continuous wheat straw pre-treating was constructed.. The reactor design involves the sequential use of the extrusion, thermal hydrolysis and steam explosion techniques.

LCM hydrolysis models have been developed for batch reactors, but most of these models are not fully scalable because heat and mass transport phenomena, which are important in larger-than-bench scales, are usually not considered. Hence, the necessity of extending them for continuous reactor schemes. These kinetic studies involve first order pseudo-homogeneous kinetics (Mittal, et al., 2009), with Arrhenius temperature dependence, (Zhuang, et al., 2009). Other models make use of a severity factor R_0 (Overend, et al., 1987) to take into account the empiric measured effects, but fail to adequately describe the rise in saccharides concentrations caused by temperature changes (Kabel, et al., 2007). Other effects that are also considered in these kinetic models are the formation of acetic acid from acetyl groups, and its role in LCM autohydrolysis (Sidiras, et al., 2011).

This work focuses on the analysis and characterization of the continuous PTR for LCM pre-treatment, in which a sequence of extrusion, thermal hydrolysis and steam explosion processes takes place. As a first attempt at process modelling, thePTR was modelled as an arrangement of Continuous Stirred Tank Reactors (CSTR), in order to have the residence time (τ) as an explicit variable to be used as input variable in the design of the associated controller law. Model validation was performed with experimental data consisting on cellulose, hemicellulose, xylose and glucose concentration profiles in the reactor outlet stream, as well as its temperature and pH. This model is a first modelling attempt, aiming to define the role of each type of pre-treatment that takes place in the reactor, to define whether a more complex model is needed or not.

2. Pretreatment reactor modelling

2.1. Experimental reactor

Wheat straw pretreatment was performed in the PTR (3 meters long, 10 cm. diameter) at 160 ºC and 90 psig steam pressure. LCM with a particle size of 1.19 mm is fed to the PTR by an arrangement of hydraulic pistons that form a compact “wheat straw plug”, managing to maintain the inner pressure, and performing the extrusion pretreatment. After this, the wheat straw goes into the main reactor body, where it is heated with saturated steam at 160 ºC, and is transported through it by a screw conveyor. Finally, at the end of the tubular reactor, the LCM enters a chamber, where a set of automatic valves perform the steam explosion, while the main reactor body remains pressurized. The residence time inside the reactor can be manipulated between 50 to 10 minutes by

controlling the screw conveyor motor speed. In order to capture the dynamic behaviour of the reactor, experiments were performed applying step changes to the residence time.

2.2. Kinetic model

The tubular reactor kinetic characterization is based on the kinetic model presented by Sidiras, et al., (2011). This model considers the cellulose and hemicellulose hydrolysis to oligosaccharides, and then to glucose and xylose respectively. Acid activity is considered to change, mainly by the formation of acetic acid, produced from the acetyl groups in the LCM. This kinetic model is based on the following set of stoichiometric reactions:

$$RRH \xrightarrow{k_{H1}} WSOH \xrightarrow{k_{H3}} xylose \xrightarrow{k_{H4}} furfural \quad (1)$$

$$ERH \xrightarrow{k_{H2}} WSOH \xrightarrow{k_{H3}} xylose \xrightarrow{k_{H4}} furfural \quad (2)$$

$$CC \xrightarrow{k_{C1}} WSOC \xrightarrow{k_{C3}} glucose \xrightarrow{k_{C4}} HMF \quad (3)$$

$$AC \xrightarrow{k_{C2}} WSOC \xrightarrow{k_{C3}} glucose \xrightarrow{k_{C4}} HMF \quad (4)$$

$$AG \xrightarrow{k_A} AA \quad (5)$$

Where *RRH* stands for reaction resistant hemicellulose, *WSOH* for water soluble oligosaccharides from hemicellulose, *ERH* for easy reaction hemicellulose, *CC* for crystalline cellulose, *WSOC* for water soluble oligosaccharides from cellulose, *HMF* for hydroxymethyl furfural, *AC* for amorphous cellulose, *AG* for acetyl groups and *AA* for acetic acid.

First order kinetics are considered for the autohydrolysis of cellulose, hemicellulose and oligosaccharides, while the acidity kinetics are a first order function of acidity and the acidity at $t \to \infty$. Equations 6 through 12 describe the kinetic behaviour of the LCM autohydrolysis, where $i = C$ for cellulose hydrolysis, $i = H$ for hemicelluloses hydrolysis, $j = 1, 2, 3$ or 4; p_{ij} and E_{ij} are the pre-exponential factor (min^{-1}) and the activation energy (kJ/mol), respectively; a is the activity of the acids produced during the autohydrolysis, while a_∞ is the value for a for $t \to \infty$; A is the subscript for activity. All concentration values C_{ij} in this model are expressed in w/w units, based on the initial quantity of dry components in the reacting system. The rate constants k_{ij} were expressed in min^{-1}, the reaction time in minutes, and the temperature T in K. Table 1 contains the kinetic parameter values of this model.

$$r_{i1} = dC_{i1}/dt = -k_{i1}\, C_{i1} \quad (6)$$

$$r_{i2} = dC_{i2}/dt = -k_{i2}\, C_{i2} \quad (7)$$

$$r_{i3} = dC_{i3}/dt = k_{i1}\, C_{i1} + k_{i2}\, C_{i2} - k_{i3}\, C_{i3} \quad (8)$$

$$r_{i4} = dC_{i4}/dt = k_{i3}\, C_{i3} - k_{i4}\, C_{i4} \quad (9)$$

$$r_A = da/dt = k_A\, (a_\infty - a) \quad (10)$$

$$k_{ij} = p_{ij}\, a\, e^{-E_{ij}/RT} \quad (11)$$

$$k_A = p_A\, e^{-E_A/RT} \quad (12)$$

Table 1. Kinetic parameter for the lignocellulosic material (LCM) autohydrolysis

Kinetic parameters			
Component	ij	Frequency factor p_{ij} (min^{-1})	Activation Energy E_{ij} (kJ/mol)
Crystalline cellulose	C1	7.82×10^{14}	116.4
Amorphous cellulose	C2	5.22×10^{15}	116.4
WSOC	C3	1.40×10^{17}	125.0
Glucose	C4	1.23×10^{20}	164.0
RRH	H1	1.93×10^{15}	104.0
ERH	H2	1.40×10^{16}	104.0
WSOH	H3	4.30×10^{21}	156.5
Xylose	H4	4.50×10^{29}	232.5
pH	A	1.89×10^{4}	58.0

2.3. PTR model

Regardless that the reactor can be described by a traditional plug flow reactor (PFR) model, assuming that the reaction takes place in the main body of the reactor (substracting the spaces occupied by the screw conveyor and all the empty spaces on the porous LCM matrix), a simpler approach is herein proposed. A model based on a series of continuous stirred tank reactors (CSTR) was developed, in order to have the residence time (τ) as an explicit variable to be manipulated in the design of the associated control scheme. This model takes into account the kinetic model described in the previous section. The extrusion and steam explosion stages are not considered in this approach, due to the inherent difficulties in their modelling. Equation 13 describes the dynamic behaviour of the concentration of the species involves in each of the CSTR's.

$$\frac{dC_{ij,k}}{dt} = \frac{1}{\tau_k}\left(C_{ij,k-1} - C_{ij,k}\right) + r_{ij.k} \tag{13}$$

where τ_k is the residence time in each of the CSTR's, and is a result of dividing the overall process residence time by the total number or CSTRs n; k is the number of each reactor in the sequence, where $k = 0$ correspond to the different concentrations in the inlet stream.

2.4. Experimental set up

First, the wheat straw size was reduced to 1.19 mm, and then it was fed into the reactor at a continuous rate of 325 g/h, during 310 minutes. The LCM at the outlet stream was sampled every 10 minutes, and the solids were separated from the extract. *pH* measurements in the extract were performed with a ORION STAR A211 *pH* meter. Glucose and xylose concentration were measured with a biochemistry analyzer YSI 2700D Select. In the case of oligosaccharides, a second hydrolysis of the extract was carried out, now with sulfuric acid (4% v/v) at 121 °C for 1h.The hydrolizates were

analyzed with the YSI; the initial oligosaccharides concentration on the extract is subtracted to this reading. Finally, the extract was subject of one last acid hydrolysis stage, now with sulfuric acid (72% v/v), for 30 minutes at 30 °C, and then the monosaccharides concentration was measured; stoichiometric relations were used to calculate the hemicellulose concentration.

Table 2. Composition of Wheat Straw

Component	% w/w [a]	Component	% w/w [a]
Cellulose	32.7	Acid - insoluble lignin	16.8
Hemicelluloses	24.5	Ashes	4.7
Xylose	19.3	Extractives	6.2
Arabinose	2.7	Acid – soluble components	15.1
Acetyl groups	2.5	Cellulose degree of crystallinity	79.5
Reaction - resisting hemicelluloses	32.6		

[a] (% dry weight)

3. Results and Discussion

The composition of the wheat straw was taken from Sidiras (2011), shown in Table 2. These concentrations were used as the inlet composition in the autohydrolysis model (Eq. 6-13), and simulations were made under non-isothermal reaction conditions. First, simulation runs were performed varying the number of total CSTR's, in order to determine the number of tanks that can describe the tubular reactor behaviour within reasonable tolerance. Experiments were carried out with residence time set to a fixed value, until the steady state was reached; then a step perturbation was induced to the screw conveyor motor speed, in order to increase (or decrease) the residence time, and reach another steady state. Since discrete temperature and *pH* measurements were performed, interpolated profiles of these two variables were used on the respective simulations. Even when the experimental concentration profiles were somewhat irregular, the 4 CSTR's model was able to reproduce the tubular reactor dynamics within reasonable tolerances, as shown on Fig. 2. The irregular flow of the wheat straw inside the tubular reactor leaves empty spaces in the LCM bed, due to the screw conveyor speed. These irregularities on the tubular reactor flow, and some temperature fluctuations may cause the oscillations on the concentration profiles.

4. Conclusions

A first attempt to obtain a dynamic model for lignocellosic material (LCM) pretreatment in a pilot-scale tubular reactor was developed. This model is based on a kinetic model for wheat straw autohydrolysis with steam at 160 °C, and the approximation of a tubular reactor behaviour by an arrangement of continuous stirred tank reactors in series. This approximation describes, within reasonable tolerances, the dynamic behaviour of an experimental pilot scale reactor. The empty spaces inside the reactor body, may cause irregularities on the mass flow, which partially explains the differences between the experimental concentration profiles and the models dynamic response.. At these low

temperatures, the extrusion and steam explosion stages present low, if no contribution to the pre-treatment process, so it is not necessary to develop more complex models. It is expected that at higher temperatures, the contribution of these two pretreatment steps, play a greater role, and a more complex model is therefore needed.

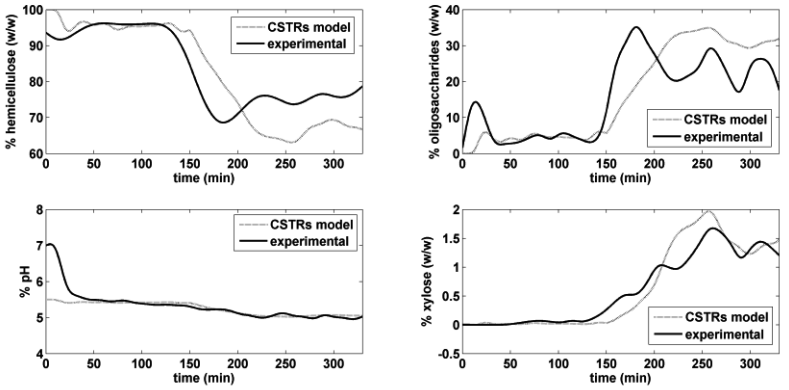

Figure 1. Experimental vs model concentration profiles: hemicellulose (top-left), oligosaccharides (top-right), pH (bottom-left) and xylose (bottom-right).

Abstract

Process/model mismatch may arise when a first-principles model is challenged against historical experimental data. In this study, a methodology recently proposed to diagnose the root cause of the mismatch in continuous processes is extended to batch systems, taking a batch drying process as a case study to test the proposed methodology. The likely sources of the mismatch are identified using a multivariate statistical model and analyzing the model residuals as well as the scores shifts. Two simulated examples demonstrate the effectiveness of the proposed methodology.

Keywords: process/model mismatch, PCA, batch processes, latent variable models

1. Introduction

When a first principles (FP) model is challenged against a historical dataset, the model outputs may not match the historical evidence with the desired accuracy, and process/model mismatch (PMM) occurs. Recently, a methodology has been proposed to diagnose the root causes of PMM (Meneghetti et al., 2014) by exploiting the available historical dataset and a simulated dataset, generated by the FP model using the same inputs as those of the historical dataset. A data-based (DB) model (namely, a multivariate statistical model) is used to analyze the correlation structure of the historical and simulated datasets, and information about from where the PMM originates is obtained using diagnostic indices and engineering judgment. The methodology was developed for continuous processes. However, for batch processes the diagnosis of an observed PMM is more difficult because of the time-varying nature of the measurements, which imply data auto-correlation and cross-correlation, as well as a more strongly nonlinear behavior that may be difficult to capture using a linear multivariate model.

In this study, the PMM diagnosis methodology is extended to batch system, using a simulated semi-batch solids drying process as a test bed. Multi-way principal component analysis (MPCA; Nomikos and MacGregor, 1994) is employed as a DB model, enhancing it with an orthogonal rotation (VARIMAX rotation) of the principal directions (Magnus and Neudecker, 1999; Wang et al., 2005). Two examples are analyzed to discuss the ability of the proposed methodology to point to the FP model sections needing improvement.

2. Case study and available data

A simulated lab-scale drying process is considered, in which hot dry air flows through a bed of wet solid alumina granules, partially evaporating the water contained in the particles. The model equations derive from the work of Burgschweiger and Tsostas (2002), and are solved in the gSOLIDS® modeling environment (gSOLIDS®, 2014). The particle size distribution is discretized in 10 bins and no shrinkage of particles is considered. The global massand energy balances for the particulate phase and vapor phase (indicated by subscripts *p* and *vap*, respectively)are:

$$\frac{dM_{i,p}}{dt} = F_p^{in} x_{i,p}^{in} - F_p^{out} x_{i,p}^{out} - R_{drying,i,p} \;,\; \frac{dH_p}{dt} = F_p^{in} h_p^{in} - F_p^{out} h_p^{out} - \Delta H_{drying,p} \quad (1)$$

$$\frac{dM_{i,vap}}{dt} = F_{vap}^{in} x_{i,vap}^{in} - F_{vap}^{out} x_{i,vap}^{out} + R_{drying,i,p} \;,\; \frac{dH_{vap}}{dt} = F_{vap}^{in} h_{vap}^{in} - F_{vap}^{out} h_{vap}^{out} + \Delta H_{drying,p} \quad (2)$$

Where F is the mass flowrate, h is the specific enthalpy,x_i is the mass fraction of species i in the solid phase (alumina or water) or in the vapor phase (dry air or water), and superscripts *in* and *out* refer to the bed inlet and outlet, respectively. The drying rate $R_{drying,i,p}$ is given by:

$$R_{drying,i,p} = A_p \nu_i \rho_i k_{c,i} \left(Y_{eq,i} - Y_{bulk,i} \right), \quad (3)$$

And $\Delta H_{drying,p}$ is the enthalpy change rate due to drying. In (3), A_p is the particle surface area available for drying, ρ_i is the density of the gas phase, k_c is the mass transfer coefficient, and $Y_{eq,i}$ and $Y_{bulk,i}$ are respectively the equilibrium and actual dry-basis moisture content of the water in the gas phase. Finally, v_i is the normalized single-particle drying rate, which can be estimated from the experimental drying curve. The latter is a function of the normalized moisture content η_i, which is in turn calculated from the dry basis moisture content X_i, the equilibrium dry-basis moisture content $X_{eq,I}$ (which is a function of the relative humidity ϕ_i), and the critical dry basis moisture content $X_{cr,i}$. Details on the values of model parameters are reported in the original work of Burgschweiger and Tsostas (2002). This FP model will be referred to as "the process" in the following.

A set of $N = 25$ batches, representing the historical dataset, are simulated using different combinations of the following measurable inputs: inlet solid mass flowrate (F_p^{in}), initial moisture content (X^{in}), inlet mass flowrate (F_{vap}^{in}), and air temperature (T_{vap}^{in}). It is assumed that four measurable outputs exist: moisture content in the granules (X_i), granules temperature (T_p^{out}), outlet air temperature (T_{vap}^{out}), and outlet air relative humidity (ϕ_i). The batch length is 1420 s and the measurement interval is 30 s; hence, T=48 samples are available for each measured variable in each batch.

The PMM diagnosis methodology is tested by considering two process models that use the same set of equations as described above, but where two different parametric mismatches are purposely introduced. These sets of equations and (wrong) parameters will be referred to as "the model" in the following.

3. Proposed methodology

In order to diagnose the root-cause of an observed PMM, the framework proposed by Meneghetti et al. (2014)is applied. However, appropriate adjustments are introduced to deal with batch data. According to the proposed rationale, a DB model (namely, a latent variable model) is first developed to model the correlation structure of appropriate combinations of the simulated process variables, these combinations being suggested by the FP model structure. Then, it is assessed whether the combinations of the same variables, but calculated from the historical measurements, conform to this correlation structure. Finally, from the analysis of some model diagnostic indices, engineering knowledge is used pinpoint the FP model sections that are mostly responsible for the observed PMM. In detail, the following steps are followed (subscripts Π and M refer to the process and to the model, respectively).

1. Auxiliary data designation. A set of $C = 9$ auxiliary variables is defined considering the modele quation terms that, according to engineering judgment, are expected to be possibly related to the observed PMM:

$$\begin{aligned} u_1(n,t) &= A_P & u_4(n,t) &= \eta_i & u_7(n,t) &= T^{vap} \\ u_2(n,t) &= v_i & u_5(n,t) &= k_{c,i} & u_8(n,t) &= X_i \\ u_3(n,t) &= X_{eq} & u_6(n,t) &= \alpha_i & u_9(n,t) &= \phi_i \end{aligned} \tag{4}$$

   Where element (n, t) of the $[N\times T]$ matrix $\mathbf{U}_c$ is indicated by $u_c(n,t)$ and represents the c-th auxiliary variable evaluated at time t for batch n.In (4), i refers to water and α is the heat transfer coefficient involved in the calculation of the energy balances. The simulated and historical datasets are separately used to estimate the values of the auxiliary variables. The values taken by the auxiliary variables throughout the whole batches are arranged in the $[N\times C\times T]$ arrays $\underline{\mathbf{U}}_{\mathrm{M}}$ and $\underline{\mathbf{U}}_{\Pi}$, which are the model matrix and the process matrix, respectively.
   Note that the values taken by some auxiliary variables (u_1, u_2, u_4, u_5 and u_6) are bin-dependent. However, only the bin including the largest number of particles is considered for their calculation. Also note that variables T^{vap}, X_i and ϕ_I(which can be measured) are purposely included in the auxiliary variable set (u_7, u_8 and u_9) to make the available measurements directly affect the correlation structures of $\underline{\mathbf{U}}_{\mathrm{M}}$ and $\underline{\mathbf{U}}_{\Pi}$.
2. Data-based model development. An MPCA model (Nomikos and MacGregor, 1994) is built from $\underline{\mathbf{U}}_{\mathrm{M}}$. MPCA is equivalent to performing PCA (Jackson, 1991) on the $[N\times(C\cdot T)]$ matrix$\mathbf{U}_{\mathrm{M}}$obtained by unfolding $\underline{\mathbf{U}}_{\mathrm{M}}$ batch-wise. Also $\underline{\mathbf{U}}_{\Pi}$ is unfolded (to $\mathbf{U}_{\Pi}$), and both $\mathbf{U}_{\mathrm{M}}$ and $\mathbf{U}_{\Pi}$ are autoscaled on the mean and standard deviation of $\mathbf{U}_{\mathrm{M}}$. PCA decomposes $\mathbf{U}_{\mathrm{M}}$ as the sum of A scores $\mathbf{t}_i$ and A loadings $\mathbf{p}_i$, where A is the number of principal components (PCs) that describe an adequate percentage of the dataset variability:

$$\mathbf{U}_{\mathrm{M}} = \mathbf{t}_{1,\mathrm{M}}\mathbf{p}_{1,\mathrm{M}} + \mathbf{t}_{2,\mathrm{M}}\mathbf{p}_{2,\mathrm{M}} + \cdots + \mathbf{t}_{A,\mathrm{M}}\mathbf{p}_{A,\mathrm{M}} + \mathbf{E}_{\mathrm{M}} = \mathbf{T}_{\mathrm{M}}\mathbf{P}_{\mathrm{M}}{}^{\mathrm{T}} + \mathbf{E}_{\mathrm{M}}, \tag{5}$$

   where $\mathbf{T}_{\mathrm{M}}$ $[N\times A]$ is the scores matrix and $\mathbf{P}_{\mathrm{M}}$ $[(C\cdot T)\times A]$ is the loadings matrix.
   In both examples,4 PCs are selected. Note however that the selected number of PCs can affect the ability of the methodology to effectively diagnose an observed PMM. How to provide a general guideline for the selection of A is still under investigation.
   In this challenging case study, most of the auxiliary variables are very strongly correlated and provide similar contributions along all latent directions, thus

confounding the analysis. In order to amplify the contribution of each auxiliary variable on one latent direction only, the VARIMAX rotation is applied (Magnus and Neudecker 1999; Wang et al., 2005). This technique uses an orthogonal rotation to transform the MPCA model space so that only a subset of the auxiliary variables show high weight values along each PC. Upon VARIMAX application, the residuals matrix $\mathbf{E}_M$ is not modified, but can be calculated also from:

$$\mathbf{U}_M - \mathbf{T}_{var,M}\mathbf{P}_{var,M}^T = \mathbf{E}_M \,, \tag{6}$$

where $\mathbf{T}_{var,M}$ and $\mathbf{P}_{var,M}$ are (respectively) the scores and loadings matrices obtained by application of the VARIMAX rotation.

3. Process matrix projection. $\mathbf{U}_\Pi$ is projected onto the rotated MPCA model space and the residuals matrix $\mathbf{E}_\Pi$ is calculated as:

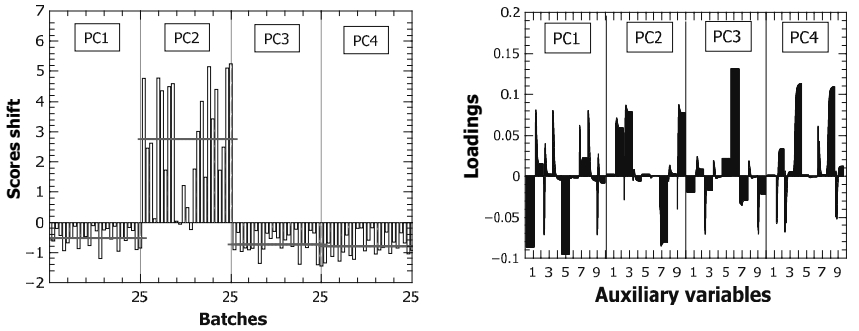
$$\mathbf{T}_{var,\Pi} = \mathbf{U}_\Pi \mathbf{P}_{var,M}\,, \quad \mathbf{U}_\Pi - \mathbf{T}_{var,\Pi}\mathbf{P}_{var,M}^T = \mathbf{E}_\Pi \tag{7}$$

4. Mismatch diagnosis. The mismatch may appear in the MPCA model as a large residual value or as a shift in the scores space (or both). For this reason, a mismatch analysis should evaluate both these aspects.
   The residuals analysis is performed by comparing $\mathbf{E}_M$ and $\mathbf{E}_\Pi$ to identify the auxiliary variables that are most responsible for the inconsistency in the correlation structures of $\mathbf{U}_M$ and $\mathbf{U}_\Pi$. These auxiliary variables, together with engineering judgment, are used to pinpoint which model sections are likely the cause of the observed PMM. In order to reduce the residuals contribution due to the fraction of data variability not described by the MPCA model, the results of residuals analysis are expressed using the mean residuals-to-limit ratio(MRLR), i.e. the mean of the ratios between the residuals of each column of $\mathbf{E}_\Pi$ and the corresponding 95 % confidence limit, calculated considering a normal distribution of the residuals for each variable (Choi and Lee, 2005;Meneghetti et al.,2014).
   An analysis of the scores shift can be performed by jointly analyzing $\mathbf{T}_{var,M}$, $\mathbf{T}_{var,\Pi}$ and $\mathbf{P}_{var,M}$. For each PC, the scores shift is calculated as $(\mathbf{t}_{a,M,var} - \mathbf{t}_{a,\Pi,var})$, i.e., as the difference between the model matrix scores and the process matrix scores. The rationale beyond this approach is to identify the auxiliary variables that most affect the scores shift. These variables are identified by analyzing the MPCA model loadings along the direction that most contributes to the shift.To this purpose, the use of the VARIMAX rotation is particularly effective, as it allows one to emphasize the contribution of a single auxiliary variable (or very few of them) along each PC.The information obtained by this analysis may reveal particularly useful when a small-dimension historical dataset is available.

4. Results for Example 1

The mismatch is forced by altering the value of the critical moisture content (which is involved in the calculation of η_i) and results in a relative error of 1.6-17 % in the simulated final dry-basis particle moisture content. Hence, to correctly diagnose the PMM, the proposed methodology should point to auxiliary variable $\mathbf{U}_4$.
The residuals analysis (not reported for the sake of conciseness) cannot clearly point to the root cause of the mismatch, since all auxiliary variables have similar and low values of MRLR (high residuals are actually seen in $\mathbf{U}_3$ and $\mathbf{U}_9$, but this happens at the very beginning of the batch only). The scores shift analysis is more effective, instead. Figure 1a reports the scores shifts for each batch together with the mean shifts through

all batches along each PC. By far the largest shifts are seen along PC2; hence, the auxiliary variables having a significant weight along this direction are possibly related to the observed PMM. The $[1\times(C\cdot T)]$ loadings $\mathbf{p}_{a,\mathrm{M,var}}$ are shown as black bars in Figure 1b. It can be seen that PC2 mainly captures the variability due to model terms $\mathbf{U}_2$ and $\mathbf{U}_3$, as well as that due to outputs $\mathbf{U}_7$ and $\mathbf{U}_9$. Hence, further investigation on the FP model should focus on the $\mathbf{U}_2$ and$\mathbf{U}_3$ terms. Model inspection suggests that their values are strongly and directly correlated to $\mathbf{U}_4$. Therefore, according to these considerations, to improve the FP model further investigation on model sections $\mathbf{U}_2$, $\mathbf{U}_3$ and $\mathbf{U}_4$ should be done. The other model sections (including those representing heat and mass transfer phenomena) are not likely sources of the observed PMM.



(*a*) (*b*)

Figure 1.Example 1. (a) Shift of $\mathbf{t}_{a,\mathrm{M,var}}$ from $\mathbf{t}_{a,\Pi,\mathrm{var}}$ for each batch(bars) and mean value of these differences (lines) for each PC. (b) Loadings for each PC obtained by applying the VARIMAX rotation to the MPCA model built on $\mathbf{U}_\mathrm{M}$.

5. Results for Example 2

The mismatch is forced by changing the mass transfer coefficient k_c, and results in a 1.3-37 % error in the simulated final dry-basis particle moisture content. Hence, to correctly diagnose the PMM, the proposed methodology should point to auxiliary variable $\mathbf{U}_5$.

Figure 2a reports the results obtained by the residuals analysis. Although, at the very beginning of the batches, MRLR peaks for auxiliary variables $\mathbf{U}_3$ and $\mathbf{U}_9$,consistently high MRLR values along the entire batch lengths are seen only on $\mathbf{U}_1$, $\mathbf{U}_5$ and $\mathbf{U}_6$. These latter auxiliary variables are therefore regarded as the most responsible ones for the observed PMM. As $\mathbf{U}_1$, $\mathbf{U}_5$ and $\mathbf{U}_6$ refer to the contact area and to the mass and heat transfer coefficients, their values are strongly correlated, so that it is difficult to furtherdiscriminate their contribution to the PMM.

Figure 2b reports the scores shift for each PC. Although the main direction of the scores shift is along PC1, this is clearly not dominant, because significant shifts occur also along the other principal directions. We conclude that several auxiliary variables concur to the shift occurrence, and the scores shift analysis does not effectively identify a likely PMM source.

Summarizing, according to proposed methodology the observed mismatch is not related to model sections $\mathbf{U}_2$, $\mathbf{U}_3$ or $\mathbf{U}_4$. Conversely, model sections $\mathbf{U}_1$, $\mathbf{U}_5$ and $\mathbf{U}_6$ should be investigated to improve the FP model performance.

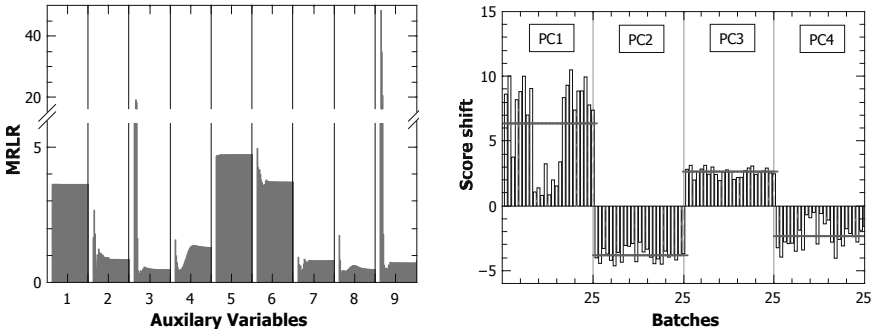


Figure 2. Example 2.(a) MRLR values for each auxiliary variable. (b) Shift of $\mathbf{t}_{a,\mathrm{M,var}}$ from $\mathbf{t}_{a,\Pi,\mathrm{var}}$ for each batch (bars) and mean value of these differences (lines) for each PC.

6. Conclusions

In this study,a recently proposed methodology to diagnose process/model mismatch has been extended to batch systems using a realistic model of a batch drying process as a test bed. The methodology exploits a set of historical data and a simulated dataset, generated by the first-principles model using the same inputs as those of the historical data set. Auxiliary variables were defined as appropriate nonlinear combinations of the model variables and parameters, as well as of process measurements. A multiway principal component analysis model was used to analyze the correlation structure of the historical and simulated data sets. Information on the root cause of the PMM was obtained by the combined analysis of two diagnostic indices: the data-based model residuals and the data-based model scores shifts. With respect to the scores shifts, an orthogonal rotation of the principal axes was carried out in order to magnify the contribution of the most significant auxiliary variables to the shifts.Two examples have been presented showing that the proposed methodology is able to direct the first-principles model improvement efforts towards the model sections that are truly affected by modeling errors.

Abstract

In this work we simulate and integrate the systems of evaporation, fermentation and distillation with direct heating. In addition, we propose a new scenario using indirect heating in order to decrease the quantity of stillage, and consequently, minimize environmental and economic impacts associated. In this sense, a reboiler using the steam produced in the evaporators is included in the distillation column to analyse the effect of such revamping. Sensitivity analyses were performed to detect some key operational variables with effect on the process. Results show that the replacement of direct steam injection by use of reboilers decreases significantly the quantity of stillage, consequently, minimizing the problems generated by it. Moreover, once there are no changes in flegma and ethanol mass flows, and the bleeding heat flow is suitable to exchange heat with reboilers, it means the replacement may be done without modify the industrial productivity.

Keywords: simulation, stillage, distillation columns, sugarcane, Aspen Hysys.

1. Introduction

Sugarcane processing is one of the most important and strategic sectors in the Brazilian economy. This important segment has steadily increased its activity in the last decades, propelling all sugarcane-related activities. It is expected that the 2013/2014 crop reaches 652 million tons, what in turn will suppose 27.17 billion liters processed in the ethanol distillation plants, a 15% increase compared to 2012/2013 (CONAB, 2013).

The success of Brazilian distilleries depends on how they overcome the new scientific challenges faced. The traditional sugarcane industry still presents a huge field to be explored, mainly regarding the optimization of process, energy integration, cogeneration, and sustainability (Amorim et al., 2011).

One of the scientific challenges to be faced is related to reduce the volume of sugarcane stillage (called vinasse). This final by-product of the biomass distillation is rich in minerals and is commonly used to irrigate sugarcane plantation (called fertirrigation); however, if it is produced in excess, may bring environment and economic problems. The direct application of stillage in the soil may cause salinization, leaching of metals present in the soil to groundwater (it may kill animals and aquatic plants), changes in

soil quality due to unbalance of nutrients, mainly manganese, alkalinity reduction, crop losses, increase of phytotoxicity and unpleasant odor (Santana and Machado, 2008). Moreover, vinasse may be a significant source of greenhouse gas emission to the atmosphere. Emissions may result from aerobic and anaerobic decomposition of the organic matter in vinasse that occurs during transportation, temporary storage or even after application to soil (Oliveira et al., 2013). In Brazil, the fertirrigation frequently becomes an economic problem once there is no enough area to apply it. This can happen when the plantation belongs to the suppliers or it is placed far away from the plant, making it impossible to transport (Christofoleti et al., 2013; Laime et al., 2011).

The rapid growth experienced by sugarcane industry in Brazil necessitates the design and installation of few new facilities, expansion, and optimization of the existing ones. Process analysis using a properly validated process simulator is essential to reduce production costs in each of these steps as well. Among the commercial process simulator, Hysys stands out due to its ease of use and quality databank even though it requires corroborating or adapting for applicability in sugarcane sector (Jorge et al., 2010).

The process simulator Aspen Hysys has been used in several technical and economic analysis of process. Modeling, simulation, validation, and analysis were successful performed by Jorge et al. (2010), using Hysys, for a sugarcane juice industrial evaporation system composed of a falling film evaporator followed by three short vertical-tube evaporators arranged in parallel. Ruhul et al. (2013) simulated the production of ethanol by fermentation of molasses using software Aspen Hysys 7.1 in order to investigate the effect of few important parameters like fermentation temperature or pressure, that affect the production of ethanol and to optimize those parameters. Sensitivity analysis is very useful to determine the impact of a particular variable or parameter on the process outcome.

In this work, simulation and analysis of a full-scale industrial evaporation system of an alcohol distillery (COCAFÉ) are performed using Aspen Hysys 8.4 process simulator. The research started using the validated industrial evaporation system made by Jorge et al. (2010) and integrated to the fermentation and distillation systems. The distillery of the Cooperativa Agrícola de Astorga Ltda (COCAFÉ), which is located in the northwest of Paraná State, Southern Brazil, processes around 180 tons/h of sugarcane juice, producing approximately 380m³/day of hydrated ethanol.

2. Methodology

The COCAFE process is simulated in Aspen Hysys 8.4. It offers a comprehensive thermodynamics foundation for accurate determination of physical properties, and phase behaviour. Aspen Hysys can be used to determine outlet process conditions if the inlet conditions are specified. The NRTL model was chosen because Marquini et al. (2007) compared the results obtained from simulations in ethanol distillation columns using the thermodynamic models and have found the NRTL model is the one that leads to the best results.

2.1. Process Description

The whole process of producing ethanol from sugarcane is shown in a block diagram in Figure 1.

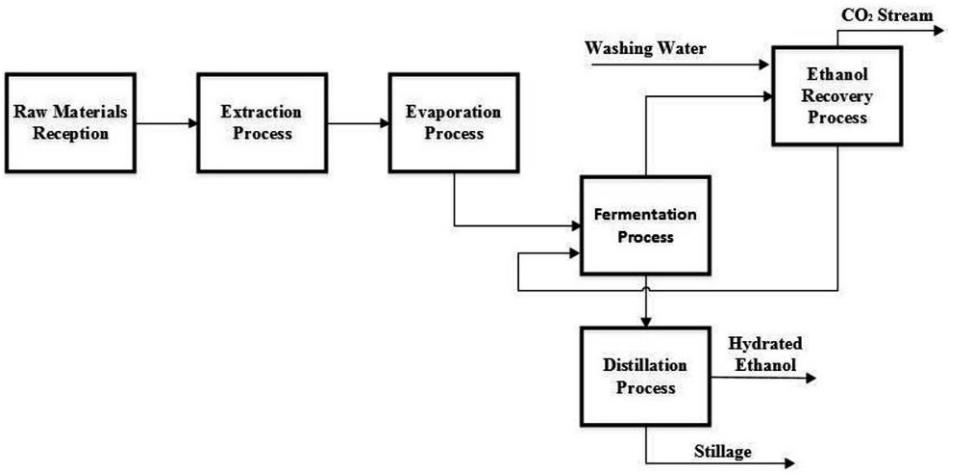

Figure 1. Process block diagram of COCAFÉ ethanol production from sugarcane.

2.2. Sugarcane Industry Hysys Model

The evaporation system was made based on Foust et al. (1982) who described an evaporator as basically consisting of a heat exchanger capable of raising the solution temperature up to the boiling point and a device for separating the vapour phase from the boiling liquid. Using this concept, Jorge et al. (2010) successfully simulated the COCAFÉ evaporation system using Aspen Hysys; each of the four evaporators was represented by the combination of a multitubular heat exchanger and a flash vessel (separator). In this work the evaporation system is composed by four combinations of heat exchanger and flash tank in order to represent four evaporators. The first combination represents the evaporation first effect which produces the Bleeding and the First Effect Stream that goes to the other three combinations of heat exchanger and flash tank representing the evaporation second effect. There is also a heater (E-100) between the first and second effect that simulates the necessity of high pressurized steam that happens when the first effect energy is not enough to heat the second effect. The input and output of the evaporation system are clarified juice, which contains 15,69% of sucrose and 84,31 of water in mass fraction, and concentrated juice, with 17,72% of sucrose and 82,28% of water in mass fraction.

The concentrated juice goes to the fermentation system which is composed by a fermentation column and an absorption column. The conversion was based on Ruhul et al. (2013) who specified the conversion of sucrose in the fermenter in 90%; glucose and fructose are converted into ethanol and carbon-dioxide, where conversion rate is defined as 95%. In this work the reaction involved is a global one (Equation 1) with 85,5% of conversion, which is the product of the two reactions cited.

$$C_{12}H_{22}O_{11} + H_2O = 4C_2H_5OH + 4CO_2 \quad (1)$$

As CO_2 gas leaving the fermenter carries away some ethanol with it, this gaseous stream is sent to absorption column. Here ethanol is absorbed by wash water. The gaseous stream leaving the absorber contains negligible amount of ethanol and this stream is vented in atmosphere. The liquid stream is recycled to the fermenter.

The liquid stream leaving the fermenter (Beer) is a very dilute ethanol solution (6,71% of ethanol and 93,29% of water in mass fraction). This stream is sent to the first distillation column (A-A1), operating with 26 equilibrium stages and total reflux in the condenser. The bottom product of this column is stillage and the middle product is called Flegma, which is a stream rich in ethanol (between 30 and 40% in volume fraction) that enters in the second distillation column (B-B1), also operated with total reflux in the condenser. The bottom product of the second column is Flegmass, also a by-product. Finally, the ethanol is withdrawn in the middle of the second distillation column with 93,2 ±0,6% of mass fraction. All the heating of the distillation columns is provided by direct steam injection in the bottom of A-A1 and B-B1 columns. In this model, the exclusive heating by direct steam injection is ensured by setting the reboilers heat flow of the streams Energy2 and Energy4 to 0 $kJ.h^{-1}$, and using the adjusts ADJ-1 and ADJ-2.

2.3. Comparative Study Between the Use of Reboilers and Direct Steam Injection

A comparative study is made removing the adjusts ADJ-1 and ADJ-2. Thus, it is analysed the heat flow offered by the Bleeding and the heat flow required by the reboilers of the first distillation columns in order to verify if Bleeding is capable to exchange heat with the reboiler. Furthermore, it is estimated the quantity of stillage decreased when the direct heating is replaced by indirect heating.

2.4. Sensitivity Analysis

After setting the process variables and with the simulation active it is possible to execute the sensitivity analysis increasing and decreasing our input variables in 5%. The input variables are the composition and the temperature of the clarified juice and the global conversion of the fermenter. The output variables are the ethanol and stillage mass flow for all cases. The quantity of steam injected in the distillation columns is fixed in order to not change the energy required.

3. Results and Discussion

The Table 1 presents the comparative study between direct steam injection and use of reboilers, which is the aim of the work. The Figure 2 shows the industrial system Hysys model including evaporation, fermentation and distillation process.

Table 1. Comparative study between the direct steam injection and the use of reboilers.

Mass Flow ($Kg.h^{-1}$)	Direct steam injection	Use of reboilers	Percentage variance (%)
Stillage	188600	161200	-14,53
Flegma	31790	31880	+0,28
Ethanol	15320	15330	+0,06

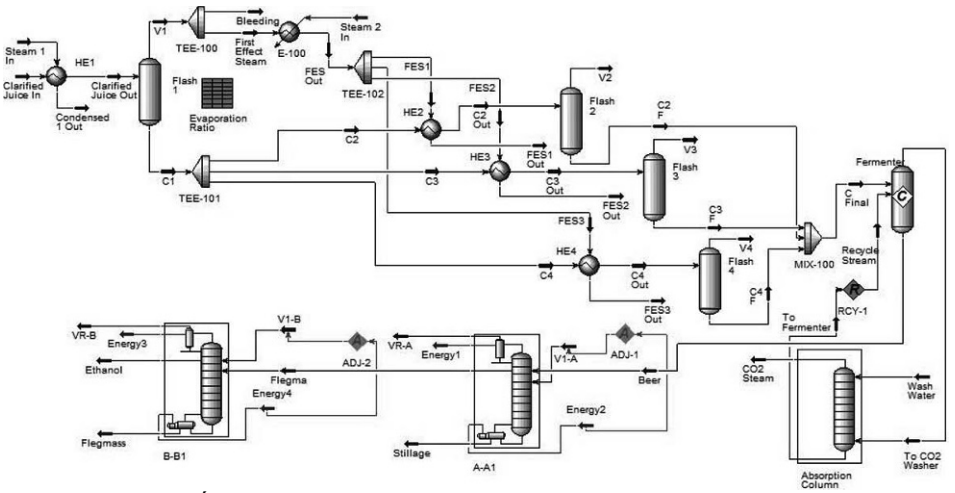

Figure 2. COCAFÉ Industrial system Hysys model.

There is a significant decrease of 14,53% of the stillage quantity produced. Decrease the amount of this by-product means to minimize the environmental and economic problems that it generates. In addition, the mass flows of flegma and ethanol have a very low variation; it shows the industry is able to do the replacement proposed without change the productivity. Figure 3 presents the results of the sensitivity analysis.

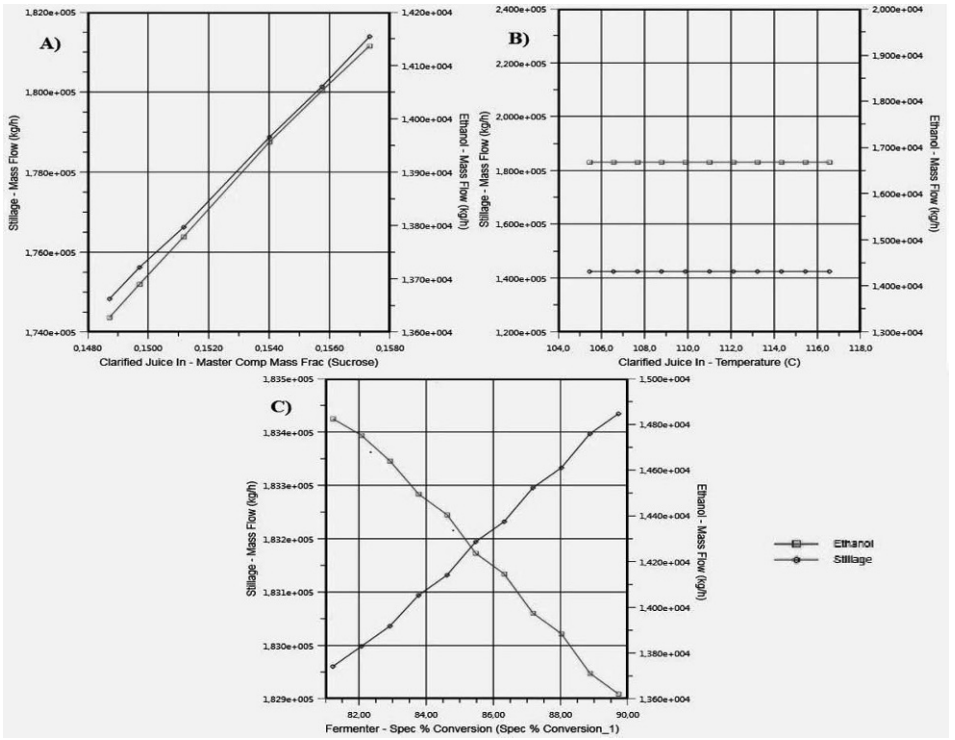

Figure 3. A) Sensitivity analysis of clarified juice composition B) Sensitivity analysis of clarified juice temperature C) Sensitivity analysis of fermenter conversion.

Figure 3 shows there is a direct proportionality between clarified juice sucrose composition and the outputs mass flow of stillage and mass flow of ethanol. On the other hand, these same outputs are not affected when clarified juice temperature is modified. The last sensitivity analysis indicates a direct proportionality between the fermenter global conversion and the mass flow of ethanol, but in inverse proportion to the mass flow of stillage.

Finally, when the adjusts ADJ-1 and ADJ-2 are removed, the stream Bleeding offers a heat flow of 1,674E08 $kJ.h^{-1}$ and the reboiler of the A-A1 column requires a heat flow of 7,378E07 $kJ.h^{-1}$. It may demonstrate that Bleeding is able to heat properly the reboiler proposed.

4. Conclusions

The adapted evaporation process was successfully integrated into the distillation process, inserting the fermentation and ethanol recovery process in Aspen Hysys V8.4. The sensitivity analysis indicated an increase in the flow of ethanol and stillage by increasing the sucrose in the clarified juice and its invariance with temperature. The variation of the fermenter global conversion is directly proportional to the flow of ethanol and inversely proportional to the mass flow of stillage.

The comparative study between direct steam injection and use of reboilers in the distillation process showed a reduction of 14.53% for stillage but a very low variation on ethanol and flegma mass flows; thus minimizing the environmental and economic impacts caused by vinasse and maintaining the standard of quality and productivity of the plant. Once the steam used in the indirect heating goes back to boiler, it shows it may optimize the heat integration of the process as well as reducing the operating cost of the plant when eliminating steam injection. Moreover, less vinasse means less cost to treat it before its application to soil. Finally, the simulated system without direct steam injection in distillation columns shows that the steam produced in the first effect evaporator has a suitable heat load to exchange heat with the proposed reboiler.

Abstract

Experiments that yield as much information as possible are desired for estimating parameters in nonlinear dynamic bioprocesses. Techniques for optimal experiment design ensure the systematic design of such informative experiments. A possible objective function in optimal experiment design is the E-criterion which corresponds to the maximization of the smallest eigenvalue of the Fisher information matrix. However, a potential problem with the minimal eigenvalue function is that it can be nondifferentiable. In addition, a closed form expression does not exist for the computation of eigenvalues of a matrix larger than a 4 by 4 one. A reformulation strategy from the field of convex optimization is presented in this paper to circumvent the aforementioned difficulties. It requires the inclusion of a matrix inequality constraint involving positive semidefiniteness. The positive semidefiniteness constraint is imposed via Sylverster's criterion. By applying the suggested reformulation, the maximization of the minimum eigenvalue function can be implemented in standard optimal control solvers through the addition of nonlinear constraints.

Keywords: Dynamic optimization, Minimum eigenvalue optimization, Nonlinear matrix inequality, Sylvester's criterion, Predictive microbiology

1. Introduction

Dynamic bioprocess models play a valuable role to analyze, control and optimize bioprocesses in the biochemical industry. Identifying parameters in biosystems is, however, not trivial as these systems often exhibit a strong nonlinear nature. Especially, for cost intensive applications, it can be beneficial to design a dynamic control input such that an experiment is as informative as possible. An overview of the state of the art has been presented in, e.g., Franceschini and Macchietto (2008).

The uncertainty in the parameters can be quantified by the Fisher information matrix (FIM) (Walter and Pronzato (1997)). If the Fisher information matrix is used in an optimization routine, a specific scalar function has to be used as an objective function. Several functions have been proposed in the literature during the past decades, e.g., minimizing the trace of the inverse of the FIM (A-criterion), maximizing the determinant of the FIM (D-criterion) or maximizing the minimum eigenvalue of the FIM (E-criterion) (Franceschini and Macchietto (2008); Walter and Pronzato (1997); Telen et al. (2012); Houska et al. (2015)).

When gradient based optimization routines are applied, the E-criterion can pose numerical challenges. The main advantage of gradient based schemes is that they are fast and can tackle a

problem with a large number of decision variables. By construction is the FIM symmetric and positive semidefinite. So, all eigenvalues are nonnegative real numbers but the minimum eigenvalue function can be nondifferentiable. Furthermore, no closed expression exists for eigenvalues of a matrix larger than a 4 by 4 matrix. A reformulation of the problem can be used (Vandenberghe and Boyd (1996)) to overcome these problems. This reformulation involves a constraint requiring positive semidefiniteness. In the current paper this constraint is addressed by using Sylvester's criterion (Wicaksono and Marquardt (2013)) in order to enable the use of classic optimal control tools for solving the resulting large scale optimization problems.

The paper is structured as follows. Dynamic systems and the mathematical formulation of optimal experiment design are presented in Section 2. Section 3 discusses the suggested reformulation strategy and how positive semidefiniteness can be enforced using Sylvester's criterion. Section 4 introduces a case study from the field of predictive microbiology. The numerical simulation and optimization results are described in Section 5. Finally, the paper concludes with Section 6.

2. Mathematical formulation

This section discusses first the mathematical description of dynamic systems. In the second part, the formulation of optimal experiment design is presented.

2.1. Dynamic systems

Consider a system that is described by the following set of ordinary differential equations in the interval $t \in [0,\, t_\mathrm{f}]$:

$$\begin{aligned} \dot{x}(t) &= f(x(t), p, u(t))\,, && (1)\\ 0 &= b_\mathrm{c}(x(0))\,, && (2)\\ z(t) &= h(x(t))\,. && (3) \end{aligned}$$

Here, $x(t) \in \mathbb{R}^{n_\mathrm{x}}$ denotes the state vector, $p \in \mathbb{R}^{n_\mathrm{p}}$ a time-invariant parameter vector and $u(t) \in \mathbb{R}^{n_\mathrm{u}}$ is the vector of the control inputs. All these variables enter the right hand side function f in a possibly nonlinear way. The vector function b_c denotes the initial conditions of the system. The function $h(x(t))$ denotes the measurement function of the system which can be nonlinear but which is usually a subset of the states $x(t)$. The vector $z(t)$ is the measured output. If there are any path or terminal constraints present, these can be formulated as:

$$\begin{aligned} 0 &\geq c_\mathrm{p}(x(t), p, u(t))\,, && (4)\\ 0 &\geq c_\mathrm{t}(x(t_\mathrm{f}), p)\,. && (5) \end{aligned}$$

The measurement error, $\varepsilon(t)$ is assumed to be additive to $h(x(t))$ and normally distributed with zero mean, and variance-covariance matrix $Q(t)$.

2.2. Optimal experiment design

In this paper *optimal experiment design for parameter estimation* (OED/PE) is considered. The information content in the experiment is quantified by a suitable measure of the Fisher information matrix. This matrix is defined as:

$$F(t_\mathrm{f}) = \int_0^{t_\mathrm{f}} \frac{\partial x}{\partial p}(t)^\top C(t)^\top Q(t)^{-1} C(t) \frac{\partial x}{\partial p}(t) dt\,. \qquad (6)$$

As the true values for p are not exactly known, the Fisher information matrix is evaluated at the current best guess. The expression $C(t) = \frac{\partial h(x(t))}{\partial x}$ denotes the derivative of the measurement function $h(x(t))$ with respect to the states, x. So, the Fisher information matrix combines information about the variance-covariance matrix of the output error measurements, $Q(t)^{-1}$ and the sensitivities of the states with respect to small variations in the model parameters, $\frac{\partial x}{\partial p}(t)$. These sensitivities are computed as the solutions of the following additional differential equations:

$$\frac{d}{dt}\frac{\partial x}{\partial p}(t) \quad = \quad \frac{\partial f}{\partial x}\frac{\partial x}{\partial p}(t) + \frac{\partial f}{\partial p} \quad \text{with} \quad \frac{\partial x}{\partial p}(0) = \frac{\partial}{\partial p} b_{\mathrm{c}}(x(0)) = 0. \tag{7}$$

Several scalar maps of the Fisher information matrix have been proposed in the literature for the design of informative experiments (Walter and Pronzato (1997)), e.g., A-criterion (minimizing the trace of the inverse of the Fisher information matrix), D-criterion (maximizing the determinant of the Fisher information matrix). In the current paper the focus is on the E-criterion, maximizing the smallest eigenvalue of the Fisher information matrix:

$$\max \lambda_{\min}\left(F(t_{\mathrm{f}})\right). \tag{8}$$

This design criterion aims at minimizing the largest parameter error and corresponds to minimizing the length of the largest uncertainty axis of the joint confidence region. For the E-criterion, there is, however, a problem with the use of the minimum eigenvalue function in the derivative-based optimization routines.

It is possible that the derivative does not exist. Consider the following tutorial example, with a parametrized matrix A:

$$A = \begin{pmatrix} 1 & 0 \\ 0 & k \end{pmatrix}. \tag{9}$$

The evolution of the minimum eigenvalue function as function of the parameter k is depicted in Figure 1. It illustrates that the minimum eigenvalue function of the matrix A is continuous everywhere but that it is not differentiable for $k = 1$. How this problem can be avoided, is discussed in the following section.

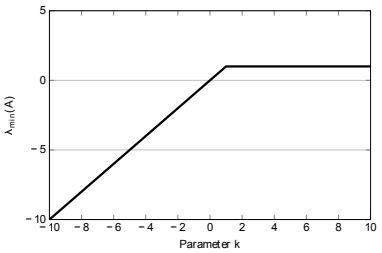

Figure 1: Illustration of the minimum eigenvalue function of the matrix A.

3. Reformulation strategy

Using a well-known reformulation strategy from the field of convex optimization, the minimum eigenvalue optimization is reformulated. An additional parameter τ is introduced which is to be maximized. To relate τ with the minimum eigenvalue, a new constraint is added, see Equation (16). The latter equation ensures that τ is bounded by the minimum eigenvalue of the Fisher information matrix. The reformulated problem is described as (Vandenberghe and Boyd (1996)):

$$\max_{u(\cdot),x(\cdot),\frac{\partial x}{\partial p}(\cdot),F(\cdot),\tau} \quad \tau \tag{10}$$

subject to:

$$\frac{dx}{dt}(t) = f(x(t), p, u(t)) \text{ with } 0 = b_{\mathrm{c}}(x(0)), \tag{11}$$

$$\frac{d}{dt}\frac{\partial x}{\partial p}(t) = \frac{\partial f}{\partial x}\frac{\partial x}{\partial p}(t) + \frac{\partial f}{\partial p} \quad \text{with} \quad \frac{\partial x}{\partial p}(0) = \frac{\partial}{\partial p} b_{\mathrm{c}}(x(0)) = 0, \tag{12}$$

$$\frac{d}{dt}F(t) = \frac{\partial x}{\partial p}(t)^{\top} C(t)^{\top} Q(t)^{-1} C(t) \frac{\partial x}{\partial p}(t) \quad \text{with} \quad F(0) = 0, \tag{13}$$

$$0 \geq c_{\mathrm{p}}(x(t), p, u(t)), \tag{14}$$

$$0 \geq c_{\mathrm{t}}(x(t_{\mathrm{f}}), p)\ , \tag{15}$$

$$F(t_{\mathrm{f}}) - \tau I \succeq 0\ . \tag{16}$$

In this dynamic optimization formulation, the last equation, $F(t_{\mathrm{f}}) - \tau I \succeq 0$ denotes that $F(t_{\mathrm{f}}) - \tau I$ is required to be positive semidefinite, i.e., $\forall z \in \mathbb{R}^{n_{\mathrm{p}}} :\ z^{\top}(F(t_{\mathrm{f}}) - \tau I) z \geq 0$. Equation (16) is a nonlinear matrix inequality as the Fisher information matrix is nonlinearly dependent on the decision variables. This optimization problem can be solved by linearization such that a *linear matrix inequality* is obtained. This formulation allows the use of a semidefinite program solver (e.g., SeDuMi (Sturm, 1999)) such that the whole dynamic optimization problem can be solved by sequential semidefinite programming (Telen et al. (2014)). The problem, however, is that standard optimal control tools do not have such dedicated semidefinite program solvers.

Positive semidefiniteness can also be guaranteed using a result from linear algebra. The Sylvester criterion states that *a matrix A is positive definite if the determinant of all its principal minors is positive* (Wicaksono and Marquardt (2013)) or mathematically expressed:

$$\det(A[(1:i) \times (1:i)]) > 0 \quad \text{with} \quad i = 1, \ldots, n_{\mathrm{p}}. \tag{17}$$

This reformulation allows the nonlinear matrix inequality (16) to be rewritten in n_{p} additional inequality constraints. This leads to the following problem formulation:

$$\max_{u(\cdot), x(\cdot), \frac{\partial x}{\partial p}(\cdot), F(\cdot), \tau} \tau \tag{18}$$

subject to:

$$\frac{dx}{dt}(t) = f(x(t), p, u(t)) \quad \text{with} \quad 0 = b_{\mathrm{c}}(x(0)), \tag{19}$$

$$\frac{d}{dt}\frac{\partial x}{\partial p}(t) = \frac{\partial f}{\partial x}\frac{\partial x}{\partial p}(t) + \frac{\partial f}{\partial p} \quad \text{with} \quad \frac{\partial x}{\partial p}(0) = \frac{\partial}{\partial p} b_{\mathrm{c}}(x(0)) = 0, \tag{20}$$

$$\frac{d}{dt}F(t) = \frac{\partial x}{\partial p}(t)^{\top} C(t)^{\top} Q(t)^{-1} C(t) \frac{\partial x}{\partial p}(t) \quad \text{with} \quad F(0) = 0, \tag{21}$$

$$0 \geq c_{\mathrm{p}}(x(t), p, u(t)), \tag{22}$$

$$0 \geq c_{\mathrm{t}}(x(t_{\mathrm{f}}), p)\ , \tag{23}$$

$$0 < \det\left((F(t_{\mathrm{f}}) - \tau I)\,[(1:i) \times (1:i)]\right) \quad \text{with} \quad i = 1, \ldots, n_{\mathrm{p}}. \tag{24}$$

The above formulation allows the incorporation of the maximization of the minimum eigenvalue in standard optimal control tools. Problems with the nondifferentiability of the objective function are avoided and positive semidefiniteness is ensured through the addition of n_{p} nonlinear constraints.

Remark. The information is quantified using the classic Fisher information matrix approach. The reformulation of Equations (18) - (24) can also be used if a different computational method for the approximation of the parameter variance-covariance is used, e.g., the unscented transformation (Heine et al. (2008)).

4. Case study

The case study considered in this paper originates from the field of predictive microbiology. In this field (dynamic) models are constructed to describe the growth, survival and inactivation of micro-organisms in food products. The model concerns the *Cardinal Temperature Model with Inflection point* (CTMI) (Rosso et al. (1993)). This is an adaptation of the Baranyi and Roberts model which describes microbial growth (Baranyi and Roberts (1994)). The dynamic model equations are:

$$\frac{dn(t)}{dt} = \frac{Q(t)}{Q(t)+1}\mu_{\max}(T)[1-\exp(n(t)-n_{\max})]\,, \tag{25}$$

$$\frac{dQ(t)}{dt} = \mu_{\max}(T)Q(t)\,. \tag{26}$$

In this set of equations $n(t)$ [ln(CFU/ml)] expresses the logarithm of the cell density. The factor containing $Q(t)$ is a black-box factor which is introduced to describe the experimentally observed lag phase. $Q(t)$ is assumed to represent a physiological state of the cell population during the lag or adaptation phase. The CTMI model describes the temperature dependency of the maximal growth rate, i.e., $\mu_{\max}(T)$ (Rosso et al. (1993)). If the temperature is below the minimum temperature for growth $T_{\min}$ or above the maximum temperature for growth $T_{\max}$, the maximum specific growth $\mu_{\max}$ is set to 0. The mathematical expression of the CTMI is:

$$\begin{cases} \mu_{\max}(T) = \mu_{\text{opt}}\gamma(T), & \forall T \in [T_{\min}, T_{\max}]\,, \\ \gamma(T) = \frac{(T-T_{\min})^2(T-T_{\max})}{(T_{\text{opt}}-T_{\min})((T_{\text{opt}}-T_{\min})(T-T_{\text{opt}})-(T_{\text{opt}}-T_{\max})(T_{\text{opt}}+T_{\min}-2T))}\,, & \\ \mu_{\max}(T) = 0, & \forall T \notin [T_{\min}, T_{\max}]\,. \end{cases} \tag{27}$$

The computation is performed with the optimal control package ACADO (Houska et al., 2011). A single shooting approach (Telen et al., 2014) is employed and all simulations are performed on a 64 bit Ubuntu 12.04 system with an Intell Core 2 Quad CPU 3.00 Hhz and 4.00 GB RAM.

5. Simulation results

The obtained E-optimal temperature profile and the corresponding predicted cell density $n(t)$ are illustrated in Figure 2 and 3. The maximum value of the smallest eigenvalue that is obtained is 1.887. For a single optimization is the computational time below 120 s when a feasible initialization is provided. The temperature profile in Figure 3 starts at the maximum allowed temperature of

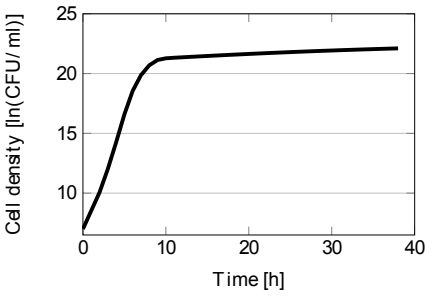

Figure 2: Cell density $n(t)$ resulting from the optimized control profile.

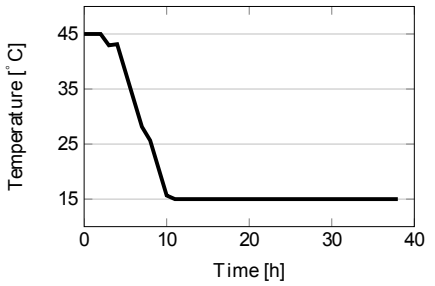

Figure 3: Optimized control profile with 38 degrees of freedom.

45°C and remains at this temperature for 2 hours after which there is a small decrease to 43°C. After 6 hours, there is a steady decrease in temperature until the lowest possible temperature value of

15°C is reached for the remainder of the experiment. The temperature profile is the result from an optimization procedure allowing for a piecewise linear approach in 38 intervals. The temperature profile results in a minimum eigenvalue of 1.89. This illustrates that small temperature changes in the complex profile are indeed contributing significantly to the information content as measured with the minimum eigenvalue of the Fisher information matrix. The effect of the temperature profile is also visible in the expected cell density profile in Figure 2. The optimized temperature profile results in a larger cell density growth. This is the result from the temperature profile evolution between 2 and 4 hours in the experiment. The designed temperature is in this interval closer to the optimal growth temperature profile T_{opt} and thus results in a larger increase of the cell density. In the next 6 hours there is a rapid increase in the cell density concentration due to the temperature being closer in the range of the optimal growth temperature. Subsequently, after 10 hours the growth decreases as the temperature remains constant at 15°C for the remainder of the experiment.

6. Conclusions

A reformulation strategy for minimum eigenvalue maximization in optimal experiment design has been presented in this work. This function can be nondifferentiable and no explicit expression exists for matrices larger than a 4 by 4 matrix. In this paper a reformulation from the field of convex optimization has been employed for designing optimal dynamic experiments. This introduces a matrix inequality requiring positive semidefiniteness. Positive semidefiniteness can be enforced using Sylvester's criterion. This approach allows the maximization of the minimum eigenvalue in standard optimal control solvers by the addition of several nonlinear constraints. Consequently, accurate derivatives can be obtained and numerical problems are avoided.

Abstract

Pollutants from diesel engines have a negative effect on urban air quality. Because of this and new legislation restricting the emission level, it is necessary to develop exhaust gas treatment systems for diesel engines that can reduce the amount of pollutants. A modular model capable of simulating the whole catalytic exhaust system would be beneficial towards this goal. A methodology for developing a modular model capable of simulating a system consisting of several sub systems is presented. The methodology describes the steps the user should take to go from problem formulation to the final modular model. Four different models in the automotive diesel exhaust gas cleaning system are presented briefly. Based on the presented methodology, it is discussed which changes are needed to the models to create a modular model of the whole catalytic system.

Keywords: Modeling, Automotive flue gas treatment, Simulation

1. Introduction

Diesel engine exhaust gases contain several harmful substances. The main pollutants are carbon monoxide (CO), hydrocarbons (HC), particulate matter (PM), and nitrous gases such as nitrogen monoxide (NO) and nitrogen dioxide (NO_2) (together abbreviated NOx). Reducing the amount of these substances is of great importance due to new legislation, and because of the effect they have on urban air quality (A. Fritz and V. Pitchon, 1997; R. M. Heck and R. J. Farrauto, 2001). In a modern EU VI exhaust gas cleaning system the flue gases are typically handled with four different catalysts: a Diesel Oxidation Catalyst (DOC) which oxidizes HC and CO, and NO into NO_2, a Diesel Particulate Filter (DPF) which filters PM, a Selective Catalytic Reduction (SCR) catalyst where ammonia (NH_3) is added to remove NO, and NO_2, and an Ammonia Slip Catalyst (ASC) which removes excess NH_3 before the gases are released to the atmosphere. A representation of the system can be seen in Fig. 1. To be able to fully understand and optimize the system without using too many resources, it is beneficial to be able to simulate the complete system under different scenarios. A modular model consisting of different blocks representing the different catalysts would be able to simulate almost all configurations of diesel flue gas cleaning systems. The main advantage with a modular structure is that it allows for changes in a single or several blocks. For example, the model structure or the catalyst formulation in one of the catalysts can be changed with minimal effort. Volumes of the catalysts, parameter values, etc. can be changed

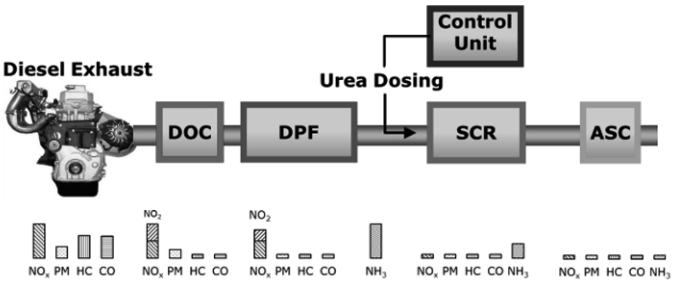

Figure 1: A typical EU VI diesel engine exhaust gas cleaning system. The column charts show the relative concentration, and the effect each catalyst has on the composition.

to investigate the effect the changes will have on the overall system performance. It would be possible to go between different catalyst setups, for example EU V and EU VI. It would also be possible to simulate combinational dynamic effects, for example how changing one catalyst will affect the dynamics of the whole system. The experimental effort can be reduced substantially if the model accurately can describe the system. To achieve this, models of the catalysts have to be developed or collected from literature and modified in a way so that they can work together.

Modeling of the different catalysts independently is a well studied area. The DOC has been modeled by for example (Y.-D. Kim and W.-S. Kim, 2009), early DPF modeling was done by (E. J. Bissett, 1984), and more recently for example by (C. Depcik et al., 2013). The SCR has been modeled by (D. Chatterjee et al., 2005) and (X. Song et al., 2013), and the ASC by (M. Colombo et al., 2012). To the authors knowledge, no effort has been done to develop a methodology to combine independently developed models to create a modular model combining all the catalyst in the system, that is aimed at simulating the complete exhaust system during transient operation. Some software exists that are able to simulate the whole system, for example AVL Boost (2014) and Exothermia SA (2014). Commercial software is however limited with regards to programming language, model structure, and interface, while the presented methodology allows the user to use his or her favourite. This paper will briefly present four different models that have been independently developed at DTU Chemical Engineering. It will present a methodology of the steps needed to make a modular model based on independently developed models. The methodology will be used to investigate the necessary steps to combine the models in the automotive exhaust gas after treatment system into a modular model for the whole catalytic system.

2. Methodology

This section will present a suggested methodology of necessary steps to make a modular model that is able to handle transient simulation. Step 1 through 7 below are the suggested steps.

1. Problem formulation.
2. Model collection and understanding.
3. Data collection.
4. Modification into dynamic formulation.
5. Equalization of the inputs and outputs for the models.
6. Implementation of the models in compatible software.
7. Model validation.

Step 1 involves a proper formulation of the problem: what is the application and how many underlying models are necessary to describe the system. This step will also clearly define if the

presented methodology is the correct one to use, since the user should realise if a modular model is needed. Based on the requirements formulated in 1, the relevant models will be collected in step 2. This involves both physical models and kinetic models if the system is chemical. It also concerns understanding the system to such a degree that it can be concluded if a fully dynamic model is necessary, or if the dynamics are so fast that a pseudo-steady state model is enough to handle a transient input. Step 3 involves collection of data for the models. If the models are collected from literature, some physical constants and kinetic constants that are required might be unavailable. Based on the analysis in step 2 and the current configuration of the collected models, step 4 requires the user to modify the models into a dynamic formulation. For the models to be able to work together, the inputs and outputs must be matched in all the underlying models, which is done in step 5 of the methodology. To be able to simulate the models together, step 6 tells the user to implement the models in compatible software. When the modular model is working, a recommended step is to validate the model. Since the nature of the model is modular, it will require much experimental effort to validate all configurations, thus it is preferable to use well validated models from the start.

3. Case Study: Automotive Diesel Exhaust Gas Cleaning System

3.1. Models

This section will present an overview of independently developed models and the physics of the catalysts. The specific information about the presented models comes from models developed at DTU, but the methodology can be used with models found in literature as well.

For the DOC, SCR and ASC, the catalyst is made up from several small channels, with two phases in each channel: a bulk phase and a washcoat phase. The channel walls are made from washcoat, which contain the active catalytic material.

3.1.1. Diesel Oxidation Catalyst Model

A single monolith channel for the DOC can be represented as in Fig. 2, which was the basis for the model development. A one dimensional heterogeneous plug-flow reactor (PFR) model was used to model the energy and mass equations for both bulk and washcoat phases. The two phases were coupled through the transport coefficients for convective heat and mass transfer. The developed model is fully dynamic and can handle transient simulations. The model is able to calculate the concentration of CO, O_2, NO, HC, CO_2, H_2O, and NO_2, as well as the gas temperature. The inputs and outputs to and from the catalyst are the gas velocity, the gas composition (CO, O_2, NO, HC, CO_2, H_2O, and NO_2), and the gas temperature. The reaction kinetics were based on the work by (S. E. Voltz et al., 1973), and the kinetic constants were also taken from literature.

3.1.2. Diesel Particulate Filter Model

The wall-flow DPF has the geometry of a catalytic converter, but with plugged opposite ends of adjacent channels. Unfiltered exhaust gases enter the inlet channels and pass through the porous substrate layer orthogonal to the inlet flow direction, before it exits through the outlet channel. During DPF operation, a deposit layer of soot will build up on the substrate layer, leading to an increasing pressure drop over time. The model was developed around a single inlet/outlet channel and involves quasi-steady state equations of mass, momentum, and energy for the exhaust gases along with dynamic equations for particle mass and temperature for the filter substrate. A schematic view of a single inlet/outlet channel can be seen in Fig. 3a. The model tracks the changes in concentration of NO, NO_2, O_2, CO, and CO_2, and uses the filter substrate temperature

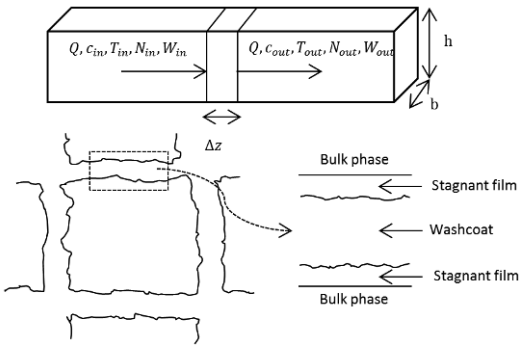

Figure 2: Schematic view of a single channel in a DOC and SCR catalyst.

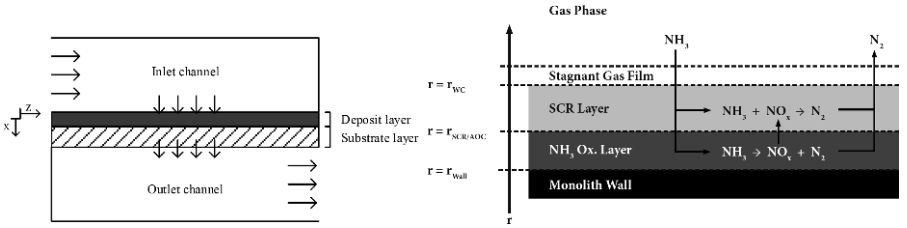
to compute reaction speed for the kinetics. The kinetics are based on the work of (A. Messerer et al., 2006). The inputs and outputs to and from the model are: exhaust mass flow rate, inlet gas composition (NO, NO_2, O_2, CO, and CO_2), gas temperature, and outlet pressure.

3.1.3. Selective Catalytic Reduction Catalyst Model

The physics of the monolith channels were described with a plug-flow reactor model, as in the DOC model. The model is dynamic and can handle transient inputs. A complicating factor in the SCR kinetics is that adsorbed NH_3 on the catalyst surface is involved in all the relevant reactions. The NH_3 is supplied to the catalyst by injecting aqueous urea before the catalyst, which decomposes into NH_3. The kinetic model used was a modification of the work done by (L. Olsson et al., 2008), and the kinetic parameters were calibrated using stationary isothermal data from a bench-scale monolith. The model was validated using transient data from a full-scale monolith and a real engine. The inputs and outputs to and from the model are the gas velocity, the gas composition (NH_3, NO, NO_2, and N_2O), and the gas temperature.

3.1.4. Ammonia Slip Catalyst Model

The washcoat of the ASC has a different configuration from the other catalysts. The washcoat phase consists of two different layers. At the top there is an SCR layer and at the bottom an NH_3-oxidation layer, as illustrated in Fig. 3b. The excess NH_3 from the SCR catalyst will enter the



(a) Schematic view of a single inlet/outlet channel in a DPF.

(b) Schematic view of the phases in the modeled ASC.

Figure 3: Schematic views of the washcoat construction in the DPF and ASC.

ASC and transport from the bulk phase to the washcoat, diffuse into the washcoat where some of it will adsorb onto the SCR surface. Some NH_3 will diffuse further into the oxidation layer. The NH_3-oxidation is not selective towards N_2, but instead produces mostly NOx. This is unwanted since the exhaust gases have already been cleaned of NOx. This is the reason for placing an SCR layer at the top of the washcoat. The produced NOx will be reduced to N_2 when its diffuses back into the bulk phase. This catalyst design requires that a model has resolution into the washcoat. To model the catalyst a steady-state tanks-in-series approach was used to describe the bulk phase, and a steady-state reactive diffusion equation was used to describe the washcoat phase. The kinetic model and the kinetic parameters for the SCR layer were taken from the work of (D. Chatterjee et al., 2007) and the NH_3-oxidation kinetic parameters were estimated with experimental data. The inputs and outputs to and from the catalyst are the volumetric flowrate, and the gas composition (NH_3, NOx, and N_2O). The model does not contain any energy equations, and therefore does not give any output temperature.

3.2. Results

This section will apply the methodology to the presented models by discussing the changes needed to make them work together.

Step 1: The requirement is a model that can simulate the whole automotive exhaust gas cleaning system, from the gases exits the engine until they are released to the atmosphere. The model should be able to be used to investigate how changes in specific catalysts will affect the performance of the exhaust system, and also make simulations on the standard EU VI system to reduce experimental effort. Based on these requirements it becomes clear that a modular model is needed, and the methodology should be used.

Step 2: The models presented in Sec. 3.1 are the ones the author would like to use. Due to the washcoat diffusion occuring in the washcoat in the DOC, SCR and ASC, it is likely that a fully dynamic model is required and a pseudo-steady state approach is not enough. Some of the DPF dynamics are fast enough to allow that some of the equations in the DPF model are pseudo-steady state.

Step 3: Physical parameters and kinetic parameters are supplied with the models, thus no additional work is needed to collect more parameters.

Step 4: The models for the DOC and SCR are already fully dynamic and no work is required for modification. As previously explained the DPF model is a combination of equations that assume pseudo-steady state and dynamic ones. The time-scale of the dynamics of the phenomena described by pseudo-steady state assumptions are however so short that they are still able to handle transient behaviour. The time-scale of the dynamics in the ASC are in the same range as the SCR dynamics. Since the equations only consider steady state, they will have to be modified into a dynamic formulation. This can be done without much effort, since the model is a tanks-in-series model.

Step 5: The different models are not consistent in their inputs and outputs regarding chemical species. Two options are available: add components missing from some sub models and state that the catalyst has no effect on the composition of these species. An example of this is to add PM, which is needed in the DPF model, to the other models. The other option is to critically examine if all species are needed. Two examples of this are CO_2 and H_2O in the DOC model. These appear in much higher concentration than the other species, so the concentration will be practically unaffected by the reactions occuring. The suggested action for this system is to add PM, N_2O, HC, CO and NH_3 to all the models, and remove the variation in CO_2, O_2, and H_2O in all the models, and say that the concentration of these species is constant. All the sub models except the ASC have heat models calculating the output temperature. This is a required input to all models and a heat model for the ASC therefore has to be developed. All the models require

a quantity related to the flow, such as velocity or volumetric flow. This can easily be changed through density and cross sectional area.

Step 6: All the models have been implemented in Matlab, and can therefore be used together in for example Simulink.

Step 7: The models have been validated separately either with data from literature or with experimental data. A useful validation test for the finished modular model would be to simulate the standard EU VI exhaust treatment system and compare with data.

4. Conclusions

The proposed methodology to develop a transient modular model based on independently developed models was used on the automotive diesel exhaust gas cleaning system by discussing the required steps needed in order to get the models to work with each other in a modular model. The methodology included problem formulation, model collection, and modifying the model inputs, outputs, and formulation so they can work together. It also included implementation in compatible software and model validation. From the case study it was concluded that the ASC model needs to be modified into a dynamic formulation, and a heat equation added. It was also concluded that N_2O, HC, CO and NH_3 should be added, and that CO_2, O_2, and H_2O should be removed from all models.

Abstract

L-lysine is an important chemical, usually produced by fed-batch fermentation process. Usually, feed stock compositions, reactant or product concentrations, and operating conditions vary with different fed-batches in this process. It is difficult to establish a kinetics-based model for an industrial fed-batch fermentation process. In this paper, we proposed a data-based approximate graphical modelling method to model this process. Variables values are treated as correlated Gaussian process. The methodology comprises of two important steps: i) the missing-data imputation within records, and ii) the dynamic Bayesian network learning, including structure learning, using the low order conditional independence method, and parameters learning, using the multivariate auto regressive method. The L-lysine fed-batch fermentation process is studied to demonstrate the effectiveness of this approximate modelling method.
Keywords: L-lysine, fed-batch fermentation, Gaussian approximate, missing-data imputation, dynamic Bayesian network

1. Introduction

L-Lysine is one of the most important amino acids, which is used as food and feed supplements, human medicine, pharmaceuticals, cosmetics, polymer materials, and agricultural chemicals. More than 2 million tons of L-lysine are annually produced by microbial fermentation (Anastassiadis, 2007; Brautaset et al., 2007). L-lysine is mainly produced by fermentation, using strains of coryneform bacteria. Corynebacterium glutamicum is commonly used. This is a multi-step process including fermentation, cell separation by centrifugation or ultrafiltration, product separation and purification by crystallization, evaporation and drying (Anastassiadis, 2007; Claes and Bathe, 2014). To get better performance (yield, productivity, and titer) than batch and continuous culture, fed-batch cultures are used in this fermentation process. There are some advantages of fed-batch culture, such as prevention of substrate inhibition, high cell density cultivation, cultivation of auxotrophic mutants, etc. (Kiss and Stephanopoulos, 1991; Zuo and Wu, 2000). However, fed-batch culture is more complicated to operate than batch or continuous cultures. Because concentrated sugar solution, ammonium sulphate solution, and liquid ammonia are continuously fed into the culture medium at speeds that frequently change during the fermentation process, to maintain concentrations of glucose, ammoniacal nitrogen and pH value, and this operation increases the complexity of non-linearity and time varying characteristics which is already very complex in batch or continuous fermentation. High cell density increases the L-lysine productivity, while costing more carbon sources and reducing the yield of L-lysine on glucose. Precise control of the feeding speeds and the fermentation conditions is essential for balancing the trade-off of obtaining high concentration and

high yield of L-lysine product with low operation cost. An accurate model is needed for optimization and controlling. However, fermentation processes are complicated for modelling, because they involve complex transport phenomena, diverse biochemical reactions, and dynamic intracellular interactions (Valente et al., 2009). Furthermore, experiences of workers also play an important role in processes operating. As a result, it is complicated to establish an accurate and kinetic-based model of fed-batch fermentation processes for bulk chemicals, such as L-lysine. Additionally, in the industrial production environments the following problems are observed: i) the compositions of energy and nutrient sources (carbon, nitrogen, mineral etc.) are complicated and may vary from batch to batch due to the demand for low-cost raw materials, ii) the lack of robust online or *in situ* continuous monitoring instruments for important fermentation process parameters in industrial fermenters (Beutel and Henkel, 2011) causes the lack of continuous recorded data for kinetic modelling, such as concentrations of substrates, products and by-products in the fermentation culture, iii) a defined feeding strategy which is the base for many kinetic modelling, such as constant feeding strategy, is usually not the optimal strategy (Salehmin et al., 2013) in industrial fermentation practices, iv) the inconsistency of workers' operation and equipment increase the inconsistency between batches. Fortunately, there are plenty of accumulated records from DCS, quality testing and regular sampling during process operating. Methods that do not rely on a kinetic model but large quantity of data sets, such as artificial neural networks, etc., have been explored in modelling and optimizing the fed-batch (Valente et al., 2009). Here we introduce our trials of applying a dynamic Bayesian network based probability graphical modelling method for modelling the fed-batch fermentation process of L-lysine with data records from the L-lysine factory of COFCO.

2. Methodology

The schematic of approximate graphical modelling methodology is shown in Figure 1. The methodology comprises of two important steps: i) the missing-data imputation, and ii) dynamic Bayesian network learning (including structure learning and parameter learning).

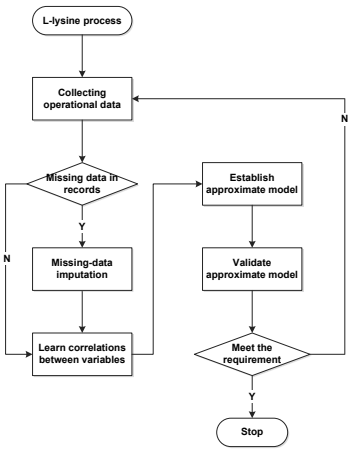

Figure 1. Approximate modelling methodology

2.1. Missing-data imputation

Operating data records are incomplete sometimes; only key variable values or broths in key stages are analyzed and recorded. Methods for treating missing data includes

discarding data, parameter estimation and imputation (Batista and Monard, 2002). Imputation methods replace missing values with estimated ones based on information available in the data set itself. There are two types of imputation methods: i)single imputation (e.g. mean/mode imputation, mean imputation, conditional mean imputation), ii) multiple imputation (e.g. hot decking, hot decking by covariate pattern, hot decking by observation, hot decking including outcome, multiple imputation by chained equations and k-nearest neighbor imputation) (Ambler et al., 2007). The mean/mode imputation is one of the most frequently used methods. This method replaces the missing data for a given attribute by the mean. In this paper, the mean/mode method is used to impute the missing data.

2.2. Dynamic Bayesian network

Bayesian networks have been applied to different areas including medical diagnosis, gene modelling, cancer classification, sensor validation, risk management, and reliability analysis (Yu and Rashid, 2013). However, there are limited literature reports on the use of Bayesian networks for approximate modelling of complex processes. Here we try to use dynamic Bayesian network (DBN) to establish the approximate fermentation process model. Dynamic Bayesian network is a type of graphical models for conducting time-varying probabilistic inference and causal analysis under system uncertainty (Yu and Rashid, 2013). Up to now, various dynamic Bayesian network representations based on different probabilistic models have been proposed: i) discrete models (Ong et al., 2002; Zou and Conzen, 2005), ii) multivariate autoregressive process (Opgen-Rhein and Strimmer, 2007) , iii) State Space or Hidden Markov Models (Beal et al., 2005; Perrin et al., 2003; Rangel et al., 2004; Wu et al., 2004), iv) nonparametric additive regression model (Imoto et al., 2001; Kim et al., 2004; Kim et al., 2003; Sugimoto and Iba, 2004), v) low order independence model (Lèbre, 2009). Dynamic Bayesian network can deal with continuous variables state (Murphy and Mian, 1999), with condition probability distribution $P(\mathbf{X}_t = \mathbf{x}_t \mid \mathbf{X}_{t-1} = \mathbf{x}_{t-1}) = N(\mathbf{x}_t; \boldsymbol{\mu} + \mathbf{W}\mathbf{x}_{t-1}, \boldsymbol{\Sigma})$ between two neighbored time slices, and the distribution is the normal distribution at $\mathbf{x}_t$. Dynamic Bayesian network can deal with cycled correlation in networks, this is an advantage compare to static Bayesian networks. Consequently, we could represent and study the multivariate time series fermentation data in an approximate graphical model. In this paper we use the low order conditional independence method (Lèbre, 2009) to learn the structure of the dynamic Bayesian network, and multivariate autoregressive process method (Opgen-Rhein and Strimmer, 2007) to learn the parameters.

3. Case study

3.1. *Operational data*

Usually, L-lysine is fermented in fed-batch culture, the variables at certain time slice, between different batches, can be treated as a normal distribution. Here, key variables, accumulated amount of sugar and $(NH_4)_2SO_4$ fed in to the fermenter, Optical Density ("OD"), pressure of the fermenter ("pressure"), dissolved oxygen ("DO"), Air flux and L-lysine concentration ("L-lysine") change with time in different fed-batch operations. These variables values are presented in Figure 2, together with means and 90% credible intervals as a Gaussian process.

3.2. *Approximate model*

We established the dynamic Bayesian network as a probability graphical model for this process. The correlations between seven recorded key variables are illustrated in the digraph network in Figure 3. Every node in the network is a Gaussian process, and the edges describe the influences between these variables.

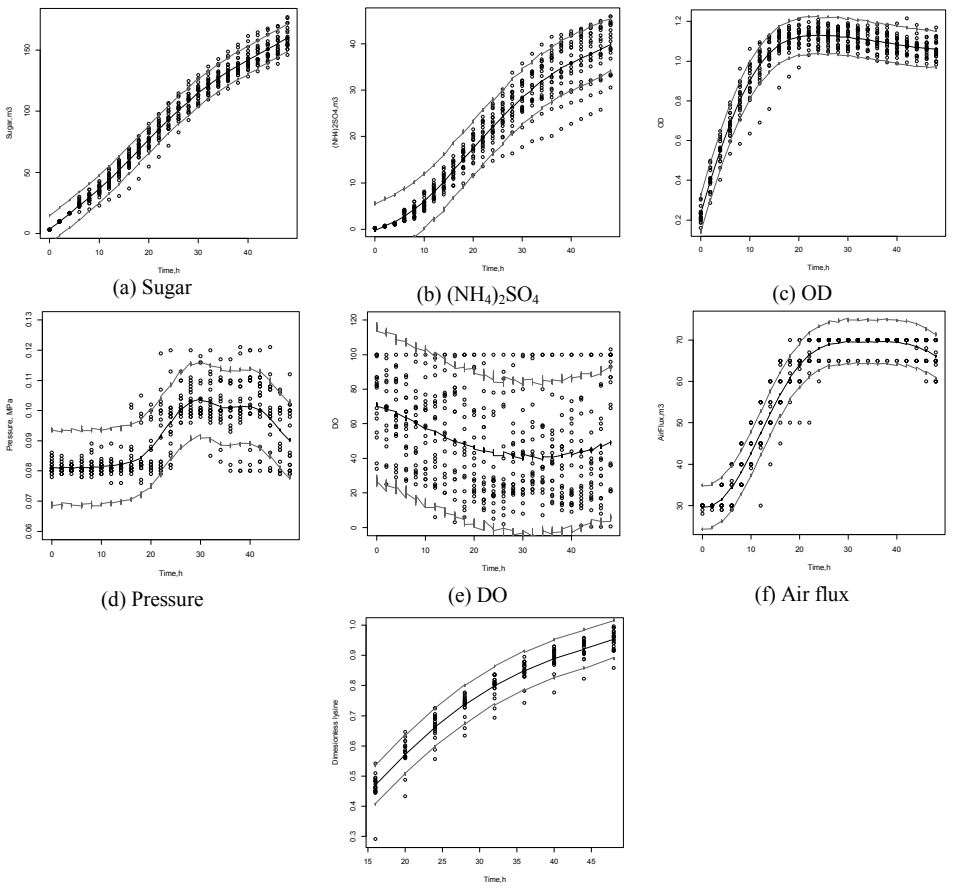

Figure 2. Sugar, $(NH_4)_2SO_4$, OD, Pressure, DO, Air flux and L-lysine change with time in different fed-batches operations, with means and 90% credible intervals as Gaussian process

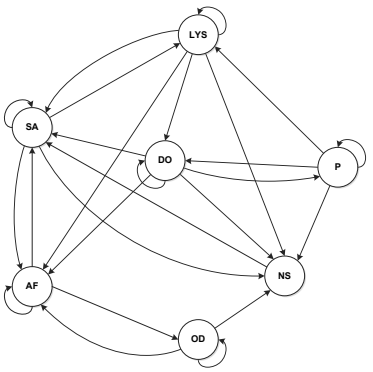

Figure 3. Approximate probability graphical model, SA: sugar, NS: (NH4)2SO4, OD: Optical Density, P: pressure; DO: dissolved oxygen, AF: Air flux and LYS: L-lysine concentration

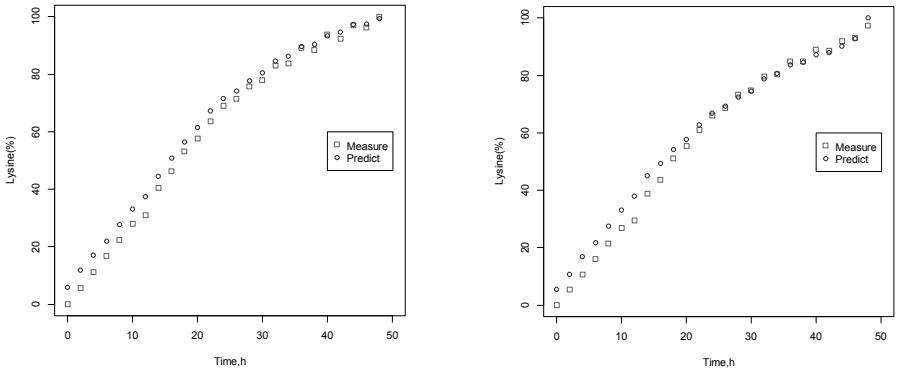
3.3. Model validation

After learning the parameters, we get the approximate graphical model. With this result, we can validate the model with predicted variable values. Such as, we can validate the

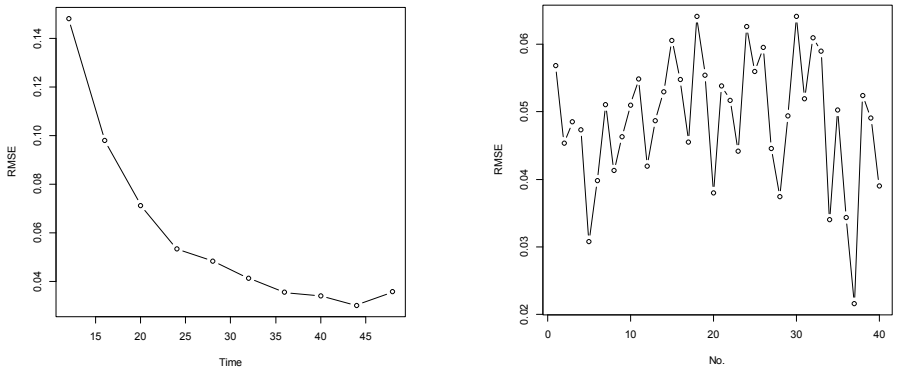
variable change through a certain fed-batch process. Compare between predicts and experiments are shown in Figure 4.



(a) No. 28 (b) No. 40

Figure 4. Measure and predict values in different fed-batches

From Figure 4, we can see the approximate graphical model can well represent the fed-batch fermentation process of L-lysine.



(a) Time slices (b) Batches

Figure 5. The RMSE between predictions values and experiments data

Figure 5 summaries the root mean square error (RMSE) between predicted product concentrations of L-lysine and experiments data. All these L-lysine concentration values are dimensionless, the concentrations varied from 0 to 1. The values of RMSE indicate that predicted values agree well with experiment data.

4. Conclusions

L-lysine is an important chemical, and it is mainly produced by fed-batch fermentation processes. In this process, the feed stock, operation conditions, and reactant/product vary all the time, also changes between different batches. It is difficult to formulate a kinetics-based model. With plenty of data records, we proposed a data-based approximate probability graphical modelling methodology to represents this L-lysine fed-batch fermentation process. Variables values in this process can be treated as a Gaussian process. First, we impute the missing-data within records, and then, the structure and parameters of dynamic Bayesian network are learned to get the graphical model. This model could be helpful in: i) identify the key state variables, ii) learn quantitative relationships between variables, and iii) improve the performance of L-lysine fed-batch fermentation process.

Abstract

Soap is a very common end-consumer product which is used worldwide, with ten billion pounds produced per year. In Mexico, for example, the annual soap production industry is valuated 200 million dollars, making the soap production profitable. During the continuous saponification process, the emulsion viscosity is an essential variable which influences the conversion due to mass transfer limitations. Viscosity also impacts the operation of the downstream processing steps, such as the extrusion and the soap compression, to achieve the final product quality. Laundry soap emulsion viscosity prediction is complex due to the heterogeneous and variable composition: moisture, free sodium hydroxide, sodium chloride, sodium sulphate and fatty acids concentrations. Therefore, in this contribution the objective is to obtain a mathematical model via response surface methodology, to predict the emulsion viscosity for the system under study, which is the production of laundry soap in a facility located in Mexico: *Jabonera Potosina*. The methodology to develop such a model is the following: 1. Definition of the response property (viscosity). 2. Analysis of the variables that influence the viscosity: compounds concentrations, fat saponification value (FSV) and fatty acid value (FAV). 3. Determination of the ranges of the variables. 4. Creation of a response surface via a central composite design. 5. Performance of the experiments. 6. Analysis of the results, and 7.Model development. The obtained equation relates all the variables mentioned previously with the emulsion viscosity. This equation will be useful to identify the operational adjustments in the process for different scenarios, such as the change of product from laundry soap to toilet soap.

Keywords: soap, viscosity, emulsion, experimental design.

1. Introduction

Soap is a widely used commodity product, but despite being produced since antiquity, the manufacturing has been more an art than a science. For example, large kettle tanks were used for centuries, manipulating a soap mass around and through various phases with cryptic names such as nigre, middle soap, neat soap, kettle wax, and curd. From the emergence of transport phenomena knowledge, it has been possible to elucidate a rational understanding of structure and phase behaviour (Paul *et al.*, 2013). As results, better production processes have been developed, such as the continuous saponification process, which consists of a stirred tank to increase the phase contact to favour the mass transfer. In the continuous saponification process the emulsion viscosity in the reactive

mixture is a property that has effect not only in the downstream process to ensure that the equipment can handle the emulsion, but also it has wide importance in the reaction process due to mass transfer limitations. For example, the conversion depends on the capacity of the reactor to ensure contact between phases, and the stirring system can only handle certain range of viscosities (Hvala *et al.*, 2011). Saponification reaction consists of a fatty acids alkaline hydrolysis. It can be carried on either neutralizing carboxylic acids with an alkali, or by the alkaline hydrolysis of triglycerides**.** There are many quality variations in fat and oils used due to the market fluctuations depending on harvesting seasons**.** In addition, the production of biodiesel, which utilize the same raw materials, is increasing. Therefore, the competition for the raw materials and its price is highly variable. Nowadays, the soap manufacturing companies are using all kinds of fats and oils, meaning that it is necessary to pre-treat the raw materials to ensure the quality for the process. For these reason *Jabonera Potosina* aims to ensure the quality of the finished soap bar by using any kind of fat just adjusting controllable variables: a) sodium hydroxide content, b) sodium chloride content, c) sodium sulphate content, d) saponification number, e) moisture and f) acid value. All these variables have been observed to have influence in the soap paste viscosity, and they have a specific function in soap formulations. In this work the objective is to verify the empirical observations that the operators and supervisor have done to control the emulsion viscosity and to build a mathematical model which includes all the variations produced by the variables involved, in order to predict the viscosity under certain conditions and then to apply corrective actions by adjusting the controllable variables. In addition, this model can be used to formulate other products such as toilet soap.

2. Materials and Methods

2.1. Materials

Industrial grade fats (palm fat and tallow) and oils (palm kernel and coconut oil) were used and provided by *Jabonera Potosina.* The saponification number and the acid value were adjusted by mixing fats with oils. The caustic soda solution used was 27% w/w in water. Sodium chloride and sodium sulphate were at industrial grade. The water content adjustment was done with tap water.

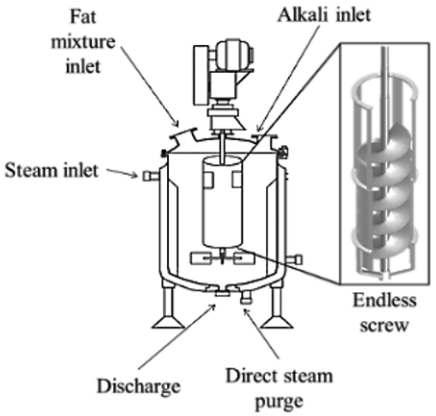

Figure 1. Pilot-scale saponification reactor.

2.2 Equipment

A pilot-scale reactor was used for the experiments. It consists of a stainless steel stirred tank with a capacity of 35 kilograms. It has a heating jacket to preheat the mixture.

Steam can be fed to the reactive mixture from the bottom of the reactor. The raw materials are fed from the top. The stirring velocity was 60 rpm. In order to measure the temperature a needle thermometer was attached. Inside the reactor, to enhance the mass transfer and to ensure a homogeneous mixture, there is an endless screw to transport the mixture from the bottom to the top. With this, the sodium hydroxide concentration can be the same in all the reactor volume. A schematic representation of the pilot-scale reactor is shown in Fig. 1.

2.2. Design of experiments

In order to correlate all the variables having impact on the viscosity, a response surface was created. A central composite design was done to minimize the number of experiments. The design was specifically structured with a minimal resolution V by the software Design Expert 7.0.0., to avoid aliasing effects in the ANOVA. (Rozet *et al.*, 2013)

2.2.1. Variables and range values

All variables that empirically demonstrated to have impact on the emulsion viscosity can be divided in operational and characteristic variables. The effect of the operational variables (e.g. flowrates, temperatures, pressure, stirring velocity, batch time) was discarded by standardizing the experimental procedure. Only the characteristic variables (compounds concentrations) were studied. Only 6 variables could be controlled and measured by the lab. The selected variables were: 1) water percent, 2) sodium chloride percent, 3) sodium sulphate percent, 4) sodium hydroxide percent, 5) saponification value and 6) acid value. The first four variables maximum values are regulated by Mexican official norms for laundry soap bars (NMX-Q-010-CNCP-2013). The minimum value was fixed with at the operational values of the subsequent steps in the process. The last two variables are raw material characteristics and can be adjusted by mixing the fat with the oils. The high and low values for these were selected considering process stability and raw material variations. The acid value provides information of the final glycerol percent in the emulsion. Therefore, this variable was regulated adding the necessary glycerol to reach the value from the design of experiments. Forty experiments were performed in total. Table 1 shows the experimental design low and high variable values.

Table 1. Range values for the design of experiments.

Name	***Units***	***Low***	***High***	***Mean***	***Std. Dev.***
Sap. Value	g-KOH/g-fat	208.72	211.28	210	1.05
% NaCl	%	0.25	0.40	0.325	0.07
% Na_2SO_4	%	0.13	0.17	0.15	0.02
% H_2O	%	30.73	31.57	31.15	0.34
% NaOH	%	0.21	0.26	0.235	0.02
% Glycerol	%	1.8	2.0	1.9	0.1

2.3. Experimental procedure

The experimental procedure begins with the melting and heating of the fats (tallow and palm fat) at 60°C. 5% of the total charge is tallow, which is added first with an excess of sodium hydroxide which is twice the saponification number measured, for example if the saponification number of tallow is 142.9 mg NaOH/gr of tallow, then 285.8 mg of NaOH are added. The next step consist of adding the necessary palm fat to neutralize

the emulsion due to the sodium hydroxide excess, followed by further addition of seven batches of palm fat and sodium hydroxide in a stoichiometric ratio of 1:1 to complete the full charge. Then, the sodium chloride and sodium sulphate are dissolved in water and added to the reactive mixture. A sample of this is carried to the lab to be analysed. Sodium hydroxide is measured by dissolution of the emulsion in alcohol and then it is filtered under vacuum. The product is titrated with sulphuric acid. Sodium chloride is measured by titration with silver nitrate after adding magnesium nitrate to separate the chlorides from the rest of the solution. Water is measured by weight difference with a heating lamp. If necessary, an adjustment is done before the viscosity measurement, to reach the variable values from experimental design. Finally the viscosity is measured at 80°C (operational process temperature) with a DV2TLVTJ0 Brookfield viscometer with a needle 64, at 10 rpm. A thermal bath was used to maintain the temperature and avoid product solidification (Maddah *et al*, 2013).

3. Results

Table 2 shows the ANOVA of the experiments. The factors that have effect in the response variables are highlighted with grey. Linear variables (despite they do not have effect) were added by hierarchy due to their quadratic effect in the ANOVA. The most important result is that binary interactions (%NaCl-%NaOH, SV-%NaOH) have effect in the model.

Table 2. Analysis of Variance (90% probability)

Source of Variation	***Sum of Squares***	***Freedom Degrees***	***Mean Square***	***F Value***	***Prob > F***
Model	2.63E-18	11	2.39E-19	3.99	0.0015

$(\%\ H_2O)^2$	2.04E-19	1	2.04E-19	3.39	0.0761
$(\%\ NaOH)^2$	2.23E-19	1	2.23E-19	3.72	0.0640
Residual	1.68E-18	28	6.00E-20		
Lack of Fit	1.36E-18	23	5.93E-20	0.93	0.5988
Pure Error	3.18E-19	5	6.36E-20		
Total	4.31E-18	39			

The resulting model equation is the following:

$$\mu = [\beta_o + (\beta_1 \cdot SV) + (\beta_2 \cdot \%NaCl) + (\beta_3 \cdot \%Na_2SO_4) + (\beta_4 \cdot \%H_2O) + (\beta_5 \cdot \%NaOH) + (\beta_6 \cdot SV.\%NaOH) + (\beta_7 \cdot \%NaOH \cdot \%NaCl) + (\beta_8 \cdot \%NaCl^2) + (\beta_9 \cdot \%Na_2SO_4{}^2) + (\beta_{10} \cdot \%H_2O^2) + (\beta_{11} \cdot \%NaOH^2)]^{2.66} \quad (1)$$

Where the values of the constants are: $\beta_0 = -1.13080 \times 10^{-8}$, $\beta_1 = 1.54994 \times 10^{-11}$, $\beta_2 = -4.13240 \times 10^{-10}$, $\beta_3 = -1.59939 \times 10^{-9}$, $\beta_4 = 5.14840 \times 10^{-10}$, $\beta_5 = 1.47619 \times 10^{-8}$, $\beta_6 = -6.40753 \times 10^{-11}$, $\beta_8 = 7.35720 \times 10^{-10}$, $\beta_9 = 5.28462 \times 10^{-9}$, $\beta_{10} = -8.18148 \times 10^{-12}$, $\beta_{11} = -3.30304 \times 10^{-9}$.

To validate the model, viscosities of normal production soap emulsions were measured and compared with the model predicted values. Results are listed in Table 3.

Table 3. Comparison between predicted and measured viscosity values

N	*Sap. Value (mg/g)*	*NaOH (%)*	*NaCl (%)*	*Na_2SO_4 (%)*	*H_2O (%)*	*Exp. (cp)*	*Mod.(cp)*	*%Error*
1	205.5	0.21	0.33	0.2	31.8	13800	13372	-3.201
2	207.5	0.22	0.31	0.2	31.7	10400	10740	3.163
3	209.5	0.25	0.27	0.21	31.6	10040	9838	-2.049
4	209.5	0.22	0.35	0.2	31.4	9940	10117	1.753
5	210	0.23	0.33	0.22	32.4	9520	9134	-4.228

Fig. 2 shows that there is no induced tendency and there is a normal dispersion for all measurements. For adjusting the model a power transformation to the response (Hou *et al.*, 2011) was necessary. Interactions behaviour was plotted in Fig. 3, where a saddle point in the sodium chloride and sodium hydroxide interaction effect can be observed.

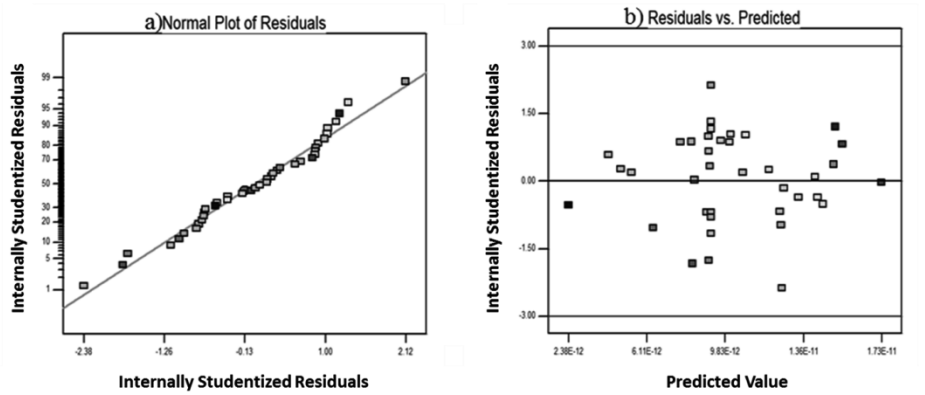

Figure 2. a) Normal plot of residuals; b) Residuals vs Predicted comparison.

4. Analysis and Discussion

From the ANOVA, only 5 variables that have effect in the viscosity were identified. The glycerol percent does not affect the response, contrary to the plant personnel empirical observations. This effect may have been covered by the fact that the range of the variable is too narrow to observe it. Water percent is the only variable that has both effects (linear and nonlinear) in the response according to Table 2. The interaction of the percent of sodium hydroxide and sodium chloride can be associated to the presence of emulsion electrolytes with a common dissociated ion. This interaction could not occur with sodium sulphate due to it hygroscopic nature instead of dissociating nature. The interaction between the saponification value and the sodium hydroxide could be related with the soap chain length and the emulsion alkalinity. Thermodynamic studies

in order to describe both interactions nature are recommended to be done. Sodium hydroxide, sodium chloride and sodium sulphate have a quadratic effect in the response, reaching a maximum or a minimum, making possible a further optimization. This behaviour is also reported in other publications with the presented regression methodology (Liu *et al., 2011).* Box-Cox analysis in Design Expert software suggested a power transformation for the response. Fig. 2 shows that the values are properly adjusted with such transformation. A mass balance model development would be the logical next step to validate the variable effect presented in the emulsion viscosity.

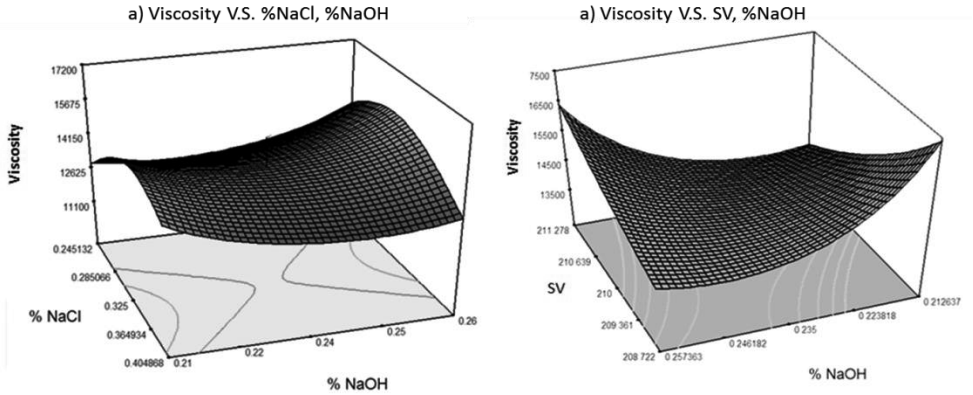

Figure 3. Interaction 3D plots

5. Conclusions

A viscosity prediction model was obtained with the response surface methodology. It was proven that it can predict accurately the soap emulsion viscosity. The model equation shows dependence from electrolytic compounds percent, water percent, interaction of saponification value-sodium hydroxide percent, and interaction of sodium hydroxide-sodium chloride percent. The model has immediate application in the company to formulate different products such as toilet soap, which can be developed without investment of new equipment. As a result the product portfolio can be diversified.

Abstract

Integration of Ordinary Differential Equations (ODE's) plays a paramount role in the dynamic simulation of a wide spectrum of processes in Chemical Engineering. This paper presents a novel approach within our discipline, namely the Quantised State Integration technique (QSI) (also known as Quantised State Simulation, QSS) which was introduced in its raw form several decades ago within Electrical Engineering for the simulation of electrical and electronic circuits in dynamic operation. While traditionally integration of ODE's considers time to be the coordinating parameter and it is discretised to allow the calculation of the state variables evolution, in QSS methods the states are discretised and time is calculated at points states go state events (changes by an amount equal to the discretisation level for each of them)–this allows effectively the decoupling of the state integration within accuracy tolerances. In the current work, we present significant theoretical and implementational extensions to the method, rendering it capable of handling large- to huge-scale applications involving stiff systems, state discontinuities (discrete events in hybrid systems) as well as the efficient calculation of sensitivity equations–all aspects that have previously been impossible to incorporate in the QSS suite of techniques presented over the years. Overall, all theoretical and preliminary computational demonstrations show it to be a very promising and powerful integration technique with a strong potential for future evolution and contributions. A mutlitude of areas that can benefit from this technique are identified in the paper.

1. Introduction and literature survey

Integration of Ordinary Differential Equations (ODE's) plays a paramount role in the dynamic simulation of a wide spectrum of processes in Chemical Engineering. Traditionally the time is treated as the free parameter, coordinating the integration of the state variables and is thus discretised. In the techniques presented here (Quantised State Integration, QSI, or Quantised State Simulation, QSS–names used equivalently) the state variables are discretised by a given (or variable) step size ('quantum') and the time at which they change becomes the calculated variable. This allows the decoupling of the integration of the state differential equations, and can be a very effective method to deal with difficult systems of very large dimensionality. Additionally the methods are matrix-free which renders them very efficient computationally.

Although equivalent to an explicit integration scheme, through our work we are able to show that they exhibit stability during integration and to a certain extent, with a specially modified limited Newton procedure per involved differential equations subject to a single changing state variable, stiff systems can be integrated adequately with good precision.

The initial concepts related to QSS can be traced to 1976 and in the most recent edition of Zeigler et al. (2000), the clear inception of this idea can be said to start with Zeigler and Lee (1998) and

the DEVS representation (Zeigler et al., 2000). DEVS or Discrete Event System Specification, is a formalism that allows modelling of system where events happen at discrete times, or hybrid systems. It found a certain popularity in Signal Processing, some types of Simulation, Electrical and Electronic Engineering; a search on Web of Knowledge turns up almost 750 articles and proceedings. **?** takes up the idea and expands it in the context of using DEVS representation in simulation environments. His group better defines the idea of trajectories approximated as piecewise polynomials, a fundamental feature of State Discretisation as we describe.

Kofman and his group started working on QSS from 2001 onward (Kofman et al., 2001). A first order "explicit" method is developed, the Quantized State Solver (QSS1) (Kofman and Junco, 2001), with quantized variables as stand-ins for the state variables. The latter are updated asynchronously only after the former have been manipulated and the conditions are verified. Among its theoretical properties the authors show that not only the state variables have continuous piecewise linear trajectories as Giambiasi did, but their derivatives as well follow piecewise constant trajectories like the quantized variables. More importantly, they show the first proofs that the method can be stable and convergent at the same time provided that the system matrix is a Hurwitz matrix (all eigenvalues negative, whatever the size), although the error is still a first order error, contained by the size of the quantum.

A second order version called QSS2 was developed (Kofman, 2002) following that, with the same properties and a better performance, though equally problematic with non-linear and stiff systems as the authors themselves note. However the limits of the system are much better defined, and the idea of defining the quantum so that those properties are respected is introduced, though it remains impossible to calculate it without effectively solving the system before the simulation. Kofman's doctoral thesis (Kofman, 2003) cleanly collects the theory developed up to that point, making the application to process control much more evident.

Nutaro is another worker in this field, although his research did not continue into more recent times. In his thesis (Nutaro, 2003) he worked on, among other things, the investigation of Adam-Bashford type linear Multi-Step methods, which he further developed up to second order in a pair of successive papers (Nutaro, 2005, 2007), with point interpolation to create virtual past time-steps that are usable. This particular form of the methods was not studied further, even though an improvement in the order of the global error was obtained. Of particular interest is the stability analysis in his papers. He concluded that QSI methods have very interesting stability properties and that they are mostly self-correcting in this regard: if the initial assumptions are respected these integrators will produce time steps that will make them remain always stable, with error cleanly bounded by the state quanta and the magnitude of the functions themselves.

In the meantime the applications of this type of solver to hybrid systems became apparent (Kofman, 2004). Being discrete, these methods handle discontinuity naturally and can easily handle state discontinuities. State discontinuities can be easily found through root-finding for the equations describing their transition conditions, in a one-variable-at-a-time fashion.

2. Advances in Quantised State Integration

Due to space limitations only the general principle of the QSS methods will be presented in this section. The method presented is equivalent to an explicit Euler scheme, but the discretised variables here are the states and not time. In any interval k we know that the next interval $k+1$ starts at a distance h_t from the beginning of the current one as in

$$t_{k+1} = t_k + h_t \,\forall\, k \in \{1,2,\ldots,N_{Intervals}\}$$

Knowing this in a regular ODE solver we can then approximate the value of the state variables at

that future time, as seen in the basic Euler method

$$x_{k+1} = x_k + \dot{x}_k h_t \tag{1}$$

In the case of state discretised solvers the perspective is turned around: we know the value that the state variables are going to have in the future. This is because we establish at the beginning of the simulation a discrete step h_x or quantum for every state variable $\{x_i \,|\, i = 1,2 \ldots N_{Variables}\}$, by which they can either increase or decrease, depending on the sign of the associated rate equation. The parameter h_x is also liable to change in some variants of the methods, such as the one presented here. What we wish to find is the future time t_{k+1} at which an absolute change by the quantum is effected. So in a system with only one state variable we know that

$$x_{k+1} = x_k \pm h_x \tag{2}$$

hence the next time step will start only when the following condition holds true

$$|x_{k+1} - x_k| = h_x \tag{3}$$

Note the absolute value, as the direction of change is not specified here. In a simple first order method the above condition is followed by first approximating a derivative at any point k as

$$f_x(x,t) = \frac{dx}{dt} \approx \dot{x}_k \tag{4}$$

implying that

$$\int_{x_k}^{x_{k+1}} dx = \int_{t_k}^{t_{k+1}} \dot{x}_k dt \Rightarrow \pm h_x = (t_{k+1} - t_k)\dot{x}_k \tag{5}$$

hence if we bring to the left hand side the current time we obtain

$$t_{k+1} = t_k + \frac{h_x}{|\dot{x}_k|} \tag{6}$$

Pictorially the integration by discretising states versus that of discretising time is shown in Figure 1.

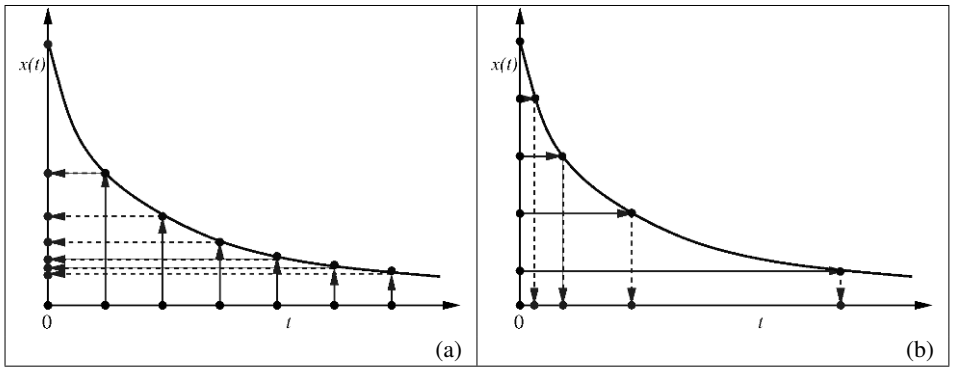

Figure 1: Time discretisation versus state discretisation integration schemes. (a) presents the time discretisation scheme with states being calculated, while (b) presents the state discretisation scheme with time calculated instead.

In our implementation many advances have been made over the state-of-the-art in QSS methods, which significantly suffer in the handling of stiff systems and in not having been extended for sensitivity equation integration. These aspects are the major ones presented next in this paper. Stiffness has been observed to cause instability in QSS methods (Migoni et al. (2013)). Kofman and coworkers presented there many methods and approaches. The shortcoming of all these presented approaches is that they handle effectively diagonally implicit systems, or at least ones that the dominant coupling is along the diagonal of the state Jacobian of the ODE systems. All these approaches are totally inadequate to handle a general stiff system reliably without depending on special properties it may possess. We generalised the approach to any stiff system of ODE's by observing that the instability in QSS methods due to stiffness results in crosses of the rate around zero, thus a root finding procedure subject to a state change over all involved rates is applied to lock to the zero location of the involved quantum for the changing state. This removes the instability observed and stiff systems can be integrated without problems, although still in a semi-explicit fashion.

The second major contribution of our work is the integration of sensitivity equations in tandem with the quantised state integration scheme. This is achieved by considering the following general ODE system

$$\begin{aligned} \frac{d}{dt}\boldsymbol{x}(t) &= \boldsymbol{f}(\boldsymbol{x}(t),\boldsymbol{p}) \\ \boldsymbol{x}(t_0) &= \boldsymbol{x}_0(\boldsymbol{p}) \end{aligned} \tag{7}$$

$$t_0 \leq t \leq t_f$$

The state vector is represented by variables $\boldsymbol{x} = (x_1, x_2, \ldots, x_{NX})^T$ and the parameter vector by variables $\boldsymbol{p} = (p_1, p_2, \ldots, p_{NP})^T$. Differentation of equation (7) w.r.t. $\boldsymbol{p}$ yields the first order sensitivity equations

$$\begin{aligned} \frac{d}{dt}\boldsymbol{x}_p(t) &= \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{x}}(\boldsymbol{x}(t),\boldsymbol{p}) \cdot \boldsymbol{x}_p + \frac{\partial \boldsymbol{f}}{\partial \boldsymbol{p}}(\boldsymbol{x}(t),\boldsymbol{p}) \\ \boldsymbol{x}_p(t_0) &= \frac{\partial \boldsymbol{x}_{0,\boldsymbol{p}}}{\partial \boldsymbol{p}}(\boldsymbol{p}) \end{aligned} \tag{8}$$

$$t_0 \leq t \leq t_f$$

where $\boldsymbol{x}_p = \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{p}} = \left[\frac{\partial x_i}{\partial p_j}\right]_{i=1,2,\ldots,NX,\ j=1,2,\ldots,NP}$. Taking a slice at a time of the sensitivity matrix $\boldsymbol{x}_{p_j},\ j = 1,2,\ldots,NP$, and assigning to it a copy of the system in equation (7) can be solved independently taking care of the coupling of the state variables into the right hand side of the parametric sensitivities. This scheme is readily parallelisable as is obvious, leading to potentially highly efficient implementations.

3. Illustrative case study

The system under investigation is a system presented in Migoni et al. (2013), integrate with state quantum equal to 1.0. Without the special Newton procedure the QSS method produces oscillations in the solution as shown in Figure 2a. This illustrates clearly a 'chattering' behaviour in the state output, a result of crossing a zero value of the rate as a result of not being able to modify the stepsize of the state to lock onto the zeros of the rate function.

With the Newton procedure discussed, our implementation produces a stable integration trajectory as in Figure 2b. The procedure simply locates within numerical tolerances a root of the right hand side of the differential equations, whenever they are found to be changing sign subject to a state updating event, for any of the states involved in the system and for all rates. It shows a remarkable difference between the standard QSS method which is effectively a totally explicit integration scheme.

In terms of events produced, without the stabilising Newton procedure there are 16,911 events (integration steps) in the integration horizon, while with the Newton procedure the number of events drops dramatically to 42. It should be noted that the stepsize used is also relatively high, covering a range of amplitudes in the profiles from 0.0 to 20.0 in steps of 1.0.

Further case studies have confirmed the stable behaviour of our proposed approach, but space limitations do not permit the exposition of many more case studies in this present paper.

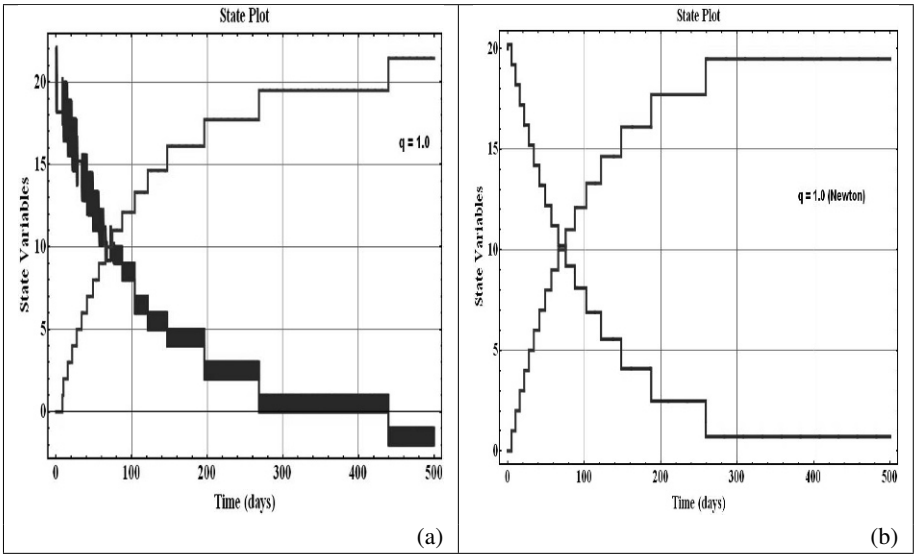

Figure 2: Integration of a stiff system: (a) presents the traditional QSS method solution, while (b) presents the solution implementing our Newton stabilisation scheme.

4. Discussion and future work

Overall, with our work we have been extending steadily the theoretical and implementational capabilities of the QSS methods so as to be able to tackle the most general and difficult huge-scale problems in Chemical Engineering dynamic process simulation. A summary of the current state-of-the-art and our contributions is given in Table 1. All the details outlined in the previously mentioned Table will be presented in a forthcoming extensive publication under preparation.

Item	Current state of published results on QSS	Our work
Stiffness	Very limited results published, specific to only "diagonally implicit-dominant" ODE systems	Generalised approach through a simple Newton procedure (single equation, single variable at a time basis)
Parametric sensitivities	No research published whatsoever	Easy to extend, no more costly than traditional methods, and additionally fully parallelisable
Discrete event location	Fully developed	Must be integrated correctly with Newton procedure and sensitivities
Error control and stepsize control	In terms of error control nothing to speak of. Some "scaling-based" work published for automatic stepsize choice, but very poorly done.	Preliminary implementation in our current prototype.
Higher order integration schemes	Some attempts published, but in a very unclear and non-general way.	Higher order multistep schemes to be implemented as a next step in our work.

Table 1: Work on QSS methods

Abstract

The current work addresses the modelling and parameter estimation of the biodiesel synthesis using supported lipases as catalysts. A kinetic reaction model was proposed in order to describe the enzymatic (trans)esterification reaction of vegetable oils and the set of kinetic parameters were numerically estimated with help of the direct search Complex algorithms. The proposed model was evaluated for different experimental conditions, leading to a very suitable prediction of the process data. In summary, the general proposed model is able to predict very well the reaction behavior of biodiesel (BD). Based on the algebraic-differential model performance, the proposed strategy can be successfully used to describe and optimize the biodiesel production through enzymatic reactions performed in batch and semibatch operating mode.

Keywords: Modelling, parameter estimation, biodiesel, enzymatic catalysis.

1. Introduction

The development of renewable sources of energy has been determined by two major issues: energy security and global warming. Biodiesel has attracted considerable attention as an alternative fuel for diesel engines, due to its remarkable characteristics of being renewable, biodegradable, less toxic and polluting than diesel. Traditionally, biodiesel is produced by chemical-catalyzed transesterification of vegetable oils carried out in homogeneous reaction medium. Although homogeneous catalysis is widely used for biodiesel production, there are several problems inherent in this process, such as difficult in the glycerol recovery, undesirable saponification reactions (when raw materials containing high contents of free fatty acids are employed), and high production cost associated to the mandatory removal of the alkali-soluble catalyst from the product, which results in effluent generation. Biodiesel produced by enzymatic route is a technology with a great potential to solve some of the problems that commonly observed in chemical-catalyzed alkaline processes. Despite this, in order to be considered economically viable, issues like high cost and inhibition of the enzyme should be resolved (Guldhe et al., 2015, Christopher et al., 2014; Gog et al., 2012).
Mathematical modelling is an important tool that allows for a better understanding of the process and therefore may assist in solving these mentioned problems. As a useful tool, process modelling based on the kinetic mechanism can successfully be used for understanding the mechanism and process behavior involved in the production of biodiesel through enzymatic route.

Process modelling can usually be performed following two main strategies: phenomenological or empirical models. Phenomenological models are more interesting for the study of new production processes as they are based on both the physical and the chemical phenomena involved in this process. However, empirical models may be successfully used to optimize the process parameters (Fedosov et al., 2013; Schwaab et al., 2008, Schwaab et al., 2006).

For the particular case of biodiesel production, independent of the adopted modelling strategy, classical process variables such as, temperature, alcohol/oil ratio, substrates flow rate, enzyme and water amounts must be considered. Additionally, mass transfer mechanism should also be taking into account when immobilized enzymes are used as heterogeneous catalysts (Yucel, 2012, Fedosov et al., 2013, Liu et al., 2014, Meunier et al., 2014). The current work objective is the modelling and parameter estimation of the enzymatic biodiesel synthesis using supported lipases as catalysts.

2. Modelling

2.1. Kinetic Mechanism and Process Model

The kinetic mechanism used to describe the enzymatic biodiesel synthesis is represented by the following reaction steps:

$$\begin{aligned}
&TG + E \underset{k_2}{\overset{k_1}{\rightleftarrows}} E \cdot TG \\
&E \cdot TG + ROH \xrightarrow{k_3} BD + DG + E \\
&E + DG \underset{k_5}{\overset{k4}{\rightleftarrows}} E \cdot DG \\
&E \cdot DG + ROH \xrightarrow{k_6} BD + MG + E \\
&E + MG \underset{k_8}{\overset{k_7}{\rightleftarrows}} E \cdot MG \\
&E \cdot MG + ROH \xrightarrow{k_9} BD + GL + E
\end{aligned} \tag{1}$$

where, *TG*, *DG*, *MG*, *GL*, *ROH*, *E* and *BD* are the concentration of triglyceride, diglyceride, monoglyceride, glycerol, alcohol, enzyme and biodiesel, respectively. Assuming that the quasi-steady-state hypotheses for the enzyme-substrate complexes are valid, Eqs.(2)-(4) can be expressed as follows:

$$\frac{d[E \cdot TG]}{dt} = \frac{d[E \cdot DG]}{dt} = \frac{d[E \cdot MG]}{dt} = 0 \tag{2}$$

$$[E]_E^T = [E] + [E \cdot TG] + [E \cdot DG] + [E \cdot MG] \tag{3}$$

$$[E]_E^T = \left(1 + \frac{k_1[TG]}{k_2 + k_3[ROH]} + \frac{k_4[DG]}{k_5 + k_6[ROH]} + \frac{k_7[MG]}{k_8 + k_9[ROH]}\right)[E] \tag{4}$$

According to the proposed kinetic mechanism for the species involved in biodiesel production, the following set of differential equation can be written:

$$\frac{d[TG]}{dt} = \left(\frac{k_2 k_1}{k_2 + k_3[ROH]} - k_1\right)[E][TG] \tag{5}$$

$$\frac{d[DG]}{dt} = \left(\frac{k_3 k_1}{k_2 + k_3[ROH]}[TG][ROH] - k_4[DG] + \frac{k_5 k_4}{k_5 + k_6[ROH]}[DG]\right)[E] \tag{6}$$

$$\frac{d[MG]}{dt} = \left(\frac{k_6 k_4}{k_5 + k_6[ROH]}[DG][ROH] - k_7[MG] + \frac{k_8 k_7}{k_8 + k_9[ROH]}[MG]\right)[E] \tag{7}$$

$$\frac{d[GL]}{dt} = \frac{k_9 k_7}{k_8 + k_9[ROH]}[E][MG][ROH] \tag{8}$$

$$\frac{d[BD]}{dt} = \left(\frac{k_3 k_1}{k_2 + k_3[ROH]}[TG] + \frac{k_6 k_4}{k_5 + k_6[ROH]}[DG] + \frac{k_9 k_7}{k_8 + k_9[ROH]}[MG] \right)[E][ROH] \tag{9}$$

$$\frac{d[ROH]}{dt} = -\frac{d[BD]}{dt} \tag{10}$$

2.2. Parameter Estimation

For the parameter estimation task, it is required that a set of ordinary differential equations be solved iteratively as a dynamic optimization problem (Machado et al., 2010, Soares et al., 2011). In this scenario, direct search methods (N.B. according to this procedure, the candidate optimum solutions of the estimation problem are generated at random inside the search region) can be regarded as an interesting tool because they do not need the computation of derivatives, the inversion of matrices nor the process constraints. According to Machado and co-authors (2010), the use of the Complex optimization technique is strongly recommended when the optimization task is carried out using a large system of differential equations. Figure 1 shows the parameter estimation procedure adopted here based on a standard sequential optimization procedure (Machado et al., 2010, Soares et al., 2011), which is responsible for the determination of an optimum solution that has to satisfy the process model represented by Eqs. (3)-(10).

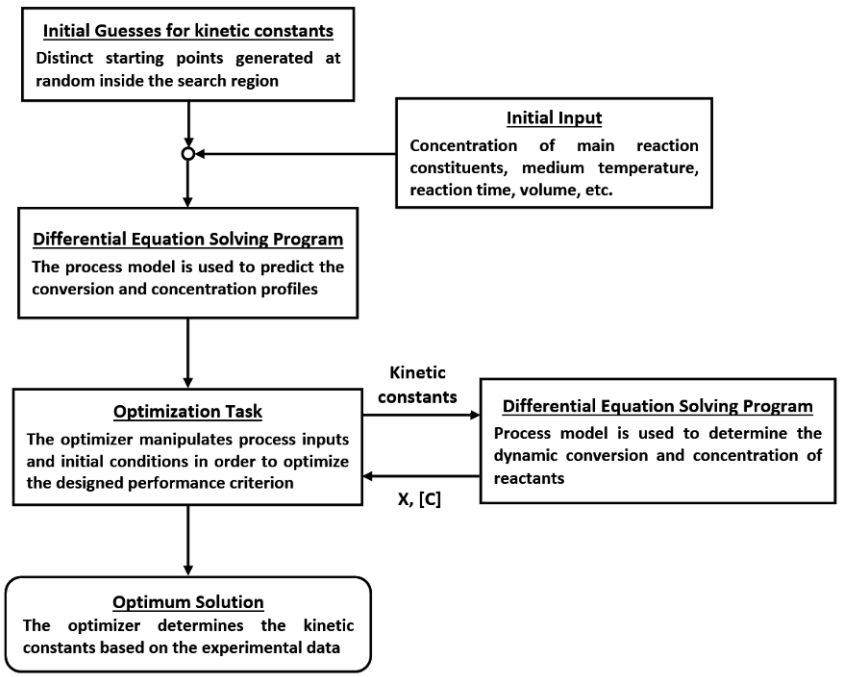

Figure 1. Proposed numerical scheme for the parameter estimation. X and [C] are the conversion and the concentration of reactants, respectively.

3. Results and Discussion

The experimental data used in this work were obtained from Salum et al. (2010), whose study was focused on the synthesis of biodiesel through the transesterification of soybean oil with ethanol in shake flasks. According to the adopted experimental conditions, 30 mmol soybean oil (871.34 g/mol), 1.5 g of fermented solid with immobilized lipase activity of 24 U/g were employed. The reactions were conducted at different alcohol:oil molar ratios (3:1, 6:1, 9:1 and 12:1) and at different water fractions (m/m) (0%, 0.5%, 1%, 5% and 10%).

Differential model equations [Eqs. (5)-(10)] were implemented in FORTRAN and solved numerically with the integration package IVPAG, whereas the parameter estimation task was performed with help of the direct search Complex algorithm. The standard numerical procedures IVAPG and BCPOL (employed for kinetic constant estimation), obtained from the IMSL^{TM} library (IMSL, 1991), were used for implementation of the computer code. Calculations were conducted on a laptop computer, equipped with an Intel® Core™ i7 processor, with CPU clock of 2.20 GHz and 8.00 Go memory RAM. The CPU computer times required to complete the estimation task were in the order of seconds, lying in the interval from 0.40 s to 1.00 s.

Based on the estimation task (Figure 1), different experimental conditions for alcohol/oil molar ratio were evaluated. Figure 2 shows the comparison between estimated and experimental data. There is a very good agreement between model and experimental data for the different experimental conditions studied. According to Figure 2, the highest conversion was obtained with a stoichiometric alcohol:oil molar ratio (3:1) and the reaction rate decreased with increase in alcohol:oil molar ratio up to 12:1. This experimental behaviour is in accordance with the works developed by Liu et al. (2014) and Yucel (2012), where it was also observed similar effect of alcohol/oil ratio on the biodiesel reaction performance.

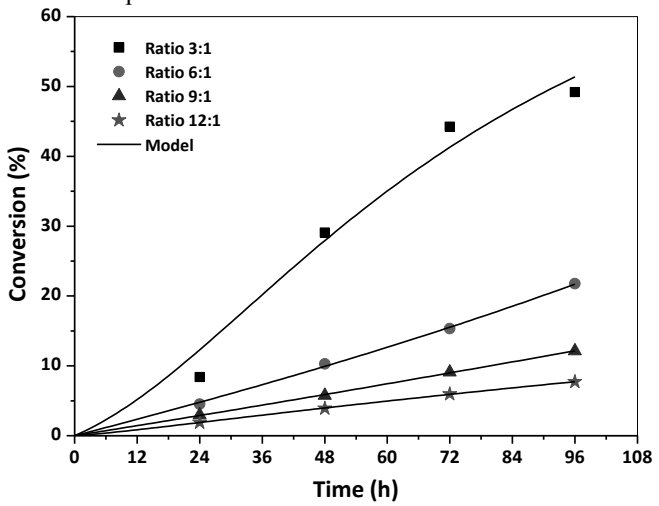

Figure 2. Influence of alcohol:oil molar ratio on the biodiesel production carried out at 37 °C and with 1 wt% of water.

The effect of water content was also explored. There is an optimal amount of water (0.5 wt% or 1.0 wt%) where biodiesel conversion is higher. Very small or very high water amount reduces conversion. Figure 3 also illustrates the process model performance against experimental data for the different conditions, illustrating that the proposed

model is able to predict very well the experimental behavior, indicating once more that the parameter estimation strategy leads to an excellent prediction of experimental data.

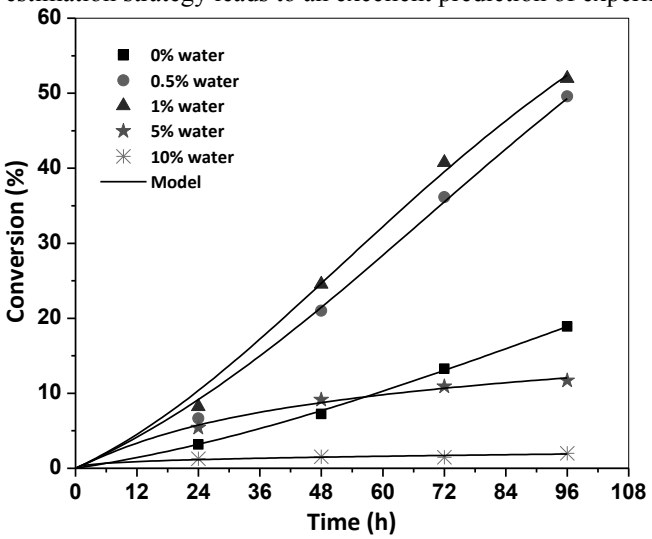

Figure 3. Influence of the water content on biodiesel synthesis performed at 37 °C and alcohol:oil molar ratio of 3:1.

Figure 4 shows for the concentration profiles for triglyceride, diglyceride, monoglyceride, glycerol, alcohol and biodiesel when the reactions is carried out with an alcohol:oil ratio of 9:1 and 1 wt% of water. The estimated kinetic constant for this experimental condition were k_1 = 0.5132 L·mol^{-1}·h^{-1}, k_2 = 3.6833 h^{-1}, k_3 = 3.6921 L·mol^{-1}·h^{-1}, k_4 = 1.4235 L·mol^{-1}·h^{-1}, k_5 = 3.6122 h^{-1}, k_6 = 1.0537 L·mol^{-1}·h^{-1}, k_7 = 2.0014 L·mol^{-1}·h^{-1}, k_8 = 0.2907 h^{-1} and k_9 = 2.3083 L·mol^{-1}·h^{-1}. As depicted in Figure 4, the model was able to describe the experimental data and it can be ultimately used to predict the concentration profiles of the main constituents in the reaction medium.

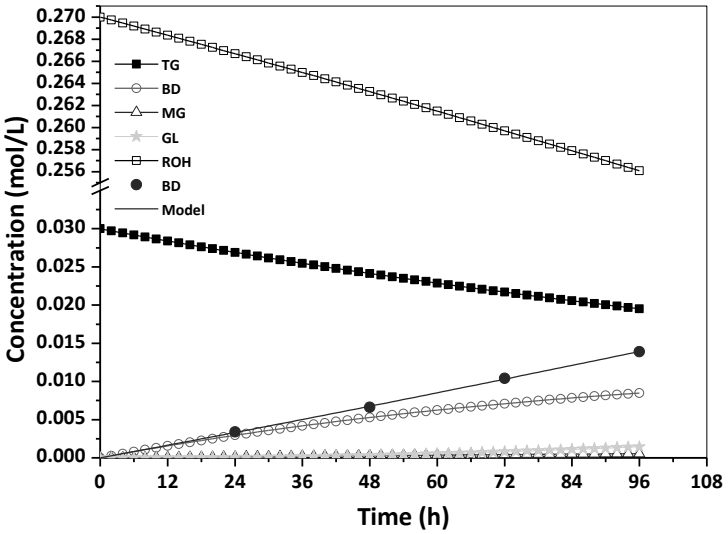

Figure 4. Estimated concentration profiles for triglyceride, diglyceride, monoglyceride, glycerol, alcohol and biodiesel when the reaction is carried out with an alcohol:oil ratio of 9:1 and 1 wt% of water.

4. Conclusion

The general proposed model is able to predict very well the reaction behavior of biodiesel production in several different experimental conditions. Based on the algebraic-differential model performance, the proposed strategy can be successfully used to describe and optimize the biodiesel production through enzymatic reactions performed in batch and semibatch operating mode.

Analysis of two Alternatives to Produce Ethylene from Shale Gas

Andrea P. Ortiz-Espinoza,[a] Mahmoud M. El-Halwagi,[b] Arturo Jiménez-Gutiérrez[a*]

[a]*Departamento de Ingeniería Química, Instituto Tecnológico de Celaya, Av. Tecnológico S/N, Celaya, Gto, 38010, México*
[b]*Chemical Engineering Department, Texas A&M University, College Station, Texas 77843, U.S.*

Abstract

The recent discoveries of shale gas have caused a decrease in the price of natural gas, which has opened a window of opportunities for its use not only as a source of energy but also as a feedstock for the production of chemical products. In this work, the use of shale gas for the production of ethylene is analysed. Two methods, the Oxidative Coupling of Methane (OCM) and the Methanol to Olefins (MTO) process are considered. The OCM is a direct-conversion process in which methane is converted to ethylene using a catalytic reactor. The MTO is a process with several steps where methane has to be first converted to syngas and then to methanol. The product, crude methanol, is finally converted to ethylene. Based on process simulations, an assessment of economic, energy and environmental considerations for each process was carried out. The results show that the MTO process provides a better alternative for the production of ethylene using shale gas. A sensitivity analysis shows that the OCM process can only be profitable under low prices of shale gas and high prices of ethylene.

Keywords: Ethylene, Shale gas, OCM process, MTO process, Techno-Economic Analysis.

1. Introduction

The availability of natural gas has increased within the last decade due to the implementation of new extraction techniques such as horizontal drilling and hydraulic fracturing, which have made possible the extraction of the denominated Shale gas, trapped in low permeability rock formations. The new abundance of natural gas has lowered the price of natural gas, encouraging its use not only as an energy source but also as a feedstock for the production of valuable chemicals (Wang et al., 2014). Although the production of some chemicals such as methanol have already been analysed, there is a need for the analysis of other production processes that could be part of the supply chain. One of the main building blocks for many products such as plastics, resins and fibers is ethylene. Although ethylene is typically produced by thermal cracking of ethane and propylene from natural gas, alternative processes for its production using methane as feedstock have been gaining significance over the past few years. Among the alternative processes for the production of ethylene, the Oxidative Coupling of Methane (OCM) and a Methanol to Olefins (MTO) technology have raised particular interest (Sundaram et al., 2010). The OCM is a direct process in which methane is converted to ethylene using a catalytic reactor (Godini et al., 2013), while the production of ethylene via methanol involves several steps (Vora et al., 1997).
The aim of this work is to evaluate the profitability of these two processes under a shale gas scenario and perform an environmental assessment, in order to find the

compromises between economics and the environmental considerations, as well as to perform a sensitivity analysis to show the impact of changes in the price of ethylene and shale gas on the profitability of the processes.

2. Description of the processes

The analysis is based on a plant capacity of 500,000 tpy for ethylene production. As the source of shale gas, the Barnet Shale Play, located in the state of Texas in the U.S. was selected. This play has been largely operated and much of the technology used for extraction of gas has been developed there (Bullin and Krouskop, 2009). The average composition of the different wells in the play shown in Table 1 was used in this work.

Table 1. Average composition for the Barnett Shale play*

Component	Composition (%)
Methane	86.8
Ethane	6.7
Propane	2.0
Carbon Dioxide	1.7
Nitrogen	2.9

*Source: Bullin and Krouskop (2009)

Before the shale gas can be sent through the pipelines to the production process, a purification process is needed. It usually consists of an acid gas removal unit, a dehydration unit, the removal of nitrogen and a series of distillation columns to remove natural gas liquids (Bullin and Krouskop, 2009). Once purified, the gas is sent to the production process that can be one of the following alternatives.

Oxidative Coupling of Methane (OCM)

In this process, methane is directly converted to ethylene through a catalytic reactor using pure oxygen provided by an air separation unit. This reactor operates at a temperature of 825 °C and a pressure of 1.1 bar. The reactions that take place in the reactor are as follows:

$$CH_4 + 2O_2 \longrightarrow CO_2 + 2H_2O \qquad C_2H_6 \longrightarrow C_2H_4 + H_2$$
$$2CH_4 + 0.5\,O_2 \longrightarrow C_2H_6 + H_2O \qquad CO + H_2O \longrightarrow CO_2 + H_2$$
$$CH_4 + O_2 \longrightarrow CO + H_2O + H_2 \qquad CO_2 + H_2 \longrightarrow CO + H_2O$$

The outlet stream from the reactor is sent to a multi-stage compressor where water is removed. Then, a cooler is used to lower the temperature before the gas stream is sent to an amine absorber, which uses MEA, to remove the CO_2. After CO_2 has been removed, the remaining stream is sent through a series of cryogenic distillation columns were unreacted methane is recovered for recycling and ethane and ethylene are separated. This process is limited due to the medium conversion of methane (less than 50%) and the poor selectivity to ethylene, leading to the production of high amounts of CO_2 and water (Godini et al., 2013). Despite this factor, the process is worth of analysis as an alternative for the production of ethylene from shale gas given its simple flowsheet. In this work yields for the reported catalysts are used.

Methanol to Olefins (MTO)

The production of ethylene via methanol involves several steps. The first step is a natural gas reforming process, where natural gas is converted into synthesis gas, which

consists of CO and H_2. For the reforming stage, different process are available (Julián-Durán et al., 2014). In this work, steam methane reforming was chosen due to its endothermic nature, which together with the high exothermic OCM process offers a possible option for integrating both processes, as suggested in other works (Godini et al., 2013). The second stage of the process is the methanol production; here the synthesis gas is sent to a catalytic reactor to obtain crude methanol. Since methanol is to be used as a feedstock, no purification process is needed. The final stages consist in the Methanol-to-Olefins process. Crude methanol is sent through a catalytic reactor, where the catalyst SAPO-34 provides a high selectivity to small linear olefins. The reactions that take place in the reactor are:

$$CO_2 + 3H_2 \longrightarrow CH_3OH + H_2O$$
$$CO_2 + H_2 \longrightarrow CO + H_2O$$

The reactor product is sent to a quenching tower, then CO_2 and water are removed by an absorber and dryer, and finally the different products are separated with a series of distillation columns (Chen et al., 2005). In addition to the production of ethylene, a significant amount of propylene is produced, which can be sold for a profit.

3. Results

Both processes were modelled in Aspen Plus using data from the literature. The consumption of raw materials is reported in Table 2, while Table 3 shows the energy requirements per kg of ethylene for each process. With the recycling of unreacted methane, the consumption of fresh natural gas for the OCM was reduced to almost half of the original amount. The energy consumption for the MTO process is slightly higher for heating and cooling, but the electricity needed for the OCM process is considerably higher than that for the MTO, which affects the process economics.

Table 2. Raw Material Consumption (kg/kg ethylene).

	OCM	MTO
Natural Gas	3.52	4.09
Oxygen	7.53	
Steam		12.28

Table 3. Energy requirements per kg of ethylene produced

		OCM	MTO
Heating	(MMBtu)	0.0350	0.0478
Cooling	(MMBtu)	0.0726	0.0838
Electricity	(kW-h)	7.1881	1.3071

Economic evaluation

For the economic analysis, an operating period of 330 days per year and a tax rate of 30% were assumed. Also, a 10-year linear depreciation with a salvage value of 10% was used. The working capital investment (WCI) was taken as 15% of the total capital investment (TCI), with the rest belonging to the fixed capital investment (FCI) (El-Halwagi, 2012). The estimations for the FCI of each process are shown in Table 4, which were based on reported data and using the six-tenths rule for capacity adjustment. For the MTO process, the value for the methanol plant and the methanol-to-olefins plant were estimated separately. In order to compare the two processes, return on investment (ROI) values were estimated (El-Halwagi, 2012),

$$ROI = \frac{(Annual\ sales - Annual\ Fixed\ Cost - Annual\ Operating\ Cost)(1 - tax\ rate) + Annual\ Fixed\ Cost}{TCI} \quad (1)$$

Table 4. FCI and TCI estimated values for ethylene production processes.

	FCI (MM$)	TCI (MM$)	References
OCM	$677.00	$796.47	Godini et al. (2013)
MTO	$1,466.00	$1,724.71	Julián-Durán et al. (2014) Wu (2013) Vora et al. (2013) Chen et al. (2004)

The ethylene price was assumed as $0.65/lb, and for the MTO process the price for propylene was set at $0.75/lb. The cost of shale gas, oxygen, and water for steam were assumed as $3.5/kscf, $0.05/lb, and $0.74/$m^3$ respectively (El-Halwagi, 2012). Table 5 summarizes the major economic results. Although the MTO plant has a higher FCI, its ROI seems attractive, while the OCM process is not profitable under the scenario considered here.

Table 5. Key Economic information for the ethylene production processes.

	MTO	OCM
Annual Income (MM$)	$1,251.90	$716.49
Annual Operating Costs (MM$)	$578.28	$1,044.38
Depreciation (MM$/yr)	$131.95	$60.93
Tax Rate	0.3	0.3
ROI (%)	29.63	-26.52

Energy Integration

The operating cost of each process can be reduced through energy integration. In order to identify the minimum cooling and heating utilities, a thermal pinch analysis was carried out. Figure 1 shows the grand composite curves for each production alternative. A minimum driving force of 10 K was used. It can be observed that the heating utilities can be reduced to zero in both cases, while the cooling utilities can be lowered to 2233 MMBtu/h for the MTO process and 1335 MMBtu/h for the OCM process. If cogeneration is considered, the cooling utilities can be further reduced to 0 for the MTO and 535 MMBtu/h for the OCM process, with the generation of 64 MW and 21 MW respectively. Details of the cogeneration method can be found in El-Halwagi (2012). Considering the energy integration and the cogeneration implementation, the ROI of the processes increases to 37.66% for the MTO and to -14.23% for the OCM.

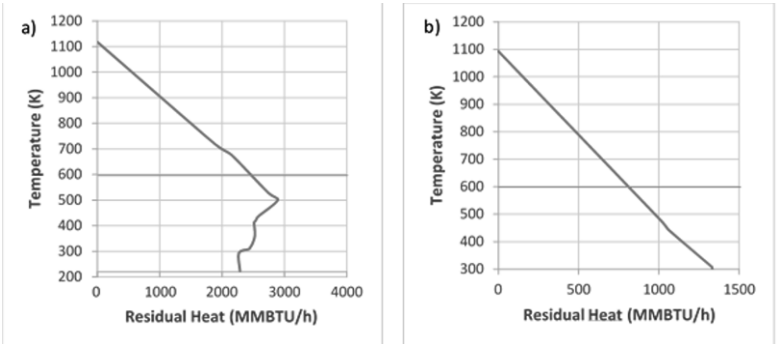

Figure 1. Grand composite curves for the MTO (a) and the OCM (b) processes.

Sensitivity analysis

A sensitivity analysis was carried out to evaluate the impact on the process profitability due to changes in products and feedstock prices. Figure 2 shows the ROI for ethylene prices ranging from \$0.5 to \$0.9 per pound and shale gas prices (pipeline quality) from \$2/kSCF to \$6/kSCF. It can be seen that the OCM process can only make a profit at high prices of ethylene and very low prices of shale gas.

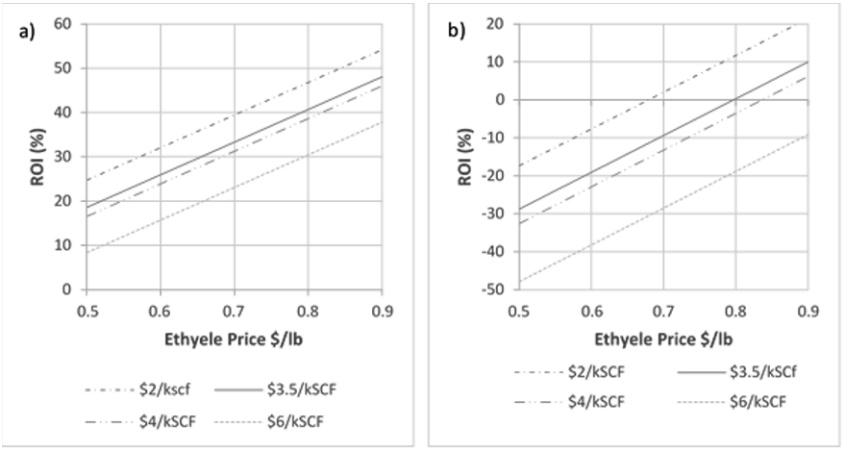

Figure 2. Sensitivity analysis for the MTO (a) and OCM (b) process at different prices of ethylene and shale gas.

Environmental Assessment

To estimate the environmental impact, CO_2 emissions were calculated for each process. CO_2 equivalents for outlet streams were obtained from Aspen Plus simulations. The emissions due to the use of the utilities were estimated with the EPA method for stationary combustion sources (EPA, 2008), and the CO_2 emissions related to the use of electricity were assessed using a factor of 0.73 MT of CO_2/MWh (EIA, 2014). The total amount of CO_2 emissions for each process is shown in Table 6. The MTO shows a higher impact due to purge streams that contain syngas, as this is translated into high CO_2 equivalents.

Table 6. CO_2 emissions, Mt/y

	MTO	OCM
Streams	19.80	12.60
Burning Fuels	1.26	0.93
Electricity	0.48	2.62
Total	21.55	16.15

4. Conclusions

The development of flowsheets for two processes to produce ethylene from shale gas and the results from their simulations using the ASPEN Plus® process simulator have been presented. From an economic basis, the MTO process showed the best profitability, with a high ROI, while the OCM process showed a suitable profitability only at low shale gas prices and high ethylene prices. Such unfavourable economics of the OCM process could be overcome with the design of new catalysts that provide

better reaction performance with respect to the information collected for the development of this work. The starting of a demonstration facility for the production of ethylene with this technology has recently been announced (Greenwood, 2014). The information about the catalyst details, however, is not available.
On energy and environmental aspects, the estimation of energy integration targets showed that both processes could be self sufficient in terms of their heating duties. From an environmental viewpoint, the MTO process showed higher CO_2 emissions than the OCM process, although this issue could be resolved by reducing purge streams or using them for another process.

A Crude Oil Economic Model for PSE applications

Davide Manca[a], Valentina Depetri[a], Clément Boisard[a,b]

[a] *PSE-Lab, CMIC Department, Politecnico di Milano, 20133 Milan – ITALY*
[b] *Process and Informatics Engineering Dep., ENSIACET – 31030 Toulouse – FRANCE*

Abstract

The paper proposes a revised economic model to forecast the price of crude oil over medium- and long-term horizons so to take into account recent variations in both Brent and WTI quotations. This model uses as sampling interval the quarters, which cover most of Conceptual Design problems such as feasibility studies, economic assessments, and production/allocation planning. The elements of volatility and market fluctuations for supply-and-demand terms are taken into account by introducing the contributions of both producers (OPEC) and consumers (OECD).

Keywords: Crude oil; Economic model; Feasibility studies; Market uncertainty.

1. Introduction

Crude oil (CO) is one of the most basic and globally used raw materials in refineries and petrochemical plants. Fluctuations of CO prices can produce significant impacts on international economies. Indeed, CO prices are tracked very closely not only by investors worldwide, but also by process designers because CO is a reference component for both Oil&Gas and petrochemical supply chains. CO quotations are either directly (*i.e.* distillates) or indirectly (*i.e.* derived commodities) taken into account for the economic assessment and feasibility study of PSE problems (Manca, 2013). Depending on the specific problem under study, the time horizon considered in the economic assessment can be a short-, medium-, or long-term interval. On one hand, short- and medium-term horizon models are involved in scheduling and planning and require covering and therefore forecasting daily/weekly/monthly intervals. On the other hand, long-term horizon models are involved in Conceptual Design and are even more challenging as they need to estimate variables such as supply, demand, production, and capacity storage for quite long periods (*i.e.* quarters/years). Manca (2013) showed how CO economics influences at a great extent the quotations of commodities and utilities, which play a major role in the assessment of OPEX (operative expenditures) terms. Furthermore, Mazzetto *et al.* (2013) used CO as the reference component for econometric models of bioprocesses and showed a functional dependency of both raw biomaterials and final bio-products from the CO market. Due to high degrees of volatility, the real price of CO is difficult to model. Both CO and distillate prices are affected by exogenous elements, which have the potential to disrupt the flow of oil and products to market (Zhang *et al.*, 2008). This paper proposes an economic model of CO prices for forecasting purposes and discusses a possible geographical localization of CO quotations. The most important global CO benchmarks are West Texas Intermediate (WTI) for the Americas and Brent for Europe and middle Asia (Rasello and Manca, 2014). From 2011 on, WTI and Brent indexes lost their mutual consistency. The reason for the coming apart of their trends consists in a number of distinct but correlated reasons. Shale gas, shale oil, international crises, embargos, available infrastructures, industrial and transport accidents, natural calamities, and weather variability are

examples of the exogenous terms that played a major role in the quotation fluctuations even over short periods with a further influence from complex geopolitical backgrounds (Manca and Rasello, 2014). According to Liu *et al.* (2014), the recent sudden abundance of shale oil in the USA since 2011 has produced a substantial discount of WTI respect to Brent quotations. Since 2005, production of conventional CO has not grown concurrently with the growth of demand, so the oil markets have undergone a so-called *phase transition*. Indeed, current manufacturing is *inelastic*, which means that it is unable to follow the demand growth. This point pushes prices to fluctuate significantly because the resources of other fossil fuels do not seem to be able to fill that gap in the supply chain. In addition, the curves of CO production and net imports are close to a cross point in the United States. As in recent years US production of shale oil has boomed, North America imports of CO have essentially halved. The roots of the last 2014 quarter price crash lie on different factors: the massive reduction of import growth in China, the stagnation of oil demand in western world and Japan, the oversupply due to the US fracking boom and growth of oil sands in Canada, the imbalance of price ratios between oil and natural gas, the role of speculative investors, and a stronger USD respect to other currencies. All these factors were responsible for the 40% drop of CO prices from May to December 2014. Technical floors of 70 and 54 USD/bbl for the CO quotations, dating back to 2010 and 2006 respectively, showed to be inconsistent as they were repeatedly broken down in last 2014 quarter (Davis and Fleming, 2014). This points out that no real support level exists for the current oil marketplace.

2. Methods

The scientific literature (Ye *et al.*, 2009) showed a significant attention to forecast *variations* (technically speaking: *shocks*) of CO quotations. Most of literature papers on economics of petroleum prices are based on a financial background that focuses on the forecasting capability to trade CO by means of futures, selling/buying options, and other financial operations that have a time horizon which is much shorter than the one typically required by PSE applications (Manca, 2013). Price fluctuations cannot be modeled simply by a trend-line (Manca, 2013). Conversely, high volatility and bull-and-bear periods put both the investors and process managers in a difficult position to track the price trend of CO and finalize feasibility studies based on sound economic assumptions. Among forecasting models, one can distinguish two major classes: economic and econometric models. Economic models involve purely economic variables and simulate fluctuations of either *spot* or *futures* markets subject to the supply-and-demand law. This is the case of OPEC model (Cooper, 2003; Kaufmann *et al.*, 2004; Dees *et al.*, 2007). Econometric models do not try to understand the forces that cause price fluctuations, but are only focused on time series, trends followed by prices, and possible future extrapolations. The use of economic models on long-term horizons is challenging as they are based on forecasts of supply-and-demand levels, and capacity storage. The inability to predict all the variables that affect the dynamics of prices, such as technical advances in exploration and production of hydrocarbons, the political dynamics or changes in collective behaviors and both national and international legislations, make the implementation of economic models rather challenging. For the sake of space, the paper focuses only on economic models. Further details on econometric models can be found in Manca (2013) and Rasello and Manca (2014).

2.1. Economic models

According to Dees *et al.* (2007), oil prices are defined by a rule based on changes in market conditions and OPEC (Organization of Petroleum Exporting Countries)

behavior. OPEC decisions about quota and capacity utilization have a significant and immediate impact on oil price and some models are developed to comply with these hypotheses. Oil markets are characterized by the presence of both OPEC cartel and independent producers. The supply-and-demand terms can be identified respectively by CO producers and consumers. For the sake of simplicity, these can be assumed to be clustered in OPEC and OECD (Organization for Economic Cooperation and Development). Some papers studied the behavior of OPEC and its decisions (Cooper, 2003; Kaufmann *et al.*, 2004; Dees *et al.*, 2007). The pivotal work of Kaufmann *et al.*, (2004) provides a model of real oil prices that includes variables representing market conditions, such as OECD stocks for CO, capacity utilization by OPEC, OPEC announced quotas, and the degree to which OPEC production adheres to those quotas. Kaufmann's model comprises also a boolean variable for the Persian Gulf War, and three boolean variables for the first three quarters of the year that are taken as initial condition for a one-step forward forecast. The last three boolean variables cannot be extended to multi-step forecasts that work on long-term horizons as the effect of the initial quarter vanishes rapidly after few predictions (*i.e.* after few quarters). Dvir and Rogoff (2014) presented evidence of significant interactions among four factors of CO international markets: production, demand, stocks, and price. The involved variables are not easy to model because they are function of the economic activities run by both producing and consuming countries. This paper draws inspiration from the work of Kaufmann *et al.*, (2004) and proposes the following adapted model to take into account the recent disturbances that influenced and changed significantly the CO markets:

$$P_t = \alpha_0 + \alpha_1 Days_t + \alpha_2 Quotas_t + \alpha_3 Cheat_t + \alpha_4 Caputil_t + \alpha_5 Q_1 \quad (1)$$

where P_t is the CO quarterly price at time t [USD/bbl]; $Days$ is the number of days of forward consumption of OECD CO stocks (it is calculated by dividing OECD CO stocks by OECD CO demand); $Quotas$ is the OPEC production quota [Mbbl/d]; $Cheat$ is the difference between OPEC CO production and OPEC quotas [Mbbl/d]; $Caputil$ is the capacity utilization by OPEC (calculated by dividing OPEC production [Mbbl/d] by OPEC production capacity [Mbbl/d]); Q_1 is a boolean variable that takes into account the level of oversupply of OPEC respect to US production. Eq. (1) is linear in the adaptive parameters α_i whose values are reported in Table 1.

Table 1: Adaptive parameters in Eq. (1) for the models of WTI and Brent quotations.

Coefficient	WTI	Brent
α_0	868.70	780.09
α_1	-10.39	-11.33
α_2	-11.22	-9.60
α_3	-11.68	-8.45
α_4	184.33	294.80
α_5	-25.42	-30.20
R	0.8160	0.8105

The last term of Eq. (1) accounts for the recent decrease between OPEC and US productions which fell under 22 Mbbl/d. The sign of the estimated adaptive parameters are in part consistent with previous results described by Dees *et al.* (2007) as per the variables $Days_t$, $Cheat_t$, $Quotas_t$, and $Caputil_t$ for WTI prices. At the same time, it is worth observing the different values of Brent parameters respect to WTI ones. This is

mainly due to the dissimilar evolution of Brent and WTI quotations subject to separate dynamics produced by the abovementioned events occurred in recent years. It is worth observing that Eq. (1) cannot forecast the unpredictable conflicts, tenses, and events that may occur all over the world and influence CO markets. For instance, the first-month events of 2011 such as the conflict in Libya and the tsunami in Japan, combined with the Fukushima nuclear accident, increased significantly the CO prices. Similar comments can also be made for the political situation of Iraq that recently impacted on the CO quotations.

Eq. (1) calls for suitable forecasting models of the input variables: OECD demand, OECD inventories, OPEC production, and OPEC production capacity. The time interval chosen to identify these models is Q1-2012 to Q4-2014 and is a compromise between being as close as possible to current situation and preserving the generality accuracy. The model of OECD demand is a modified version of Cooper's model (Cooper, 2003):

$$Demand_{t+1}^{OECD} = \alpha_0 GGDP_{t+1} + \alpha_1 P_t + \alpha_2 Q_1 + \alpha_3 Q_2 + \alpha_4 Q_3 + \alpha_5 Q_4 \quad (2)$$

where *GGDP* is the Global Gross Domestic Product of the corresponding quarter whose growth (*GGGDP*) seems to be stable at around 2% (in terms of annual variations) and Q_1, Q_2, Q_3, Q_4 are boolean variables respectively referred to first, second, third, and fourth quarters. Just for the demand term the contribution played by quarters should not be neglected as it allows improving significantly the forecast capability of the whole economic model. The effect of *GGGDP* is interesting as it can create different scenarios according to the degree of economic activity in a country, region, and the world. Although oil demand conditions respect the periodic trend in OECD countries, the supply modeling is extremely difficult to model as oil markets reflect the complex background of production conditions and OPEC behavior (Dees *et al.*, 2007). OECD inventory is the result of the difference between the OECD demand and the OPEC supply. At our knowledge, the literature does not report any forecasting models for OPEC inventories, production, and capacity utilization to be fruitfully applied to PSE problems. Our research efforts on the OECD inventories showed that they are correlated with OECD demand and OPEC production capacity:

$$Inventory_{t+1}^{OECD} = \alpha_0 + \alpha_1 Capacity_t^{OPEC} + \alpha_2 Demand_{t+1}^{OECD} \quad (3)$$

The OPEC production depends on several ambiguous and unpredictable parameters, such as local political situations in the different countries of the cartel, even if OPEC itself tries to regulate the production by means of compensations in case of an unintended production decrease or increase by a country member. For the sake of clarity, the model proposed in this paper depends on current OECD inventories and on the previous price of CO:

$$Production_{t+1}^{OPEC} = \alpha_0 + \alpha_1 Inventory_{t+1}^{OECD} + \alpha_2 P_t \quad (4)$$

OPEC tries to produce less than its capacities allow so to be able to intervene in case of sudden variations in CO demand and produce a price impact. A very basic model representing the OPEC competitive behavior assumes that:

$$Production^{OPEC} = 0.95 \cdot Capacity^{OPEC} \quad (5)$$

As American CO production started a new growth in 2008, a dedicated rather simple model for recent trend of the American production assumes that:

$$Production_{t+1}^{USA} = \alpha_0 + \alpha_1 \cdot Production_t^{USA} \quad (6)$$

Eq. (6) is used to trigger the boolean variable Q_1 in Eq. (1) so to account for the offer

surplus originated by the shale-oil revolution. Eventually, as far as OECD inventories are concerned, the proposed model is:

$$Capacity_{t+1}^{OPEC} = \alpha_0 + \alpha_1 Inventory_{t+1}^{OECD} \quad (7)$$

Since our economic model was designed to reproduce as faithfully as possible the future trends of CO quotations, which depend on different geopolitical and economic scenarios (*e.g.*, wars, tensions, local crisis) then the standard deviation of petroleum prices ought to be taken into account when shaping the model stochastic features. In particular, by analyzing the CO trend, it is possible to quantify that the standard deviation (σ) of WTI CO price in the last five years was 9.5%. Major increases of the price ($+3\sigma$) were due to major variations (*e.g.*, wars, attacks, crashes) and were characterized by a 10-year period. Minor increases of the price ($+1.5\sigma$) were due to minor variations (*e.g.*, tensions and growth in China) and were characterized by a 3-year period. Minor decreases of the price (-1.5σ) were due to minor variations (*e.g.*, economic or social issues, technical defects) and had a frequency of about 7 years. Finally, major price reductions (-3σ) were due to major economic/financial instabilities and were rather rare having a return frequency of about 10 years. Other critical elements are given by OPEC decisions about quota and capacity utilization, which have a significant and immediate impact on oil quotation and act as a control term on prices even if the cartel does not have the same power as the one it had in the past (*i.e.* in the 70's of last century) when OPEC could set almost independently the CO prices. In the 70-80's, OPEC strategy of pushing up prices by restricting supply was responsible for the development of competing oil resources and deep-water technology.

Nowadays, the economic background has changed and is more complex than just 5-10 years ago as OPEC and OECD do not include the so-called BRIC countries (*i.e.* Brazil, Russia, India, and China) and other emerging countries such as Indonesia. Furthermore, the increasing concern about tar sands in both USA and Canada has given a new power to the American economy that could become independent of OPEC decisions about quotas and production in the short future.

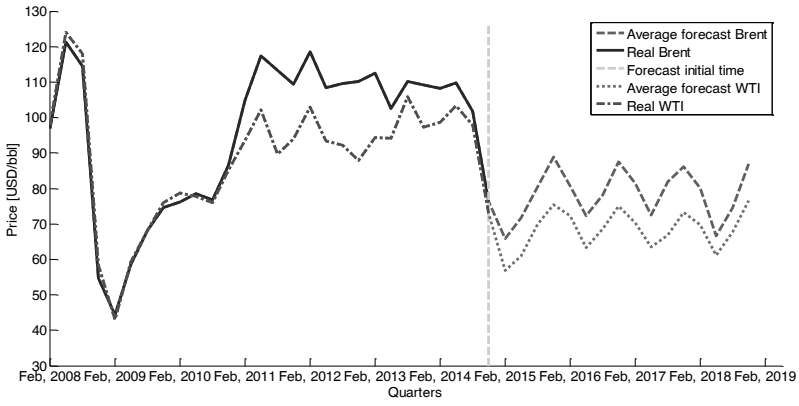

Figure 1: Brent and WTI forecast prices start from the vertical dashed green line (Nov, 2014).

In front of these emerging scenarios, Middle East producers decided not to cut their quotas at the end of 2014 to maintain their production competitive with the global crude oil spot market. The highest authorities of Saudi Arabia declared acceptable that prices remained low for long periods if that would reduce investments in shale oil and rebalance global markets. The recent highly-variable trend of CO prices made oil

companies and some traditional producers (*i.e.* Iran, Venezuela, and Russia) afraid about breaking their own neutrality threshold between incomes and outcomes (*i.e.* their breakeven point). Figure 1 shows on the left of the vertical dashed line the real past quotations of Brent and WTI, and on the right the corresponding forecast average prices resulting from 50 stochastic scenarios based on Eq. (1) under the hypothesis of bullish trend of the *GGGDP* (*i.e.* 2% annual constant increase). It is worth observing that according to the very drastic changes measured at the end of 2014, the expected *GGGDP* ratings were decreased. To confirm this, EIA expects WTI monthly average prices fluctuating in 2015 between 34 and 76 USD/bbl with a 95% confidence interval.

3. Conclusions

Starting from the qualitative classification of economic and econometric models, the paper proposed a new economic model to forecast the evolution of CO quotations over long-term horizons. Eq. (1) summarized the proposed economic model to be supplemented by Eqs. (2-7) that describe the future dynamics of input variables. These equations can simulate different reference scenarios based on a set of stochastic trends. The call for creating distinct scenarios comes from the necessity to identify possible distributions of economic trends to answer the typical question of PSE applications about the feasibility of products and processes. It is advisable to update Eq. (1) rather often because of the ever-changing events that can influence market quotations. Today, more than ever, CO markets are seeing the emergence of new countries, the economic development of other ones, and the revival of interest and investment in nonconventional petroleum reservoirs (*e.g.*, shale oil, tar sands). The power of the proposed economic model consists in its capacity to account for the stochastic nature of CO prices that are globally influenced by the abovementioned events and factors. Similarly, the model accounts for both CO producers and consumers to influence and determine the price dynamics.

Simulation Study of Temperature Distribution in the Thermal Drying Oven for a Lacquer Coating Process

Paisan Kittisupakorn,[a*] Patsarawan Lipikanjanakul[a]

[a]*Chulalongkorn University, Pathum Wan, Bangkok 10330, Thailand*

Abstract

Metal sheets have to be coated with food grade lacquer and dried at thermal drying oven for metal can making process. At the thermal drying oven, exhaust gas is delivered out by the blower to eliminate the solvent. This leads to the temperature decreasing at the drying zone of the thermal drying oven, especially to unloading. To handle this, an inverter has been implemented to provide saving of electricity bill. In this work, temperature distribution and flow pattern of gas mixture between air and solvent have been studied. A three-dimensional model of the transient heat transfer has been developed and validated against the real data. Comparison of the temperature distribution and flow pattern between the conventional system or full speed and the new system with the inverter by changing speed of outflow has been made. Simulation results show that the system with the inverter obtains low temperature of the exhaust gas released out to the incinerator leading to heat loss decreasing of 10.4%. It is applicable to energy saving for the thermal drying oven.

Keywords:thermal drying oven, temperature distribution, flow pattern, gas mixture.

1. Introduction

In a metal can making process for food products, the metal sheets have to be coated with coating solution in order to protect any corrosion caused by chemical reaction between products and metal containers. Basically, a coating process can be divided into three steps; varnishing, drying, and curing. In the varnishing step, lacquer is transferred to metal sheets by roller coating. After that, the metal sheets are passed to a thermal drying oven in which either drying or curing is operated. In a drying zone, solvent medium in lacquer on the metal sheets are removed. The parameters leading to the oven's performance are air velocity, relative humidity, temperature, time, and nature of the coating solution (Blotta et al., 2011). The temperature must be kept at 453 K to completely dry all the solvent off. Moreover, to reduce the solvent accumulation, a blower operating at full speed has been employed to remove the exhaust gas in the oven. In spite of unloading, the blower still drives with full speed. This leads to heat losses, the decrease in the oven's temperature, and insufficient consumption in electricity and fuel. Consequently, an inverter, adjustable-speed drive used to control AC motor speed and torque by varying motor input frequency and voltage, has been implemented to control the operation of the blower by adjusting the rotating speed corresponding to a desired loading condition. Therefore, the implementation of the inverter can save electricity cost and increase thermal performance.

[*]Corresponding author: Paisan.k@chula.ac.th (P. Kittisupakorn)

The simulation study for the thermal system has been reported in several studies. The simulation must be analyzed under turbulence flow. Therefore, Reynolds-averaged Navier–Stokes (RANS) equations including heat transfer are frequently applied to study for temperature distribution. Simulation studies using the RANS equations are, for examples, the continuous bread-breaking oven (Khatir et al., 2012), the newly designed economizer (Niamsuwan et al., 2013) and the heating oven (Smolka et al., 2013).

The objective of this work is to study temperature distribution and flow pattern of gas mixtures between air and the solvent in the thermal drying oven. A mathematical model has been developed and validated with real data. The temperature distribution and the flow patter are presented in two cases: the conventional system or full speed and the new system with the inverter by changing speed of outflow.

2. Oven geometry and parameter

Geometry of the oven has been formulated in a three-dimensional model as shown in Figure 1. The oven is 5.1 m long, 2.095 m high and 1.2975 m wide. The width is considered as half width of real scale due to symmetry surface (a). Surface (b) is an inlet duct with cross section of 0.292 m × 5.1 m and surface (c) is an interface between drying zone and curing zone. Semi-circle in surface (d) is represented an outlet chimney of the oven with diameter of 0.502 m. It is located at 1.435 m from the oven entrance which is presented by surface (e) and surface (f), (g), and (h) are walls of the oven.

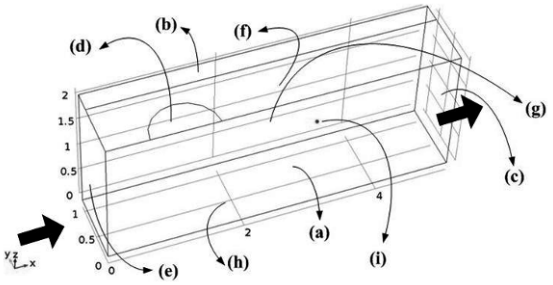

Figure 1 Geometry of the oven

In this study, fluid domain is specified as the gas mixture between air and solvent vapour. Normally, the solvent used is Butyl Cellosolve ($C_6H_{14}O_2$) for food grade lacquer. The gas mixture is considered as incompressible and Newtonian fluid and its properties are based on data in the Aspen plus software; the heat capacity, density, viscosity, and thermal conductivity are 1,135.81 J/kg-K, 0.408271 kg/m^3, 3.8348× 10^{-5} Pa·s, and 6.1103× 10^{-5} kW/m-K, respectively.

3. Mathematical model

A mathematical model of an air flow characteristic in a turbulent condition has been developed. The turbulent Reynolds Averaged Navier-Stokes standard model (RANS) is applied to provide the temperature distribution and flow pattern by Cartesian coordinate. It contains three governing equations: the mass, momentum, and energy conservation.

The equation of mass conservation (Continuity equation)

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x_x}\rho u_x + \frac{\partial}{\partial x_y}\rho u_y + \frac{\partial}{\partial x_z}\rho u_z = 0 \tag{1}$$

The equation of momentum conservation (Navier-Stokes equation)

$$\rho\left(\frac{\partial u_i}{\partial t} + u_x\frac{\partial u_i}{\partial x_x} + u_y\frac{\partial u_i}{\partial x_y} + u_z\frac{\partial u_i}{\partial x_z}\right) = -\frac{\partial p}{\partial x} - \left(\frac{\partial u}{\partial x_x}\tau_{xi} + \frac{\partial u}{\partial x_y}\tau_{yi} + \frac{\partial u}{\partial x_z}\tau_{zi}\right) + \rho g_i \tag{2}$$

The equation of energy conservation

$$\rho C_p\left(\frac{\partial T}{\partial t} + u_x\frac{\partial T}{\partial x_x} + u_y\frac{\partial T}{\partial x_y} + u_z\frac{\partial T}{\partial x_z}\right) = k'\left(\frac{\partial^2 T}{\partial x_x^{\,2}} + \frac{\partial^2 T}{\partial x_y^{\,2}} + \frac{\partial^2 T}{\partial x_z^{\,2}}\right) + Q \tag{3}$$

ρ is the density. x is Cartesian coordinate in the subscript is coordinate direction (x, y, z). u is the velocity component in the subscript is coordinate direction (x, y, z). The subscript i is an index of Cartesian components. p is pressure. τ is viscous stress tensor. g is gravity force in coordinate axis. C_p is the specific heat capacity at constant pressure. T is the absolute temperature. k′ is the thermal conductivity. Q is a heat source.

In the turbulence term, the standard k-ε model incorporated with the turbulence kinetic energy is used to give convection and diffusion transport. This model consists of two model equations: turbulence kinetic energy (k) and viscous dissipation (ε).

Equation of turbulence kinetic energy

$$\frac{\partial(\rho k)}{\partial t} + \rho(u\cdot\nabla)k = \nabla\cdot\left[\left(\mu + \frac{\mu_T}{\sigma_k}\right)\nabla k\right] + P_k - \rho\varepsilon \tag{4}$$

Equation of viscous dissipation

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \rho(u\cdot\nabla)\varepsilon = \nabla\cdot\left[\left(\mu + \frac{\mu_T}{\sigma_\varepsilon}\right)\nabla k\right] + C_{\varepsilon 1}\frac{\varepsilon}{k}P_k - C_{\varepsilon 2}\rho\frac{\varepsilon^2}{k} \tag{5}$$

In eq.(4) and eq.(5), μ_T is eddy viscosity. The five adjustable constants: C_μ, σ_k, σ_ε, $C_{\varepsilon 1}$, and $C_{\varepsilon 2}$ are 0.09, 1.00, 1.30, 1.44, and 1.92, respectively (Versteeg and Malalasekera, 2007).

A completely mathematical model with boundary and initial conditions is formulated and solved. The boundary and initial conditions are given in Table 1. The velocity is constant over the inlet surface. At outlet surface, there is no viscous stress. The surface (a) is set as symmetry condition in heat and flow simulation. At the external wall of the geometry, heat at the surface losses to the surrounding. Therefore, it is considered as the convective heat flux with external natural force.

Table 1 Boundary condition

Boundary	Surface*	Convectional	New system	Unit
Initial temperature		453.1500		K
Mass flow rate		1.6667	1.5000	m^3/s
Normal velocity inlet	(b)	0.1584	0.1584	m/s
Normal velocity inlet	(c)	0.6223	0.5498	m/s
Normal velocity outlet	(d)	4.2104	3.7893	m/s
Temperature inlet	(b)	473.1500		K
Temperature inlet	(c)	453.1500		K
Temperature inlet	(e)	303.1500		K
Pressure	(e)	101,314.9978		bar
Outlet velocity	(e)			
Outflow temperature	(d)			
Symmetry heat and flow	(a)			
Convectional heat flux	(f), (g), (h)			

* Surface boundary shown in Figure 1

The model is solved by a numerical method on the commercial software (COMSOL multiphysics version 4.3b). The mesh geometry is generated by fine element size in free tetrahedral. The numbers of generated meshes are 149,475 domain elements, 12,967 boundary elements, and 518 edge elements.

4. Computational validation and result

4.1. Validation with measurement values

To validate the temperature prediction, the calculated data based on the model is plotted against observed data. A type K thermocouple is used to give measured temperature data. It has been installed at a center of the oven for width, 0.5 m height from the top of the oven, and 3 m length from the entrance. The measurement position is displayed at the point (i) in Figure 1. The measurement has been observed in unloading period for 10 minutes with every 15 seconds. The temperature is kept at the operating condition for loading period at around 453±1 K before changing to unloading period. The simulated and measured temperatures are compared as shown in Figure 2. It can be seen that the model gives a good agreement of the temperature with an error of ±1.1 K.

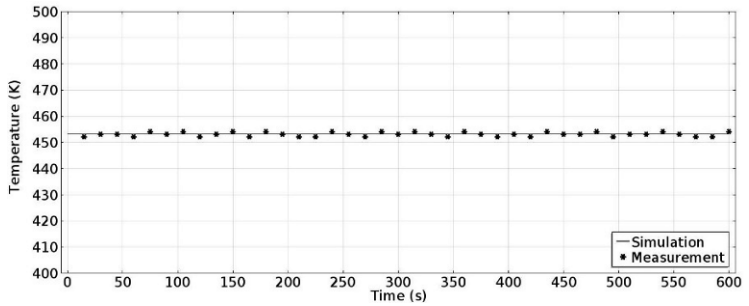

Figure 2 Temperature comparison between the simulation and measurement

4.2. Case 1: The conventional system or full speed

In this case, the blower operates at full speed in order to remove the exhaust gas of 1.6667 m^3/s. Simulation results show temperature distribution and flow pattern for the gas mixture at the drying zone. The temperature distribution at time of 5 min is presented in Figure 3(A). Near the entrance, the gas mixture temperature is initially at

295 K because heat is lost to the surrounding. Then, the gas mixture temperature rapidly goes to a desired temperature of 453.15 K after moving into 1.5 m from the entrance.

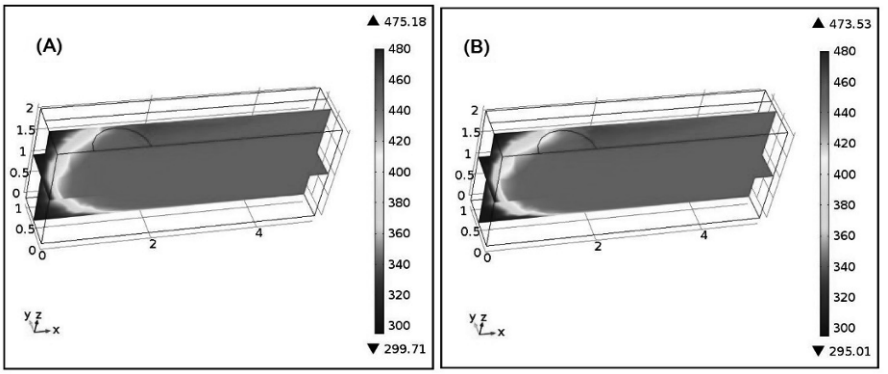

Figure 3 Temperature distribution (K) at time = 5 min: (A) Case 1 and (B) Case 2

In addition, the flow pattern at time of 5 min is illustrated in Figure 4(A). It can be seen that most gas mixture is moved from the interface to discharge at the chimney. Some gas mixture leaks out at the entrance. Figure 4(B) shows the profile of average velocity over x-y surface throughout the distance of drying zone at time of 2 min. As shown in solid line, the maximum velocity occurs at 1.5 m from the entrance owing to driving force by the blower.

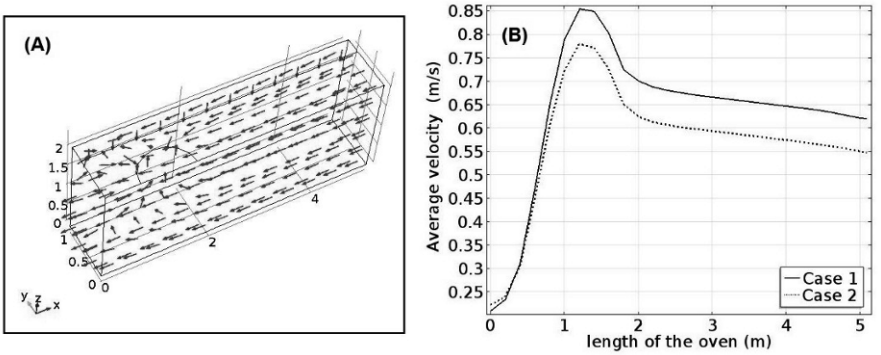

Figure 4 Velocity in the oven: (A) Flow pattern and (B) Velocity change by length of the oven

4.3. Case 2: The new system with the inverter to provide a change of outflow speed

In case of the new system, the inverter controls the blower's speed to operate at 1.5 m^3/s flow rate corresponding to unloading condition. Regarding to Figure 3(B), decrease of the blower's speed directly causes to the different temperature distribution around the outlet. Meanwhile, the similar profile is presented at other zones. According to Figure 4(B), the profile in dash line presents the analogous profile with low velocity. This is because of the decrease of the blower's speed leading to lower movement of the gas mixture compared to case 1.

Comparison of the temperature profiles of the exhaust gas released out to the incinerator for both systems has been made. As shown in Figure 5, the temperature profiles for full speed (case 1) and optimum speed (case 2) are represented by solid line and dot line,

respectively. It was found that the difference of average temperature between case 1 and case 2 is about 2 K. With Eq. (6), the calculated decrease in the heat loss (Q′) of about 10.4% is obtained.

$$Q' = \int_t m_1 c_p T_1(t)dt - \int_t m_2 c_p T_2(t)dt \tag{6}$$

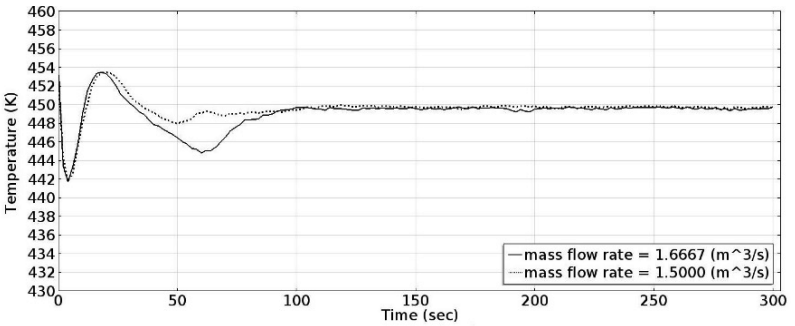

Figure 5 Temperature profiles at outlet surface

5. Conclusions

This work presents the simulation study for the temperature distribution in the drying zone of the thermal drying oven. The three-dimensional model of the transient heat transfer has been developed and validated with real data. The temperature distribution and flow pattern have been studied in two cases: full blower's speed and optimum blower's speed. The simulation results show that both cases give the similar profiles for temperature distribution and flow pattern. However, with the inverter installed, less blower's speed gives lower temperature of the exhaust gas released out to the incinerator leading to the decrease in the heat loss of 10.4%.

Abstract

Flammability data is needed to assess the risk of fire and explosions. This study presents a new group contribution (GC) model to predict the upper flammability limit UFL of organic chemicals. Furthermore, it provides a systematic method for outlier treatment in order to improve the parameter estimation of the GC model. The new method identifies and removes outliers based on the empirical cumulative distribution plot. It is compared to outlier detection based on Cook's distance and normal cumulative distribution.

Keywords: Outlier treatment, Flammability limit, Group contribution

1. Introduction

Flammability data provide important information in order to quantify the risk of fire and explosion in process safety studies and assessments. The upper flammability limit (UFL) is defined as the highest possible concentration of a substance in air at which a flammable mixture is formed (Crowl and Louvar, 2013). Experimental data on UFL are not always available due to cost and time constraints in particular at the early stage of process development where alternative concepts are evaluated and ranked before proceeding for more detailed analysis. Property prediction models can in this case be used to estimate the desired flammability data.

Group contribution (GC) based prediction methods use structurally dependent parameters in order to determine the property of pure components. The aim of the parameter estimation is to find the best possible set of model parameters that fits the experimental data.

However, outliers from the model set can strongly influence the parameter estimation, such that the property prediction can be inaccurate in the end. Therefore, it is necessary to identify possible outliers and remove them from the experimental data set. The outlier detection should be simple, following the structure of the model and mathematically consistent.

The Cook's distance (Cook, 1977) measures, how large the degree of influence of a data point is on the parameter set. A large Cook's distance indicates an outlier.

The approach suggested by Furguson, (1961) considers residuals between the experimental and the predicted values as observations coming from a hypothetical distribution, i.e. the normal distribution. The latter can be used in order to determine the outliers of the model.

In this study a methodology for outlier identification based on empirical cumulative distribution function (empirical CDF) is suggested and compared to the outlier treatments using normal probability and Cook's distance.

2. Methodology

2.1 Property model structure according to Marrero and Gani group contribution method

The Marrero Gani (MG) method considers the group contribution in three levels: The contributions from a specific functional group (1st order parameters), from polyfunctional (2nd order parameters) as well as from structural groups (3rd order parameters). Eq. (1) shows its general form.

$$f_i(\mathrm{X}) = \sum_j N_j C_j + \sum_k M_k D_k + \sum_l E_l O_l \qquad f(\mathrm{X}) = T \cdot \theta \tag{1}$$

In Eq. (1) C_j is the contribution of the 1st order group of type-*j* that occurs N_j times whereas D_k is the contribution of the 2nd order group of type-*k* that occurs M_k times in the molecular structure of a pure component. E_l is the contribution of the 3rd order group of type l that has O_l occurrences. The function $f(X)$ is specific for a certain property X (Marrero and Gani, 2001). The parameters can be summarized into the vector θ and the occurrences of the groups can be depicted in the matrix T. As examples, the different GC-factors of Adiponitrile and Methacrylonitrile are visualized in figure 1.

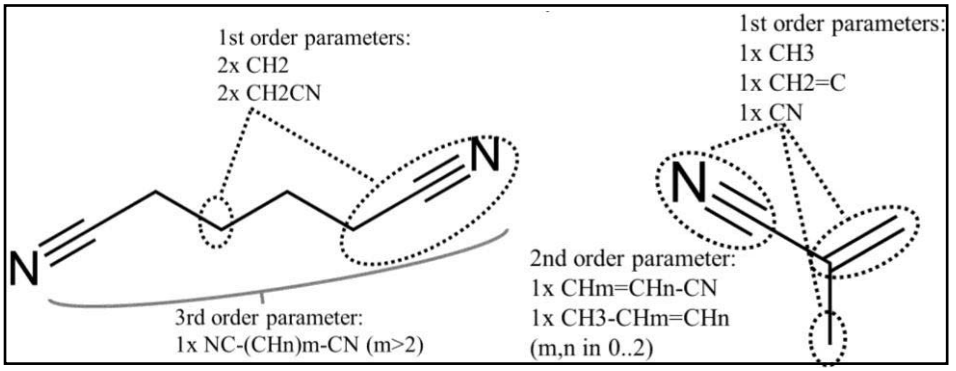

Figure 1. Example of GC-factors of Adiponitrile (left) and Methacrylonitrile (right).

The underlying assumption of group contribution principles is that a certain function of the property is linearly dependent on the contributions of the functional groups. Plots of various classes of pure components versus their increasing carbon number suggest that the appropriate form of the model function is logarithmic as specified in Eq. (2), where UFL_{const} is a universal constant. A selection of classes of compounds is showed in figure 2.

$$f_i(UFL) = \log\left(\frac{UFL_i}{UFL_{const}}\right) \tag{2}$$

2.2 Flammability limit data

Experimental data for UFL of 371 compounds, which includes alkanes, alkenes, alkynes, alcohols, aldehydes, halogenated substances, esters, aromatics and nitrogen compounds, are used from AIChE DIPPR 801 Database (AIChE, 2014). Flammability limits of each compound are provided in percentage volume in air at 298 K.

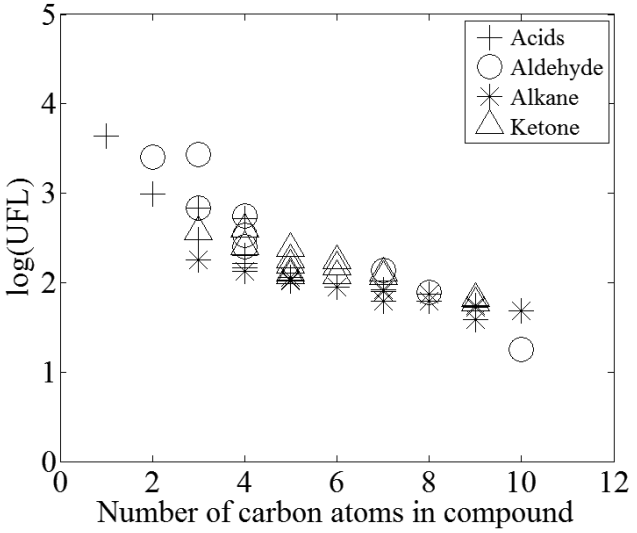

Figure 2. UFL of a selection of pure components versus their increasing carbon number.

2.3 Initialization and sequential parameter estimation

A first guess for the a priori unknown universal constants and MC-GC factors is provided by an approximation using linear algebra according to equation (3).

$$\hat{\theta} = (T^T T)^{-1} \cdot T^T \cdot f(UFL) \tag{3}$$

A value for the constant UFL_{const} is assumed in order to calculate the first guess for the parameters $\hat{\theta}$ from UFL data and the occurrence matrix *T*.

Afterwards the universal constants as well as the 1st, 2nd and 3rd order parameters are estimated separately applying ordinary non-linear regression according to Eq. (4).

$$\theta^* = \arg\min \sum_i (y_i^{\exp} - y_i^{pred})^2 \tag{4}$$

where θ^* corresponds to the estimated parameters and y_i^{exp} to the measurement and y_i^{pred} to the predicted value of compound *i*.

2.4 Simultaneous parameter estimation

The result of the sequential estimation serves as initial guess for the simultaneous parameter estimation algorithm, where all the parameters are estimated together for the ordinary non-linear regression problem.

2.5. Outlier treatment

Three ways of outlier treatment are applied separately to identify the corresponding outliers. The latter are then excluded and the parameter estimation is performed again. The three outlier treatments are compared and evaluated.

2.5.1 Outlier treatment using Cook's distance

Cook's distance measures the influence of a particular data point on the parameter estimation. A particular Cook´s distance D_i can be assigned to every value *i* according

to Eq. (5) (Cook, 1977). By definition compounds having a Cook´s distance larger than 4 divided by the number of data *n* is considered as an outlier (Hardin and Hilbe, 2007).

$$D_i = \frac{\sum_{k=1}^{n}(y_k^{pred} - y_{k(i)}^{pred})^2}{p \cdot MSE} \qquad D_i > \frac{4}{n} \tag{5}$$

In Eq.(5) y_k^{pred} is the prediction from the full regression for compound *k*, whereas $y_{k(i)}^{pred}$ is the prediction for compound *k* from a refitted regression where observation *i* is excluded. *MSE* is the mean square error and *p* is the number of parameters.

2.6.2 Outlier treatment using normal distribution

The underlying assumption is that the residuals between the predicted and experimental values are normally distributed and centred around zero (Ferguson, 1961). 95% of the data lie within two times the standard deviation σ of the residuals $y_j^{pred} - y_j^{pred}$. Residuals that fall outside this range of values that could reasonably be expected to occur, i.e. plus and minus 2 times the standard deviation σ, can be considered as outliers. The criterion is formulated in Eq. (6) for the data point *j* to be an outlier.

$$r_j = \left| y_j^{pred} - y_j^{pred} \right| > 2\sigma \tag{6}$$

2.6.2 Outlier treatment using empirical cumulative distribution

In this study we suggest a methodology where the residuals are not assumed to be normally distributed. The empirical cumulative distribution function (empirical CDF) tries instead to estimate the true underlying CDF. For the current data the empirical is depicted in figure 3.

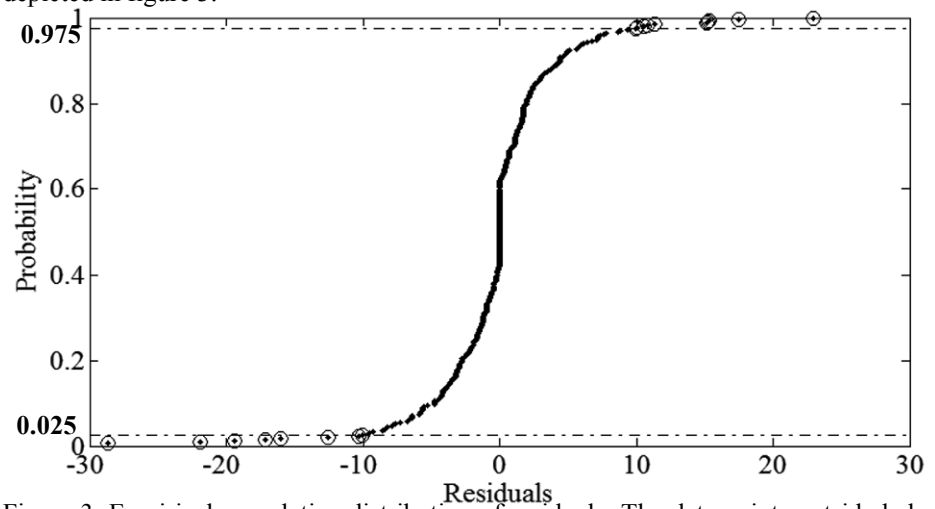

Figure 3. Empirical cumulative distribution of residuals. The data points outside below 0.025 and above the 0. 975 probability levels are considered as outliers.

The emperical CDF is a step function that increases by *1/n* in every data point.

Data points that are not reasonably likely expected to occur according to the empirical CDF can be considered as outliers, i.e. data points that lie below the 2.5% or above the 97.5% probability levels (see figure 3).

3. Results and discussion

The performance statistics of the regression before and after outlier exclusion is depicted in table 1. R^2 is the squared Pearson correlation coefficient between the experimental and the predicted values, N_{out} is the number of outliers removed, *SD* is the standard deviation, *ARE* is the average relative error between the predicted and the experimental values, *SSE* is the sum of squared errors, P_{rc} represents the percentage of the experimental data-points found within ± 25% relative error range respectively (Hukkerikar et al. 2012). In figure 4 the identified outliers are compared by depicting the prediction versus the experimental value. The equality line indicates a perfect fit.

Table 1. Model performance statistics

	R^2	N_{out}	*SD*	*AAD*	*ARE*	*SSE*	P_{rc} *25%*
Before outlier exclusion	0.72	0	6.2	3.0	24	14,398	66
After exclusion of Cook´s outliers	0.81	18	3	1.7	16	3,106	77
After exclusion of normal probability outliers	0.93	18	2.5	1.7	16	2,284	78
After exclusion of empirical CDF outliers	0.93	20	2.5	1.7	16	2,247	78

All three outlier treatments improve the regression performance. The outlier treatment using empirical cumulative distribution improves the regression similar to outlier detection using normal probability.

Considering figure 4, there are large value data points that are identified as outliers according to Cook's distance even though these compounds match the model. They influence the regression strongly and are assigned a large Cook's distance. Hence, large data points are removed from the data set, even though their prediction matches the experimental value and therefore should not be deemed as outliers. Although removing Cook's distance outliers improves the performance statistics, this outlier treatment is not recommended, because it also removes data points which are clearly in perfect agreement with the model prediction trends.

However, for the outlier treatment using normal CDF and empirical CDF approach of outlier identification, the potential outliers are those that differ a lot from the equality-line. The advantage of empirical CDF is that it does not a priori assume the property to be normally distributed, but tries to reveal the real underlining CDF. In cases where residuals follow a normal distribution, the difference between our approach that uses empirical distribution function and the Ferguson's method will indeed be negligible as is the case in this contribution. In that case, the empirical CDF will approximate a normal CDF distribution hence verifying the validity of the Ferguson's approach. However, in cases where residuals do not confirm to normal distribution and in particular the residual distribution displays long tails – as can be observed in several property model fittings in Hukkerikar et al. (2012), the empirical CDF approach is expected to guide better outlier detection hence model fitting. A potential caveat of using empirical CDF is that the number of data points (i.e. the size of sample used to

construct the cumulative probability function is expected to be representative of residuals distribution) will influence the outcome hence it is recommended to use the empirical CDF approach for relatively large size of data samples as often the case in building GC models.

Table 2 shows an example of the prediction of UFL for Methacrylonitrile, which is depicted in figure 1, using model Eq. (1) and (2).

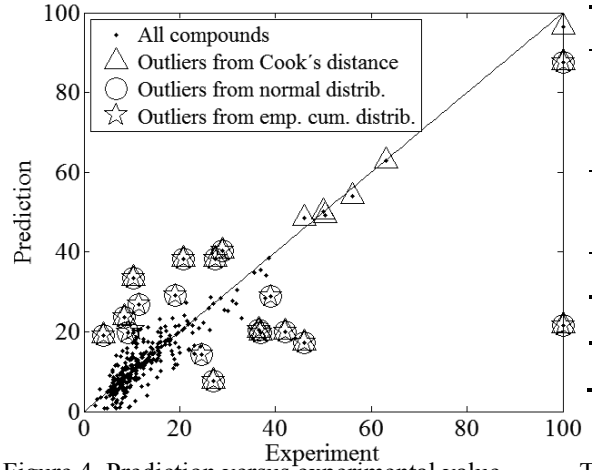

Figure 4. Prediction versus experimental value with identified outliers.

UFL_{const}		123.29
1st	CH3	-1.11
	CH2=C	0.52
	CN	-0.69
2nd	CH3-CHm=CHn	-0.53
	CHm=CHn-CN	-0.61
3rd	none	-
Predicted	*UFL*	10.96
Experim.	*UFL*	11.00

Table 2. Example of prediction of UFL for Methacrylonitrile

4. Conclusion

The study shows a novel prediction model for UFL using the MR-GC method. In this scope an outlier treatment methodology based on the empirical CDF is suggested. The performance statistics of the regression improves similarly to the use of normal CDF. However, the usage of empirical CDF is not restricted by the assumption that residuals should follow a normal distribution and hence have a wider application range. The usage of Cook's distance as an outlier detection method is found unreliable with high number of false detection of data points. This is not surprising since Cook's distance is in fact just a measure of data influence on the regression. High data influence is necessary but not sufficient condition of an outlier since data points in good agreement with regression line may also have a high influence on the regression.

Abstract

The integrated gasification combined cycle (IGCC) is a promising and efficient electrical power generation technology with less environmental effects than conventional coal power plant. However, improvement of its efficiency is an important task needs to be achieved. In this paper, a mathematical model of an IGCC plant is built, which includes a gasification unit, an air separation unit (ASU) and a combined cycle unit with energy and mass conversion. Gibbs free energy minimization method is used for predicting the composition of the syngas. Isentropic process calculation with efficiencies are taken into account for modelling the combined cycle. ASU is simulated mainly using bubble point method which can give rigorous prediction of the double distillation columns. Some contributions have been done to give the better strategy for supplying initial value to converge and to achieve the integration. The overall efficiency of 39.8 % can be reached considered as a base case, and simulated using Microsoft® Excel 2013. An additional case with not standard ASU is followed. The comparison between two cases shows that the Standard ASU may not the best choice of each IGCC plant. Some adjustments may be needed to fit the ASU with the whole plant to improve the overall efficiency.

Keywords: ASU, Heat integration, IGCC, optimization.

1. Introduction

As one of the promising green technologies, IGCC offers an efficient way to generate electricity from coal, biomass or any other suitable solid or liquid fuels with lower impact to the environment. The biggest challenge of making IGCC to become a viable technology is its high energy production cost. This creates a barrier for this green technology to enter into the stage of a highly competitive electricity market. In another aspect, the target of developing the IGCC technology should be increase the efficiency of the power plant.

Among the IGCC power plant, ASU is considered as most energy intensive part, which still using the traditional cryogenic technology (Nakaiwa, 2003). So heat integration is considered to play a very important role in ASU optimization. Pinch Analysis, which was introduced by Linnhoff and Flower (1978), is used to analyze ASU in order to create constrains for achieving minimize cold utility usage.

Previous researches are mostly aimed at optimization of the ASU with fixing the ASU product streams are nearly pure oxygen or nitrogen (Cornelissen, 1998). When it comes to the IGCC, one product stream of ASU is used as the oxidation agent instead of reactant. So oxygen purity from ASU product stream can be not only 99 %, but also lower like 96

%. So far, it is rarely discussed in literature. This paper is focused on the influence of this change for the plant efficiency by doing case study.

2. Process description

The process flow diagram given in Figure 1 describes the simulated IGCC power plant. The coal (Illinois #6), is crushed and mixed with water and is pumped into the gasifier with oxygen produced by ASU. The crude syngas is mainly composed of H_2, CO, CO_2 and H_2O. Sensible heat is used to generate steam for recovery. After cooling and cleaning, the clean syngas drives a gas turbine after combustion with additional air and injected nitrogen. The heat of fuel gases from gas turbine is used to generate superheated steam in the heat recovery steam generator (HRSG). A steam turbine is drove by that steam to product additional power.

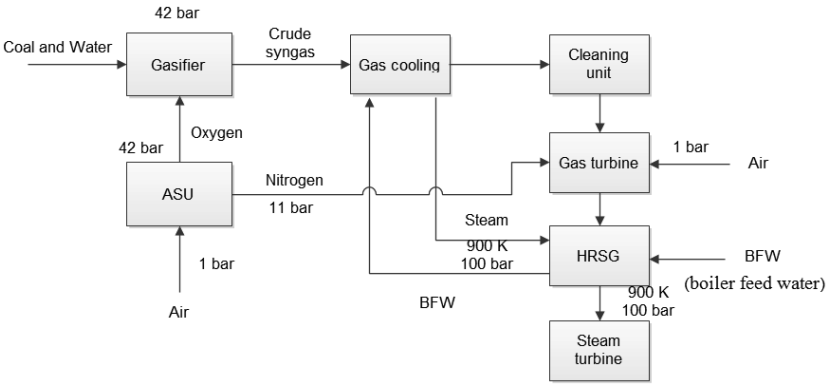

Figure 1. Schematic diagram of the process.

3. Modelling methods

The overall efficiency of the IGCC plant, η_{all}, is defined to measure the performance :

$$\eta_{all} = \left(\frac{P_{out} - W_{asu}}{\sum HHV}\right) * 100\% \quad (1)$$

Where P_{out} is the net produced electricity, W_{asu} is energy consumption of ASU and HHV is the higher heating value of coal which injects into the power plant.In the thermodynamics aspect, all the components in the IGCC plant are assumed as ideal. So the properties can be calculated according to the conditions, such as enthalpy and entropy values of the gases can be identified as below:

$$H^o - H^o_{298.15} = At + B\,t^2/_2 + C\,t^3/_3 + D\,t^4/_4 - E/_t - H \quad (2)$$

$$S^o = Aln(t) + Bt + C\,t^2/_2 + D\,t^3/_3 - E/(2t^2) + G \quad (3)$$

Where H^o is standard enthalpy (kJ/mole) and S^o is standard entropy (J/mole*K). A, B, C, D, E, H, G are constant values that can be found from NIST chemistry database. t equals physical temperature divided by 1000 K. The simulation of the ASU unit and IGCC plant is built as a Macro in Excel 2013 cooperating with Standard GRG Non-linear Solver and Water 97 add-in, which is property database using the industrial standard IAPWS-IF97 (Spang, 2002).

3.1. Modelling of the Gasifier

Gasification is completed in the gasifier, including a series of reactions which can convert the solid fuel to combustible gases, such as carbon monoxide and hydrogen, by supplying gasifying agent like oxygen (Minchener, 2005). Considering the complexity of the gasification, equilibrium models have been developed to simulate the gasifier which can directly calculate the outcome compositions based on the feed stock and operation conditions without taking any reaction details into consideration.

The crude syngas is assumed as a mixture of CH_4, H_2, CO, CO_2, H_2S, COS, NH_3, NO_2, SO_2, N_2O, SO_3. The composition is calculated simultaneously with the equilibrium temperature in adiabatic statement. At the equilibrium state, the total Gibbs free energy of the system is minimized. The total Gibbs free energy of a system, G_{system}, is defined:

$$G_{system} = \sum_{i=1}^{N} n_i (G_{f,i}^0 + RT \ln \frac{\hat{f}_i}{f_i^0}) \tag{4}$$

Where $G_{f,i}^0$ is the standard Gibbs free energy of formation (kJ/mole), n_i (mole) is amount of component i of the system. T (K) is system temperature and R is gas constant. With ideal gas assumption, $\hat{f}_i$ is related with system mole composition y_i and pressure P (Pa):

$$\hat{f}_i = y_i P \tag{5}$$

When at low pressures, f_i^0 is taken as the standard state pressure. $G_{f,i}^0$, is the calculated based on the concept using equation (6) which is presented as:

$$G_{f,i}^0(T) = \Delta H_{f,i}^0(T) - T\Delta S_i^0(T) \tag{6}$$

The enthalpy and entropy changes from standard state to system state at T (K), $\Delta H_{f,i}^0(T)$ and $\Delta S_i^0(T)$, are calculate based on the equation (2) and (3). Heat balance and mass balance are also achieved for the gasifier as a whole.

3.2. Modelling of the combined cycle

The combined cycle is referred to the combination of gas turbine, steam turbine and HRSG. Simplified mathematical model of the gas turbine is consist of three key units: a compressor, a combustor and a turbine. In another hand, the process of steam turbine is proposed including a turbine and a pump. Those two sections are connected by HRSG to recover fuel gas sensible heat. The principle of modelling the combined cycle unit is idealizing the process then adding the efficiency. Isentropic process is assumed as the ideal process for the compressor, turbine and pump in the combined cycle unit. For steam turbine and HRSG, the isentropic process is calculated based on the concept using Water97 database. Those differences are due to the ideal gas, then the entropy equation is not related with the pressure. So the isentropic relation for an ideal gas assumption in gas turbine expresses as below:

$$(T_2/T_1) = (p_2/p_1)^{(\gamma-1)/\gamma} \tag{7}$$

Where through the isentropic process, gas temperature T_1 (K) will be changed to T_2 (K), and the gas pressure will simultaneously changes from p_1 (Pa) to p_2 (Pa). γ , for an ideal gas, is the heat capacity ratio which is calculated. When it comes to the efficiencies, The HRSG feed water pumps are assumed to operate at 90 % isentropic efficiency, η_{pump}, defined by equation (8).

$$\eta_{pump} = \frac{(H_{out,s} - H_{in})}{(H_{out} - H_{in})} \times 100\% \quad (8)$$

Where $H_{out,s}$ is enthalpy of the outlet stream of the pump by isentropic process. H_{out} is the actual enthalpy of the stream from the pump. Two turbines in combined cycle are assumed to operate at 80 % isentropic efficiency. And the compressor is assumed to operate at 90 % isentropic efficiency. The definitions of those efficiencies are similar as η_{pump} in equation (8).

The combustor in the gas turbine is treated as an adiabatic reactor. The output compositions and the operating temperature can be decided by energy and mass conservation principles. The efficiency of HRSG is defined as the ratio of output enthalpy and input enthalpy, which is fixed as 90 %.

The total power output, P_{out} (MW), for the combined cycle of the IGCC power plant can be calculated by equation (9). W (MW) stands for the overall power output of the two turbines and W_{ax} (MW) stands for all of the auxiliary work:

$$P_{out} = W - W_{ax} \quad (9)$$

3.3. Modelling of the ASU

The process of cryogenic ASU is shown in Figure 2, which is consist of a feed compression section, two multi-phase heat exchangers (MHEX), a distillation section (low-pressure (LP) column and high-pressure (HP) column) and a product compression section. The air is compressed and cooled down to 298 K and split into two stream. Those streams are respectively injected into LP column and HP column after heat exchange with products of LP column in MHEX1 and pressure controlling pretreatment. Two product streams firstly go through the valve to control the pressure and cool down in MHEX2 by cooling the top product from LP column. High-purity nitrogen and oxygen streams from MHEX1 are compressed in order to inject into the combustor and gasifier.

The models of the compressors and expanders are built similar as the ones in combined cycled. MHEX is assumed as the general heat exchanger with the temperature constraints and satisfying the energy balance.

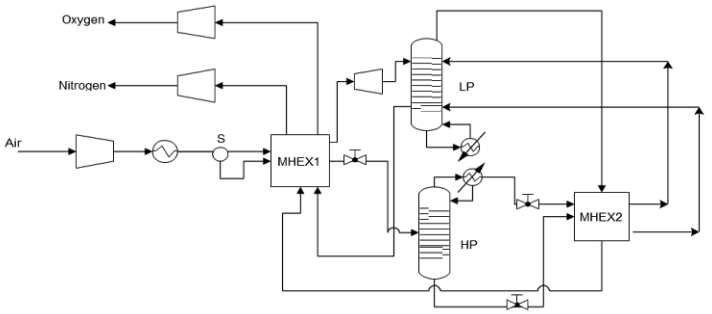

Figure 2. Schematic diagram of the ASU.

The models of LP and HP columns are based on the Mass balance equations (M), Equilibrium relations (E), Sum (or conservation) equation(S) and Enthalpy balance relations (H), which are call MESH equations together. Bubble point method (Wang, 1966) is used by solving those equations in the formation of triple diagonal matrix. A strategy to create initial values is added before the bubble method. The prediction of initial value is either calculated based on the constant molar flow hypothesis or get from

previous calculation experiences. LP column has zero bottom rate with only reboiler and HP column has only a total condenser.

Because integration inside the ASU is quite critical, Pinch analysis is used to measure the performance of ASU, which proves nonexistence of hot utility. In the model, constrains about relationships among the condenser duty, reboiler duty and MHEX heat duty are used to minimized cold utility. What's more, air feedstock is only consist of ideal gas: O_2 and N_2, which the mole ratio 1:4. The total energy consumption of ASU, W_{asu} (MW) , is the difference of total compressor consumption $W_{compressor}$ (MW) and total expander consumption $W_{expanders}$ (MW), which represents as:

$$W_{asu} = \sum W_{compressor} - \sum W_{expanders} \quad (10)$$

4. Results and discussions

One base case with standard ASU, which can produce 99 % purity oxygen and 99 % purity nitrogen, is built. And one additional case with non-standard ASU, which supply 96 % purity oxygen and same level nitrogen is followed. The detail parameters and results of both IGCC plants are shown in Table 1.

Table 1 Simulation Results of IGCC Plant

Parameter	Case 1(base case)	Case 2
Reference fuel type	Illinois No.6 coal	Illinois No.6 coal
Coal feed flow rate	17 kg/s	17 kg/s
Gasifier pressure	42 bar	42 bar
Gasification temperature	1550 K	1475 K
Air flow rate	8000 kmol/h	8000 kmol/h
Injected Nitrogen flow rate	100000 kmol/h	100000 kmol/h
GT Combustor Temperature	1120 K	1120 K
Steam Temperature (Gas Cooling)	900 K	900 K
Steam Pressure (Gas Cooling)	100 bar	100 bar
Steam Temperature (HRSG)	900 K	900 K
Steam Pressure (HRSG)	100 bar	100 bar
Net Power Output of GT	152.8 MW	152.8 MW
Net Power Output of ST	88.1 MW	87.8 MW
Work consumption of ASU	34.7 MW	30.7 MW
Net Power Output of Plant	206.2 MW	209.9 MW
Total HHV Input	518.6 MW	518.6 MW
Overall efficiency	0.398	0.405

With comparison, using non-standard ASU causes slightly negative effects for the other parts of IGCC. The Gasifier Temperature decreases because some nitrogen are inject into the gasifier. The dilution effect not only decrease the amount of steam generate in Gas Cooling unit, but also have slight negative effect the total net power output. The interesting part is that the overall efficiency increase about 1 % instead of going down. The decrement of energy consumption of ASU contributes a lot as shown in Table 1. But for further discussion, the detail ASU operation conditions are needed which are listed in Table 2. Based on that, the decrement is the combined influence of increasing the main air compressor energy consumption and decreasing the energy consumption of product compressors. For two cases, the suitable non-standard ASU can save about 10 % energy of the standard configuration in case 1.

Table 2 Simulation Results of ASU Unit

Parameter	Case 1(base case)	Case 2
Air compressor discharge pressure	7 bar	10.2 bar
Split ratio	0.95	0.95
No. of stage in LP column	100	100
LP column Pressure	1.2 bar	3 bar
No. of stage in HP column	45	45
HP column Pressure	6.8 bar	10 bar
Oxygen product purity	0.99	0.96
Nitrogen product purity	0.99	0.99
Oxygen product pressure	42 bar	42 bar
Nitrogen product pressure	11 bar	11 bar
Air compressor work	14883 kW	18935 kW
Oxygen compressor work	6638 kW	4717 kW
Nitrogen compressor work	13293 kW	7110 kW
Expander work	116 kW	89 kW
Total energy consumption of ASU	34698 kW	30673 kW

The comparison between two cases shows that the Standard ASU may not the best choice of each IGCC plant. Some adjustments may be needed to fit the ASU with the whole plant to improve the overall efficiency.

5. Conclusions

In this paper, a mathematical model of an IGCC plant is built, which includes a gasifier, an ASU and a combined cycle unit with energy and mass conversion. The overall efficiency of 39.8 % can be reached in base case which simulated using Microsoft® Excel 2013. An additional case with non-standard ASU is followed, which performs slightly better in efficiency aspect. The comparison between two cases shows that the Standard ASU may not the best choice of each IGCC plant. Some adjustments may be needed to fit the ASU with the whole plant to improve the overall efficiency. It gives a suggestion and a starting point to integrate and optimize the IGCC plant in the future.

Abstract

This paper describes the mathematical modeling of the physical-chemical phenomena in the coking furnace and coke drum in a steady-state delayed coking unit based in a lumped kinetic scheme and vapor-liquid equilibrium conditions. Feedstock and products composition, and molecular structure are also required. For better understanding of the coking process and effect of the feedstock physical-chemical properties on yield and quality parameter of the products, especially the petroleum coke, molecular characterization of crude oil and heavy fraction was carried out by MALDI TOF mass spectrometry. Mathematical algorithm has been developed based on experimental data and operating conditions from an industrial delayed coking unit. A good prediction capability of the model and an accurate industrial unit representation of the industrial unit is expected. The developed model will be used for monitoring the industrial process and implementing real time optimization (RTO). Meanwhile, the acquired knowledge obtained during the model development has already improved the quality of green coke produced and the operational procedure of industrial plant.

Keywords: Delayed Coking, Mathematical Modeling, Lumps.

1. Introduction

The increasing competitive market, the frequent changes in prices, higher demand for oil and petroleum availability, restrictions on product specifications and operational bottlenecks require quick responses. The delayed coking is a semi continuous thermal cracking process used in petroleum refineries to upgrade and convert vacuum residue into liquid and gas products leaving behind a solid concentrated carbon material, known as petroleum coke (Ellis et. al.,, 1998). However, the delayed coking unit is one of the most difficult process to operate and control. That is so, because the furnace supplies thermal energy demanded by the thermal cracking of the hydrocarbon molecules, while the coke drum provides the residence time for chemical reactions to continue and accumulation coke formed. Being highly endothermic, the coking reactions rate drops dramatically as coke drum temperature decreases. The residue compositions are much more complicated that of heavy gas oil fractions. They are much larger and heteroatoms compounds with sulfur, nitrogen and oxygen groups (Zhou et. al., 2007). The basic idea of this work is to develop a mathematical model of the reaction kinetics and conditions of vapor-liquid equilibrium using an industrial plant as base to determine the parameters of the model in question.

2. Mathematical Modeling

2.1 Mass Balance Data to Reconciliation

Measured process data inevitably contain some inaccurate information, since measurements are obtained with uncertainties. The problem consists in obtaining more accurate estimates for process variable measurements, satisfying the mass and energy conservation laws, according to the least square objective function:

$$min. \quad F.O. = \left(\underline{X} - \underline{\hat{X}}\right)^T \cdot \underline{\underline{W}}^{-1} \cdot \left(\underline{X} - \underline{\hat{X}}\right) \tag{1}$$

Subject to the constraints:

$$X_1 = X_2 + X_3 + X_4 + X_5 + X_6 \qquad \left(\underline{X} \geq 0\right) \tag{2}$$

where $\underline{X}$ is a vector of measurements for n process variables, $\underline{\hat{X}}$ is a vector of estimates for the n process variables and $\underline{\underline{W}}$ is a weight matrix of the measurements.

2.2 Effluent Coke Drum Characterization

The methodology to determine the coke drum effluent characteristics is based on extrapolation of the true boiling point distillation curve, given the mass and energy balance and the dew point temperature in the overhead coke drum (Figure 1).

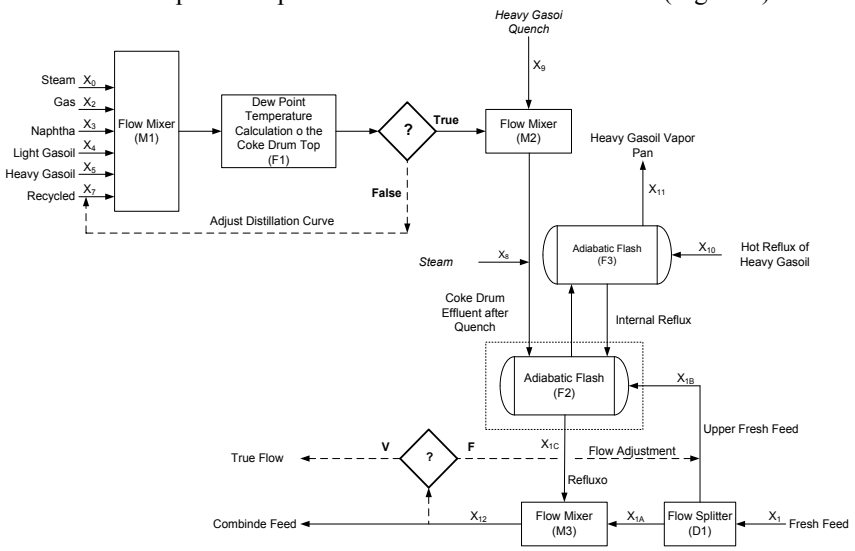

Figure 1. Strategy to determine the recycled charactheristics.

The coke drum effluent is divided into 22 pure components and 74 pseudo-components, which properties are calculated by different methods and correlations available in literature (Riazi, 2005). Liquid-vapor equilibrium calculations are carried out by Peng-Robinson equation of state.

2.3 Mass and Energy Balance of the System Furnace-Coke Drum

The components obtained in the coke drum are used in the mass and energy balances and vapor-liquid equilibrium calculations. In the kinetic thermal cracking model was assumed six discrete lumps: gas, naphtha, light gasoil, heavy gasoil, coke and residue. These lumps were selected based on the five main streams from the coking process (Figure 2).

As the vacuum residue and reaction products are complex mixtures of hydrocarbons, it is difficult to develop a mechanistic approach for each molecule to explain the true kinetics and their behavior. Thus, the pseudo-components are obtained by group composition based on their physic-chemical properties such as boiling point and density.

Following are the main related mass and energy balance equations for the system:

Boundary N. 1:

$$X_1 + S = X_0 + X_2 + X_3 + X_4 + X_5 + X_6 \tag{3}$$

Boundary N. 2:

$$X_1 + X_7 + S = Y_0 + Y_1 + Y_2 + Y_3 + Y_4 + Y_5 + Y_6 + Y_7 \tag{4}$$

Outlet Coil:

$$Y_i = \alpha_i \cdot X_i \tag{5}$$

Boundary N. 3:

$$\Delta X_i = (1 - \alpha_i) \cdot X_i \tag{6}$$

Boundary N. 1 and N. 2:

$$(\Delta H)_{IN} + Q_0 = (\Delta H)_{OUT} + (\Delta H)_{REACTION} + Q_1 \tag{7}$$

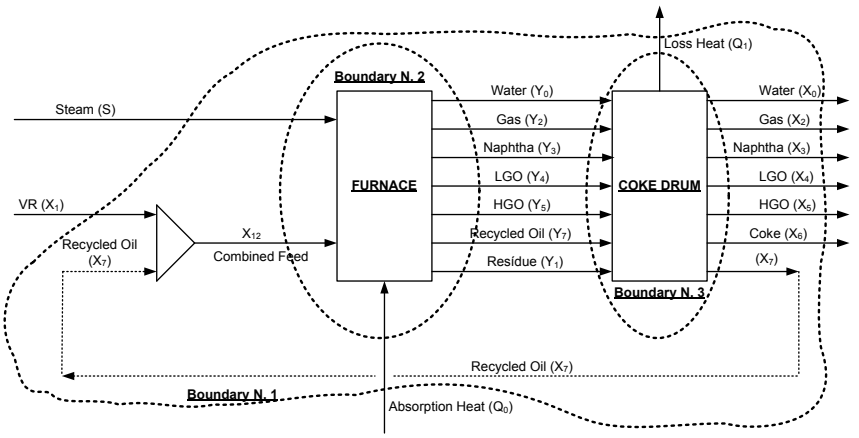

Figure 2. Boundaries for mass and energy balances.

2.4 Coking Furnace

After the establishment of the product distribution coefficient at the exit of the coking furnace (α_i), the composition profile is determined through the coil to the different lumps from the heat flow based on the flue gas, wall tubes temperature, and fluid pressure and temperature profiles.

The furnace are divided into two sections: pre-heating and reaction. The furnace reaction section can be considered as a tubular reactor in steady state with two-phase flow. The result of simultaneous solution of the set of equations of mass and energy balances, heat transfer and liquid-vapor equilibrium predicts the lumps composition through the coil. As the fluid moves through the furnace coil, the chemical reaction takes place, producing larger amounts of light components and changes in the conditions physical-chemical.

The fluid temperature profile inside the furnace coil is directly measured from the industrial plant by thermocouples located in different positions. As a result, it is possible to determine the fluid physical properties at any coil location and the heat absorbed in both pre-heating and reaction sections.

The kinetic model proposed for the thermal cracking furnace is constituted by five lumps (Figure 3). The first lump represents the total amount of cracked oil from vacuum residue (VR). The other four lumps represent products, which are progressively vaporized inside the coil. The coke formation rate was considered negligible.

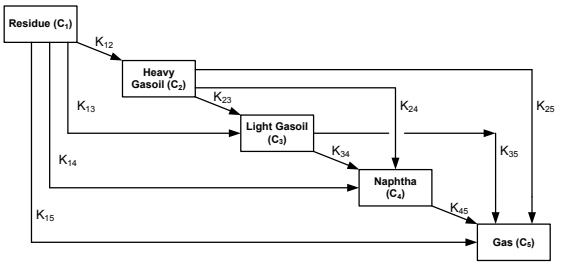

Figure 3. Proposed five lumped kinetic models with 10 rate parameters.

Given the lumps composition from mass and energy balances, it is possible to predict the furnace coil kinetics. From Figure 3 the following reaction rate expressions for the five groups can be written by assuming first order irreversible approach:

$$\left(\frac{d[C_1]}{dt}\right) = -(K_{12} + K_{13} + K_{14} + K_{15}) \cdot [C_1] \tag{8}$$

$$\left(\frac{d[C_2]}{dt}\right) = K_{12} \cdot [C_1] - (K_{23} + K_{24} + K_{25}) \cdot [C_2] \tag{9}$$

$$\left(\frac{d[C_3]}{dt}\right) = K_{13} \cdot [C_1] + K_{23} \cdot [C_2] - (K_{34} + K_{35}) \cdot [C_3] \tag{10}$$

$$\left(\frac{d[C_4]}{dt}\right) = K_{14} \cdot [C_1] + K_{24} \cdot [C_2] + K_{34} \cdot [C_3] - K_{45} \cdot [C_4] \tag{11}$$

$$\left(\frac{d[C_5]}{dt}\right) = K_{15} \cdot [C_1] + K_{25} \cdot [C_2] + K_{35} \cdot [C_3] + K_{45} \cdot [C_4] \tag{12}$$

The kinetic constants of the Arrhenius equations are calculated as a function of the feed physical-chemical properties.

$$\ln(K_{ij}) = \ln(A_{ij}) - \frac{E_{ij}}{R \cdot T} \tag{13}$$

The compositions of the five lumps through the furnace coil, together with the temperature profile will allow determining the kinetic constants (A_{ij} and E_{ij}) of the model by the least squares method.

2.5 Coke Drum

The coke drum is considered a perfect continuous stirred tank reactor in pseudo-steady state, which can be represented by the equation (14).

$$\frac{V}{(F_i)_0} = \frac{[(f_i)_{OUT} - (f_i)_{IN}]}{\left(\pm r_i^*\right)_F} \tag{14}$$

Based on operational experience of the thermal cracking process Eureka (Takatsuba et al., 1996), the minimum residence time required to start the coke formation is about four hours. The kinetic model proposed for the thermal cracking coke drum was divided in three phases: vapor, liquid and solid (Figure 4 and 5).

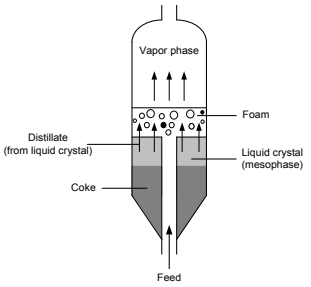

Figure 4. The coke drum filling system.

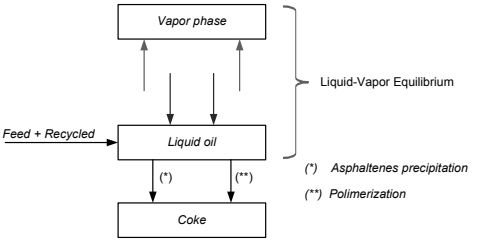

Figure 5. The coke drum modeling strategy.

The coke formed from the precipitation of asphaltenes tends to be amorphous and it is a poor quality sponge coke, while the coke derived from the reactions of polymerization and polycondensation tends to be more crystalline. This coke formed contains a small amount of liquid hydrocarbons trapped in the pores, known as volatile combustible material (VCM).

3. Vacuum Residue Characterization

The vacuum residue is classified in four fractions: saturates, aromatics, resins and asphaltenes. Being the asphaltenes was characterized by Mass Spectrometry Matrix-Assisted Laser Desorption/Ionization (MALDI TOF). Results can be found elsewhere (Borges et al., 2012).

4. Results and Discussion

To solve the problem of mass balance reconciliation was using the LCONF subprogram in IMSL Fortran library to minimize the objective function for linear equality and inequality constraints. A summary of data reconciliation results is presented in Table 1.

Table 1. Data reconciliation results.

Run Number	Yields, weight %				
	Gas	Naphtha	Light Gasoil	Heavy Gasoil	Coke
10	8.43	15.96	17.75	35.86	23.50
33	9.75	23.75	26.75	26.92	27.62

Figure 5 shows the true boiling point curve as a result from the mass and energy balance in the main fractionator bottom section and the coke drum overhead according to the strategy in Figure 1. Based on Figure 5, the yields are estimated according to Table 2.
The reported lumped kinetic models are used due to the complexity of coker feed and products, which makes it extremely difficult to characterize and describe its kinetics at a molecular level.

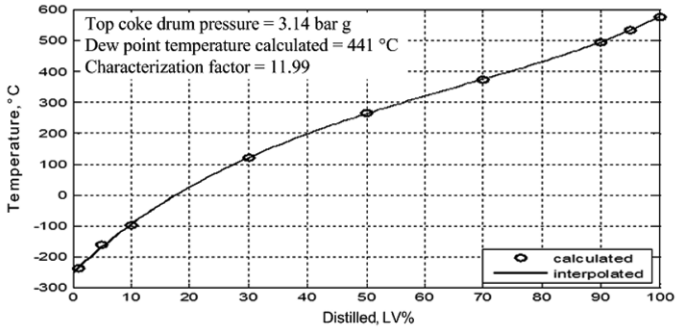

Figure 5. Effluent true boiling point distillation curve from the coke drum.

Table 2. Lumps yields form effluent coke drum.

Lump	Range	Yield, LV %
Gas	$^{-}C_4$	17.42
Naphtha	C_5 – 200°C	23.22
Light Gasoil	200 – 370°C	28.26
Heavy Gasoil	370 – 540°C	27.27
Residue	> 540°C	3.82

5. Conclusion

The strategy to characterize the feedstock and the products using the molecular information with the phenomena observed in the actual industrial unit provided a rigorous mathematical modeling in delayed coking process. Besides, to be capable to simulate the effects of the feedstock in the coking process, it is necessary to include the coke drum and the bottom section main fractionator in the model. The simultaneous solution of mass and energy balances involving the furnace and coke drum is the key element to determine the conversion among them. The results obtained so far from coke drum effluent indicate that it is capable to predict the recycle characteristics, as well as lumps yields.

Abstract

In this work, new experimental data on vapour-liquid equilibrium (VLE) of CO_2 in piperazine (PZ) activated aqueous solutions of n-methyldiethylamine (MDEA) and hybrid solvents containing sulfolane as physical solvent along with aqueous (MDEA+PZ) have been reported over the temperature range of (313-333) K and CO_2 partial pressure range of (1-1400) kPa. PZ is used as a rate activator with a concentration range of 2 to 8 mass% and the total amine concentration in the aqueous solution of (MDEA+PZ) has been kept within 50 mass%, while the concentration of physical solvent sulfolane has been maintained at 10 mass%. Electrolyte non random two-liquid (ENRTL) theory has been used to model the VLE. A simulation work has been carried out using Aspen Plus (V7.1) to evaluate the energy requirements on % CO_2 removal. The hybrid solvent showed higher % CO_2 removal when compared with those of PZ-activated aqueous MDEA.

Keywords: CO_2 capture, VLE, activated solvent, modelling and simulation.

1. Introduction

Carbon dioxide (CO_2) removal from flue gas stream of fossil fuel power plants has received much attention because of the environmental need for reducing CO_2 emission to the atmosphere. There are many processes for removal of CO_2 from power plant flue gas. The emphasis in the present work is post-combustion CO_2 absorption involving (MDEA + PZ + sulfolane) based solvent. The main objective of this work is to investigate the efficiency of the hybrid solvent in achieving higher %CO_2 removal from low CO_2 partial pressure flue gas streams. Although sulfolane has been used in the hybrid solvents sulfinol-D and sulfinol-M of Shell Oil Company along with DIPA and MDEA, resprctively, no work has been reported so far using sulfolane with PZ activated aqueous MDEA solvent for CO_2 capture. In a regenerative chemical absorption process, the amount of solvent which needs to be circulated in the process between absorber and stripper depends on the amine concentration in the aqueous solution, the required CO_2 capture and the difference in CO_2 loading between the rich and the lean solution. A higher total amine concentration in the selected solvents has been chosen in order to increase the cyclic loading capacity of the solvent in the CO_2 removal process. The increased cyclic loading reduces the solvent circulation rate and higher amine concentration reduces the regeneration heat requirement. Methyldiethylamine (MDEA) has a stable structure and does not degrade readily, so it does not cause corrosion

problems for carbon steel (Bishnoi and Rochelle, 2002). Because of chemical reactions in the liquid phase and the strong deviation from ideality, the thermodynamic description of aqueous systems containing (CO_2+MDEA+PZ+sulfolane) is a difficult task (Dash et al., 2011). Reliable experimental data for the solubility of CO_2 in these solvents are required to develop and test thermodynamic models used to describe VLE of this systems. However, reliable data on these systems are scarce in the open literature. In this work, the solubility of CO_2 in aqueous solutions containing MDEA, sulfolane, and PZ for a wide range of concentrations and temperatures was measured and modeled. To explore further industrial benefits of the (MDEA+PZ+sulfolane) based solvent, a modeling and simulation study of CO_2 capture process using a commercial simulator is essential. Hence simulation of CO_2 separation process using this solvent has been carried our using Aspen Plus.

2. Experimental

MDEA, PZ and solfolane (> 95 % pure) was supplied by Sigma Aldrich, USA and was used without further purification. CO_2 gas (> 99.9 % pure) was obtained from Chemtron Science Pvt. Ltd., India. Double distilled degassed water was used to prepare aqueous amine solutions.

The VLE measurements were conducted in a high pressure stainless steel stirred equilibrium cell which was connected to a high pressure stainless steel gas buffer vessel. A detail description of the experimental set up, procedure and validation of experimental procedure is presented in Dash et al. (2011a). VLE of CO_2 in the activated and hybrid solvents are calculated in terms of CO_2 loading (mole of CO_2 absorbed per mole of total amine) as shown in equation (1). In calculating CO_2 loading non-ideality of the gas phase is accounted for by considering Peng-Robinson equation of state.

$$\alpha_{CO_2} = \left((n_{CO_2} - n^g_{CO_2}) / n_{(MDEA+PZ)} \right) \quad (1)$$

where $(n_{CO_2} - n^g_{CO_2})$ is the no of moles of CO_2 present in amine solution and $n_{(MDEA+PZ)}$ is the total moles of amine (MDEA + PZ) present in the liquid phase.

3. Modeling

3.1 Phase and chemical equilibrium

Model development of the chemical and phase equilibria of the system (CO_2 + PZ + H_2O) has been discussed by Dash et al. (2011). The models for (CO_2 + MDEA + PZ+ H_2O) and (CO_2 + MDEA + PZ + sulfolane+H_2O) are developed by considering the following reactions in aqueous phase.

$$2H_2O \overset{K_1}{\rightleftharpoons} H_3O^+ + OH^- \quad (R1)$$

$$CO_2 + 2H_2O \overset{K_2}{\rightleftharpoons} H_3O^+ + HCO_3^- \quad (R2)$$

$$HCO_3^- + H_2O \overset{K_3}{\rightleftharpoons} H_3O^+ + CO_3^{2-} \quad (R3)$$

$$PZH^+ + H_2O \overset{K_4}{\rightleftharpoons} PZ + H_3O^+ \quad (R4)$$

$$PZ + CO_2 + H_2O \overset{K_5}{\rightleftharpoons} PZCOO^- + H_3O^+ \quad (R5)$$

$$H^+PZCOO^- + H_2O \overset{K_6}{\rightleftharpoons} PZCOO^- + H_3O^+ \quad (R6)$$

$$PZCOO^- + CO_2 + H_2O \overset{K_7}{\rightleftharpoons} PZ(COO^-)_2 + H_3O^+ \quad (R7)$$

$$MDEA + H_2O \overset{K_8}{\rightleftharpoons} MDEAH^+ + OH^- \quad (R8)$$

Sulfolane does not undergo any reaction in carbonated aqueous medium. Each of the above chemical equilibria is characterized by the thermodynamic equilibrium constant, K_j , defined in terms of mole fraction, x_i , and activity coefficient, γ_i, of the i th component as,

$$K_j = \prod_i (x_i \gamma_i)^{v_{ij}} \tag{2}$$

where ϑ_{ij} is the reaction stoichiometric coefficient of component *i* in j^{th} reaction.
Equilibrium constant for the reactions are taken form Aspen data bank (2008). In this work water, MDEA, sulfolane and PZ are considered as solvents leading to a mixed solvent system. The standard state associated with each solvent is the pure liquid at the system temperature and pressure. The chosen reference state for ionic solutes and the molecular solute (CO_2) is the ideal, infinitely dilute aqueous solution at the system temperature and pressure. Vapour phase model has been described by equation (3) and (4) for CO_2 and amines respectively according to the activity coefficient approach.

$$\phi_i^v y_i P = x_i \gamma_i^* H_i \exp\left(\frac{v_i^\infty (P - P_{solv}^0)}{RT}\right) \tag{3}$$

$$\phi_i^v y_i P = x_i \gamma_i P_i^0 \exp\left(\frac{v_i (P - P_i^0)}{RT}\right) \tag{4}$$

where y_i and x_i are concentration of species in vapour and liquid phase, v_i^∞, partial molar volume of CO_2 at infinite dilution, can be calculated from the Brelvi-O' Connell method. H_i is the Henry's law constant, P^0 is the Vapour pressure. Henry's constant of CO_2 is adjusted in this work for the mixed solvent system.

3.2 Electrolyte NRTL activity coefficient model
The ENRTL equation (Austgen et al., 1989) which is based on excess Gibbs energy, have been used in this work to model VLE data. In this model excess Gibbs energy is calculated using the following equation.

$$\frac{G^{*E}}{RT} = \frac{G_{PDH}^E}{RT} + \frac{G_{BORN}^E}{RT} + \frac{G_{NRTL}^E}{RT} \tag{5}$$

Where G^{*E} is excess Gibbs energy of mixed solvent electrolyte system, G_{PDH}^E is excess Gibbs energy calculated by Pitzer-Debye-Huckel formula, G_{BORN}^E is excess Gibbs energy calculated by Born expression and G_{NRTL}^E is excess Gibbs energy calculated by non random two-liquid hypothesis. The first two terms of the equation account for the long range interactions and the third term account for the local interaction contribution. The interaction parameters are expressed in temperature dependent form as given below.

$$\tau_{ij} = a_{ij} + \frac{b_{ij}}{T} \tag{6}$$

The activity coefficient for any species (ionic or molecular, solute or solvent) is calculated from the partial derivative of the excess Gibbs energy with respect to mole number.

$$\ln \gamma_i = \frac{1}{RT}\left[\frac{\partial\left(n_i G^{*E}\right)}{\partial n_i}\right]_{T,P,n_{j\neq i}} \tag{7}$$

The interaction parameters of ENRTL equation are regressed from VLE data using data regression system in Aspen Plus (V7.1) software.

3.3. Simulation of absorption-regeneration

Process simulation software Aspen Plus® (V7.1) has been used to estimate the percentage CO_2 capture from the flue gas of coal based power plant by absorption at steady state conditions using aqueous MDEA, PZ activated aqueous MDEA and the hybrid solvents. The CO_2 capture process used in this study is shown in Fig. 1. The flue gas enters the bottom of the absorber with the lean amine solvent introduced at the top of the absorber. The lean amine enters with a loading of 0.1- 0.12 and leaves with a loading close to 0.45-0.55. The rich stream from the lean-rich heat exchanger is fed to the regenerator. The regenerator is a packed column with a kettle reboiler. The regenerator typically operates at slightly elevated pressures (~0.18-0.2 Mpa). The rich amine enters the second stage of the regenerator and flows down the column. The vapour from the reboiler flows counter currently to the liquid. The stream from the top of the column is taken to a condenser in order to condense the water and lower the temperature and then flashed in order to separate CO_2 from water.

A part of the liquid reflux is returned to the first stage of the regenerator column. The first stage in the regenerator acts as a water wash stage to return any entrained amine in the vapor to the reboilor. In the reboiler of the regenerator, steam from the power plant is used to furnish the required heat duty. Typical values of the CO_2 partial pressure are 4-6 kPa for gas-fired power plants and 10-14 kPa for coal-fired power plants. This study has been performed considering a CO_2 partial pressure of 13 kPa.

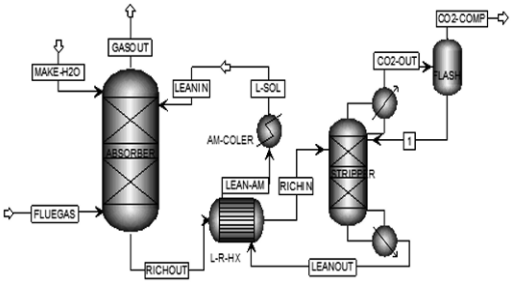

Figure 1: Process flow diagram of CO_2 capture

The diameter of the column has been determined based on flooding approach. A design factor of 80% approach to flooding has been chosen since this also allows for some safety factors in case the operating conditions change suddenly. There is also a limit set on the pressure drop of the column and this translates into a constraint on the calculation of the diameter of the column. As the CO_2 capture rate depends on process parameters such as L/G ratio, lean loading etc., the desired extent of capture has been achieved by varying the amount of amine flow rate and lean loading. The appropriate lean loading is achieved by suitably choosing the reboiler duty in the regenerator in an iterative process during each simulation run.

4. Results and Discussion

ENRTL theory has been used to model the VLE of CO_2 in all the solvents used. The model predicted CO_2 partial pressures have been plotted against experimental results of this work and from literature in Figure 2 and 3. Figure 2 shows the comparison of experimental CO_2 solubility data over aqueous MDEA from literature with our eNRTL model. Figure 3 shows the comparison of experimental CO_2 solubility data over aqueous (MDEA+PZ) from literature with our ENRTL model.

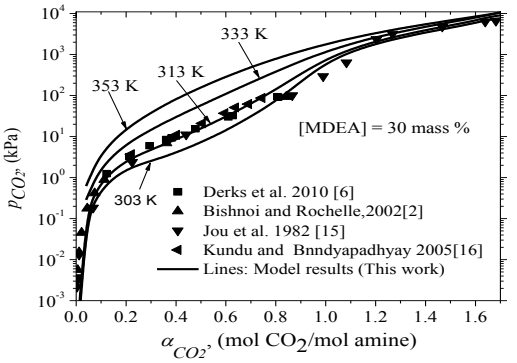

Figure 2: Comparison of model predicted equilibrium partial pressure of CO_2 above aqueous 30 mass% MDEA at various temperatures with the experimental data from literature.

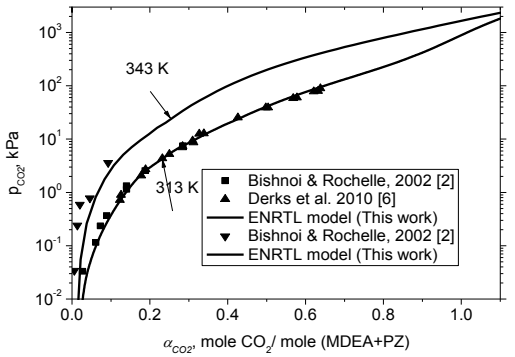

Figure 3: Comparison of model predicted VLE of CO_2 over aqueous (MDEA+PZ) with the experimental data from literature.

From the results presented in Figure 2-3, it is clear that there is a good agreement between the model predicted results and experimental results.
It has also been observed that the solvent capacity increases with the PZ concentration and decreases with the increasing in lean loading. The solvent circulation rate decreases with the increases in PZ concentration and increases with increase in the lean loading. It has also been observed that the solvent capacity increases with the PZ concentration and decreases with the increasing in lean loading. The solvent circulation rate decreases with the increases in PZ concentration and increases with increase in the lean loading. From the simulation study it is observed that the $\%CO_2$ removal is higher with all hybrid solvent formulations compared to that with PZ activated aqueous MDEA solvents. At an L/G ratio of 3 the hybrid solvent (42 mass% MDEA+8 mass% PZ+10 mass% sulfolane + 40 mass% H_2O) achieved 85% CO_2 capture at 40 ^oC. All hybrid solvents have been found to have about 35-40% higher solvent capacity compared to that of the corresponding activated amine solvents.

The reboiler heat duty represents the largest fraction of the overall cost in a PCC plant. The reboiler heat duty is therefore an important quantity which needs to be considered carefully. The energy requirement for solvent regeneration have three components viz.,

energy to be supplied (i) for providing the desorption enthalpy of CO_2, (ii) to generate additional stripping steam, and (iii) for heating up the solvent and provide the condensate reflux. Estimation of all these quantities requires an energy balance around the regenerator. The overall mass-specific heat duty, Q_{reb}, which is supplied in the reboiler of the regenerator column, can be expressed as the sum of three terms:

$$Q_{reb} = Q_{sensible}(\text{sensible heat}) + Q_{Vapour.H_2O}(\text{stripping steam}) + Q_{absorption,CO_2}(\text{heat of desorption}) \quad (8)$$

where, $Q_{sensible}$ is the sensible heat to raise the temperature of the solution and reflux water at the regenerator inlet to the conditions in the reboiler. $Q_{vapour, H2O}$ is the heat of vaporisation required to generate the stripping steam in the regenerator, $Q_{absorption,CO2}$ is the heat of desorption required to strip the CO_2 from the solution. Out of this three quantities, the heat of desorption is the most important contribution to the total energy requirement and can be estimated by utilizing an energy balance around the regenerator. The split of energy requirement estimated by simulation study is represented by Figure 4.

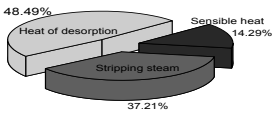

Figure 4: Split of reboiler duty (kJ/kg CO_2) for CO_2 capture at a constant lean loading and a ΔT of 5K at the lean-rich heat exchanger

5. Conclusions:

In this work the CO_2 capture performance of a new hybrid solvent system (MDEA + PZ + Sulfolane + H_2O) has been studied and compared with that of the corresponding PZ activated aqueous MDEA solvent. The hybrid solvent has been found to achieve much better performance than the PZ activated aqueous MDEA solvent with respect to solvent capacity, regeneration energy requirement and %CO_2 capture even at low L/G ratio and higher temperatures.

Modeling and Sensitivity Analysis of a Medium-Temperature Gas Cleaning Process of Biogenous Synthesis Gas

Michaela Fraubaum*, Heimo Walter

Vienna University of Technology, Institute for Energy Systems and Thermodynamics, Getreidemarkt 9, 1060 Vienna, Austria
michaela.fraubaum@tuwien.ac.at

Abstract

Tar removal is the major technical obstacle in the implementation of the gasification technology. This paper deals with the modelling, simulation and design of a small scale production process of biogenous synthetic natural gas (SNG) using a novel catalytic gas cleaning process which operates in a considerably lower temperature range than catalytic hot gas cleaning methods. Mathematical models for the different gas cleaning steps are developed and implemented into an already existing model library of the commercial simulation software IPSEpro. A special focus lies on the tar reforming reactor, which is modelled by applying mass and energy balances, reaction kinetics and chemical equilibrium equations. Energy savings of the individual process steps are identified and the overall process, which is based on an allothermal gasifier, is integrated in the software. Additionally, a sensitivity analysis is performed to show the influence of various operating parameters on the single elements and the whole system. Their effects on the overall process efficiencies as well as on important process factors are evaluated and discussed in this paper. The analysis described in this paper shows that a promising total efficiency for the overall process (with district heating) of approximately 90% can be reached.

Keywords: biomass gasification, tar conversion, methanation, process modelling

1. Introduction

In addition to the main components CO, CO_2, CH_4, H_2 and H_2O, synthetic natural gas (SNG), which is produced by gasification of biomass, contains considerable amounts of particulate matter, inorganic impurities and organic impurities. Especially high molecular weight polyaromatic hydrocarbons (tars) pose a serious threat to downstream equipment due to condensation or polymerization. Depending on the type of gasifier and the operating conditions, biomass gasifiers produce a gas with tar content levels between 0.01 and 150 g/ Nm^3 (Hasler and Nussbaumer, 1999). The so-called Heatpipe Reformer, which is considered in this work, shows a total tar concentration in the dry product gas between 1 and 8 g/Nm^3 (Gallmetzer et al., 2012). Since the gas quality requirements are considerably lower, under 100 mg/ Nm^3 for internal combustion engines and as low as 0.1 mg/Nm^3 for methanol synthesis (Laurence and Ashenafi, 2012), tar removal is essential in SNG production.

The current state-of-the-art tar removal technologies can be broadly divided into five groups: physical methods like cyclones, filters, and scrubbers; self-modification of the gasifier; Catalytic Cracking; Thermal Cracking and Plasma methods (Han and Kim, 2008). Industrial CHP-Plants in Oberwart, Güssing (Austria), Ulm/Senden (Germany) and Götenborg (Sweden) clean the gas in a wet scrubber, using organic liquids.

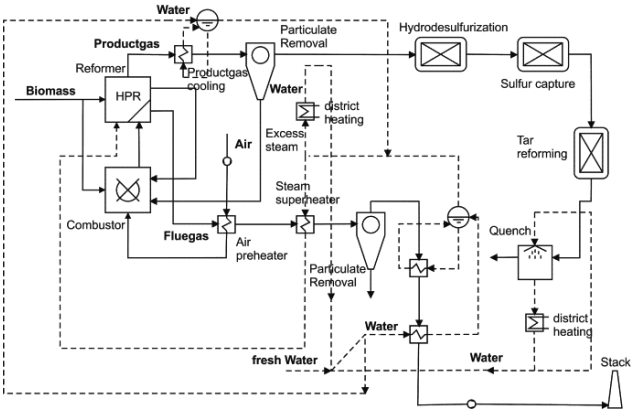

Figure 1: Detailed flow sheet of the SNG process

A promising prospective alternative is catalytic hydrocarbon reforming. Great advantage of this method is the high degree of gas purity combined with an increased fuel heat value.
A process modelling and design of a small-scale production of Raw-SNG with an innovative catalytic tar removal process, operating at a considerably lower temperature than conventional catalytic hot gas cleaning methods is presented in this contribution.

2. Process description and modelling methodology

The overall process, as illustrated in Figure 1, is integrated into the commercial simulation software IPSEpro, using thermodynamic models of the individual process steps.
IPSEpro is a steady state, equation oriented software environment for simulating and analyzing processes in energy- and chemical engineering and related areas. New user defined component models can be prepared and already existing models can be modified with IPSEpro's Model Development Kit (MDK). The IPSEpro Pyrolysis and Gasification Process Library (PGP-Library) is used as a basic library (Proell and Hofbauer, 2008). Mathematical models for different desulfurization steps, for scrubbing as well as for tar removal and methanation of SNG are developed by applying mass and energy balances and reaction kinetics and chemical equilibrium equations. Missing kinetic data and property data in IPSEpro were adopted from an Aspen Plus model of the process, created on the basis of experimental data which was measured with the test plant described in (Zuber et al., 2014). The additional model of the gas cleaning process in Aspen Plus allows analysing aspects not considered in the IPSEpro models like coke formation in the tar reforming reactor and solubility of components in the scrubber.
The process uses an allothermal gasifier, the so-called Heatpipe Reformer. Groebl et al. (2012) describes the mathematical models and the main design parameter for the gasification. After the gasifier the synthesis gas (SNG) is cooled to 300°C before passing a particle filter. To avoid catalyst deactivation in the tar reforming reactor, the sulphur is captured by chemical adsorption on a zinc-oxide sorbent. The removal of H_2S using a metal oxide can be described by following thermodynamic equilibrium equation.

$$MeO + H_2S \leftrightarrow MeS + H_2S \quad (1)$$

The steam reforming of tars occurs simultaneously with the methanisation reaction in the following fixed bed reactor. The exothermic gas reactions lead to the necessary temperature rise to approximately 550 °C for the tar reforming reaction. As an essential

step in the gas cleaning process, the model for the catalytic tar reforming reactor is described in Section 2.1. To cool the gas to the outlet temperature of 70 °C, the SNG passes a spray tower.
Partially modified standard models from the PGP-Library (heat exchangers, pumps...) are used for the remaining process units.

2.1. Tar reforming

The tar reforming occurs simultaneously with exothermic gas reactions in one fixed bed reactor. The following gas reactions are considered in the model. To calculate the outlet gas stream thermodynamic equilibrium of reactions (2) – (4) is assumed or the outlet composition of the corresponding components is defined.

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (2)$$

$$CH_4 + H_2O \leftrightarrow CO + 3H_2 \quad (3)$$

$$C_2H_4 + 2\ H_2O \leftrightarrow 2CO + 4H_2 \quad (4)$$

To distinguish different tar components, the tar loading of the inlet gas stream is split into two organic pseudo components. The differentiation is based on the commonly accepted ECN classification system (Rabou et al., 2009), heterocyclic tars (Tar class 2) and polyaromatic tars (Tar class 4 and 5). The weight distribution of the model components is based on experimental data.
Tar and water steam are converted into CO and H_2 according to reaction (5). Optionally the tar removal rate can be defined by the user or calculated as a kinetic reaction first order.

$$C_xH_yO + (x\text{-}z)H_2O \leftrightarrow xCO + (y/2+x\text{-}z)H_2 \quad (5)$$

If fast methanation is assumed, equilibrium temperature can be presumed over the whole length of the catalytic bed and the tar conversion will be calculated using the equilibrium temperature, the overall residence time t and kinetic data provided by the user.
For more precise results, the tar reforming reactor is modelled as two separate zones, before and after the equilibrium of the methanation reaction is reached. The time to reach equilibrium Δt_1 is calculated according to (6), using the generated CH_4 amount ΔC_{CH4}, the volume flow $\dot{V}$, the reaction rate of (3) r_{CH4} and the catalyst density ρ_{Cat}.

$$\Delta t_1 = \frac{\Delta C_{CH4} / \dot{V}}{r_{CH4} * \rho_{Cat}} \quad (6)$$

Based on experimental data and due to the logarithmic temperature profile in the reactor a medium temperature T_m, which only varies slightly over time, can be calculated in the reactor part before equilibrium is reached. Using user provided kinetic data and T_m, the tar conversion rate can be calculated for the time Δt_1 and the time $t\text{-}\Delta t_1$. This approach further allows the implementation of catalyst deactivation.
In addition an energy balance, elementary mass balances and equations of mass conservation for the components which are not affected by reactions (2) – (5) are implemented in the model. The pressure loss in the packed bed Δp is calculated according to the Ergun equation (Wirth, 2010) considering bed length L, porosity ψ, dynamic viscosity η, superficial fluid velocity ν, fluid density ρ_f and Sauter diameter d_p.

$$\frac{\Delta p}{L} = 150\frac{(1-\psi)^2}{\psi^3}\frac{\eta \nu}{\bar{d}_p^2} + 1.75\frac{(1-\psi)^2}{\psi^3}\frac{\rho_f \nu^2}{\bar{d}_p^2} \quad (7)$$

3. Results and discussion

The individual models are combined in the IPSEpro Process Simulation Environment (PSE) to build up a complete model from biomass to raw-SNG. A flowsheet of the complete process can be seen in Figure 1 including the optimal thermal integration.
The high temperature waste heat of the fluegas and the productgas is used for air preheating as well as for production and superheating of process steam. The produced excess steam and the low temperature heat generated in the spray quench tower can be delivered to a district heat system. This polygeneration approach improves the overall efficiency substantially.
To show the influence of different operating parameters on the process a sensitivity analysis was performed. In this contribution the influence of steam excess ratio, gasification pressure and the temperature of the SNG after the productgas cooling will be evaluated. Table 1 shows the limits in which the parameters were varied and gives the chosen design parameter.

Table 1: parameter of the sensitivity analyse

Parameter	Lower limit	Upper limit	Design value	Unit
Steam excess ratio	2	6	4	-
Outlet temp. of SNG cooling	300	500	300	°C
Gasification pressure	1.5	5	5	bar_{abs}

In this work the parameters cold gas efficiency η_{chem} (ratio of the chemical energy content of the SNG $\dot{m}_{SNG}LHV_{SNG}$ compared to the chemical energy in the fuel $\dot{m}_{F}LHV_{F}$) and the overall thermal utilization rate η_{tot} (ratio of the chemical energy content of the SNG minus the electric power consumption $\sum P_{el}$ plus the district heat P_{DH} compared to the chemical energy in the fuel) are used to evaluate the performance of the whole process. To assess the influence of the parameters on the catalyst amount in the reactor a dimensionless factor was developed. It is defined as the minimum catalyst mass for complete tar reforming without considering catalyst deactivation in relation to the value at design conditions. The definition of the evaluated values is given in Table 2.

Table 2: evaluated process values

Parameter	Definition
Cold gas efficiency	$\eta_{chem} = \frac{\dot{m}_{SNG}LHV_{SNG}}{\dot{m}_{F}LHV_{F}}$ %
Overall thermal utilization rate	$\eta_{tot} = \frac{\dot{m}_{SNG}LHV_{SNG} + P_{DH} - \sum P_{el}}{\dot{m}_{F}LHV_{F}}$ %
Catalyst mass	$\frac{m_{Cat,min}}{m_{Cat,min\ at\ design\ parameters}}$ %

3.1. Influence of steam excess ratio σ

The steam excess ratio is an important operational parameter for the gasification as well as for the downstream gas cleaning processes. Steam is used as a gasification and fluidization agent in the gasifier. It impacts the composition and heating value of the productgas of the gasification. Further the productgas composition influences the sulphur capture and especially the methanation and tar reforming. Figure 2 and 3 show that the cold gas efficiency and the overall thermal efficiency are decreasing while the necessary catalyst mass is increasing with increasing σ. Although a lower σ benefits the

process, it cannot be chosen arbitrarily low. Considering process requirements like the necessary fluidization in the gasifier and the prevention of coke formation in the tar reforming reactor, an optimum steam excess ratio of 4 was chosen.

Influence of outlet temperature of SNG cooling

Figure 4 shows that a high SNG temperature after productgas cooling has a positive effect on the cold gas efficiency due to a lower H_2O content in the SNG. Since more steam is needed in the gasifier, the amount of excess steam, which can be used for district heating, decreases. This leads to a decreasing overall efficiency with rising gas temperature. Although the influence is less distinct than with gasification pressure and steam excess ratio, the necessary catalyst amount reduces with higher temperatures (Figure 5). Since a lower SNG temperature leads to a better sulphur capture by ZnO which is necessary to avoid catalyst deactivation, a design value of 300°C was chosen.

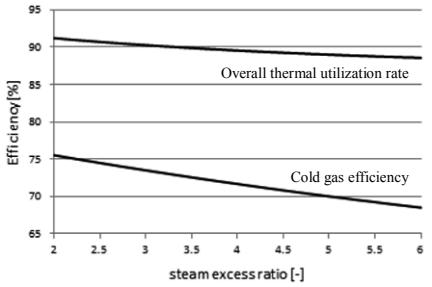

Figure 2: steam excess ratio vs. efficiency

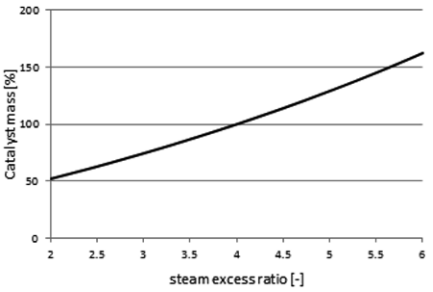

Figure 3: steam excess ratio vs. catalyst mass

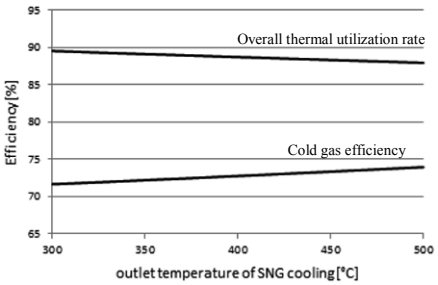

Figure 4: outlet temperature of SNG cooling vs. efficiency

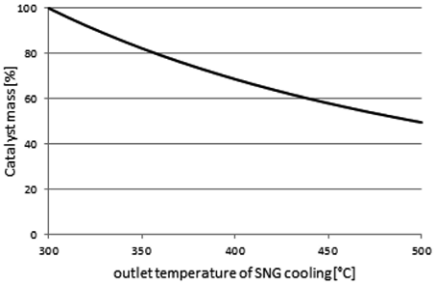

Figure 5: outlet temperature of SNG cooling vs. catalyst mass

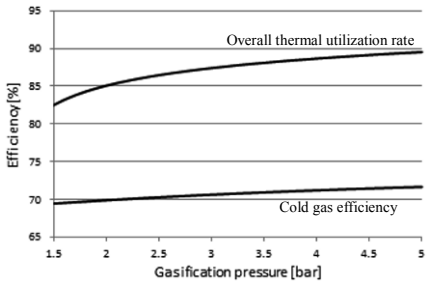

Figure 6: gasification pressure vs. efficiency

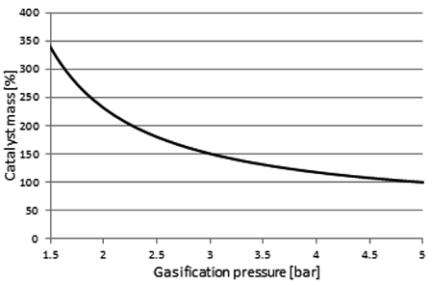

Figure 7: gasification pressure vs. catalyst mass

3.2. Influence of gasification pressure

In contrast to most conventional gasifiers, the Heatpipe Reformer can operate under pressure. Figure 6 shows that the cold gas efficiency and the overall thermal utilization rate, benefit from higher gasifier pressure. This correlation can be explained by a higher CH_4 content in the productgas after the gasifier and in the SNG after the tar reforming reactor. In addition, the heat extracted from the quench water cycle rises substantially with high process pressures due to the higher amount of condensate from the SNG. An increasing gasification pressure lowers the necessary catalyst mass in the tar reformer significantly (Figure 7). This correlation could be explained by the higher reaction rate of reaction (5). Due to the positive influence of a high gasifier pressure on the overall process and based on practical experience of the project partner Agnion a design pressure of 5 bar_{abs} was chosen.

4. Conclusions

Process modelling and simulation are useful tools for primary process design and the evaluation of process parameters. Using mathematical models for the individual steps the overall process was analysed and optimized. The analysis shows that under optimized process conditions a cold gas efficiency of over 70% can be achieved. By using the waste heat, the total efficiency for the overall process can be increased to approximately 90%. Moreover the necessary amount of consumables like catalyst can be reduced considerably by working under optimized operating parameters.

All of the most relevant issues regarding the design of the process are implemented in the model. On the basis of the simulated data and practical experience a basic engineering of the overall system will be performed, which facilitates the technical and economic analysis and comparison with other gas cleaning processes.

Acknowledgments

The authors thank the Austrian Research Promotion Agency FFG for funding the project “InnoGasClean” (FFG 838730) and the project partner Agnion (www.agnion.de) for the pleasant and constructive working relationship.

Abstract

Hydrates are ice-like compounds comprised of water and light hydrocarbons whose formation in natural gas pipelines can lead to several problems such as pipeline blockage. To avoid these problems, the injection of Thermodynamic Hydrate Inhibitors (THI) in well-heads is widely employed. There are several options of THIs. In the present work, Monoethylene Glycol (MEG) was chosen due to its comparative advantages. As MEG can be reused, it must be re-concentrated and stripped of salts before recirculation through subsea pipelines. MEG Recovery Units (MRU) can be divided into three types: Traditional Process (TP), Full-Stream Process (FS) and Slip-Stream Process (SS). TP, FS and SS were discussed and compared via Energy and Exergy Analyses. The Exergy Analysis was based on two different approaches: firstly allocating the Reference Environmental Reservoir (RER) as the atmosphere at sea level; secondly allocating the RER as sea level atmospheric air saturated with water in equilibrium with liquid water containing MEG at infinite dilution. Those two approaches led to different results, but, in both cases TP shows the highest exergy efficiency and lowest energy consumption, while FS exhibits the lowest exergy efficiency and highest energy consumption. SS occupied an intermediate position.

Keywords: exergy; energy; monoethylene glycol; hydrate.

1. Introduction

The recent advent of deep-water offshore exploration of oil & gas entailed the arrival of stringent challenges. Concerning deep-water natural gas (NG) production, a main challenge is to avoid the formation of methane hydrates, which may cause clogging and even stopping NG flow. Formation of CH_4 hydrates is propelled by three factors (Gupta and Singh, 2012): (i) coexistence of water with NG; (ii) high pressure flow; (iii) external temperature close to 0^oC. Therefore prevention of hydrate formation is required. One approach that has been widely used is the injection of a Thermodynamic Hydrate Inhibitor (THI) in well-heads (Chandragupthan, 2011). MEG has been successfully used as THI due to its advantages compared to other inhibitors. In this study only applications of MEG as THI are considered. MEG is injected in well-heads and returns to the platform along with the production fluids. This stream is separated into three phases: (i) bottom aqueous phase with MEG and salts; (ii) hydrocarbon condensate; and (iii) NG phase. The MEG-H_2O-Salts stream is pre-treated to remove hydrocarbons and sent to the MEG Recovery Unit (MRU). This stream is the Rich MEG feed which is processed by the MRU to regenerate MEG to be returned to the NG wells as Lean MEG; i.e. regeneration means water and salt removal. Salt accumulation in the MEG loop is an issue because it causes fouling at saturation.

MRU falls into three categories: Traditional Process (TP), Full-Stream Process (FS) and Slip-Stream Process (SS). In offshore platforms, where space and resources are limited, it is of great importance to determine the energy requirements of each process, as well as to perform a thermodynamic analysis to assess degradation of energy quality. This last approach can be done via Exergy Analysis (ExA). ExA quantifies and compares the percentage of exergy destroyed via process irreversibilities. ExA also assesses the sinks of exergy destruction or inefficiencies (BoroumandJazi et al., 2013).

2. Objectives and Methodology

Three steady-state MRU processes (TP, FS, SS) were compared in terms of energy consumption (EC) and exergy efficiency. TP, FS and SS were installed in a process simulator for solving mass/energy balances, providing values of EC and thermodynamic properties of streams for ExA. The expression of exergy flow was developed by applying conservation laws and the First and Second Laws of Thermodynamics. The Reference Environment Reservoir (RER) was defined using two different criteria for the reference atmosphere and the reference state of MEG. Exergy flows were calculated for the relevant streams via spreadsheets with properties extracted from simulations.

3. MRU Implementation in Process Simulator

3.1. Premises

Typical flow rates and conditions reported in the literature of real MRUs were used for TP, FS and SS (Nazzer and Keogh, 2006). Operating pressure of MEG boiling systems was set at 0.2 bar abs (boiling points $\leq 140^{o}C$) to avoid thermal degradation of MEG above $162^{o}C$. NaCl is the main ionic species, representing 1-3% w/w of Rich MEG, whereas other salts – $CaCl_2$, etc – reach only hundreds of ppm and are irrelevant in terms of thermal effects. Even so, NaCl was not included in the simulation for two reasons: (i) NaCl only settles in the flash-evaporator after vaporization of MEG and H_2O, which are responsible for the main energy effects associated with phase changes – to confirm this, MRU was simulated with/without NaCl and the differences in terms of heat duties were always found below 1-2% (Teixeira, 2014); (ii) Aqueous solution models are not reliable with strong electrolytes at saturation, leading to inaccurate thermodynamic properties and ExA. Thus, after discarding NaCl, Rich MEG stream was defined as: 100t/d, 55%w/w H_2O + 45%w/w MEG at $25^{o}C$, 1 bar. The Slip Fraction in SS was chosen as 50%. Temperature and pressure of Rich and Lean MEG have same values for TP, FS, SS. Thermodynamic calculations used the simulator Glycol Package.

3.2. Traditional Process (TP)

TP simply distillates water from Rich MEG via an atmospheric distillation column (ADC) with Lean MEG as bottoms. TP works well without formation water. However, with formation water there is accumulation of salts and dissolved minerals in the MEG loop overtime, leading to saturation and precipitations on exchangers, thermally degrading MEG. Figure 1 depicts the simulation implementation of TP.

3.3. Full-Stream Process (FS)

FS treats Rich MEG with three serial steps: (i) Atmospheric Distillation Column (ADC) for a first removal of water below 140°C; (ii) Flash-Evaporator (FLS) at 0.2 bar, wherein the feed instantaneously vaporizes after mixing with the recycled hot liquor, precipitating salt; and (iii) vapor from FLS goes to Sub-atmospheric Distillation Column (SDC) at 0.2 bar giving pure H_2O distillate and Lean MEG as bottoms. Figure 2 illustrates the simulation implementation of FS.

3.4. Slip-Stream Process (SS)

SS combines TP with a smaller FLS-SDC train to treat the Slip Fraction of the effluent from TP section. An advantage of SS is the reuse of inhibitors and pH stabilizers, which are lost in the FS within the FLS solids. SS is suitable for low to intermediate water loads (Brustad et al., 2005). Figure 3 shows the implementation of SS.

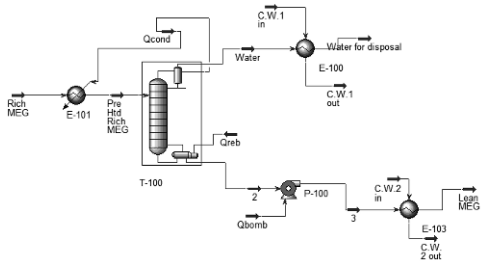

Figure 1. TP Implementation

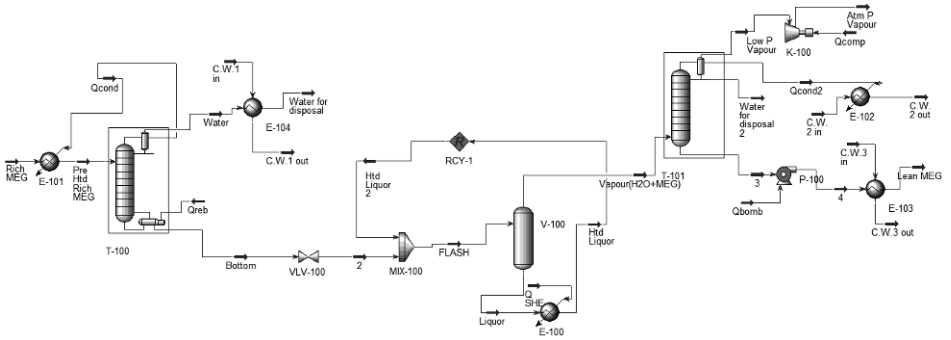

Figure 2. FS Implementation

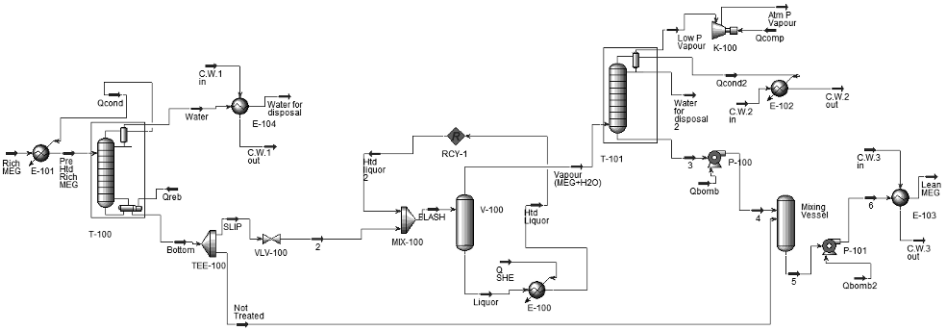

Figure 3. SS Implementation

3.5. Energy Consumption (EC)

EC was found for TP, FS and SS in Table 1, which also shows the respective Lean MEG composition. All heating duties represent direct electricity consumptions as usual in offshore rigs (Myhre, 2001). TP has the lowest EC, as it is the simplest process with only one separation. On the other hand, FS has the highest EC. SS is the second as only part of the Rich MEG is evaporated.

Table 1. Electric Energy Consumptions (EC) and Lean MEG Compositions for MRU Processes

Process	%w/w MEG of Lean MEG	EC (kW)
TP	89.46	1685.73
FS	91.36	2330.38
SS	86.77	1894.50

4. Exergy Analysis (ExA)

4.1. Exergy Definition

The exergy flow of a stream is the maximum rate of work obtainable when it is brought to equilibrium with the environment. Exergy is destroyed due to irreversibilities in real processes. ExA evaluates the exergy efficiency by calculating the % of destroyed exergy. From the First and Second Laws of Thermodynamics for a multi-stream, steady-state, open system, the rate of maximum work obtainable is the difference between the input and output flows of exergy in Eqs. (1) and (2) (Teixeira, 2014; De Medeiros, 2011):

$$\dot{B}_{in} + \dot{B}_{in}^{W} = \sum_{j}^{nfs} F_j \left(\overline{H}_{F_j} + P_0 \overline{V}_{F_j} - T_0 \overline{S}_{F_j} - \sum_{k=1}^{nc} \mu_k^0 Y_{kF_j} \right) + \sum_{j=1}^{nwi} \left| \dot{W}_j^{imported} \right| \tag{1}$$

$$\dot{B}_{out} + \dot{B}_{out}^{W} = \sum_{j}^{nps} K_j \left(\overline{H}_{K_j} + P_0 \overline{V}_{K_j} - T_0 \overline{S}_{K_j} - \sum_{k=1}^{nc} \mu_k^0 Y_{kK_j} \right) + \sum_{k=1}^{nwe} \left| \dot{W}_k^{exported} \right| \tag{2}$$

Where $\dot{B}_{in}$, $\dot{B}_{out}$ are the exergy flows of input and output streams; $\dot{B}_{in}^{W}$, $\dot{B}_{out}^{W}$ are the exergy flows assigned to input/output streams of pure electric energy; F_j is the mol flow rate of inlet stream *j*; K_j is the mol flow rate of outlet stream *j*; *nfs* and *nps* refer to the numbers of feed and product streams; μ^0_k is the chemical potential of *k* species in the Reference Environment Reservoir (RER); $\overline{H}, \overline{S}, \overline{V}$ refer to molar enthalpy, entropy and volume; P_0 and T_0 are the pressure and temperature of RER; *W* represents a rate of work imported/exported by the system; and Y_k refers to the mol fraction of *k*. All properties are obtained from simulations, except μ^0_k, which belongs to RER. In this regard, two approaches are used for RER: (i) RER Approach#1: usual in the literature with atmospheric air at T_0=298.15 K and P_0=1 atm, Y^0_{N2}=0.7652, Y^0_{O2}=0.2053, Y^0_{Ar}=0.0092, Y^0_{H2O}=0.02, Y^0_{CO2}=0.0004, where MEG is at Chemical Equilibrium (ChE) with RER species via a combustion reaction; (ii) RER Approach#2: Air at T_0=298.15 K and P_0=1 atm, with the same dry basis composition as before, but now saturated with H_2O in Vapor-Liquid Equilibrium (VLE) with liquid H_2O containing MEG at infinite dilution.

4.2. RER Approach #1

RER is an ideal gas with chemical potentials of species by Eq. (3), where the first term in the right side is found via process simulator with pure low pressure gas. Since MEG is absent in atmospheric air, μ^0_{MEG} comes via ChE with other RER species as in Eq. (4).

$$\mu_i^0 = \mu_i^{f,0}(T_0, P_0) + RT_0 \ln Y_i^0 \tag{3}$$

$$\mu_{MEG}^0 = 2\mu_{CO2}^0 + 3\mu_{H_2O}^0 - 2.5\mu_{O2}^0 \tag{4}$$

4.3. RER Approach #2

Chemical potentials of N_2, O_2, Ar, CO_2 and H_2O are also given by Eq. (3) assuming VLE of H_2O. For MEG, its RER chemical potential is calculated at infinite dilution in liquid H_2O at (T_0, P_0) with Eq. (5), where X is the mol fraction of MEG (Smith et al., 2007). The derivative term is obtained via numerical differentiation on the curve $\overline{G} = \overline{H}(X, T_0, P_0) - T_0\overline{S}(X, T_0, P_0)$ generated by several composition definitions of H_2O+MEG liquid streams at (T_0, P_0) in the process simulator.

$$\mu_{MEG}^{\infty,H2O} = \overline{G}\Big|_{X=0} + \frac{d\overline{G}}{dX}\Big|_{X=0} \tag{5}$$

5. Results and Discussion

Exergy efficiency is a ratio between output and input flows of exergy, respectively from Eqs. (2) and (1). Table 2 shows the ExA performances of TP, FS and SS for both RER approaches.

Table 2. Exergy Efficiencies (%) of MRU Configurations for RER Approaches #1 and #2

Process	RER Approach #1	RER Approach #2
TP	91.49	18.83
FS	90.19	14.97
SS	91.02	17.14

TP had always the highest efficiency, while FS had the lowest. TP is a brute technology with only one primary sink of exergy destruction (ADC) with low exergy losses. FS performs a huge effort of separation (ADC, FLS, SDC) vaporizing all MEG and H_2O from Rich MEG producing the best Lean MEG with the highest EC and exergy destruction rate, and lowest exergy efficiency. SS is intermediate. Table 2 also shows why RER Approach#2 is better than Approach#1. Both calculate the same rate of lost exergy, but Approach#1 achieves very high efficiencies (≈90%). The reason is that in Approach#1 μ^0_{MEG} is obtained via ChE with a very negative value (-1.71.10^6 J/mol), giving MEG streams with very high positive exergy flows (≈11500 kW) much greater than typical EC (≈1700 kW). As the MRU does not destroy MEG, the input and output flows of exergy are very high positive numbers, with only ≈1600kW of lost exergy. Thus the total flow of exergy has a small relative fall, entailing exergy efficiencies close

to 90%. On the other hand, Approach#2 assign the RER condition of MEG closer to the MRU state of MEG, entailing much lower positive values of exergy flows of streams (≈280 kW). Since the same rate of exergy is lost in both approaches, much lower (but more meaningful) exergy efficiencies are obtained in Approach#2. These more realistic efficiencies are closer to what is expected for distillation trains.

6. Conclusions

Exergy Analysis was conducted for MRU processes in offshore NG production. Exergy efficiencies result from the exergy flows entering/leaving processes. Since exergy depends both on the state of streams and on the RER, two RER approaches were used: (i) Usual RER Approach#1, allocating MEG in ChE with atmospheric species; and (ii) RER Approach#2 where the atmosphere is in VLE with liquid H_2O containing MEG at infinite dilution. Both approaches calculated the same rate of lost exergy for the same MRU. But Approach#1 seems inappropriate because exergy flows of streams are too high, masking results. On the other hand, Approach#2 defines the RER condition of MEG as a liquid in water, thus exergy flows of streams are much lower, with better discrimination of exergy efficiencies.

7. Acknowledgments

Financial support from PETROBRAS S.A., FINEP-Brazil and ANP-Brazil (PRH-ANP / MCT via PRH-13 of Escola de Química/UFRJ) is gratefully acknowledged.

Abstract

Biodiesel is an alternative fuel that has become attractive due to its environmental benefits compared to conventional diesel. Over the years an initial reaction rate based on the Ping Pong Bi Bi enzyme mechanism has been adopted to represent the kinetics of the enzymatic transesterification in several references in the open literature. However, in this work, a two parameters model taking into account the inhibitory effects due to the concentration of both product species was proposed and the experimental oil conversion data were fitted to the model. The kinetic study of the palm oil ethanolysis reaction catalyzed by immobilized lipase Novozyme 435 (from *Candida antarctica*) has been made in a temperature of 42 °C at atmospheric pressure. A maximum conversion of 70% of oil was obtained after 7 hours of reaction. The model proposed was successful in predicting the experimental data behavior (mean absolute deviation <5%) with the reactor operating in batch. The confidence interval of the parameters was small, and the parameters did not show a high dependency between each other with a correlation coefficient between them equal to 0.855, ratifying the excellent fit of the rate equation proposed.
Keywords: biodiesel, transesterification, lipase, palm oil, Ping Pong Bi Bi model.

1. Introduction

By definition, biodiesel is a mixture of fatty acid alkyl esters (FAAE) derived from renewable sources. It can be synthesized through the reaction of edible/non-edible oils or animal fats with an alcohol. The oils and fats consist of a mixture of triglycerides which can be transformed to FAAE through a chemical reaction with a short chain alcohol known as transesterification (or alcoholysis).

The general scheme of the ethanolysis reaction can be seen in Figure 1; a triglyceride molecule reacts with three alcohol molecules producing three molecules of alkyl esters, named as biodiesel, and one glycerol molecule as the main by-product. In fact, the reaction consists of three consecutive steps in which first the triglyceride is converted into diglyceride; the second step is the conversion of the diglyceride into monoglyceride which is converted into glycerol at the final step (Shahid and Jamal, 2011). Furthermore, due to its reversibility, an excess of alcohol is usually required to perform the transesterication reaction.

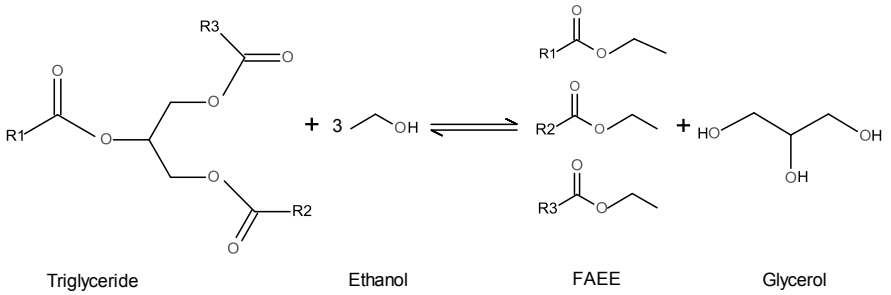

Figure 1: Transesterification reaction of triglycerides with ethanol. R1, R2, and R3 represent the fatty acid chains; FAEE is the fatty acid ethyl esters.

Different types of oils can be used as feedstock to produce biodiesel; soybean, palm, sunflower, canola, rapeseed, and cotton are among the most common vegetable oils employed. Palm oil is the major feedstock for biodiesel production in Malaysia and is also commonly used in others countries like Brazil and Indonesia. Up to date, palm is the most effective oilseed due to the large quantity of oil produced with a minimum land demand (Lam and Lee, 2011).

Although methanol is mainly obtained from fossil sources, it is currently the primary alcohol used to synthesize the biodiesel fuel; however, ethanol has been frequently employed due to its advantages such as a higher dissolving power and lower toxicity in comparison to the previous one (Stamenkovic et al., 2011). In Brazil, bioethanol derived from sugarcane is widely available. Thus, its use as a reactant is advantageous since the biodiesel produced can be considered as 100% renewable based (Gui et al., 2009).

The catalyst is needed to increase the speed of the reaction and it can be alkaline, acid, or an enzyme. Concerning to the biocatalysts, the lipases are enzymes able to catalyze reactions of the triglycerides by acting on their ester bond (Pessoa et al., 2010). In spite of the drawbacks of the enzymatic transesterification such as the deactivation of enzymes by the presence of the alcohol and their high cost, this technology is widely studied once the problems characteristics of the reactions with alkaline and acid catalysts, like the difficulties during some downstream processes (glycerol recovery, catalyst removal and purification steps) are not found in lipase catalyzed alcoholysis.

Different studies related to the ethanolysis of vegetable oils via enzymatic catalysis to produce biodiesel can be found in the open literature (Wang et al., 2011, Ribeiro et al., 2012). Despite that, works that deal with a kinetic modeling are rarely found. Therefore, the objective of this work is study the kinetic of the ethanolysis of palm oil with the commercial lipase Novozyme 435 as the catalyst. Experimental oil conversion data versus reaction time was obtained and these values were used to fit an empirical model proposed and the results were compared with the Ping Pong Bi Bi with alcohol inhibition model.

2. Materials and methods

2.1. Materials

Absolute ethanol was supplied by Vetec Química Fina with a mass fraction purity of 0.998; refined palm oil was kindly donated by Agropalma S/A, Brazil. According to the company, the free fatty acid contained in the oil is <0.5% and its composition (% mass) is: 37.6% triolein, 46.8% tripalmitin, 10.5% trilinolein, 3.8% triestearin, 1.2% trimyristin, 0.1% trilaurin. Based on this composition, the oil molecular weight is 843.46 g/gmol. Novozyme 435 (lipase from *C. antarctica* immobilized on acrylic resin) was purchased from Sigma-Aldrich, USA. Standard fatty acid ethyl esters were acquired from Sigma-Aldrich, USA. All other reagents were of chromatographic grade and were also purchased from Sigma-Aldrich.

2.2. Enzymatic ethanolysis

The batch reactions were carried out in 50 mL closed glass flasks. The commercial lipase (0.4% of reactants mass) was added to flasks containing palm oil (12 g) and 4 g of ethanol (6:1 alcohol:oil initial molar ratio). The mixture was incubated at 42 °C with constant shaking at 170 rpm. The reactions were carried out in triplicate and allowed to proceed for 7 h. Samples were periodically taken and analyzed. The aliquots (100 μL) were diluted with n-heptane (800 μL) and mixed with the internal standard (IS) ethyl heptadecanoate (100 μL) and analyzed by gas chromatography (CG).

2.3. Gas-chromatography analysis

The ethyl esters were analyzed on an Agilent (Palo Alto, CA) gas chromatograph model 7890A with a mass spectrometer (MS) detector and a DB-WAX column (30 m x 0.25 mm x 0.25 μm). The injector temperature was 250 °C and helium was used as the carrier gas (1mL/min). The temperature program was as follows: the column temperature started at 60 °C for 2 min and then heated to 200 °C at 10 °C/min and then raised to 240 °C at 5 °C/min and held for 7 min.

3. Kinetic modeling

The reactions involving materials derived from natural products, such as in the enzymatic transesterification of vegetable oils, can be described by a two-step mechanism where the products of each step are released between additions of the substrates (Pessoa et al., 2009). As reported by several authors (Dossat et al., 2002; Al-Zuhair et al., 2006; and Fjerbaek et al., 2009), the lipase alcoholysis of triglycerides are in accordance with the Ping Pong Bi Bi mechanism and an initial reaction rate equation (called here, model 1) can be expressed by Eq. (1), including the influence of the alcohol on the deactivation of the enzyme.

$$(-r_{oil,model\ 1}) = \frac{V_{max}}{\frac{Km_1}{[oil]} + Km_2 \cdot [alc]/[oil] + 1} \quad (1)$$

where ($-r_{oil}$) denotes the initial rate of oil consumption; [oil] and [alc] represent the initial molar concentrations of oil and alcohol, respectively; V_{max} is the maximum initial rate for the reaction; $Km_1 = Km_{oil} + Km_{alc}/\theta$ and $Km_2 = Km_{oil}/K_i$ with θ representing the initial alcohol:oil molar ratio, Km_{oil} and Km_{alc} representing the apparent Michaelis constants for the oil and alcohol, respectively, and K_i is the apparent inhibition constant of the alcohol.

Different authors (Dossat et al., 2002; Shimada et al, 2002; Fjerbaek et al., 2009; Ko et al., 2012), however, have reported that the glycerol obtained during the transesterification reduces the catalytic activity of the lipase by forming a film layer around the support of the immobilized enzyme which affects the internal mass transfer resistance within the solid support. This effect is not accounted in model 1 once it is an initial reaction rate expression. Hence, an empirical model (called model 2) was proposed in this work to consider it. The model rate expression is given by Eq. (2). Due to the possibility of internal diffusion limitations when using immobilized lipases, the kinetic parameters from models 1 and 2 may be considered as apparent values. In addition to considering the presence of the products, another advantage of the proposed model is that it has only two adjustable parameters.

$$(-r_{oil,model\ 2}) = \frac{K_1 \cdot \{[oil] \cdot [alc] - 3 \cdot [oil]^2 \cdot X_{oil}^2\}}{\left(1 + \frac{3 \cdot [oil]^2 \cdot X_{oil}^2}{K_2}\right) \cdot [oil] \cdot [alc]} \quad (2)$$

where X_{oil} is the conversion of oil; K_1 and K_2 are the apparent kinetic constants.

Thereby, combining the reaction velocity expression (model 1 or model 2) with the mass balance for a batch reactor, the kinetic parameters of each model were fitted to the experimental data for the ethanolysis of palm oil catalyzed by enzyme Novozyme 435 according to the Eq. (3). The parameters were determined by nonlinear regression using the software Mathcad to perform the particle swarm optimization (PSO) and the gradient-conjugated methods. The ordinary differential equation was solved using the fixed-step fourth-order Runge-Kutta method.

$$\frac{dX_{oil}}{dt} = \frac{V}{n_0^{oil}} \cdot (-r_{oil}) \quad (3)$$

where t is the time of reaction; V is the reaction volume; n_0^{oil} represents the initial mol of oil.

4. Results and Discussion

Regarding to the kinetic modeling showed above, the comparison between the experimental and predicted conversions for the palm oil transesterification is illustrated in Figure 2. It can be observed that, qualitatively, the model proposed in this work (model 2) and the model 1 were able to describe the experimental data. However, the model predicted the experimental data with an absolute mean deviation of 8% for model 1 and 4% for model 2. Hence, according to these values, it can be notice that the model 2 showed a better fit of the data than the modified Ping Pong Bi Bi model (model 1).

In order to make a better selection of the most suitable model do fit the experimental data, the standard deviation of best-fit parameters and the correlation coefficient between the parameters were calculated. The results are shown in Table 1.

The confidence interval identifies how tightly the determination of the parameters values was. From the values on Table 1 is possible to see that for model 1 the confidence interval (with 95% of confidence level) is very wide, starting from negatives values, which has no physical meaning. Therefore, the data do not define the parameters well and the model cannot be consider appropriate. On the other hand, the confidence

interval for model 2 is small meaning that the experimental data define well the best-fit curve of this model.

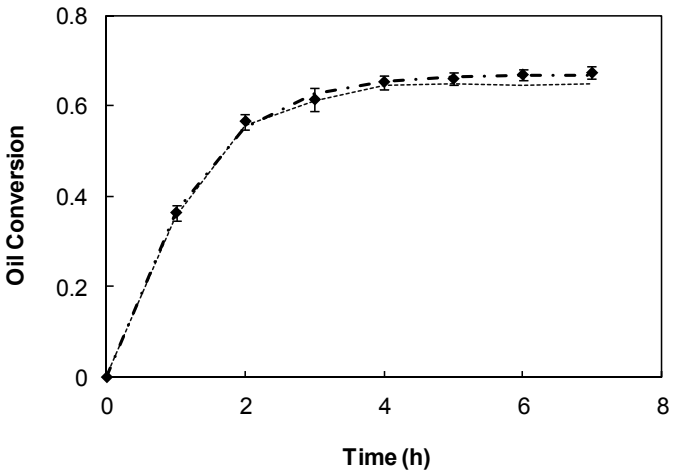

Figure 2: Palm oil conversion for a batch reactor. (■) Experimental data; (- - -) Model 1; (— · -) Model 2. Conditions: 42 ºC, 12g palm oil, ethanol:oil molar ratio=6:1, 4 % w/w enzyme.

Table 1: Kinetic parameters, standard deviation and confidence level of parameters for model 1 and model 2.

Model	Parameter	Estimated Value	Standard deviation	Lower limit (95% confidence level)	Upper limit (95% confidence level)
Model 1	V_{max} (mol/L·h)	11.11	145.25	-344.30	366.52
	Km_1 (mol/L)	3.21	96.56	-233.06	239.48
	Km_2	0.42	23.46	-56.98	57.81
Model 2					
	K_1(mol/L)	0.33	0.025	0.27	0.39
	K_2 $(mol/L)^2$	0.50	0.029	0.44	0.57
Correlation coefficients between the parameters					
	$\rho_{Vmax, Km1}$, $\rho_{Vmax, Km2}$, $\rho_{Km1, Km2}$		1.000		
	$\rho_{K1, K2}$		-0.855		

Notwithstanding, the correlation coefficient between parameters V_{max} and Km_1, V_{max} and Km_2, Km_1 and Km_2 from model 1 are equal to one suggesting that the parameters are redundant, i.e., a change made in the value of one parameter, changes the value of the other. On the opposite, the absolute value of correlation coefficient between parameters K_1 and K_2 from model 2 (i.e, $|\rho_{K1, K2}| = 0.855$) do not show a high dependency between them. These results confirm the model 2 as the best choice to describe the data obtained.

5. Conclusion

In this study the palm oil was used to successfully produce biodiesel through the lipase-catalyzed transesterification with ethanol. Under 42 °C and atmospheric pressure, a maximum oil conversion of 70% was obtained after 7 hours of reaction. Moreover, the experimental data were used to fit two different kinetic models and their apparent kinetic parameters were estimated. Considering the results obtained, the rate expression proposed in this work (Model 2) proved to be a better choice to fit the experimental data than the model based on the Ping Pong Bi Bi mechanism (Model 1), considering the fact that Model 2 accounts for the presence of the products. The parameters from Model 2 are not intertwined ($\rho_{K1, K2} = -0.855$) and have a small confidence interval suggesting that the data define the parameters very well. The high correlation coefficient values found for Model 1 indicate an over-parameterization of the model.

Abstract

Post-combustion carbon dioxide (CO_2) capture using aqueous monoethanolamine (MEA) has been the most widely implicated method utilizing existing coal-fired power plants. However, the heat and energy requirement of the solvent regeneration and CO_2 liquefaction results in a 30% decrease in net power output, which is called "power de-rate". In this study, optimum operating conditions of the integrated CCS process are proposed by simulation-based parametric optimization to reduce the power de-rate. Post-combustion CO_2 capture with aqueous MEA and CO_2 liquefaction integrated with a 550 MWe supercritical coal-fired power plant was simulated base on the data of a 0.1 MW pilot plant in South Korea. The stripper operating pressure and liquid to gas ratio were chosen as the manipulated variables based on the variable evaluation. The power de-rate was reduced to 17.4% when operating at optimum conditions.

Keywords: power de-rate, variable evaluation, parametric optimization, CCS

1. Introduction

The International Panel on Climate Change (IPCC) reported that the energy sector is the largest greenhouse gas (GHG) source, and coal is accounted for 40.58% of electricity generation in 2010 (IPCC, 2014). Owing to the abundance of coal, it is highly possible that energy generation will continue to depend on coal-related power generation for a while. Therefore, technology is needed that allows coal to be utilized for power generation while mitigating climate change, which is carbon capture and storage (CCS).
Unfortunately, the power de-rate is a significant issue when introducing the CCS process into an existing steam power plant. In the post-combustion capture process, CO_2 is captured through a chemical reaction with a solvent. The heat requirement for regenerating the solvent is often met using steam extracted from a power plant. Steam extraction for solvent regeneration causes a decrease in net power output. Furthermore, the compression energy during the liquefaction process also increases the power de-rate. Therefore, reducing the power de-rate is the one of keys to CCS implementation.
The process and heat integration have been studied to reduce the power de-rate. Hanak et al. (2014) investigated several new heat exchanger network (HEN) designs for a high ash coal-fired power plant with CCS and proposed to use flue gas for heating the feedwater. Liew et al. (2014) analyzed capture module design options for the heat and process integration, cooling, and using waste heat by HEN design and process modification. However, considerable modification of the existing system is required in order to introduce HEN designs into it. Since the optimization of operating variables, on

the other hand, achieves the reduction of power de-rate with less modification, it can be more practical way of minimizing power de-rate with the existing CCS plants.
The evaluation of the power de-rate based on the different operating scenarios also has been conducted by many researchers. Dave et al. (2011) performed case studies on the plant efficiencies of existing coal-fired power plants and new coal-fired power plants by evaluating the CO_2 capture demand and cooling options. Liang et al. (2011) conducted an optimization of some important process parameters, including the operating stripper pressure, CO_2 capture efficiency, and steam extraction location. However, many of previous studies have focused on finding the optimum operating conditions for the unit CCS processes, not for the integrated CCS system. Also, the influences of operating variables lack quantitative evaluation in terms of the power de-rate.
In this study, the power de-rate of an integrated retrofitted coal-fired power plant with CCS was minimized by parametric optimization. To validate the simulation model, the simulation model of a 550 MWe steam cycle integrated with CO_2 capture and liquefaction processes was rigorously developed based on the data obtained from a 0.1 MW CO_2 capture pilot plant in South Korea. All of possibly influential variables in the power de-rate were quantitatively evaluated. Steam extraction unit options with different locations and depressurizers are also taken into account for the reduction of the power de-rate. In addition, the nonlinearity between the selected influential variables and the power de-rate are discussed to achieve much insight on the overall process.

2. Process description

2.1. The steam cycle

A 550 MWe air-based supercritical steam cycle was developed based on a DOE/NERL report (Ciferno, 2008). STEAMNBS was used for the property method. Superheated steam that is generated in a coal-fired boiler is expanded through two high pressure, two intermediate pressure, five low pressure turbines connected to an electrical generator, and finally condensed. Part of the turbine energy is converted into mechanical energy. At the same time, a small amount of steam is extracted from the inlet stream of each turbine in order to regenerate the feedwater so that the irreversibility of steam generation is reduced. In seven feedwater heaters, the temperature of the condensed feedwater is increased through the heat exchange with the extracted steam.

2.2. CO_2 capture model using aqueous MEA solvent

A typical post-combustion CO_2 capture process with an absorber, a stripper and a lean-rich solvent heat exchanger was used. The model specifications were obtained from the data of a 0.1 MW CO_2 capture pilot plant in Boryeong, Republic of Korea. The capture efficiency of the plant is 90% CO_2 removal when 30 wt% aqueous MEA is used as the solvent. To properly validate the model, mass transfer coefficient and interfacial area methods were used for the absorber and the stripper as 0.7 and 0.5, respectively. The Henley IMTP model was used to predict the temperature profile in the columns, and the Electrolyte-NRTL model was used as the property method to estimate the MEA–H_2O–CO_2 system with a kinetic model suggested by Hikita et al. (1977).
Flue gas from a power plant is contacted with the cold lean solvent in the absorber column, and the solvent absorbs CO_2 exothermically. The cold rich solvent drained out from the absorber is fed to the stripper column after exchanging heat with the hot lean solvent drained out from the stripper. The hot rich solvent desorbs CO_2 endothermically at high temperature. Captured CO_2 is sent to the liquefaction process while the hot lean solvent is sent back to the heat exchanger to increase the temperature of the cold rich solvent.

2.3. CO_2 liquefaction model

The simulation model for the liquefaction process was built based on the report of Lee et al. (2012). Soave-Redlich-Kwong (SRK) was used as the property method with a modified binary interaction parameter (k_{ij}) of 0.193 in the van der Waals mixing rule (Heggum et al., 2005). Captured CO_2 is compressed up to 54.4 bar through four stage compressors, and expanded through three stage valves. Between the compression stages, the stream is cooled by cold gaseous CO_2 that is generated in the expansion by passing through the two process heat exchangers. Cold liquefied CO_2 is obtained at the target conditions of 6.5 bar and -52 °C.

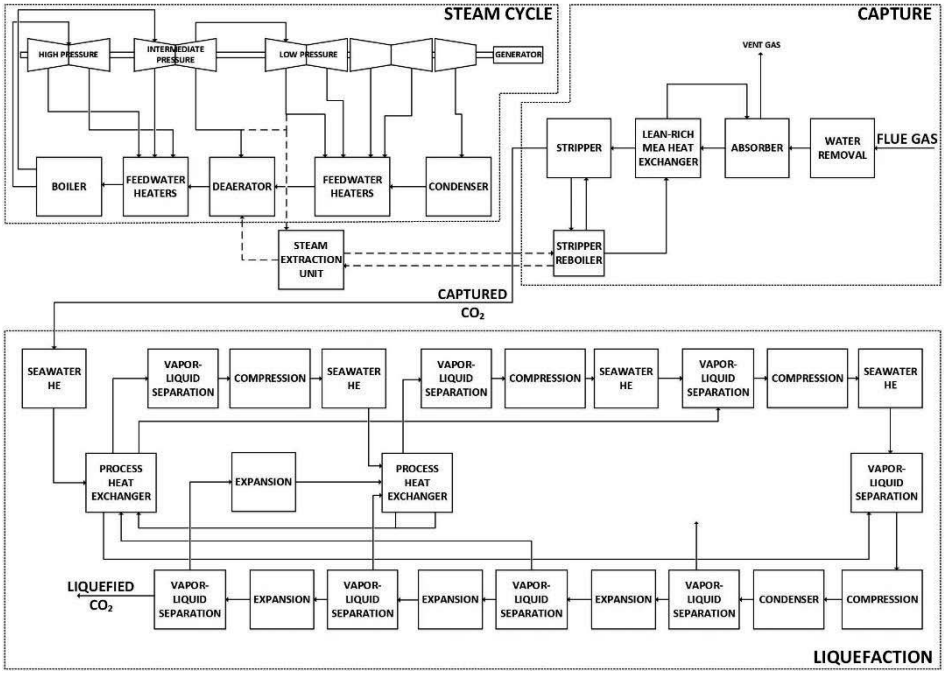

Figure 1. Block diagram of the integrated CCS process

3. Integration of steam cycle with CO_2 capture and liquefaction processes

3.1. Definition of power de-rate

To introduce CCS processes into existing steam cycles, a heat source should be supplied to a reboiler of the stripper for solvent regeneration. The steam cycle is a suitable option owing to the abundance in low quality steam. However, the steam extraction decreases the steam flowrate, thus decrease in the net plant power is inevitable. The compression energy in the liquefaction process also decreases the net plant power. This plant efficiency penalty is called "power de-rate" (D) as calculated following Eq.(1).

$$D = 1 - \frac{W_{power\ plant\ w/\ ccs} + W_{depressurizer} - W_{compressor}}{W_{power\ plant\ w/o\ CCS}} \quad (1)$$

As increase in the power de-rate means a power plant generates less energy than the original power plant with the same amount of coal, the power de-rate can be an indicator of operational economics.

3.2. Steam extraction from an existing power plant

To extract steam from the steam cycle, finding optimum extraction locations is important to avoid extracting steam with unnecessarily high temperature and pressure. Figure 1 shows a flow diagram of the integrated CCS process with the two possible steam extraction locations, which are intermediate pressure-low pressure (IP-LP) crossover steam and the first LP turbine steam.

A steam extraction unit is necessary for steam to obtain suitable conditions for the reboiler. Steam extraction units consist of three pieces of equipment: depressurizer (valve and turbine), desuperheater, and saturated water pump. The depressurizer and desuperheater vary the pressure and temperature of the extracted steam to be suitable for a reboiler. The saturated water pump delivers saturated feedwater drained out from the stripper reboiler into the deaerator of the steam cycle.

3.3. Variable selection

The following variables (x_i) possibly influence the power de-rate (D).

- CO_2 capture process: temperature of flue gas (T_{fg}), liquid to gas ratio (L/G), stripper operating pressure (P_{str}), temperature of lean solvent (T_{lean}), temperatures of condensers of absorber and stripper (T_c)
- CO_2 liquefaction process: pressure ratio of compressors (C_R)

Parameter evaluation was performed to investigate the influence of each parameter and to decide which parameters should be included in the analysis as the following Eq.(2).

$$J = \frac{\partial D}{\partial x_i} \cong \lim_{\Delta x \to 0} \left| \frac{D_{x+\Delta x} - D_x}{\frac{x_{i,x+\Delta x} - x_{i,x}}{\Delta x}} \right|_{x_j} \tag{2}$$

If $\partial D / \partial x_i$ is close to zero, variable i has little impact on the power de-rate within a chosen range. The results of the variable evaluation showed that J values of P_{str} and L/G were 7.5 %/bar and 7.3 %/(L/m^3) respectively, whereas the J value of the rest variables were near zero.

4. Results and discussion

4.1. CO_2 capture process

4.1.1. Effect of stripper operating pressure

The operating pressure of the stripper is a sole variable that affects not only the solvent regeneration energy but also the compression energy of the liquefaction process. The operating range was set from 1 to 2 bar based on the reboiler temperature. In the CO_2 capture process, an increased operating pressure tends to decrease the solvent regeneration energy and elevate the temperature at the reboiler of the stripper as shown in Figure 2. The regeneration energy is 5.03 GJ/tonCO_2 at 1 bar, sharply decreased to 3.84 GJ/tonCO_2 for a pressure of 1.25 bar, and then stabilizes at about 3.3 GJ/tonCO_2 as the stripper operating pressure is further increased.

4.1.2. Effect of liquid to gas ratio

The L/G in the capture process is the amount of lean amine solvent supplied compared with the amount of incoming flue gas to the absorber; this variable is solely influential in the capture process. When L/G is manipulated at fixed stripper operating pressure, the regeneration energy has its optimum value where the slope of the curve is near zero. As the stripper pressure increased, the optimum L/G was observed at lower values.

4.2. Liquefaction process for shipping

The compressors are the major energy consumer in the liquefaction. The compression energy is mainly determined by the compression ratio (P_2/P_1) and flowrate ($\dot{m}$). The incoming flowrate increases owing to having the target amount of CO_2 with the different pressures. However, the compression ratio greatly decreases as the stripper pressure increases. Therefore, the compression energy decreases from 39 MW to 31 MW as the stripper pressure increases from 1 to 2 bar.

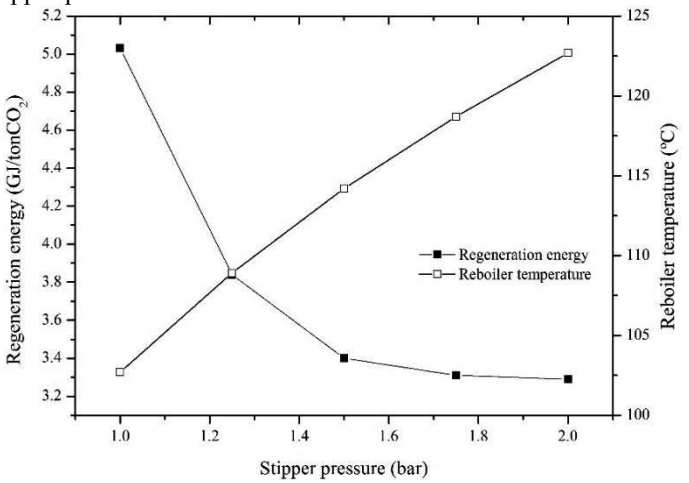

Figure 2. Simulation results for the effect of the stripper pressure on the stripper temperature and the regeneration energy

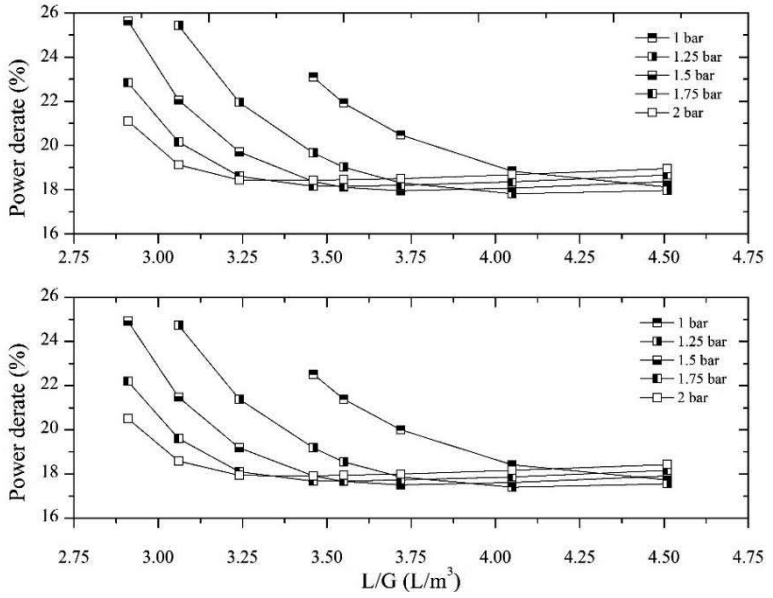

Figure 3. Effect of stripper pressure and L/G on the power de-rate from the steam extraction locations of LP steam (top) and IP-LP crossover pipe steam (bottom)

4.3. Power de-rate minimization

The power de-rate was derived from the simulation result for the integrated process. Figure 3 shows a power de-rate graph by manipulating the stripper pressure and L/G.

Higher power de-rate are generally observed at lower pressure with lower L/G, whereas high operating pressure shows less power de-rate regardless of L/G. However, the lowest power de-rate occurs at a lower pressure with an intermediate L/G of 1.25 bar and 4.05 L/m^3, respectively. The result is significantly different from previous research that proposed higher operating pressures for optimum operating conditions. This means that the optimum operating conditions of the integrated process are different from those of the unit process owing to the steam extraction unit. Higher operating pressure requires less amount of steam extracted allowing less power de-rate to the steam cycle. However, the increased reboiler temperature decreases the expansion ratio of the auxiliary turbine from 6.2 to 3.2, recovering less energy from the auxiliary turbine per unit flowrate of extracted steam.

5. Conclusion

Although CCS is considered a realistic near-term technology to decelerate global warming, the power de-rate caused by the heat required for solvent regeneration and compression energy blocks CCS implementation. In this study, simulation based parametric optimization was performed to reduce the power de-rate. A 550 MWe supercritical coal-fired power plant integrated with a post-combustion capture and liquefaction process was developed based on the data for a 0.1 MW CO_2 capture pilot plant. The stripper operating pressure and L/G were the manipulated variables. The results show that the optimum operating condition was 1.25 bar of the stripper pressure and 4.05 L/m^3 of L/G, and the minimum power de-rate was 17.3 %. This indicates that the optimum conditions for the integrated CCS process are different from those for the unit processes. Also, it is predictable that the achievable minimum power de-rate that could be obtained by including all the possible variables would be at a similar level to the suggested value.

CUDA-optimized cellular automata for diffusion limited processes

Andrey Kolnoochenko[a] and Natalia Menshutina[a]

[a]*Department of Computer Aided Process Engineering; MUCTR; Moscow, Russia*
andrey@kolnoochenko.ru

Abstract

In this work diffusion-limited processes are considered in terms of cellular automata (CA) approach. This method allows to simulate processes in different size scales and levels of accuracy. The transition rules allows to take into account main mass transfer processes that drive system to thermodynamic equilibrium: diffusion, adsorption/desorption and directed flow. CA simulations even in small scales show good similarity with real world systems.

Proposed model can be used for simulations in different processes, such as adsorption in porous media and chromatography.

Use of parallel computing (process level parallelism and GPU-based CUDA technology) in all stages gave from 5x to 100x speed up in comparison with standard sequential realization.

Keywords: diffusion, CUDA, GPGPU, cellular automata

1. Introduction

A lot of chemical technology processes in porous media are limited mainly by diffusion mass transfer. Adsorption, drying and chromatography are good examples of such processes. After certain time the process depends only by molecular diffusion in disordered porous media and energy interactions between moving particles in mobile phase and stationary solid body. Modeling of this processes demand for taking into account transport properties including tortuosity, permeability and local characteristics of the internal structure. Especially all those properties are hard to estimate for high porous disordered media.

The main object of research is a process of supercritical fluid chromatography (SFC) with carbon dioxide as an eluent. This process have several advantages over HPLC and gas chromatography:

- It faster than HPLC thanks to lower viscosity of eluent and higher diffusion coefficient of analyte.
- Solvating power of mobile phase is higher than it in gas chromatography.
- Lower pressure gradient in column.
- Use same chromatography columns as in HPLC.

In this work aerogels were chosen for modeling. Aerogels — are very perspective materials with unique properties such as low density, high internal surface area, low thermal an electric conductivity and with diameter of pores in only about few nanometers. The stochastic model of aerogel structure was developed for further simulations.

Cellular automata as well as many modern techniques for numerical simulations are hardly possible without high performance computing (HPC) units and methods. In this work multi-CPU parallelism and also CUDA technology (Compute Unified Device Architecture) by nVidia was used for different steps of modeling.

2. Cellular automata for diffusion

Cellular automata are the computational systems with discrete space and time. They allow to describe local interactions using uniform transition rules for each selected point of space (*cell*). Each cell can be in one of the states from *state alphabet* (Toffoli and Margolus, 1990). In each "time" step (it's better to call it iteration) algorithm should:

- select either all or some part of cells;
- determine the *neighborhood* cells to each selected cell;
- return a new state of cell, based on current cell state and the state of neighborhood cells.

For our purposes developed model should simulate main steps of chromatography process:

- diffusion, as a random walk of molecules;
- adsorption, as a continuous movement to local thermodynamic equilibrium;
- convection, as a directed flow of molecules.

The main difference of adsorption process is the lack of last step due to main role of diffusion and adsorption steps.

As the backbone of developed model the CA with Margolus neighborhood was chosen to simulate the diffusion of particles. In its original version (Toffoli and Margolus, 1987) it allows to simulate random walk of molecules in space with constant diffusion coefficient. The simple illustration of CA is shown in Figure 1. On each iteration the lattice of cells divided down into blocks 2×2 (for 2D case) and each block rotated in random direction: clockwise or counterclockwise. In this case blocks became cells in terms of CA for time of half-iteration. The state alphabet of block consists of alphabets of all contained cells.

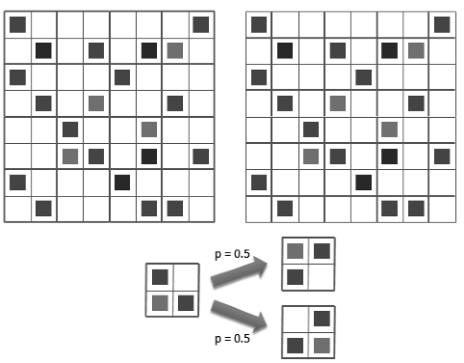

Figure 1: Diffusion simulation in CA. Division of cells by blocks in two ways. Probability on rotations distributed equaly.

Diffusion coefficient can be hardly calculated analytically, but computational experiments allow to estimate the limit value $D = 1$. It can be stated using, for instance, infinite lattice with independent moving particles. Dynamic of such systems can be described by Einstein relation:

$$D = \frac{< z^2 >}{4t} \tag{1}$$

Where $< z^2 >$ is a mean square displacement of particles in current moment t.

The results of such simulations gives a straight line in coordinates $< \bar{z}^2 >= f(t)$, what means good agreement with theoretical analysis of CA.

To generalize Margolus model, there are several changes were taken:

1. besides clockwise (cw) and counterclockwise (ccw) rotations, a block is allowed to remain unmoved (um);
2. all components of the system had been divided to three classes: a) solid, stationary phase; b) solute, a mixture of different substances, moving through the column and interacting with solid; c) solvent or carrier cells acts like an free space. In such system solvent particles are not prevent solute movement and solid particles are always preserve their positions;
3. interaction energies between solute and solid phase was taken into account.

To describe thermodynamic considerations, the probabilities of block rotations were derived from the local equilibrium assumption. To take into account both energetic and entropic effects, the energy of interaction between neighbor cells represented as:

$$f_{jk} = \varepsilon_{jk} - T s_{jk} \tag{2}$$

In that case full energy of the block after rotation $r \in R$ is

$$F_r = \sum_{j=1}^{4} \sum_{k \in N} f_{jk} \tag{3}$$

Where N are all neighbors of cell, j is the index of cell in the block. R is a set of all possible rotations for current block. Not all kinds of rotations could be available inside the block, due to possible collisions of solute and solid cells.

The partition function Z is determine probabilities of rotations:

$$Z = \sum_{r} \exp\left\{ -\frac{F_r}{kT} \right\} \tag{4}$$

$$p(r) = \frac{1}{Z} \exp\left\{ -\frac{F_r}{kT} \right\} \tag{5}$$

Where k is the Boltzmann constant and T is the thermodynamic temperature.

Finally, to describe directed flow it was represented as an additional negative free energy for preferred rotations. If after rotation r solute moved to the direction of the flow, when its F_r was changed to the flow rate intencity:

$$F'_r = F_r + \varepsilon_{mov} \tag{6}$$

Altogether these changes allows to simulate more complicated behavior than classical CA with Margolus neighborhood, preserve its synchronous work and locality of transition rules which is essential for use of HPC with maximum throughput.

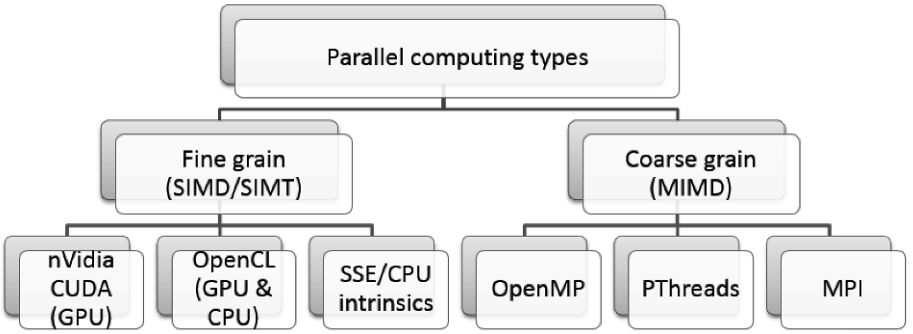

Figure 2: Main parallel computing types and technologies

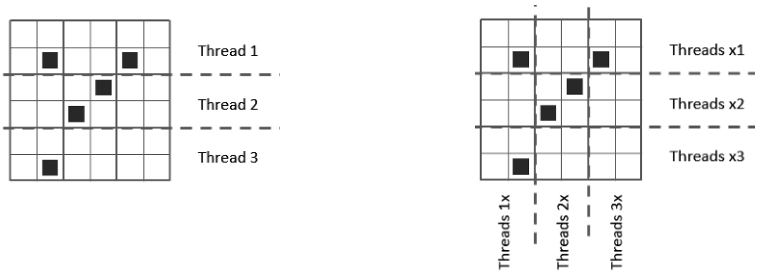

(a) MIMD approach (b) SIMD approach

Figure 3: Examples of lattice division by threads in different types of parallelism

3. Parallel computing techniques

The main types of parallel computing techniques and most widely used standard libraries are shown on Figure 2. Every technology have its own best practices and suitability.

Coarse grain parallelism is widely used in numerous applications due to universality, good support in hardware (multicore systems), operating systems (using of simultaneous multithreading), programming languages and standart libraries. In this approach every execution thread compute its current instruction independent from other threads (multiple instruction/multiple data or MIMD). Threads can also have or have no shared memory, in last case the computations can be effectively distributed between multiple units. The main advantage of coarse grain parallelism is applicability even for sequential algorithms with complicated internal logic running on demand in separated processes with different starting points. Support of multiple execution threads result in big overhead of resources. Due high cost of context switching, for CPU-intensive tasks number of threads less or equal to number of CPUs in system. For input/output intensive tasks number of threads can be higher than number of CPUs to hide the IO-latency.

Fine grain parallelism allows to create a large number of very lightweight threads with minimum context switching time. Threads are usually group together and each thread in group compute the same instruction using different input data (single instruction/multiple data or SIMD). Also additional internal processing unit logic is reduced: threads shares memory, registers, caches, constants, etc, so units became more compact and energy effective (in terms of FLOPS/W).

In case of CA simulations main points of division problem between threads are different for coarse

grain and fine grain approaches. In MIMD systems usually different init states of lattice are used, which allows to observe an evolution of system in different conditions. The main tools for such programms are message-passing libraries and frameworks: MPI, Hadoop, etc. This approach is the only one that can be used in distributed systems and compute clusters with low-speed shared memory access. Also for multicore systems with fast shared memory MIMD parallelism can be used by division of cellular automata lattice to smaller "slices" (Figure 3a). Unfortunately in that case big overhead in threads synchronization between iterations leads to low throughput, but this technique can be reasonable in systems with complicated transition rules with a lot of execution branches.

In SIMD systems the main path of optimization is not to decrease synchronization time, but rather minimize non-consecutive memory access and remove branching from execution flow. In most cases synchronous CA are work naturally in fine grained environment, thanks to simple, local and uniform rules. In SIMD approach the number of created threads should be significantly higher than number of streaming processing units to hide memory access latency. While one group of threads suspended and waiting response from memory, scheduler switch context and run another group. Division of lattice to threads for developed CA is shown on Figure 3b. So in each sub-iteration entire block is considered as one cell with widened state alphabet.

4. Results

Developed cellular automaton show good agreement with analytic solutions of test problems and simulations of real-world experiments.

4.1. Test case: steady state diffusion in pore

Let's consider the system of pore and the substance that moves along it with boundary conditions:

$$\begin{cases} c(x=0,t)=1 \\ c(x=L,t)=0 \end{cases} \tag{7}$$

Pore with length L, and radiuses $r(x=0)=a$ and $r(x=L)=b$. For some shapes of the pore the analytical solutions of Fick law could be found:

$$\frac{\partial c}{\partial t} = \frac{1}{S}\frac{\partial}{\partial x}\left(DS\frac{\partial c}{\partial x}\right) \tag{8}$$

$$\text{for conical pore: } c(x) = \frac{\ln(a+\beta x)-\ln b}{\ln a-\ln b},\ \beta = \frac{b-a}{L} \tag{9}$$

$$\text{for parabolic pore: } c(x) = 1-\frac{\tan^{-1}\sqrt{\frac{\gamma}{a}}x}{\tan^{-1}\sqrt{\frac{b-a}{a}}},\ \gamma = \frac{b-a}{L^2} \tag{10}$$

Where $c(x,t)$ — concentration, $S(x)$ is a cross-section of pore, $D(x)$ — diffusion coefficient. CA shows perfect agreement with analytical solutions. More complicated shapes of pore leads to changes of initial lattice in CA (rearrangement of solid cells) and haven't affect computational complexity.

4.2. Test case: adsorption within a disordered porous media

Study of the adsorption was aimed to show that not only dynamic character of diffusion, but also reaching of thermodynamic equilibrium which correspond monolayer adsorption can be reached by this model. Non-zero energy ε_{MS} and entropy s_{MS} correspond to the adsorptive interaction between movable cells (adsorbate) and solid porous structure (adsorbent).

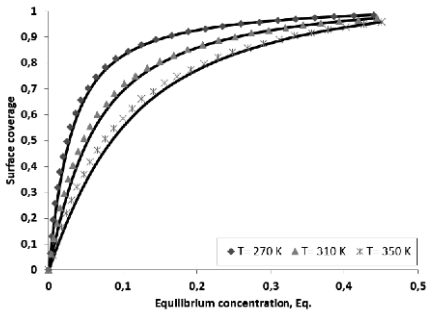

Figure 4: Comparison between computed (points) and Langmuir isotherms (solid lines) at three different temperatures

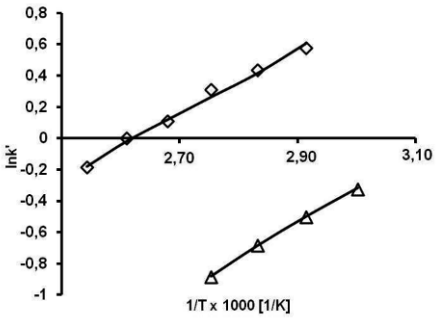

Figure 5: Comparison between retention factor in experiment of SFC (dots) and CA modeling (lines) at different fluid densities

For these energies Langmuir isotherms were found and particles are treated as the ideal gas with excluded volume, since they are not allowed to overlap. Results of comparison are shown in Fig. 4.

4.3. Test case: chromatography

Chromatography is the most complex test of representation of real-world phenomena in model. As the model of solid porous media an algorithm of slightly overlapped spheres was used (see details in Gurikov et al. (2009) and Gavalda et al. (2001)). For generation of larger size structures, it was accelerated using CUDA technology. That affect not only the generation itself, but also the step of measure the parameters of final structure: specific surface area and pore size distribution.

In the initial state of CA left side of lattice (the input of column) was filled by movable cells, solid porous media was generated to correspond experimental aerogel structure. In the right side of lattice boundary condition $c(x = L,t) = 0$ had been applied. Each movable cell at $x = L$ was counted and transformed to solvent state. It allows to get plots similar to chromatograms, and work with them in the same way as the experimental data. For example, retention factor was calculated: $k' = (t_R - t_0)/t_0$, as a ratio of time an analyte is retained in the stationary phase to the time it is retained in the mobile phase. As it shown in Figure 5 model with same energies of interactions shows the same behavior as the experimental system.

Abstract

Acid gases (H_2S and CO_2) must be removed from the crude natural gas. The process performance may be deteriorated because of ship movement on FPSO (Floating production, storage and offloading). This research aims to investigate the effects of ship motion on acid gas removal performance in the amine absorber with Mellapak 500.X structured packing.

A simple cylindrical column (packed zone: 0.1 m diameter × 2.205 m high) was used as the domain for the calculations. A porous media CFD (computational fluid dynamics) model was developed in the framework of Eulerian two-fluid flows with user-defined functions (UDF) taking into account liquid dispersion, mass-transfer and chemical reaction in the packed zone. The effective interfacial area, CO_2 concentration profile and mal-distribution factor were compared for two cases of vertical standing and ship motion.

Keywords: FPSO (Floating production, storage and offloading), Natural gas, Amine absorber, Structured-packing, Ship motion, CFD.

1. Introduction

A floating production, storage and offloading (FPSO) unit is a floating vessel used by the offshore oil and gas industry for the processing of hydrocarbons and for the storage of oil or natural gas. FLNG (Floating Liquid Natural Gas) is a new type of floating LNG (Liquid Natural Gas) platform that consists of a ship-type FPSO hull equipped with LNG storage tanks and liquefaction plants (Zhao et al., 2011).

The crude natural gas is treated to remove acid gases (H_2S and CO_2) on FPSO, where the process performance can be deteriorated because of ship motion. This research aims to investigate the effects of ship motion on acid gas removal performance in the amine absorber with structured packing. The computational fluid dynamics (CFD) has been considered as a good alternative to identify the motion effect. Table 1 shows the literature survey on CFD studies with simplified geometry of structured-packing (Aroonwilas et al., 2003; Fourati et al., 2013; Haroun et al., 2012; Shilkin et al., 2006).

Table 1 - Literature survey on simplified geometry models of structured-packing.

Classification	Authors	Remarks
2D one vertical channel model	Haroun et al. (2012)	2 phases VOF model, mass transfer & chemical reactions
2D tubular channel model	Shilkin et al. (2006)	2 phases CFD model & no mass transfer
Pseudo 3D model	Aroonwilas et al. (2003)	Steady-state 2 phases pseudo 3D hydrodynamics, & mass transfer
Porous media model	Fourati et al. (2013)	Unsteady-state 2 phases porous medium 3D model, liquid dispersion & momentum transfer

An Eulerian multiphase isotropic porous media model is used to simulate the structured-packing for gas (G) and liquid (L) contact. The effective interfacial areas are compared in two cases of vertical standing (case 1) and ship motion (case 2) of the absorber. The mal-distribution coefficient of the liquid defined by the standard deviation per mean velocity is also compared for the two cases. The CO_2 concentration profile of vertical standing case is compared to experiments in order to validate the model.

2. Eulerian multiphase porous media model

Local liquid hold-up which directly relates to the effective area is studied by using the porous media model. In the present study, incompressible and isothermal flows are considered. The governing equations of the CFD model deal with average quantities that are volume-averaged over a representative averaging porous volume as shown in Figure. 1 (Fourati et al., 2013). For a continuous phase, the governing equation contains continuity equation, momentum conservation equation, and species transport equation.

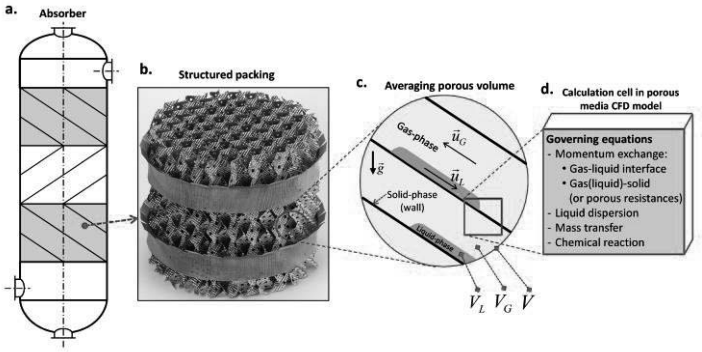

Figure. 1. Porous media CFD model for structured-packing.

2.1 Mass conservation equation

The incompressible gas-liquid system is expressed as in the porous medium:

$$\frac{\partial}{\partial t}(\alpha_q \rho_q) = -\nabla \cdot \left(\alpha_q \rho_q \vec{u}_q\right) + \dot{m} + \alpha_q R_q, \quad q = G,\ L \tag{1}$$

where $\alpha_q = \varepsilon \times V_q / \left(V - V_s\right)$ means the volume fraction of q phase, $\dot{m}$ [kg/m^3-s] is the mass transfer rate and R_q is the homogeneous chemical reaction rate. Here, V is the total volume, V_s is the solid volume and ε is the porosity.

2.2 Momentum conservation equation

The Eulerian two-phases porous media model adds source terms ($\vec{S}$) into the original Navier-Stokes equation:

$$\rho_q \frac{\partial}{\partial t}\left(\alpha_q \vec{u}_q\right) + \rho_q \vec{\nabla}\cdot\left(\alpha_q \vec{u}_q \vec{u}_q\right) = -\alpha_q \vec{\nabla} P + \vec{\nabla}\cdot\left(\alpha_q \tau_q\right) + \alpha_q \rho_q \vec{g} + \vec{S}_q \tag{2}$$

where *P* is the pressure, $\vec{g}$ is the gravity, τ *i*s the viscous stress tensor, and the source terms $(\vec{S})$ include the isotropic porous resistances ($\vec{F}_{porous}$), gas-liquid momentum exchanges ($\vec{F}_{exch}$), and liquid dispersion ($\vec{F}_{disp}$) terms (Fourati et al., 2013).

$$\begin{aligned}\vec{S}_q &= -\frac{\alpha_q}{\varepsilon}\vec{F}_{porous,q} + \varepsilon\vec{F}_{exch,q} + \vec{F}_{disp,q} \\ &= -\frac{\alpha_q}{\varepsilon}\left(\mu_q R_{vis,q}\vec{u}_q + \frac{1}{2}\rho_q R_{in,q}\left|\vec{u}_q\right|\vec{u}_q\right) + \varepsilon\left(K_{exch}\cdot\vec{U}_{Slip}\right) + \left(K_{qS}\cdot\vec{U}_{Drift,q}\right)\end{aligned} \tag{3}$$

Here, $\vec{u}$ is the interstitial volume-averaged velocity, and $\vec{R}_{vis,q}$ and $\vec{R}_{in,q}$ are a kind of tensor implying the viscous loss resistance and the inertial loss resistance, respectively.

2.3 Species transport equation

The interphase species transport equations are solved along with the mass and momentum equations. Assuming that mass transfer between the gas and liquid phases occurs for only CO_2, the transport equation of species *i* in *q* phase is:

$$\rho_q \frac{\partial}{\partial t}\left(\alpha_q Y_q^i\right) + \rho_q \vec{\nabla}\cdot\left(\alpha_q \vec{u}_q Y_q^i\right) = -\rho_q D_q \vec{\nabla}\cdot\left(\alpha_q \vec{\nabla} Y_q^i\right) + \dot{m}^i + \alpha_q R_q^i \tag{4}$$

where Y_q^i is the local mass fraction of species *i* in *q* phase, D is the diffusivity (m^2/s).

The volumetric rate of species mass transfer is a function of mass concentration gradient.

$$\dot{m}^i = K_L a_e\left(\rho_{L,equilibrium}^i - \rho_L^i\right) \tag{5}$$

The overall liquid mass transfer coefficient (K_L) can be derived from the two film theory (McCabe et al., 2005):

$$1/K_L = 1/k_L + 1/\left(H_{CO_2-MEA}\cdot k_G\right) \tag{6}$$

For the CO_2-MEA system, the reaction rate may be expressed by the 2^{nd} -order kinetics (Hikita et al., 1977):

$$\begin{aligned}&CO_2(l) + 2HORNH_2 \leftrightarrow HORNH_3^+ + HORNHCOO^- \\ &R_L^{CO_2} = d\left(\rho_L^{CO_2}\right)/dt = -k_c \rho_L^{CO_2}\rho_L^{MEA}, \quad k_c = k_0 e^{-E_a/(RT)}\end{aligned} \tag{7}$$

3. Geometry and mesh of amine absorber

The three dimensional (3D) geometry of the amine absorber is illustrated in Figure. 2a, 2b and 2c. The amine absorber consists of nine elements (element height of 24.5 cm), a liquid distributor in the top, and a bottom side for the uniform gas inlet. The monoethanolamine (MEA) solution is injected through the liquid distributor.

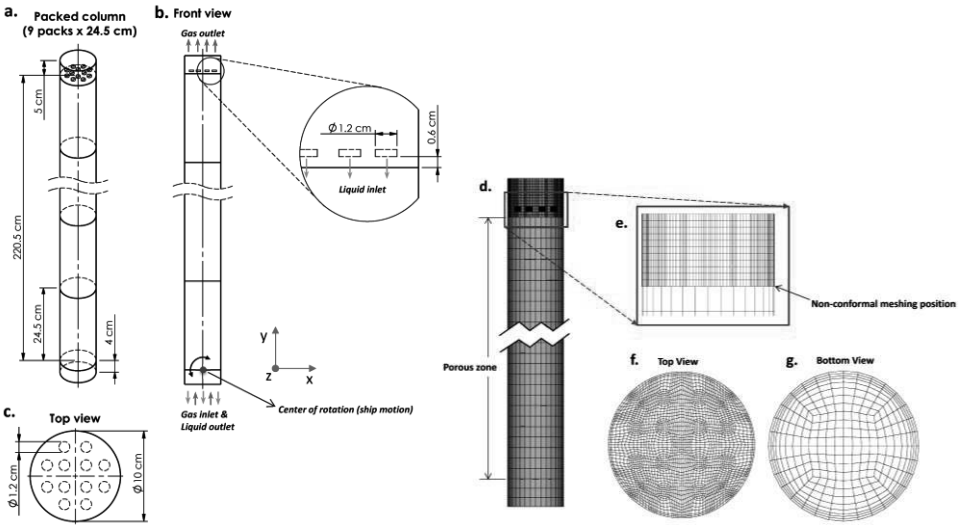

Figure. 2. Geometry and mesh of amine absorber for CFD calculation domain.

The mesh structure of the amine absorber is shown in Figure. 2d-g. The top of the column has a fine hexahedral mesh structure to represent the twelve holes in the liquid distributor. For the ship motion case. The absorber has a harmonic oscillation with the angular amplitude of 1.57^{o} and the period is equal to 12 seconds.

4. Simulation setup

The continuity equation, momentum and mass conservation equations were solved by using a commercial code ANSYS Fluent (ANSYS Inc., USA). Table 2 and Table 3 show simulation parameters.

Table 2 - Model parameters of mass-transfer and chemical reaction.

Maximum effective interfacial area (m^2/m^3) ,a_e	225 (Aroonwilas et al., 2003)
Overall mass-transfer coefficient (m/s), K_x	0.00293
Operating pressure (atm), P	1.0
Operating temperature (K), T	304 (isothermal)
Henry's constant ($Pa \cdot m^3/mol$), $H_{CO2\text{-}MEA}$	3690
Pre-exponential factor ($m^3/kmol/s$), k_0	5.928×10^4
Activation energy (cal/gmol), E_a	4.274×10^3
Diffusivities of gas and liquid (m^2/s), D	2.8×10^{-7}, 2.88×10^{-9}

Table 3 - Boundary condition (BC) and simulation parameters.

Parameters	Value
Mesh number (N_{cell})	About 60,000 cells
Eulerian multiphase model	Un-steady state, sequential, and implicit solver
Bottom-side BC	Incompressible ideal gas inlet (back flow), liquid (pressure-outlet), gas load (natural gas) = 38.5 kmol/m^2/h, and gas mole composition: CH_4 = 0.85, CO_2 = 0.15.
Top-side BC	Gas (mass flow outlet)
Liquid distributor BC	Liquid (mass flow inlet), liquid load = 22.9 m^3/m^2/h, and liquid mass composition: MEA = 0.317, H_2O = 0.683.
Maximum number of iterations	100
Convergence tolerance	1×10^{-3}
Total operation time (s)	43

5. Results and discussion

In Fig. 3a, the contour of the CO_2 mole fraction (y_{CO_2}) is shown for the whole column.

The radially-averaged mole fraction along the height is compared to experimental data in Fig. 3b. A decline of the CO_2 capturing performance can be seen in Fig. 3c.

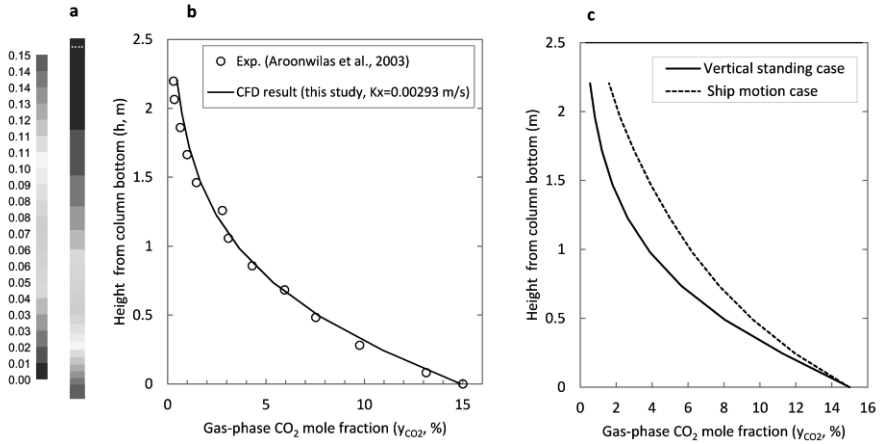

Figure. 3. CO_2 mole fraction (y_{CO2}, %) along column height (h, m). a/CFD results in whole column in case (1); b/comparison between CFD results and experimental data in case (1); c/comparison CFD results between case (1) and case (2).

Fig. 4 compares the contour of liquid hold-up in the porous zone for the two cases. The radical liquid distribution was affected significantly by the ship motion. This is attributed by the fact that the tangential and inertial forces influences the liquid phase, when the column rolls. A reduction of local liquid hold-up may lead to the reduction of the effective interfacial area. Thus, in order to obtain a good liquid distribution, it is necessary to design or arrange appropriately liquid collectors and distributors inside an absorption column.

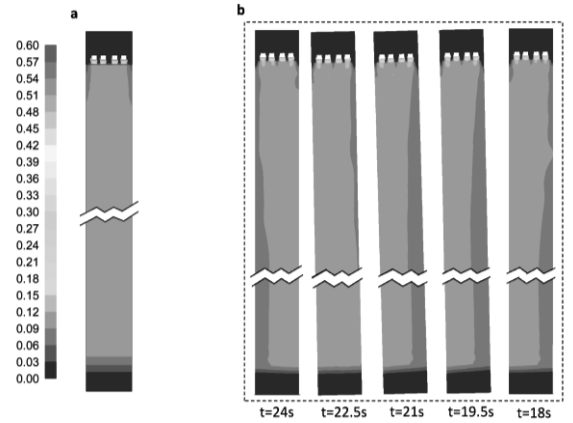

Figure. 4. Contour of liquid hold-up in CO_2-MEA Eulerian CFD simulation. a/Case 1; b/Case 2 (a half period, flow time is from right hand side)

Table 4 indicates the effective interfacial area between two phases (a_e), the standard deviation of velocity (σ), the means velocity (μ), and the coefficient of variation (C_v). The ship motion affects significantly a_e and C_v.

Table 4. Comparison of vertical standing and ship motion on mal-distribution factors.

	a_e (m^2/m^3)	μ (m/s)	σ (m/s)	C_v
Case 1	225	0.146	0.001	0.007
Case 2	196 (mean value)	0.147	0.006	0.042

6. Conclusions

A porous medium Eulerian multiphase model was used for the simulation of corrugated structured-packing in CO_2-amine absorber. The effect of ship motion was significant on the effective interfacial area and the mal-distribution of velocity. Anisotropic porous resistance would be useful for more realistic simulation of structured-packing. More complex ship motions (sway, heave, etc) will also be considered in the future.

Abstract

The application of computer-aided model based methods within an integrated systematic framework is illustrated with the objective to assist the multi-purpose pharmaceutical/biochemical industry to systematically solve the complex problems that are experienced when aiming at improving the process efficiency. The objective of this study is the application of the developed framework on an industrial case study of a glucose isomerization (GI) reactor plant that is part of a corn refinery, with the objective to improve the productivity of the process. Therefore, a multi-scale reactor model is developedfor use as a building block for the GI reactor plant simulation. An optimal operation strategy is proposed on the basis of the simulation results.

Keywords: Systematic Model-Based Analysis, Glucose Isomerization, Reactor Plant Modelling, Operation.

1. Introduction

Model-based computer aided methods and tools can play an important role in the development and improvement of pharma/biochemical processes. The mathematical models however, need to be developed first and require detailed understanding and analysis of the phenomena that govern the operation of these processes. When validated against experimental data, mathematical models are useful tools to predict the behavior of a system subject to different scenarios. In this way, the models can in general be used to supplement the available knowledge with new data and to reduce the cost and the time related to performing expensive experiments (Gernaey and Gani, 2010, Marquardt et al., 2009). Mathematical models can be used in optimization studies, to improve the operation of the system or to predict the behavior of the system in different scenarios such that process operability and design can be studied.

In this study, the use of model-based methods within a systematic framework is developed by integrating parts of other studies (Cervera et al. 2012; Jaksland et al. 1995), and illustrated through a glucose isomerization (GI) reactor case study. The objective of this study is the use of a multi-scale reactor model which includes the reaction kinetics and the enzyme activity decay as a function of temperature with and without the diffusion term, to simulate the reactor and to investigate opportunities for improving the productivity of the reactor.

2. Methodology

The systematic framework (Figure 1) is developed to obtain enhanced process understanding and to exploit potential opportunities for improvements of the pharma/biochemical processes. In this work, only the relevant parts of the methodology (Section A, B and D) are used to achieve the final objective of the case study. The overall effectiveness and detailed description of the complete framework will be presented in a future paper. The framework (Figure 1) starts with the problem definition where the objectives of the study are defined. The subsequent reaction pathway identification section (Section A) aims at identifying the reaction pathway producing a pharma/bio-product of interest. Section B is the reaction analysis, and aims at the efficient reaction development, reactor design and separation objectives definition. Section C (Separation Synthesis and Design) is performed in case separation of a specific compound is needed. Section C aims at generating separation process alternatives based on feasible separation techniques (Jaksland et al., 1995) and based on the driving force principles (Bek-Pedersen and Gani, 2004). Once a flowsheet (or the state-task network) has been obtained, a process simulation (Section D) needs to be performed in order to evaluate the process and identify the process hotspots. Based on the process evaluation, process optimization and process operation can be performed.

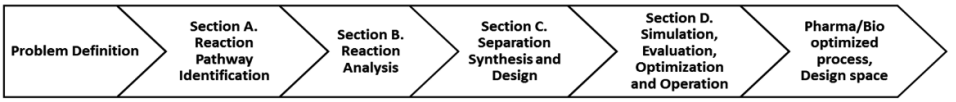

Figure 1. The Integrated Systematic Methodology for pharma/biochemical processes.

3. Case Study: Glucose Isomerization

Problem Definition: The aim of the study is the development of a multi-scale reactor model for the glucose isomerization which includes the enzyme activity decay with and without diffusion limitation as function of the temperature. The reactor model is used to simulate a typical reactor plant (Figure 2, 20-30 reactors in parallel) in order to improve the operation and increase the productivity.

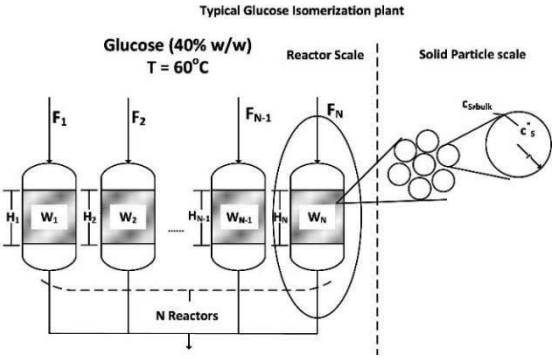

Figure 2. Typical Glucose Isomerization plant with N reactors.

Section A. Reaction Pathway: The reaction pathway is presented in Eq. (1):

$$E + S \leftrightarrow SE \leftrightarrow P + E \tag{1}$$

Section B. Reaction Analysis: Glucose (S) syrup (40% w/w) reacts with the immobilized Sweetzyme® to produce fructose. The glucose isomerization is a reversible reaction given by Eq. (1) and it has been proven to follow the reversible modified Michaelis-Menten

kinetics. The reaction is equilibrium limited and it takes place in a continuous fixed bed reactor where the enzyme is immobilized. The reactor model needs to be developed and evaluated, and used as a tool for investigating more efficient operation of a typical GI reactor plant. The development of the multi-scale reactor model is illustrated through a modelling framework developed by Heitzig (2011). The multi-scale reactor plant (Figure 2) requires a model describing the reaction kinetics, the enzyme activity decay and the internal diffusion as a function of temperature. The framework consists of five phases (Heitzig, 2011): Phase I: Modelling objective/System Information, Phase II: Model construction, Phase III: Model Identification/ Discrimination, Phase IV: Model Evaluation/Validation and Phase V: Application.

Phase I: Modelling objective/System Information: The modelling objective has been defined in the *Problem Definition* section.

Phase II: Model Construction: To achieve the objectives, models for the reaction kinetics, the fixed bed reactor, the diffusion in the reaction pellet and the enzyme activity decay need to be developed and combined in one multi-scale reactor model.

Reaction Kinetics (Dehkordi et al., 2008, 2009):

$$R_s = -\frac{\rho_p V_m c_{S,0}\ \left(y_S^* - y_{S,eq}\right)}{K_m + c_{S,0}\ \left(y_S^* - y_{S,eq}\right)} \tag{2}$$

$$V_m = \left[1 + \frac{1}{K_e}\right]\frac{k_{mr} v_{mr}}{k_{mr} - k_{mf}} \tag{3}$$

$$K_m = \left[1 + \left(\frac{1}{k_{mf}} + \frac{K_e}{k_{mr}} c_{S,eq}\right)\right]\frac{k_{mr} k_{mf}}{k_{mr} - k_{mf}} \tag{4}$$

Fixed Bed Reactor (Papathanasiou et al., 1988; Asif et al, 1998):

$$\begin{aligned} &\frac{\partial y_s}{\partial \tau} = \frac{1}{Pe}\frac{\partial^2 y_s}{\partial z^2} - \frac{\partial y_s}{\partial z} - a\ \left(y_s - y_s^*\right) \\ &IC: y_s = 0\ \ for\ \tau = 0,\ z \geq 0 \\ &BC1: -\frac{1}{Pe}\frac{\partial y_s}{\partial z} + y_s = 1,\ \ for\ \ \tau > 0,\ z = 0 \\ &BC2: \frac{\partial y_s}{\partial z} = 0,\ \ for\ \ \tau > 0,\ z = 1 \end{aligned} \tag{5}$$

Solid Particle (Papathanasiou et al., 1988; Asif et al., 1998):

$$\begin{aligned} &\frac{\partial y_s^*}{\partial \tau} = Q_2\left(\frac{\partial^2 y_s^*}{\partial \lambda^2} + \frac{2}{\lambda}\frac{\partial y_s^*}{\partial \lambda}\right) - Q_1 y_E \frac{y_s^* - y_{s,eq}}{1 + \left(y_s - y_{s,eq}\right)\ Q_3} \\ &IC: y_s^* = 0\ \ for\ \tau = 0,\ \xi \geq 0 \\ &BC1: \left.\frac{dy_s^*}{d\lambda}\right|_{\lambda=0} = 0,\ \ for\ \ \tau > 0,\ \xi = 0 \\ &BC2: \left.y_s^*\right|_{\lambda=1} = y_{S,bulk}\ \ for\ \ \tau > 0,\ \xi = 1 \end{aligned} \tag{6}$$

Enzyme Activity Decay (Verhoff et al., 1982; Houng et al., 1992):

$$\begin{aligned} &\frac{dy_E}{d\tau} = -k_d y_E \\ &IC: y_E = 1,\ \tau = 0 \end{aligned} \tag{7}$$

Activity decay(Jørgensen et al., 1988):

$$A[\text{IGU/ gr enzyme}] = 0.926\frac{F}{w}\cdot DP\cdot DS\cdot \ln\left(\frac{X_{eq}}{X_{eq}-X}\right) \quad (8)$$

*Productivity (*Houng et al., 1992):

$$P = \frac{\int Fc_{S,0}dt}{w} \quad (9)$$

Model Analysis: The model consists of different types of equations, ODEs (1), PDEs (2) and AEs (29), 32 in total. The total number of variables (system variables, model parameters, and known variables, dependent and algebraic variables) is 59. A degree of freedom analysis showed that 27 variables (system variables, model parameters, and known variables) need to be specified and 32 variables need to be predicted from the model (dependent and algebraic variables).

Phase III: Model Identification: The kinetic parameters have been identified from the literature (Dehkordi et al., 2008, 2009). They have been evaluated against experimental data, and they produce results which are consistent with these data.

Phase IV. Model Evaluation/Validation: In that phase different scenarios are tested to evaluate the developed multi-scale model for the reactor. Figure 3 shows the glucose concentration profile in the reactor (with (a) and without (b) diffusion) with respect to dimensionless time τ for different locations z in the reactor (where z is the dimensionless length of the reactor). The glucose concentration profiles show the glucose conversion through the rector length, where the decrease of glucose conversion is due to enzyme deactivation during the operation.

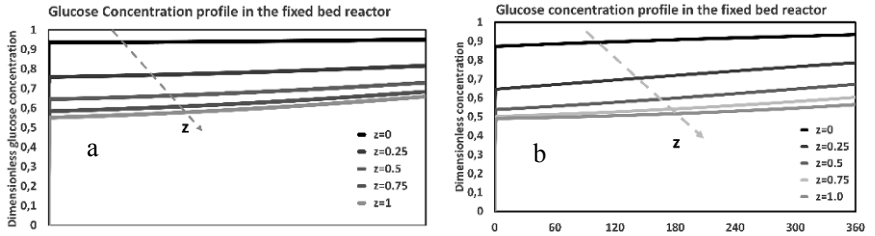

Figure 3. Glucose concentration profile in the reactor (a) with diffusion limitation; and, (b) without diffusion limitation,where z is the dimensionless length of the reactor.

The Figure 4a illustrates the glucose conversion at the outlet of the reactor with respect to Reynolds number, which decreases as the Re number increases. The Figure 4b presents the conversion with respect to the dimensionless time which also decreases with time.

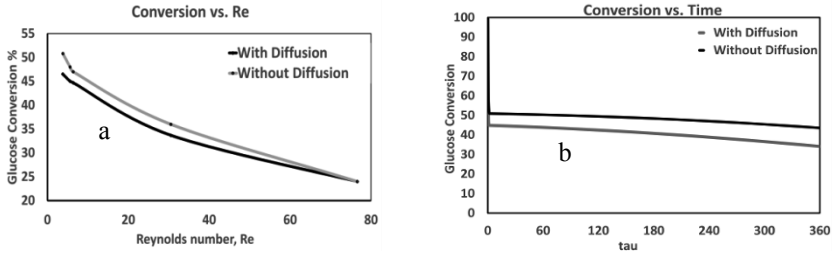

Figure 4. Glucose conversion in the reactor for different Reynolds number (a) and with respect to operation time (b).

The Figure 5a shows the enzyme deactivation due to decay with respect to dimensionless time, with and without considering the diffusion term. Figure 5b, shows

the specific activity of the enzyme in IGU/g enzyme, where IGU is the amount of enzyme that converts glucose to fructose at an initial rate of 1 μmol min^{-1}.

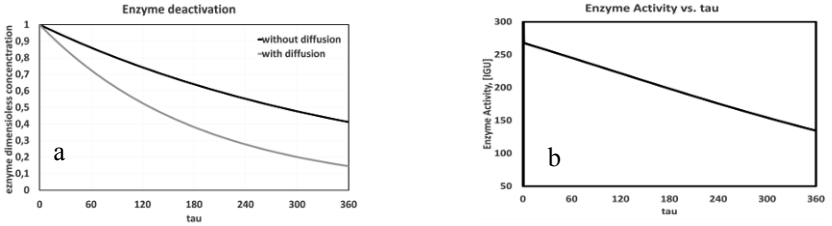

Figure 5. (a) Enzyme deactivation with respect to time, (b) enzyme activity decay vs. time.

*Section C. Separation Synthesis and Design:*The separation of the reaction mixture is fixed and separation is not included in the objectives of the problem.
Section D. Simulation, Evaluation, Optimization and Operation: Once the multi-scale reactor model has been evaluated. The GI reactor plant can be simulated. The operation conditions and the values of the physical variables are presented in Table 1.

Table 1. Process Variables for the reactor operation and physical variables for the enzyme.

Reactor Variables		
Variable	Value	Units
Temperature	55-60	^oC
Flow rate	3.6	$m^3 h^{-1}$
Catalyst weight	560	kg enzyme/reactor
Bed Height	3.3	m
Diameter	0.8	m

Physical Variables		
Variable	Value	Units
Density	3300	kg m^{-3}
Porosity, ε	0.36	-
Particle Diameter	0.2	cm
Effective Diffusivity	$6.9x10^{-6}$	m sec^{-1}

The GI reactor plant consists of 10 parallel reactors. The operation of the GI reactor plant is based on constant glucose conversion (~45%) which can be maintained either by recycling the enzyme to keep its activity constant or by decreasing the inlet glucose flowrate during the operation. In this case, fixed bed reactors are used and the conversion is maintained constant by decreasing the flowrate. Once the residual enzyme activity is 10% compared to the initial one, the temperature in the reactor is increased and then the reactor is shut down. The relative flowrate is presented in Figure 6a and it is based on the enzyme activity decay for temperatures 55^{o}C and 60^{o}C. The Figure 6b illustrates the productivity (kg glucose/kg enzyme) of the reactor for constant flow rate and constant glucose conversion at 55^{o}C and 60^{o}C. The results in the Figure 6 (a and b) strongly depend on the enzyme deactivation parameter k_d. The inlet concentration also plays an important role in the improvement of the reactor efficiency because it affects the viscosity of the inlet syrup and the pressure drop in the reactor.

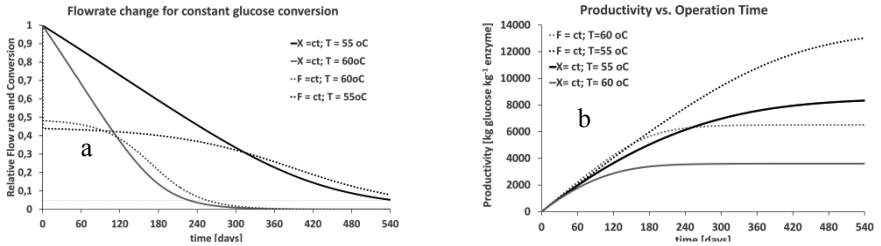

Figure 6. (a) The inlet flowrate change to maintain constant glucose conversion (X= 45%) and conversion for constant flowrate; (b) The productivity for the cases in Figure 6a.

4. Conclusions

In this study, the application of model-based computer aided methods as a tool within an integrated framework to enhance the pharma/biochemical process operation is illustrated. The framework was applied to a GI case study with the objective to analyse and improve the operation of a GI reactor plant. Mathematical models to describe phenomena at different scales were used in order to simulate the GI reactor plant. The analysis has shown that the enzyme deactivation is an important parameter for the reactor plant efficiency improvement. Moreover, the productivity of the plant can also be enhanced by selecting the proper inlet glucose concentration. To conclude, the analysis has shown the importance of computer-aided model based methods and tools in the evaluation, analysis and improvement of pharma/biochemical processes, and especially the usefulness of these tools in supporting the decision making process during the early stage design and during the industrial operation.

Abstract

Mathematical models are used in many scientific areas such as enzyme kinetics and process engineering. They can be used for process analysis and optimization. However, a model is always a simplified representation of the real process and predictions always come with uncertainty. Therefore, the model building process should be performed thoroughly addressing calibration and validation procedures. Specific modeling tools (e.g. sensitivity analysis, optimization algorithms, experimental design techniques,...) to derive additional information (e.g. importance of parameters, estimate parameter uncertainty,...) are at hand and available in existing software. First, implementing these algorithms is time-consuming and often suboptimal in efficiency. Second, existing software is in many cases closed-source and not flexible in use. In both cases this results in the unavailability of the programmed algorithms in the corresponding articles making use of them. Therefore it is hard to validate the published findings and in some cases even impossible to reproduce the presented results. To address this problem the scientific community needs a certain critical mass of 'off-the-shelf' algorithms to perform model analyses which are available to the modeling community. To improve overall quality and reliability, such kind of code library should be open source and well documented.
We hereby present pyIDEAS, an open source Python package to thoroughly but swiftly analyze systems represented by a set of (possibly mixed) differential and algebraic equations. The pyIDEAS package allows performing a model analysis in a straightforward and fast way. pyIDEAS provides a well-structured and logic framework which allows non-programmers to perform some model analysis and more advanced users to extend or adapt current functionality to their own requirements.

Keywords: model analysis, optimal experimental design, open source, Python

1. Introduction

Nowadays, model analysis and optimization is performed by many people and for these objectives specific tools such as sensitivity analysis and experimental design techniques are used. These algorithms are at hand in existing software packages, but in many cases the software is closed-source and not flexible in use. For academics this poses the extra burden that the source cannot be adapted and poses philosophical questions too (Heron et al., 2013). Moreover, only publishing the algorithm descriptions and code diagrams is most of the time not sufficient, because there are always implementation subtleties that make it difficult for others to recreate the software and reproduce the presented results (Heron et al., 2013). Therefore, all code implementations should be available and ultimately lead to the so-called 'open science'. This way of publishing research is being supported by an increasing number of people and journals (Nature Editorial, 2014). An open source

initiative could provide the sufficient toolset to perform model analyses for most people and even allow them to go a step further than they did before. The flexibility of the package allows more experienced users to extend and optimize current functionalities. To achieve these goals, the open source package needs to be well documented, because most developers over-estimate the computer literacy of novice users (Knight and Jefsioutine, 2002).
We hereby present an open source Python package which tries to address the issues mentioned above. The aim of the package is to provide an integrated environment to perform basic actions like model definition and calibration, but also provide easy access to more advanced tools such as the estimation of parameter confidence and optimal experimental design. In this way these techniques can be applied by less experienced modellers in a reliable way without requiring advanced modelling knowledge and costly, non-flexible closed-source software. The use of this package will not only allow people to calibrate models, but also to estimate the parameter confidence. The availability of optimal experimental design tools creates an extra value which is not yet available in other open source packages. By providing a well-documented and structured package with illustrative examples, the aim is to convince both novice and experienced users that they can benefit from such an open source framework and maybe even contribute. Such an approach also helps to guard the principles of good modelling practice by making the tools needed for this explicitly available.

The core abilities of the presented package will be discussed based on a real-life model building process applied to the Michaelis-Menten model of Johnson and Goody (2011).

2. Methods

2.1. Michaelis-Menten Model

The reaction used in this paper is the conversion of sucrose to fructose and glucose catalysed by the enzyme invertase (Johnson and Goody, 2011):

$$E + S \underset{k_r}{\overset{k_f}{\rightleftharpoons}} ES \xrightarrow{k_{cat}} E + F + G$$

with enzyme E, sucrose S, enzyme-substrate complex ES, fructose F and glucose G. The rate constants are represented by k_f $[mM^{-1} \cdot s^{-1}]$, k_r $[s^{-1}]$ and k_{cat} $[s^{-1}]$. This diagram can be used to set up a system of ordinary differential equations (ODEs) from which the widely used Michaelis-Menten equation (Equation 1) can be derived by using the quasi steady-state assumption.

$$v = \frac{V_{max}[S]}{K_S + [S]} \tag{1}$$

with V_{max} $[mM \cdot s^{-1}]$ the maximum rate of the enzyme, which is equal to $k_{cat} \cdot (E + ES)$. K_S $[mM]$ is the substrate concentration at which half V_{max} is reached, which is equal to $(k_r + k_{cat}) \cdot k_f^{-1}$.

2.2. Package core capabilities

The implemented package makes use of widely used Python packages like Pandas (McKinney, 2010), Scipy (Jones et al., 2001), Sympy (SymPy Development Team, 2014) and matplotlib (Hunter, 2007). These packages are well-established in the Python community and provide many functionalities which are used in pyIDEAS. The core abilities of pyIDEAS will be presented by using the procedure shown in Figure 1. The presented procedure is based on real-life experience and illustrates the power of an integrated framework.

2.2.1. Model definition

The first step is to create the model under consideration $\hat{y}(x, \theta, args)$, so that it can be used to perform model simulations. The aim of the package is to minimise the user effort to implement,

run and analyse a model. The model is defined by using the built-in Python dictionaries. Currently, models consisting of ordinary differential equations (ODEs) and/or algebraic equations can be used as input, possible dependencies between the different equations are automatically taken care of in the underlying algorithms. So the order of defining equations is not important. Parameters also need to be defined when initiating the model instance. Subsequently, the model initialisation is executed to perform a symbolic model integrity check and to generate the underlying functions to run the model simulations. To define the Michaelis-Menten model (Equation 1) and the corresponding parameters, following Python dictionaries have to be constructed:

```
parameters = {'Vmax': 0.76, # mM/s
              'Ks': 16.7}   # mM
model = {'v':'Vmax*S/(Ks + S)'}
```

These two dictionaries and a string containing the model name are the only inputs required for generating the model instance.

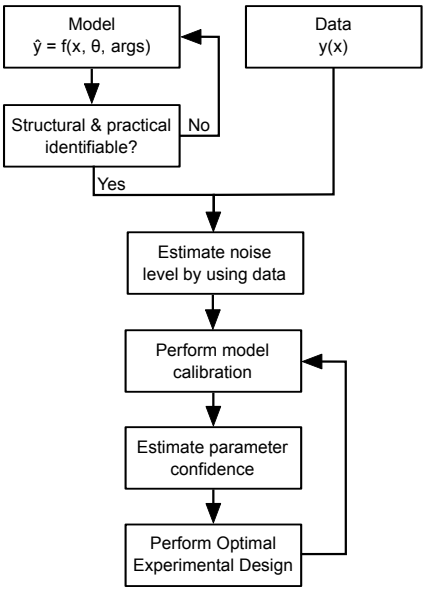

Figure 1: The presented model analysis requires a model $\hat{y}(x, \theta, args)$ and data $y(x)$ to perform the model calibration. Afterwards the parameter confidence intervals can be estimated and if necessary additional experiments can be developed using optimal experimental design.

2.2.2. Identifiability analysis

After the model definition it should be verified whether the model is (at least locally) identifiable, i.e. only one unique parameter set should be able to predict the observed input-output behaviour. If this is not the case the model should be adapted. A collinearity analysis based on the local sensitivities is implemented to verify whether (local) identifiability problems occur. Moreover, the pyIDEAS package provides a framework to implement more advanced identifiability methods in the future.

2.2.3. Model calibration

In many cases the model has to be calibrated by use of experimental data $y(x)$. Before starting the actual model calibration, it is necessary to estimate the measurement error characterics. This can be done based on the available data and/or based on expert knowledge. One should try to determine which error characterics are most realistic: is the noise level the same for every data point (e.g. absolute noise) or is the noise dependent on the y value (e.g. relative noise)? These questions have to be answered before starting the model calibration, because this has an impact on the shape of the objective function and consequently also on the retrieved estimates of the different parameters. The objective function available in the package is the weighted sum of squared errors (WSSE) and is typically used for performing parameter estimations (Equation 2).

$$WSSE(\theta) = \sum_{i=0}^{n_m} \sum_{j=0}^{n_{sp_i}} w_{i,j} \left(y_i(x_j) - \hat{y}_i(x_j, \theta)\right)^2 \tag{2}$$

with y_i the data for measurable output i, $\hat{y}_i$ the model output for measurable i, $w_{i,j}$ the weight of sample j of measurable i, n_m the total number of measurable outputs and n_{sp_i} the total number of samples for each specific measurable output (Donckels, 2009).

To perform the model calibration, local and global minimisation methods are available by using the 'minimize' function of the Scipy package. More advanced global optimisation methods (e.g. particle swarm optimisation) are also available by coupling the package with the Inspyred package (Garrett, 2012).

2.2.4. Estimate parameter confidence

After finishing the model calibration it is important to assess whether the parameter estimates can be regarded as reliable. For this the Fisher Information Matrix (FIM) can be used (Donckels et al., 2009). Under the conditions of uncorrelated and white measurement noise, the inverse of the FIM gives a lower bound of the variance-covariance matrix and contains information about parameter confidence intervals and correlations (Donckels, 2009). The calculation of the FIM can be challenging, which makes the technique less accessible for less experienced modellers. However, by providing well-documented access to these kind of functionalities it will be possible for anyone to verify the quality of the parameter estimations without the need to know how to implement the technique. The function not only returns the confidence interval for each parameter, but also verifies whether the parameter estimates can be regarded as reliable using the Student's t-test (Donckels, 2009).

2.2.5. Optimal Experimental Design for parameter estimation

Assume a model structure and some preliminary data is available for the system under study. Then it would be possible to calibrate the model parameters using the model calibration function discussed above. However, the amount of available data is limited and noise-corrupted, thereby reducing overall confidence levels of the parameters. To reduce this uncertainty, more experiments have to be carried out. Instead of randomly choosing new experiments, one could use the preliminary data to design new experiments. By using logical sense, one would select new measuring points for which the parameters show a high sensitivity and low correlation, but also conditions at which the noise is low. All this 'logic' is combined in one matrix: the FIM. To optimise the information of the FIM, different optimality criteria exist (A, modA, D, E and modE), which are all available in the software package. In this paper only the D-optimality design criterion will be used. For this criterion the idea is to maximise the determinant of the FIM. The FIM is inversely proportional to the volume of the confidence region of the parameter estimates, and this volume is minimised by maximising the FIM (Donckels et al., 2009). By maximising the FIM, future experiments can be designed which are highly informative. After performing these optimal experiments, it is important to perform the model calibration and estimate the confidence intervals of the different parameters (see Figure 1). The OED loop which consist of designing experiments, calibrating the model and estimating the parameter confidence intervals, should be repeated until the required confidence levels are met. This allows one to achieve the required confidence levels while keeping the experimental effort to a minimum.

3. Results

The Michaelis-Menten equation (see Equation 1) will be used to illustrate the different core functionalities of the package by following the stepwise approach of Figure 1. The following results were achieved by using only 25 lines of code from model definition until OED (ignoring loading of packages and comments), this illustrates the power and accessibility of the package. This limited number of lines gives the user access to advanced functionalities. In the following part only the results and figures of the different steps are shown, the code will be made publicly available prior to the conference. A (local) identifiability analysis was performed by using collinearity analysis, and showed no identifiability problems.

3.1. Model calibration

First the parameters V_{max} and K_S of the Michaelis-Menten reaction have to be estimated by use of some data. Six data points were generated in silico, using the parameter values of the paper published by Johnson and Goody (2011). For each of these data points relative noise was added, what means that higher model output values of v can have a higher absolute noise compared to low values of v. This noise was randomly sampled from a normal distribution with mean zero and a standard deviation of 0.05. The six data points were taken at substrate concentrations S of 5, 10, 20, 30, 75 and 100 mM. By using a WSSE with relative weights more weight/certainty was given to low v values. This resulted in the fit shown in Figure 2. The estimated parameter values were slightly different from the real parameter values (a V_{max} value of 0.746 mM/min and a K_S value of 17.55 mM). This is due to the normal noise that was added. To assure that the objective function is not prone to local minima, it is considered good practice to repeat a parameter estimation multiple times with different starting points to assure that the same values are always retrieved. If this is not the case, one should use global minimisation methods (e.g. particle swarm optimisation) or verify whether the model is (practical) identifiable.

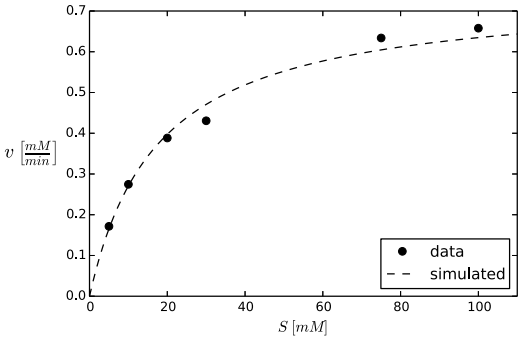

Figure 2: The in silico data with noise was used to estimate the parameters V_{max} and K_S of the Michaelis-Menten model (Equation 1). The minimisation of the objective function yielded a V_{max} value of 0.746 mM/min and a K_S value of 17.55 mM. These results are slightly different from the real parameter values, because of the normal noise which was added.

3.2. Estimate parameter confidence

After finishing the parameter estimation the confidence levels for the different parameters can be calculated using the FIM. Using the built-in function 'get_parameter_confidence', the different parameter and corresponding 95 % confidence intervals are retrieved: $V_{max} = 0.746 \pm 0.094$ mM/min and $K_S = 17.55 \pm 4.55$ mM and were both considered as reliable based on the Student's t-test.

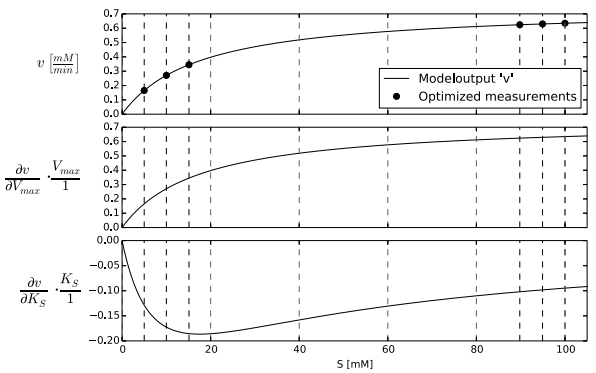

Figure 3: By using optimal experimental design and the D-optimality criterion, the experiments are optimised and the confidence intervals are decreased for both parameters. In the two lower figures, the local parameter relative sensitivity is showed for both V_{max} and K_S.

3.3. Optimal Experimental Design for parameter estimation

Instead of ignoring available knowledge reported in the paper of Johnson and Goody (2011), it is possible to take this knowl-

edge into account when designing experiments. The total number of experiments is still equal to six and the only experimental degree of freedom is the sucrose concentration S, which can be varied between 5 and 100 mM. The minimum sucrose concentration was set to 5 mM to assure sufficiently high reaction rates. An extra optimisation constraint was added, i.e. the difference in sucrose concentration between two experiments should be at least 5 mM. This allows to make the design less dependent on the actual parameter values. This optimisation led to lower confidence intervals for both parameters. For V_{max} the optimised experimental design led to a 95 % confidence interval of only 0.070, a decrease of 25.5 %. For K_S the 95 % confidence interval decreased to 3.73, which is 18.0 % lower compared the the original experimental setup. This illustrates that OED is a powerful technique which can improve the confidence levels of the models without requiring an additional experimental effort.

4. Conclusions

The pyIDEAS package allows novice and experienced modellers to execute basic and more advanced techniques by executing just a few lines of code. pyIDEAS will be open source and well-documented so that everybody is able to use it and has the ability of extending or adding functionalities. Such an integrated and flexible modelling package, providing access to optimal experimental design techniques, is not yet available to our knowledge and could improve overall access to these kind of tools and, hence, the quality of many modelling studies which often ignore this. Moreover, it allows modelling experts to verify current implementations and to debug them, something which is not possible for closed-software packages. We believe that an integrated package such as pyIDEAS can speed up research and innovation.

Abstract

The proper calibration of models describing enzyme kinetics can be quite challenging. In the literature, different procedures are available to calibrate these enzymatic models in an efficient way. However, in most cases the model structure is already decided on prior to the actual calibration exercise, thereby bypassing the challenging task of model structure determination and identification. Parameter identification problems can thus lead to ill-calibrated models with low predictive power and large model uncertainty. Every calibration exercise should therefore be preceded by a proper model structure evaluation by assessing the local identifiability characteristics of the parameters. Moreover, such a procedure should be generic to make sure it can be applied independent from the structure of the model.
We hereby apply a numerical identifiability approach which is based on the work of Walter and Pronzato (1997) and which can be easily set up for any type of model. In this paper the proposed approach is applied to the forward reaction rate of the enzyme kinetics proposed by Shin and Kim (1998). Structural identifiability analysis showed that no local structural model problems were occurring. In contrast, the practical identifiability analysis revealed that high values of the forward rate parameter V_f led to identifiability problems. These problems were even more pronounced at higher substrate concentrations, which illustrates the importance of a proper experimental design to avoid (practical) identifiability problems. By using the presented approach it is possible to detect potential identifiability problems and avoid pointless calibration (and experimental!) effort.

Keywords: model analysis, structural identifiability, practical identifiability, enzyme kinetics

1. Introduction

Nowadays, mathematical models are often used to describe enzymatic reactions, because in that way it is possible to gain information about the underlying kinetics (i.e. parameter values) and optimize overall performance of these reactions. By improving the performance, enzymatic reactions can become competitive with the chemical synthesis and yield a greener process. This is also the case for the production of chiral amines, for which transaminases can provide an interesting alternative for current chemical production (Tufvesson et al., 2011). Shin and Kim (1998) and Al-Haque et al. (2012) presented ping-pong bi-bi models to describe the observed behaviour, but the parameter identifiability was not investigated in these articles. Identifiability is an important model characteristic and can be defined as the existence of a unique combination of parameter values describing the system's behaviour. However two types of identifiability problems exist:

structural and practical identifiability problems. In a structural identifiability problem, multiple parameter sets result in the same input/output behaviour because of the model structure. Practical identifiability also includes the quality and availability of data. The latter gives an answer to the question: is the available data informative enough to allow finding this unique parameter set? A parameter which is practically identifiable is per definition also structurally identifiable but not vice versa. Therefore it is also important to assess the practical identifiability of parameters (Dochain et al., 1995; De Pauw et al., 2008).

For the assessment of the structural identifiability of non-linear models different techniques are available. The techniques which are used most often are the Taylor Series Approach (TSA), Generating Series Approach (GSA) and Differential Algebra Approach (DAA) (Chis et al., 2011). All techniques require significant computational resources and the question whether the model is identifiable or not, may even remain unanswered. TSA and GSA rely on the fact that one should take a certain (in most cases a priori unknown) number of derivatives and check whether the combination of all these derivatives yield a unique solution. An additional burden for the structural identifiability analysis for enzymatic models is the presence of (large) expressions in the denumerators, which drastically reduce the applicability of methods relying on mathematical differentation. In order to use DAA, it is necessary to have a model which has a polynomial form and is generally controllable. This adds an extra burden and reduces the attractiveness of the method. In order to counter these problems an identifiability tool is required which is model independent and is also able to take into account noise, hence allowing to use the same tool for both structural and practical identifiability analyses.

We hereby present an identifiability procedure which is based on the numerical local approach of Walter and Pronzato (1997). The original technique consists of two steps: first some nominal value for the parameters is selected and the model under investigation is used to generate a lot of high quality, but fictitious data y^f. Second, the aim is to estimate the parameters from y^f by minimizing an objective function. The minimization is started at the nominal parameter values, so if the parameter set remains stable the solution is structurally locally identifiable, otherwise it is structurally unidentifiable. This procedure needs to be repeated for different nominal values before drawing conclusions about the model identifiability (Walter and Pronzato, 1997). The extended identifiability procedure we present in this paper is developed to cope with both structural and practical identifiability issues. The forward reaction rate of the ping-pong bi-bi kinetic model of Shin and Kim (1998) is used to show the advantages of the proposed technique.

2. Methods

2.1. Kinetic model of ω-transaminase

The reaction under study is the conversion of isopropylamine (IPA) and benzylacetone (BA) to 1-methyl-3-phenylpropylamine (MPPA) and acetone (ACE) by the ω-transaminase (Figure 1). The enzyme requires the cofactor pyridoxal phosphate (PLP) to act as a shuttle to transfer the amine moiety between the molecules. The ω-transamination reaction obeys the ping-pong bi-bi kinetics for which the quasi steady-state reaction equation was proposed by Shin and Kim (1998). Based on the robust methodology of Al-Haque et al. (2012), the model is split to submodels and the identifiability procedure is performed for the initial forward reaction rate.

The initial forward reaction rate v (without considering inhibition) is shown in Equation 1.

$$v = \frac{V_f[IPA][BA]}{K_m[BA] + K_p[IPA] + [IPA][BA]} \tag{1}$$

with $[IPA]$ and $[BA]$ the concentrations of respectively isopropylamine and benzylacetone in mM. V_f is the maximum forward rate $[mM/min]$ and K_m $[mM]$ and K_p $[mM]$ are Michaelis-Menten constants.

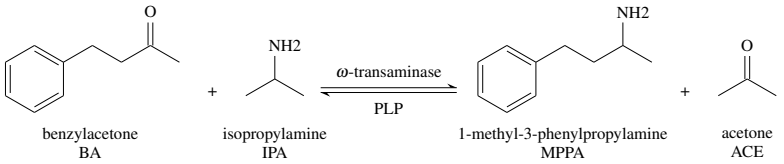

Figure 1: Transamination of isopropylamine (IPA) and benzylacetone (BA) to 1-methyl-3-phenylpropylamine (MPPA) and acetone (ACE) catalysed by the ω-transaminase enzyme in presence of the required cofactor pyridoxal phosphate (PLP).

2.2. Extended numerical identifiability analysis approach

To assess whether a model is both structurally and practically (locally) identifiable, the structural numerical local approach of Walter and Pronzato (1997) was adapted on two major points. First, instead of starting the identifiability procedure at the real parameter values, the procedure is started at a random point in the parameter space P. Second, in case of practical identifiability, noise is added to the model output to mimic the behaviour of real-life experimental data.

The developed numerical identifiability procedure can be divided in three parts: 1) preparative part, 2) actual identifiability part and 3) postprocessing part.

2.2.1. Part 1: Preprocessing

The first step in the preprocessing part is to select a model to perform the numerical identifiability analysis on. However, one needs to keep in mind that the model complexity should always be related with the available data. Second, the initial parameter values need to be chosen based on preliminary data or on expert knowledge. The final preprocessing step is to calculate the noise-free model output and select those outputs which can be measured. For each of the measurable outputs a certain number of datapoints must be selected. For assessing structural local identifiability, the number of datapoints can be almost infinite. When assessing practical (local) identifiability, the actual experimental facilities and the type and number of experiments should reflect what is feasible in practice.

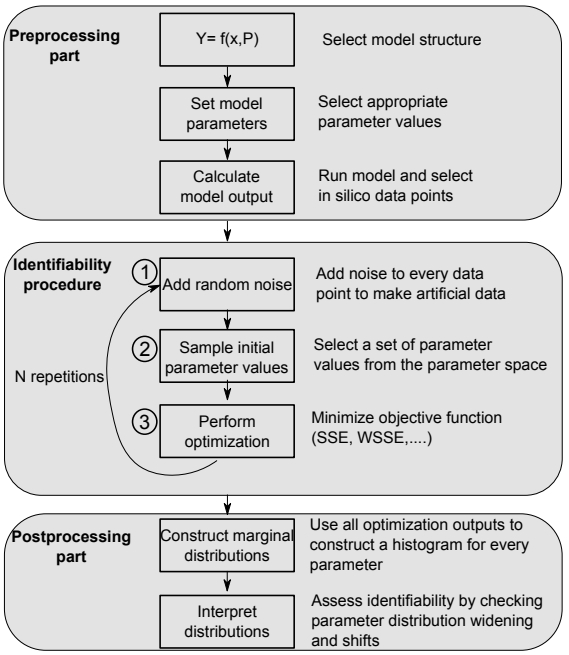

Figure 2: Schematic overview of the proposed numberical procedure for assessing structural and practical identifiability of (simple) models.

2.2.2. Part 2: Identifiability procedure

Now the actual identifiability procedure, which consists of three steps, can be started. When structural identifiability is the aim, the first step (①) may be ignored. For assessing practical identifiability, add random noise to each datapoint (①). The noise level and distribution can be chosen freely however, in most cases the normal distribution (white noise) is most logical to choose. The noise level or variance can be chosen accordingly, however the higher the noise levels the less likely it will be that the model will be practically identifiable. Noise levels should therefore be chosen wisely and if possible based on prior experiments or knowledge. Second (②), one should sample an initial parameter set from the parameter space P according to the underlying marginal distribution of every parameter. The final step (③) in the identification procedure is to perform the optimization, thus minimizing the objective function based on the difference between the model and the in silico data. The identifiability procedure is repeated N times to cover the entire parameter space. N should be sufficiently large to obey the a priori assumption of random white noise and be based on the dimensionality of the problem.

2.2.3. Part 3: Postprocessing

The postprocessing part consist of two steps: First from the N repetitions of the identifiability procedure, one gets N optimized parameter sets. For each individual parameter a histogram can be constructed. The second step is to interpret these distributions and detect whether identifiability problems are occurring or not.

2.3. Implementations

The approach described above was implemented using the IPython Notebook environment (Pérez and Granger, 2007). This environment was selected because of the availability of the so-called magic functions, which drastically reduced the effort to use multiple cores at the calculation cluster. In order to perform the optimizations the optimization module of the Scipy package was used and gave access to the minimize function (Jones et al., 2001). This function gives access to different local (and global) minimization approaches. The plotting of the histograms was done by using the hist function in matplotlib.pyplot (Hunter, 2007).

3. Results and Discussion

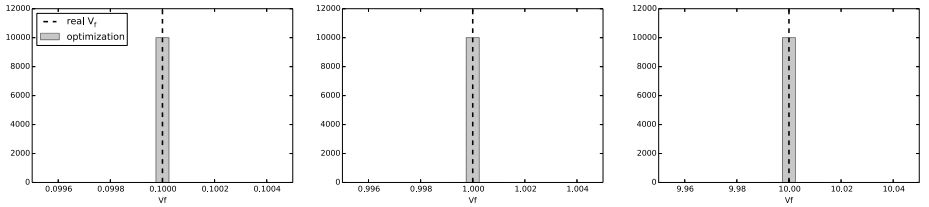
In this section the presented methodology is applied to the forward reaction rate of the ping-pong bi-bi kinetics to examine whether the model structure of the forward rate equation (Equation 1) is at least locally identifiable. Preliminary data was available, from which three plausible parameter sets were derived (Table 1). For each of the parameter sets both structural local identifiability (i.e. sufficient and noise free data) and practical local identifiability (i.e. experimental limited and noisy data) were investigated. In both cases, the chosen objective function was the sum of squared errors (SSE).

Table 1: Three plausible parameter sets were selected from the relationships derived from the preliminary data.

Parameter	$V_f[mM \cdot min^{-1}]$	$K_m[mM]$	$K_p[mM]$
low set	0.1	174.41	3.59
moderate set	1.0	1744.19	125.93
high set	10.0	17441.97	1349.27

3.1. Structural local identifiability

For each of the three parameter sets in Table 1, 10000 repetitions (N) of the identifiability procedure were executed by using sufficient and noise free data. This resulted in the marginal distributions of Figure 3. For each of the parameter sets, the optimization retrieved the original values. Therefore it could be concluded that, the model is (at least locally) structurally identifiable. It is important to assess this characteristic, because deviations of the real value can point out that the model is under/overparametrized or the model structure is inappropriate (De Pauw et al., 2008). In the case of a model overparametrization, one needs to reduce or simplify the current model or generate additional data to solve this issue.

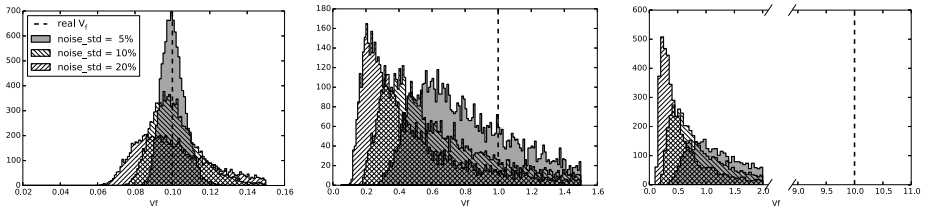


(a) $V_f = 0.1\,mM \cdot min^{-1}$ (b) $V_f = 1\,mM \cdot min^{-1}$ (c) $V_f = 10\,mM \cdot min^{-1}$

Figure 3: Histogram for each of the parameter sets in Table 1, 10000 initial parameter samples were optimized with the in silico data. Each optimization ended at the real parameter values which shows that the model is structurally identifiable. For visibility reasons the gray optimization bar is made much wider.

3.2. Practical local identifiability

After checking the structural local identifiability, a practical identifiability analysis was performed for each of the parameter sets in Table 1. This procedure was done for each of the parameter sets for 3 different noise levels: a relative white noise with a standard deviation of 5 %, 10 % and 20 %. In that way higher values of v can have a larger absolute noise compared to lower v values. For each combination of parameter sets and noise levels 10000 repetitions were performed, resulting in marginal distributions showed in Figure 4. The identifiability procedure was also conducted for absolute noise levels (constant for all datapoints), however this did not result in significant output changes and is therefore not shown.



(a) $V_f = 0.1\,mM \cdot min^{-1}$ (b) $V_f = 1\,mM \cdot min^{-1}$ (c) $V_f = 10\,mM \cdot min^{-1}$

Figure 4: Histogram for each parameter set in Table 1. The practical identifiability procedure was done for 3 different noise levels (standard deviations of 5, 10 and 20 %). At higher values of V_f (1.0 and 10.0 mM) a clear shift of the distribution can be observed, indicating practical identifiability problems. As could be expected, this effect even gets worse at higher noise levels. Therefore it can be concluded that the model is only practically identifiable at low V_f levels and for low levels of noise.

From Figure 4, it can be concluded that the model is practically locally unidentifiable at high V_f values, even if the noise levels are low (5 % standard deviation). This has a huge impact on the reliability of the calibration and validation of the model under study. A calibrated V_f value of 0.5, would be unreliable based on Figure 4. Maybe V_f is truly 0.5 but it is also possible that V_f was 1.0 or even 10.0. The conclusion would be that a V_f parameter value of 0.5 (given the selected noise levels and data) can never be regarded as a reliable estimate. One should bear in mind that the conclusions drawn from Figure 4 are only valid for the data which is provided. For other data sets, which may be more informative or less noisy, no conclusions can be drawn about the practical identifiability. In this case different data sets were tried, but it seemed that varying isopropylamine between 0 and 800 mM at a constant benzylacetone concentration (5 and 10 mM) resulted in slightly lower uncertainties compared to the variation of benzylacetone at a constant isopropylamine concentration. This information is useful for deciding which experiments yield less uncertainty and might be used as a basic method for optimal experimental design.

4. Conclusions

A conceptually simple yet powerful technique to assess the structural and practical local identifiability was presented. This technique allows the model user who wants to perform modelling and calibration to verify whether the model under study is (at least locally) identifiable. The technique requires the use of a considerable amount of computational power, however this requirement depends on the desired accuracy and the complexity of the model. For simple models one can obtain high accuracy at a reasonable cost. The choice of which kind of data will be used to check the identifiability of a model is of major importance for this technique. The dependence of the technique on the provided data, makes it suitable for designing experiments.

Integrated Simulation Platform of Chemical Processes Based on Virtual Reality and Dynamic Model

Na Luo, Xiaoqiang Wang, Feng Van, Zhen-Cheng Ye, Feng Qian*

Key Laboratory of Advanced Control and Optimization for Chemical Processes (East China University of Science and Technology), Ministry of Education, Shanghai, 200237, China

Abstract

Due to the upcoming shortages of plant operators, more and more simulation platforms are widely developed for training. However, the conventional simulation environment is not intuitive for the beginners. In this study, a new integrated simulation platform based on virtual reality and dynamic model was proposed. Realistic 3D model of the chemical plant was developed which interacts with the dynamic model and the companied control system. Also the scene on site was integrated for monitoring the real process conditions. With the OPC interface, the dynamic model could run simultaneously with the actual plant. As a case study, the integrated simulation platform of ethylene process was illustrated. The simulation results showed that the integrated platform is more friendly and accurate to be used for training operators.

Keywords: simulation platform, dynamic modeling, virtual reality, chemical process.

1. Introduction

As an important production process, chemical processes are dynamic systems in which states of material change according to various physical and chemical changes. Generally, the role of the operator have to monitor a sophisticated system and make decisions about the health of the process and the performance of the system based upon trends and meta-information. Nowadays, the reliable system and process avoid upset conditions in industry, so the operators often have no chance to deal with critical situations, which may cause the operators to quickly lose the skills. On the other hand, though modern, field-based automation systems have great reliability and performance, the risk introduced by human engineering still remains. Especially when advanced control strategies are used in process, the system cannot be trusted because of error or incompletion. From this point of view, virtual plant provides an important platform in automated process plant.

In the last two decades, virtual factory theories and concepts are developing rapidly, significantly improving the efficiency of design, planning and reconfiguration in the manufacturing system. Nowadays, many manufacturing enterprises are facing challenges such as faster product design changes, shortened planning and delivery time or more flexible production schedule [1]. Jain et al.[2] classify virtual factory definitions into four categories: a) representation of all major aspects of a factory; b) a virtual organization; c) the virtual reality representation of a factory and d) an emulation facility for production activity in a factory. In the definitions, more studies were developed in every aspect of the relevant technology. With the development of virtual reality, virtual plant is not only a dynamic process simulator integrated with a control

system simulator. Virtual reality technology is used widely in industrial applications, especially in early planning stages of manufacturing system, e.g. the assembly design; machining process simulation; evaluation and visualization of planned facility or training employees parallel to the running production. With more virtual reality approach, the user and the information support elements are put in direct relation with the operation of the system in a realistic environment. Based on a virtual reality approach, Manesh[3] developed a real industrial plant, a medium sized die-casting factory. Though virtual factory is been applied successfully to hundreds if not thousands of scenarios, only a single research group worked specifically on the application of virtual reality to chemical engineering is aware. Bell[4; 5] Presented their work to apply virtual reality to engineering education, in three broad project areas: Virtual chemical plants, virtual laboratory accidents, and a virtual UIC campus. Quan[6] proposed a three-dimensional interactive virtual chemical laboratory framework based on constructivist learning theory, three-dimensional modeling and scene interactive technology of VRML. Also they developed a real experimental environment and implement the complex human-machine interaction in chemistry to make the learners get the senses of realism and immersion. Chen[7] built a distributed interactive chemical process simulation system with the abilities of chemical process training, monitoring, testing and replaying.

In this study, a virtual factory is developed which simulate the chemical process. A 3-D visualization platform provided through a virtual reality based simulation tool allows system users to create any kind of common manufacturing operations. The underlying control architecture is built upon the real control system in the process. The bottom is the dynamic simulation of the process which provides operation data for the above control system. The overall methodology has been implemented as an easy-to-use tool for manufacturing systems education and operation training.

2. Framework of the virtual factory

A brief diagram for virtual factory is shown in Figure 1, which includes three layers. The bottom layer is the dynamic model which represents the units, pipes, sensors and control valve in the factory. Upper is the control system layer, developed using the factory commonly-used control platform, such as IFIX. On the top, actual industrial scene is portrayed in 3D virtual environment in real time.

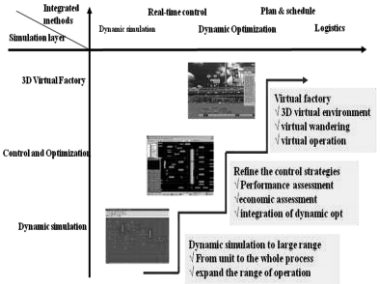

Figure 1. Diagram for virtual factory

In the bottom layer, dynamic simulations are from unit to the whole process. Also the simulated model expands the range of operations. The generated data are provided to the upper layer for control and optimization. In the platform of the control strategies, performance assessment, economic assessment is made. In addition, dynamic optimization to the process is integrated. These operations are represented using the

virtual reality in 3-D environment. Also the virtual wandering, virtual operations can be realized in the platform.

2.1. Virtual reality

Virtual Reality (VR) is a comprehensive and widely developed concept. It is usually understood as computer technologies to create virtual environments consisting of realistic 3D models and their interrelationships. To facilitate the operation process in manufacturing system, the simulation results are implemented in virtual reality.

Virtual reality can attract and affect the operators mostly. The key area is the navigation and orientation. There are three modes in our work: randomly automatic walking, role operation and orientation location. The directional cues are related with the location of the unit in the control system. Teleports are used to move from one unit to another.

The information of units is shown in the 3D environment to make the greener to be familiar with the process. In addition, operational conditions, such as stream flow, valve location are also illustrated in the scene.

2.2. Control system

A virtual control system is selected according to the real control system running in the real plant. The control strategies duplicate the real ones in the process. This allows testing of the identical control strategies running in the actual process controllers with a virtual I/O system. It allows operator training on graphics, alarms and controls that are identical to the actual plant HMI.

In addition, a virtual process and I/O dynamic simulation system is used. The system is complementary to the virtual control system, providing real-time I/O and model updates so that the virtual control system appears to control the real process. The dynamic simulation allows the user to develop process models to the level of complexity or fidelity required by the task at hand. The system needs to be easy to use and change so that modeling changes can be made quickly and efficiently.

2.3. Dynamic model

The simulation system is built to support both control system testing and operator training, so that it can provide the greatest benefit to the system user. Ideally, the virtual plant will be available for plant operations as a strategic asset to improve the quality of control system enhancements and increase the effectiveness of plant operators.

Dynamic simulation interact real-time changes with the environment. Layouts for models are changed, dynamic simulation is update. Also simulation signals can be transferred to a physical models and these physical models' signal can be transferred to virtual units, which will enable us to perform an integrated simulations with a whole virtual/physical model.

2.4. communications between three layers

Based on Microsoft's OLE, Component Object Model (COM) and Distributed Component Object Model (DCOM) technologies, OPC consists of standard interfaces, properties and methods for the use in process control and manufacturing-automation applications. One of the valuable features of OPC is that it provides a common interface for communicating with diverse process control devices, regardless of the controlling software or protocols used in the process. Before OPC became available, application developers had to create specific communications drivers for each control system with which they wanted to connect. With OPC, application vendors no longer need separate drivers for each new processor or protocol. Instead, the manufacturers create a single optimized OPC driver for their product.

3. An illustrative Example

In the following section a real industrial plant, a full-scale sized ethylene factory is analyzed. This example is a model of a plant located in China. The factory comprises of several cracking furnaces and dozens of columns, accompanied by lots of bumps, heat-exchanges, valves and so on.

The production process begins with the arrival of naphtha to react in cracking furnace. In the furnace, the naphtha is cracked to ethylene, propylene, butane and other raw materials. In next units, different materials are purified.

3.1. VR model

The VR model of ethylene factory is shown in Fig. 2. In it, units, pipes, bumps and buildings are all illustrated. The operators can have a role of worker who is male or female. Then the role can do some routine work in the virtual plant such as monitoring the unit, checking the location of the liquid level and so on. Also the role can adjust the valve location and change the operation of the process. For the beginner, the role needs to be familiar with the process. The automatic walking mode will direct the role to visit the virtual plant and show the information of the important equipment.

The VR model is developed in 3D max environment and animated using the software named VRP. The scene of the virtual plant is vivid and the integration is easy. For complex process, the development work is enlarged and the reusing of the unit model is a difficult problem to be solved.

Figure 2. Snapshot of the VR model

3.2. Control system

Most industrial SCADA (Supervisory Control And Data Acquisition) systems like iFix (General Electric), WinCC (Siemens) or RSView (Rockwell Automation) can be used for process visualization as well because they naturally directly operate with the OPC data. In this study, iFix is used as the control system. The system emulates the SCADA system in the industrial plant which is shown in Fig. 3.

3.3. dynamic simulation

HYSYS dynamics has been recently used in real industry, served as a simulation platform to experiment with new control technologies for similar units. Steady-state and dynamic simulation for ethylene process is done using Aspen HYSYS. The

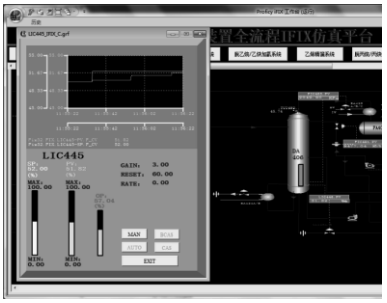

Figure 3. Snapshot of SCADA system

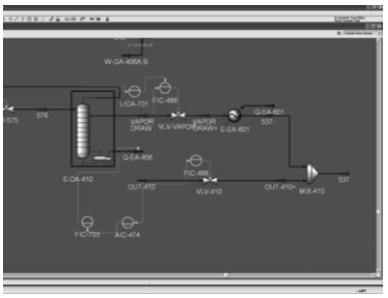

Figure 4. Snapshot of dynamic system

control loops are implemented, together with the corresponding manipulator, with is shown in Fig. 4.

4. Conclusion

This study proposed a dynamic modeling environment based on virtual reality. Realistic 3D model of the plant was developed and interacted with the dynamic modeling and the companied control system. With the OPC interface, the dynamic modeling environment ran simultaneously with the actual plant. A case study of ethylene virtual plant was illustrated as a case study. Other virtual plants could be also developed using this method. As the web has grown in popularity and utility, the transplant to the web is the direction of the virtual plant.

Abstract

In this paper, we present our recent work on the implementation of an Energy Systems Integration platform allowing the modeling of Energy Systems integrating LCI (Life Cycle Inventory), LCIA (Life Cycle Impact Assessment) and GIS (Geographical Information Systems) data as modeling parameters and variables included in an industrial process model.
Based on our previous experience in methodologies and models of Energy Systems Integrations, we developed a new generation of the platform using the script language Lua. The main motivation for choosing Lua was to radically improve the performance of the system, which was the main drawback of the existing Matlab-based system, while proposing a more convenient way of describing the modeling elements and their combination.
The second objective of our work was to integrate LCI and LCIA aspects as a generic part of the Energy Systems modeling methodology. We are currently working on the process data mapping algorithm in order to match the appropriate Unit process and Elementary flows identifiers used in the ecoinvent v3 database.
Thirdly, by having the possibility of importing GIS databases (in csv format), some coordination data, such as longitude and latitude, can be directly included as Energy System elements' location parameters. This possibility improves the efficiency in modeling the energy integration of urban systems.

Keywords: process system engineering, energy integration, LCA, Lua, OSMOSE

1. Introduction

Many different modeling environments (e.g. MATLAB®, GAMS®, AMPL®, gPROMS®, BELSIM®) and commercial solvers (e.g. GLPK®, CPLEX®) exist for process system engineering (Martin, 2015). One of the biggest challenges is to handle the communication among them, while performing design and optimization of the overall system. With this in mind, the OSMOSE® platform was designed in the Laboratory of Industrial Energy Systems (LENI software, 2005) at EPFL as a flexible and robust tool for the design of complex integrated energy systems in a Matlab environment.

Figure 1 illustrates the methodology implemented in OSMOSE® for the design and optimization of energy systems. Energy systems are generally Mixed-Integer Non Linear Programming (MINLP) models with multiple conflicting objectives (e.g. economic, thermodynamic and environmental indicators). Following a two-stage decomposition strategy the problem is divided into a master problem and a slave sub-problem (Gerber et al. 2013, Weber, 2008). The master problem is solved using a

Queueing Multi-Objective Optimization (QMOO) technique (Leyland 2002). QMOO is a robust evolutionary algorithm designed at EPFL to find the global optimum together with many local sub-optimal solutions. This is important as it provides the decision maker with many possibilities. The slave sub-problem is a Mixed-Integer Linear Programming (MILP) model solved by using a branch-and-bound algorithm. In the Matlab-based platform, the LCA database was based on ecoinvent version 2.2.

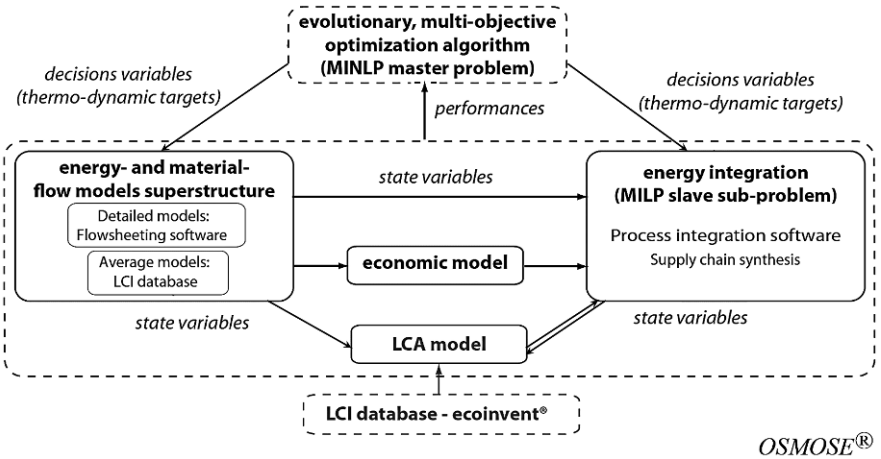

Figure 1. OSMOSE computational framework for energy system optimization. Adapted from (Gerber et al., 2013)

2. OSMOSE Generation II - OsmoseLua

Based on our previous experience with the OSMOSE methodology, we developed a new approach using the script language Lua (Ierusalimschy, 2013). As a first step, the slave sub-problem of OSMOSE was handled while integrating GLPK and Belsim-Vali for solving MILP problems. We are continuing to complement the multi-objective optimization algorithm in Lua. The main motivation for choosing Lua was to radically improve the performance of the system, which was the main drawback of the existing Matlab-based system, while proposing a more convenient way of describing the modeling elements and their combination.

Another important feature of the Lua version of OSMOSE is its extensibility and ease of integration (Figure 2). This was taken into consideration while designing the core architecture. The interface part depicted as GenericFrontend and GUI in Figure 2 is the user interfacing API either on the users' stationary computing environment or on portable devices. Due to the Lua language's portability and small footprint, the integration on mobile devices for model search and results consultation is strongly encouraged as our future development plan.

Finally, while implementing the OSMOSE core part in Lua, we redesigned the LCI and LCIA parts as pluggable and extensible generic SW modules rather than integrating the LCA database as part of the energy and material structures as depicted in Figure 1. Consequently, in the currently available OsmoseLua architecture we provide two types of library elements: on the one hand the Energy process model ((1) in Figure 1); and on the other hand the associated LCA dataset model ((2) in Figure 1) where both are generic and reusable. The main advantage of such improvement is twofold: i) firstly, modelers can achieve a more detailed analysis while including LCI material flows

and/or life cycle impact assessment separately or jointly. ii) secondly, the evolution of both model parts can be dealt with independently by modifying the process model without changing the LCA aspects, or inversely by updating only the LCA database.
In the following section we discuss LCI and LCIA principles in more detail.

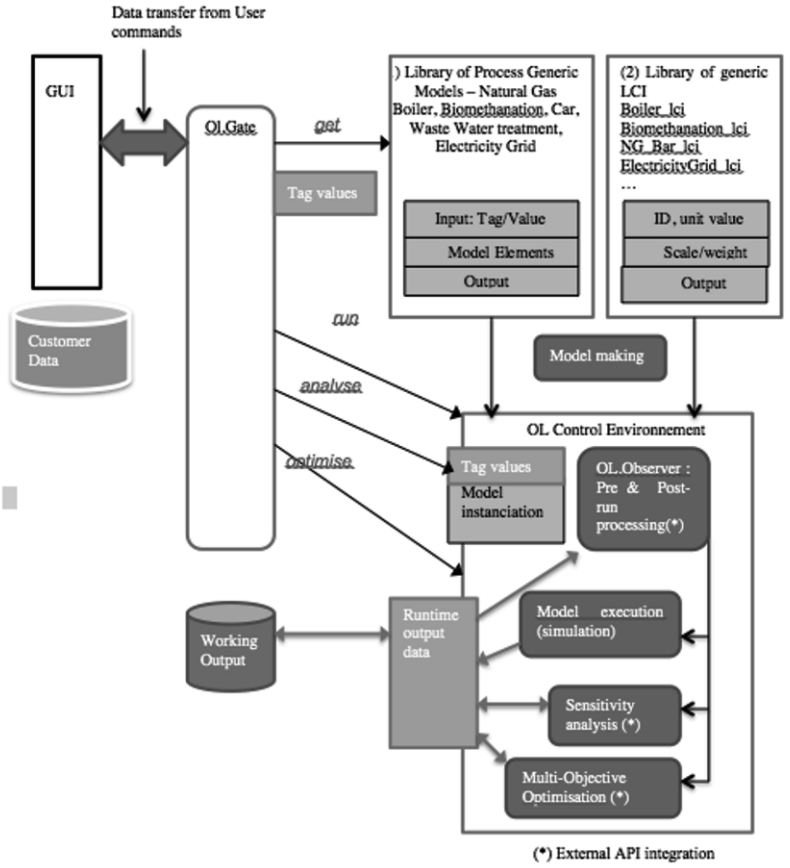

Figure 2. Global overview of OsmoseLua architecture

3. LCI and LCIA with ecoinvent version 3.1

Life cycle assessment (LCA) is the evaluation of environmental impacts over the life cycle of a product, process or activity, from the extraction of raw materials to the end-of-life. LCA can be used to identify opportunities to reduce environmental impacts of a product, to inform decision makers in order to aid in strategic planning and design, to select relevant indicators based on environmental performance and/or for marketing purposes (ISO 2006).
In our work, one of the objectives is to integrate life cycle inventory (LCI) and life cycle impact assessment (LCIA) into the energy systems modeling methodology. The database ecoinvent version 3.1 was used for the integration of energy modeling variables accessible for the optimization modeling (Weidema et al. 2013). As done by Gerber et al. (2013), energy flows such as fuel or electricity consumption are modeled by associating with each flow a corresponding LCI ecoinvent unit process. Likewise,

material flows and flows are modeled in this manner. Direct emissions are modeled by associating with each flow a corresponding elementary flow, again from the ecoinvent database. A general representation of the above methodology is shown in Figure 3. Care is taken to avoid double counting of emissions; if an emission is already included in the unit process, then the same emission is not modeled with an elementary flow.

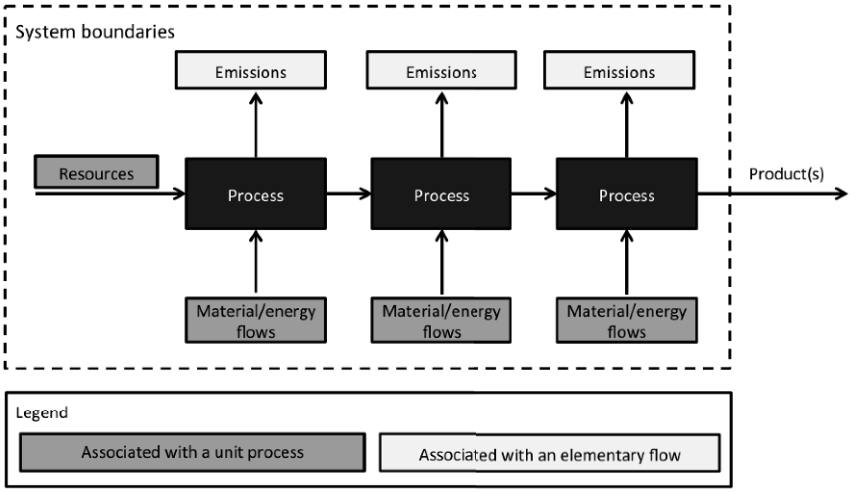

Figure 3. General representation for association of material/energy flows and resources with unit processes and emissions with elementary flows.

Different LCA methods (e.g. IMPACT 2002+) and indicators can be used for the impact assessment, to be included in the energy optimization. LCIA results are obtained by multiplying life cycle inventory flows with the appropriate characterization factor for each inventory flow. This results in environmental impacts for different midpoint categories such as, Global warming, Aquatic eutrophication, Respiratory effects, etc. One or more environmental indicator(s) may be considered as an objective function in the optimization.

In the following section, OsmoseLua application architecture is presented which includes a discussion of LCIA pluggable architecture.

4. OsmoseLua generic architecture

4.1. LCA plug-in model

We modeled the LCA dataset as a distinguishable part of the process model definition while cutting off the tight-coupling relationship in the previous approach (Figure1). The separated LCA dataset was then modeled as Lua module definitions for data construction and necessary functions for scaling and weighting factor setting.

One of the advantages of a loosely coupled LCA model is that, if the modeler has no detailed information of its energy process model, the modeler can reference existing LCA elements from the LCA libraries which provide a set of generic databases while selecting a similar energy process model. The OsmoseLua plug-in then provides methods for further specialization of dataset elements. The scaling and weight factors are implemented as LCA dataset parameters which can be customized according to the target model.

When applying impact assessment methods, two types of identifiers were taken considered: Unit process IDs, based on ecoinvent v2.2 and Activity IDs based on ecoinvent v3. This requirement is for recovering all the available Energy Processing Models and previously defined LCA datasets declared within each Model element. As we are in the transition phase from ecoinvent v2.2 to ecoinvent v3, this method will allow us to reuse our existing LCA database of models. Such cross-referencing is possible now with our OsmoseLua LCA plugins.

4.2. Integration of GIS information

One evolving aspect with OsmoseLua is its way of handling GIS data from a standard file format and recovering values as state information of energy model superstructure. By having the possibility of importing GIS databases (in csv format as a first trial), data such as longitude and latitude can be directly included as Energy System elements' location parameters. This improves the efficiency of modeling urban systems energy integration, where building locations or heights are often necessary as a constituent of the modeling units.

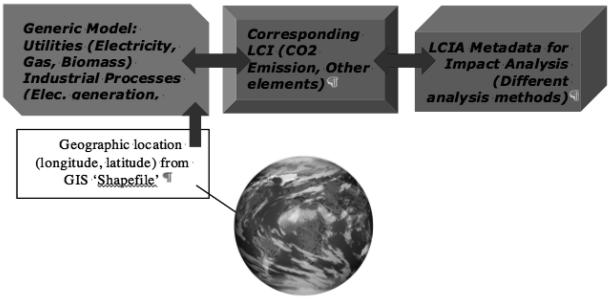

Figure 4. Overall relationship between GIS data handling and LCI-LCIA plug-in in OsmoseLua .

4.3. Validation

In the context of the project PFE3 (PFE3), two case studies are studied among project partners for the purpose of validating the modeling approach and the technical feasibility. One case study considers a hypothetical system with a population of 450'000 inhabitants including four categories of energy services: space heating, domestic hot water production, electricity and transport. Waste treatment includes municipal solid waste, organic waste and wastewater. Four industries are studied: a sawmill, a greenhouse producing vegetables, an industrial laundry service and a bio-refinery. A baseline model of the mentioned case study was implemented and analyzed in the Matlab version of. Afterward, the same conceptual model was re-written, as a proof-of-concept example, in the OsmoseLua environment and similar energy integration results were obtained. The life cycle impact assessment was analyzed with the IMPACT 2002+ method.

5. Conclusions

Throughout the implementation phase in Lua, we recognized that Lua made it easy to achieve the implementation of new sub-systems, such as a GIS data handler, LCA dataset integration and LCIA meta tables. It is due to the Lua language feature which is suitable for rapid prototyping and developing high level domain specific languages (DSL).

Currently, other partners of the project are working on a Java-based User interface layer for the purpose of customizing and integrating visualized GIS integration.
A future objective is to include the customization of the Generic Frontend layer on a mobile application environment. Lua is a popular language for many types of application developments on portable devices and game development. The Lua community provides a rich set of specialized IDE tools almost all of which are freely available.
It would be of interest to use and integrate a specialized tool such as OpenLCA into OsmoseLua. In this case, it might become more efficient to construct a new LCA dataset starting from process system specifications to be studied. An important benefit of such a tool is the possibility of composing a new process model and life cycle impact matrix with the capability of exporting/importing standard data formats such as XML, csv or database files. With OpenLca, such kind of process composition and data exportation is possible using executable system libraries. In this case, the exported dataset from OpenLCA under the XML format, for example, would be directly interpreted by the Lua LCA data handler and can be used in combination with other parts of our Lua LCA plug-in.

Incremental Kinetic Identification based on Experimental data From Steady-state Plug Flow Reactors

Nirav Bhatt[a] and Srividhya Visvanathan[a]

[a]*Systems & Control Group; Department of Chemical Engineering; IIT Madras, Chennai, India*
niravbhatt@iitm.ac.in

Abstract

This work develops an incremental model identification approach for analyzing concentrations from non-isothermal steady-state plug flow reactors (SPFR) with tubular geometry. A model of non-isothermal SPFRs consists of the material and energy balance equations of SPFR in form of a set of differential equations. Since SPFRs often are used for studying gas phase reactions, the pressure drop equation will also be included. Two scenarios of reactor operations for collecting concentration measurements are distinguished: (S1) Concentrations of species are measured along the length of reactors, and (S2) concentrations of species in the outlet stream are measured for the given inlet concentration condition at various volumetric flowrates. For Scenarios S1 and S2, the incremental identification is extended to identify reaction kinetics from experimental data. Scenario S1 is corroborated with a simulated example of pyrolysis of dimethylformamide in an isothermal tubular reactor.

Keywords: Reaction kinetics, Incremental identification, Plug flow reactor, Non-isothermal

1. Introduction

The distributed reactors such as plug flow reactor, axial flow reactor are often used in chemical process industries. Thermal cracking, catalytic gas phase reactions etc., are some examples where these reactors are employed in industries. Plug flow reactors (PFR) are often used to identify reaction kinetics for these reactions in the laboratory. These experiments of kinetic identification are performed at steady-state operation of the reactor where concentrations at inlet and outlet of the reactor or along the length of reactors are often measured. Then, these data can be analyzed using the simultaneous kinetic identification approach (Thaore and Gaikar, 2013; Marquardt, 2005).

Recently, the incremental approaches have been proposed to identify reaction and mass-transfer rates based on experimental data from tank reactors (Marquardt, 2005). The incremental model identification (IMI) approaches decompose task of identification into a sequence of subtask such as the identification of stoichiometry and rate expressions. Hence, the number of model candidates can be kept small in each subtask, and the information available from one task can be used in the subsequent steps. The incremental kinetic identification approaches can be classified as: (i) Rate-based methods, and (ii) extent-based methods (Bhatt et al., 2011, 2012). A comparison of these approaches has been given in Bhatt et al. (2012). The best of our knowledge, these approaches have not been developed to analyze experimental data from plug flow reactors. The objective of this paper is to extend the framework of IMI to analyze the experimental data obtained from steady-state PFR.

The paper is organized as follows. The second section sets up the material balance and energy balance equations for a steady-state non-isothermal PFR. Further, the pressure-drop equation is

also written. Then, the linear transformation of the concentrations (or the molar flux) is extended for computing the contribution of each reaction.

2. Model Equations

2.1. Mole balance equations

The mole balance equations for a homogeneous reaction system involving S species, and R independent reaction in steady-state plug flow reactor (SPFR) can be written generically as follows:

$$\frac{d\mathbf{F}}{dV_r} = \mathbf{N}^{\mathrm{T}}\mathbf{r}, \quad \mathbf{F}(0) = \mathbf{F}_0 \tag{1}$$

where $\mathbf{F}$ is an S-dimensional vector of molar flow-rate exiting the control volume V_r, $\mathbf{N}$ is the $R \times S$ stoichiometric matrix, and $\mathbf{r}$ is the R dimensional reaction-rate vector. The molar flow-rate $\mathbf{F}$ can be expressed as: $\mathbf{F} = q\,\mathbf{c}$ where $\mathbf{c}$ is an S-dimensional vector of concentrations, and q is the volumetric flow-rate. The symbols $\bar{u}$, L, and A are defined as the fluid velocity, the length and the cross-section area of the reactor. It is also assumed that they are constant during the operation of the reactor. Then, Eq. (1) can be written in terms of the molar flux, and concentration as:

$$\frac{d\mathbf{F}_r}{dz} = \mathbf{N}^{\mathrm{T}}\mathbf{r}, \quad \mathbf{F}_r(0) = \mathbf{F}_{r,in} \tag{2}$$

$$\frac{d\mathbf{c}}{d\tau} = \mathbf{N}^{\mathrm{T}}\mathbf{r}, \quad \mathbf{c}(0) = \mathbf{c}_{in} \tag{3}$$

where $\mathbf{F}_r$ is the S-dimensional vector of molar flux, and $\mathbf{c}$ is the S-dimensional vector of concentrations of the S species spending the space-time (mean residence time, $\tau = \frac{z}{\bar{u}}$) in the reactor. τ can be interpreted in terms of batch time t. Under the assumption of plug behaviour (no mixing), suppose that a plug of material enters SPFR at $\tau = 0$ and leaves it τ time. Then, the concentrations $\mathbf{c}$ at the outlet of SPFR can be interpreted as the concentrations of species as if they have been processed in a batch reactor for t time. In SPFR, the concentrations of species vary along the length of reactor while in batch reactor, the concentrations vary with the batch time. This analogy will be useful for extending the IMI approach to SPFR.

2.2. Energy balance equation

The steady-state energy balance along the length of the reactor can be written as follows (Rawlings and Ekertdt, 2002):

$$\frac{d\left(q\sum_{i=1}^{S} c_i H_i\right)}{dV_r} = UA_{ext}(T_{ext} - T), \tag{4}$$

where H_i is the enthalpy of the ith component; U is the heat-transfer coefficient expressed; A_{ext} is the external surface area per unit volume. Using material balance and Gibbs-Duhem equation, Eq. (4) can be written in terms of reactor temperature as follows:

$$q\rho\hat{C}_p\frac{dT}{dV_r} = -\Delta\mathbf{H_R}\mathbf{r} + UA_{ext}(T_{ext} - T) - q(1 - \alpha T)\frac{dP}{dV_r}, \tag{5}$$

where ρ is the reacting mixture density, $\hat{C}_p$ the mass heat capacity of the reacting mixture, $\Delta\mathbf{H}_R$ is an R-dimensional reaction rate vector, α is the compressibility factor, P is pressure. Under the

assumption an ideal gas ($\alpha T = 1$), Eq. (5) reduces to:

$$q\rho\hat{C}_p\frac{dT}{dV_r} = -\Delta\mathbf{H_R}\mathbf{r} + UA_{ext}(T_{ext} - T), \quad T(0) = T_{in}. \tag{6}$$

For the constant cross-section area, Eq. (6) can be written as follows:

$$\frac{dT}{d\tau} = -\Delta\mathbf{H_R}\mathbf{r}/\rho\hat{C}_p + UA_{ext}(T_{ext} - T)/\rho\hat{C}_p, \quad T(0) = T_{in}. \tag{7}$$

2.3. Pressure drop equation

For liquid flow and gas phase with average density, the pressure drop across the tube is modeled as:

$$-\frac{dP}{dz} = \frac{2\rho\bar{u}^2 f}{d_i}, \quad P(0) = P_{in} \tag{8}$$

where $f = \frac{16}{N_{Re}}$ is the frictional factor for a tube with the Reynolds number $N_{Re} = \frac{d_i\bar{u}\rho}{\mu}$. For gas phase, the velocity can be computed using the total flux using the ideal gas law as follows:

$$u(z) = \frac{\sum_{i=1}^{S} F_{r,i}(z)RT(z)}{P(z)}. \tag{9}$$

The residence time can be computed using the velocity at particular length ($u(z)$) and the dimension of the reactor z.

3. Computation of Contribution of Each Reaction

This section extends a linear transformation of computing the contribution of each reaction using the concept of reaction variants and invariants (Amrhein et al., 2010). It will be shown that the S dimensional space in which the concentrations (or molar fluxes) evolve can be split into an R dimensional reaction space and an $(S-R)$-dimensional reaction invariant space.

Reaction Variants: Any set of R linearly independent variables that evolve in the reaction space constitutes a reaction variant set.

Reaction invariants: Any set of $(S-R)$ linearly independent variables that evolve in space orthogonal to the reaction space constitutes a reaction invariant set.

Using Eq. (3), a linear transformation of the concentration vector into the reaction variants and invariant can be given by

$$\mathbf{c}(\tau) \longrightarrow \begin{bmatrix} \mathbf{x}_r \\ \mathbf{x}_{iv} \end{bmatrix} = \begin{bmatrix} \mathbf{N}^{\mathrm{T}+} \\ \mathbf{P}^{\mathrm{T}} \end{bmatrix} (\mathbf{c}(\tau) - \mathbf{c}_{in}) \tag{10}$$

with

$$\begin{aligned} \dot{x}_{r,i} &= r_i(\mathbf{c}), \qquad x_{r,i}(0) = 0, \forall\, i = 1,\ldots,R, \\ \dot{x}_{iv,j} &= 0, \qquad x_{iv,j}(0) = 0, \forall\, j = 1,\ldots,(S-R). \end{aligned} \tag{11}$$

The concentrations can be reconstructed from $\mathbf{x}_r$ and $\mathbf{x}_{iv}$:

$$\mathbf{c}(\tau) = \mathbf{N}^T\mathbf{x}_r + \mathbf{c}_{in} \tag{12}$$

where "+" indicates the Moore-Penrose pseudo inverse of a matrix, $\mathbf{x}_r$ is the R-dimensional vector of reaction variants, $\mathbf{x}_{iv}$ is the $(S-R)$-dimensional vector of reaction invariants. $\mathbf{P}$ is an $S \times (S-R)$ matrix describing the null space of $\mathbf{N}$, i.e $\mathbf{NP} = \mathbf{0}_{R\times(S-R)}$. Note $x_{r,i}$ describes the progress of the ith reaction after spending the space-time τ in the reactor. Note that $x_{r,i}$ cannot be interpreted as the extent of reaction. The linear transformation can be also be applied to $\mathbf{F}_r(\tau)$, and Eq. (12) can also be used for the reconstruction.

4. Extension of Incremental Identification Approach to SPFR

This section extends the idea of incremental identification method to SPFR. The IMI approach can be implemented as follows: (i) compute the extent of each reaction, and (ii) identify the rate expressions and corresponding parameters. For sake of demonstration, we will assume that the volumetric flowrate does not vary considerably along the length of the reactor, i.e. $\bar{q} = q(z) = \bar{u}A$. Often, the volumetric flowrate will be varied in different experiments and the concentrations at the inlet and outlet of the reactor can be measured. Then, the mean residence time (τ_h) at the length z_h with $h = 0, 1, \ldots, l$ can be computed using $\bar{u}$. Further, if pressure drop between two points in the reactor is measured, then $\bar{u}$ can be computed using Eq. (8) for the liquid or the gas phase with average density.

We consider two scenarios of experimental data in SPFR as follows: (S1) Concentrations of species are measured along the length of reactors, and (S2) concentrations of species in the outlet stream are measured for the given inlet concentration at various volumetric flowrates.

4.1. Scenario 1

Let $\mathbf{c}(\tau_h)$ be the S-dimensional vector of the concentration measurements spending τ_h space-time in the reactor. Note that $\tau_0 = 0$ (at the inlet of PFR) and $\tau_l = L$ (at the outlet of PFR). The following corollary states the conditions required to compute the extents of the ith reaction $x_{r,i}, \forall\, i = 1, \ldots, R$ from $\mathbf{c}(\tau_h)$.

Corollary 1 *If (i) the matrix* $\mathbf{N}$ *is known, (ii)* $\mathbf{c}(\tau_h)$ *and* $\mathbf{c}_{in}$ *are measured, and (iii)* $\text{rank}([\mathbf{N}, \mathbf{c}_{in}]) = R + 1$*, then the contribution of each reaction* $x_{r,i}(\tau_h), i = 1, \ldots, R$ *at the space-time* τ_h *can be computed as:*

$$x_{r,i}(\tau_h) = (\mathbf{N}^{\mathrm{T}})^{+}(\mathbf{c}(\tau_h) - \mathbf{c}_{in}). \tag{13}$$

(Proof follows from Theorem 2 of Amrhein at al Amrhein et al. (2010))

4.2. Scenario 2

In Scenario 2, multiple experiments are performed at different volumetric flowrates, and consequently, the velocity will be different in each experiment. In this scenario, the concentrations are measured at the outlet of the reactor ($z_l = L$), and the corresponding time can be computed from q. Let assume that the inlet concentration ($\mathbf{c}_{in}$) is fixed,and the experiments are conducted at various flowrates. In other words, the experimental data are collected under the identical conditions except varying flowrates. The values of the volumetric flowrates in different experiments can be arranged in ascending order as: $q_1 < q_2 <, \ldots, < q_n$. The corresponding space-time can also be arranged $\tau_1 > \tau_2 >, \ldots, > \tau_n$. The corresponding concentrations can also be tabulated. Since the inlet concentration is identical in each experiment, this arrangement can be visualized as the reactor with the larger length with $\mathbf{c}(\tau_1)$, $\mathbf{c}(\tau_2), \ldots, \mathbf{c}(\tau_n)$ being concentrations along the length. Then, we can apply Corollary 1 to the experimental data obtained in Scenario 2 after the arrangement. Further, the larger space-time allows further the progress of the reactions, $\mathbf{x}_r$, and thus,

the computed contribution of each reaction for different space-time at the outlet can be arranged as: $x_{r,i}(\tau_1) > x_{r,i}(\tau_2) >, \ldots, > x_{r,i}(\tau_n)$. The contribution of each reaction can be used to identify reaction rates as described in the next sectioin.

4.3. Identification of Reaction Kinetics

For the ith reaction, let $\hat{\mathbf{x}}_{r,i}(\tau)$ and $\mathbf{x}_{r,i}(\tau)$ denote the H-dimensional vectors of computed (according to Corollary 1) and simulated (according to a postulated rate law involving the parameters $\theta_{r,i}$) contribution of reaction H space-time instants. The following parameter estimation problem can be formulated:

$$\begin{aligned} &\min_{\theta_{r,i}} f_i = (\hat{\mathbf{x}}_{r,i} - \mathbf{x}_{r,i}(\theta_{r,i}))^{\mathrm{T}} (\hat{\mathbf{x}}_{r,i} - \mathbf{x}_{r,i}(\theta_{r,i})) \\ &\text{s.t.} \quad \dot{x}_{r,i}(\tau_h, \theta_{r,i}) = r_i(\mathbf{c}_l(t_h), \theta_{r,i}), \quad x_{r,i}(0) = 0, \\ &\qquad \theta_{r,i}^L \leq \theta_{r,i} \leq \theta_{r,i}^U, \end{aligned} \tag{14}$$

where J_i is the cost to be minimized, r_i is the rate of the ith reaction, which is a known function of the measured molar concentrations $\mathbf{c}_l$ and the l-dimensional unknown parameter vector $\theta_{r,i}$ that can vary between the bounds $\theta_{r,i}^L$ and $\theta_{r,i}^U$.

5. Simulation studies

The pyrolysis of Dimethylformamide (DMA) in an isothermal tubular reactor is studied for the simulation studies (Thaore and Gaikar, 2013). The following four reactions are considered for this study:

$$\begin{array}{lccccccccc} \text{R1:} & (CH_3)_2NCOH & + & H_2O & \xrightarrow{k_1} & (CH_3)_2NH & + & HCOOH \\ \text{R2:} & & & HCOOH & \xrightarrow{k_2} & HCHO & + & 0.5O_2 \\ \text{R3:} & & & HCHO & \xrightarrow{k_3} & CO & + & H_2 \\ \text{R4:} & 2CO & + & O_2 & \xrightarrow{k_4} & 2CO_2, & & \end{array}$$

from which one can write the stoichiometric matrix $\mathbf{N}$:

$$\mathbf{N} = \begin{bmatrix} -1 & -1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -1 & 1 & 0.5 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 & -2 & 0 & 2 \end{bmatrix}. \tag{15}$$

It is assumed that the all reactions are elementary reactions. The inlet concentration vector $\mathbf{F}_{r,in} = [1, 4.3, 0, 0, 0, 0, 0, 0, 0]^{\mathrm{T}}$. The temperature is maintained at 775 degK. The length of reactor is taken to be 0.25 m. The data are collected along the length of the reactor (Scenario 1). It is assumed that the noisy concentrations along the length of reactor and the pressure drop are measured. Using Eq. (8), the velocity are computed under the assumption of the constant density and viscosity properties. Corollary 1 is applied to compute the contribution of each reaction. The computed extents are shown in Figure 1. The computed extent of each reaction is used to estimate the parameters (k_1, k_2, k_3, and k_4) in the rate expressions using Eq. (14). The estimated parameters along with the confidence intervals are shown in Table 1. The IMI approach provides a good estimates of the parameters. However, it has introduced a bias in the rate constants k_1 and k_4.

6. Conclusions

In this paper, we have extended the IMI approach to non-isothermal varying pressure SPFR. Two experimental scenarios of data collection in steady-state PFR have been considered. For Scenario 1, it has shown that the contribution of each reaction can be computed from the data collected

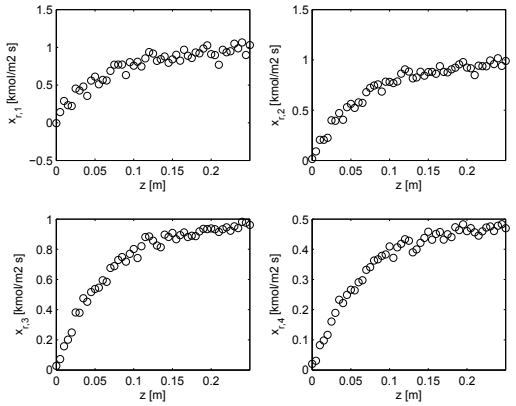

Figure 1: The computed contribution of each reaction along the reactor length

Table 1: True, initial and estimated values of the four kinetic parameters along with the 95% confidence interval for the estimated parameters.

Parameter	True value	Initial value	Estimated value	Confidence interval
k_1 [m^3 mol^{-2} s^{-1}]	0.5551	0.8000	0.5252	[0.5247, 0.5256]
k_2 [s^{-1}]	155.47	0.8000	160.3	[153.1842, 167.4060]
k_3 [s^{-1}]	843.46	0.8000	863.6451	[841.36, 885.9302]
k_4 [m^3 mol^{-1} s^{-1}]	1.665×10^5	8000	1.678×10^5	$[1.667 \times 10^5, 1.686 \times 10^5]$

along the reactor length. For Scenario 2, the multiple experiments need to rearrange such that the results of Scenario 1 can be applied compute the contribution of each reaction from data. Then, the computed contribution of each reaction has been used to estimate parameters. The method has been demonstrated on an pyrolysis of DMA in an varying pressure steady-state PFR for Scenario 1. Note that the method can be applied to non-isothermal and varying pressure SPFR. Future work will extend the IMI approach to axial flow reactors.

Abstract

First-principles modelling of polymer systems is usually complex and time-consuming, often leading to correlations of restricted range of applicability with unavailable parameters. Thus, the optimal control of polymerization processes using such models is a demanding task, especially when tracked batch reactors in which the systems have typical transient behaviour. In this paper, the fuzzy logic is applied to model discontinuous polymerization reactors. The proposed fuzzy methodology allows the formulation of a global nonlinear long-range prediction model from the conjunction of a number of local linear fuzzy dynamic models. The pilot-plant-scale synthesis of poly(lactic acid) (PLA) and nylon-6 were adopted for performance evaluation of proposed method. Satisfactory results were achieved. Therefore, the proposed technique can be useful to obtain appropriate representations of systems of complex modelling.

Keywords: fuzzy modelling; nonlinear system identification; batch reactor; polymerization.

1. Introduction

It is well-known that batch systems are very important in chemical engineering. Batch reactors comprise an essential operation unit of laboratory pilot-plants scale, since they are suitable for small-scale operation, for testing new processes that have not been fully developed, for the manufacture of expensive products and for processes that are difficult to convert to continuous operations (Lima et al, 2014). According to Aziz and Mujtaba (2002), batch processes are particularly suitable for products such as pharmaceuticals, polymers, biotechnological or other fine chemicals products for which total requirement can be manufactured in a few days or a few batches in an existing plant. Nevertheless, the control of batch reactors is rather complex due to intrinsic dynamic nature of the system that either moves from one steady-state condition to others or never reaches a steady-state at all during the overall batch operation. Therefore, the physical and chemical properties of the compounds in the bulk, such as viscosity, heat transfer coefficient, heat capacity, and reaction rate vary, sometimes significantly, with time. Additionally, the dynamic of polymerization processes is highly complex. These systems have inherent strong nonlinearities and multivariable nature with significant interactions and constraints. Thus, both modelling and consequently control of batch

polymerization reactors is still a cumbersome and open issue for the community and a challenging task.

Although nonlinear classic modelling approaches have still been commonly used, new learning technologies in process engineering that allow better, simpler, and more accurate behaviour predictions have recently been introduced. However, according to Mehran (2008), for many chemical processes, building an accurate mathematical model is very difficult and time consuming and only the input-output data yielded from running the process are generally accessible for an estimation. The use of fuzzy systems is interesting from this perspective since they allow to develop a global nonlinear long-term prediction model using some pieces of information and composing a number of local linear sub-models which are straightforward, understandable, and responsible for respective sub-domains.

This paper describes the application of the fuzzy logic to model batch polymerization reactors. The proposed fuzzy methodology is quite effective to handle modelling and control issues typical of processes with nonlinear and time-varying behaviours and complex dynamics (such as the ones here considered). The selection of an appropriate model structure for a future design of advanced controllers is also broached. For dynamic analysis, each generated fuzzy output must be fed back to the fuzzy structure to calculate the current output through one or more time-delay units. The production processes of Poly(Lactic Acid) (PLA) and nylon-6 were adopted for performance evaluation of proposed method. The reactions were carried out in a laboratory pilot-plant scale. A rigorous phenomenological model is available for such a system. The mathematical model for the PLA process is solved using a Runge-Kutta type algorithm implemented in C++ programming language and, for the production of nylon-6, the equations system was implemented in Aspen Plus process simulator. Therefore, the two resulting computational programs were experimentally validated and they are considered as virtual plants for obtaining of identification dynamic data. Additionally, data sets from experimental measurements were used. Then, appropriate techniques for fuzzy models identification were used and the formulations were built in Fortran 90 and Matlab programming languages. Satisfactory results were achieved from the pilot-plant and this is confirming that the proposed method can be useful to obtain appropriate mathematical representations of complex modelling systems and it can be applied in several ways, as on the tracking of processes as well as on optimization techniques and advanced control.

2. Experimental campaign

Figure 1 provides the schematic diagram of the batch polymerization system used in this work. The jacketed stainless-steel reactor has a capacity of 15 L and it is equipped with a pitched-turbine stirrer for mixing the reactants. An inverter is adopted to maintain the stirring speed at 360 rpm. The reactor temperature may be controlled by manipulating the electrical power of the thermal oil heater (serpentine) and by manipulating the electrical power supplied to the six resistances that act on the water stream in the jacket. The collar type resistances connected in parallel to the tube of the jacket inflow can vary in the range of 0.0 – 581.0 W. A HP personal computer (s5520br) and a PLC are employed for data acquisition and polymer process control. A flow rate of 0.04 L/min of gaseous nitrogen (grade 5.0 Praxair-White Martins) is bubbled through the reacting

medium to keep oxygen out of the reactor. Samples of each polymeric mixture were taken time to time (30 to 30 minutes) to determine the respective properties.

3. Working equations and processes simulation

3.1. Synthesis of PLA

The polymerization mechanism that represents the reaction kinetics and a phenomenological mathematical model are obtained from Yu et al. (2011). In addition, based on the peculiar design of the laboratory pilot-plant scale, such rigorous model was adjusted. Each kinetic rate constant is computed by Arrhenius expression and the kinetic parameters were estimated using the *BzzMath* Library (Refinetti et al, 2014; Buzzi-Ferraris and Manenti, 2012). The mathematical model is solved by a Runge-Kutta type algorithm implemented in C++ programming language.

3.2. Synthesis of nylon-6

The polymerization kinetic and a model equations system have been already described in Seavey et al. (2003) and Arai et al. (1981). In addition, based on the particular design of the laboratory pilot-plant scale, the phenomenological model was adjusted and the Arrhenius expression is used to calculate each kinetic rate constant. The kinetic parameters have been obtained by Funai et al. (2012). Subsequently, the process was implemented in Aspen Plus simulator (by Aspen Technology).

These mathematical models are in good agreement with the behaviour of the laboratory pilot-plant and reused as virtual plants for the purposes of this work.

4. Fuzzy modelling

Fuzzy set theory was introduced by Zadeh (1965) and it is an extension of the classical crisp logic into a multivariate form. Fuzzy approaches have several advantages over crisp ones: the main one being that they have more flexible decision boundaries, and thus are characterized by their higher ability to adjust to a specific domain of application and more accurately reflect its particularities (Tsipouras et al., 2008). Such models are expressed by a set of linguistic fuzzy rules, which are derived from the experience of skilled operators, or by a set of fuzzy implications that locally represents the input–output relationship in the process.

The first point to be considered in the procedure of fuzzy modelling is the definition of the model structure that makes up the system rule base. The structure considered in this work was originally proposed by Takagi-Sugeno (1985). In this approach, fuzzy IF-THEN rules represent local input-output relations of a nonlinear system. Thus, a fuzzy model can be regarded as a collection of several linear models applied locally in the fuzzy regions defined by the rule premises where the overall model is represented as the interpolation of these linear models. According to Lima et al. (2010), it has a conveniently dynamic structure so that well-established linear systems theory can easily apply to the theoretical analysis and design of the overall closed-loop system. After, the identification data for the fuzzy models are generated. Thus, the training and test data set are obtained and the models parameters are evaluated.

Here, the formulation of the functional fuzzy models was realized in two steps: first, the techniques for fuzzy models identification were tested on Matlab platform; second, the appropriate methodologies were used to build a fuzzy modeling algorithm in Fortran 90 programming language. The resulting program was reached by using subtractive clustering and least-squares methods (Lima et al., 2010). The results of model validation are illustrated through figures and quantified as follows by average quadratic error:

$$Error = \sqrt{\frac{\sum_{k=1}^{m} (\bar{y}_k - y_k)^2}{m}} \tag{1}$$

where k = time, m = number of considered discrete instants, $\bar{y}_k$ = predicted output by the fuzzy model, and y_k = output of the process (from phenomenological model).

5. Results and discussion

For the PLA production, a total simulation time equal to 2 h and a sampling rate of 0.001 h were adopted. A data set with 2,000 points was used as for training as for validation of the fuzzy model. A Takagi-Sugeno fuzzy model was formulated for the real-time identification of the weight average molecular weight (*Mw*). The temperature of the water stream in the jacket (*Tj*) is used as manipulated variable. Three inputs are considered for the model: *Tj* at the *k*th sampling time, *Tj* at the (*k* - 1)th sampling time, and *Mw* at the (*k* - 1)th sampling time. Five rules were generated for the fuzzy model. Average quadratic errors lower than 1 % were obtained. The results of validation are illustrated in Figure 2, which shows a very good prediction for the output variable since fuzzy and phenomenological models are practically overlapped. In addition, the long-

range predictions are quite accurate and can be reliable to apply on a future development of optimal control policies.

In the synthesis of nylon-6, a total simulation of 6 h was considered. In this case, the simulation occurs in steady state (no dynamics in the simulation and only the final value is considered). A data set from 9 different operating conditions was used as for training as for validation of the fuzzy model. Thus, a Takagi-Sugeno fuzzy model was formulated for the steady identification of the number average molecular weight (*Mn*). Three control variables were adopted: the reactor temperature, the reactor pressure, and the initial mass of acetic acid, which is used as chain terminator. Two rules were generated for the fuzzy model. Average quadratic errors of about 9 % were obtained, indicating the need for more identification data. However, good results of validation were achieved and these are illustrated in Figure 3, which shows a very good prediction for the output variable as fuzzy and phenomenological data are very close.

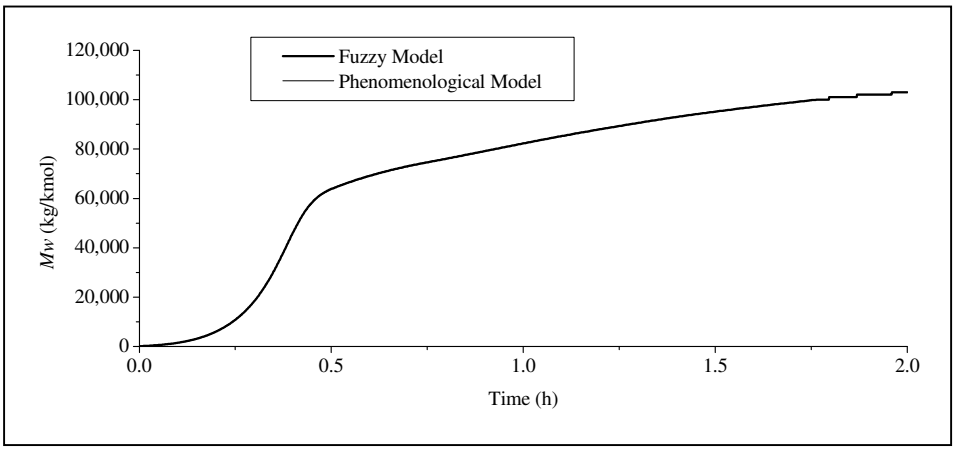

Figure 2. Validation of the fuzzy model for the PLA production.

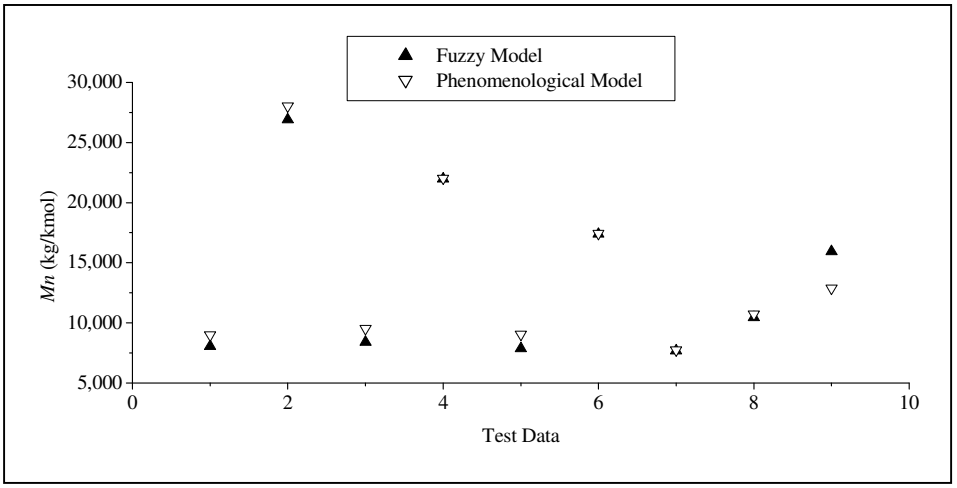

Figure 3. Validation of the fuzzy model for the synthesis of nylon-6.

6. Conclusions

Fuzzy models were developed in this work for two batch polymerization processes. The analysis of results has demonstrated that the Takagi-Sugeno fuzzy models represent the systems in a very satisfactory way for the respective average molecular weights. In fact, the use of functional fuzzy models is a good and promising alternative to model complex chemical reaction processes such as the polymerization systems. The main advantage of such a model approach is the use of an input/output data set together with qualitative information. As described, discontinuous polymerization reactors are usually tricky and they are represented by complicated differential equations, particularly hard to solve. On the other hand, a fuzzy model is simpler to construct, identify, and solve and, therefore, presents an efficient way to model a system for control and real-time optimization purposes, among others.

Abstract

Nowadays the actual task for science and industry development (aerospace, pharmaceutics, construction and etc.) is obtaining of new materials with desired properties. To obtain new materials it is necessary to carry out a lot of experiments and as a result, it demands much labor and energy costs. This work presents the mathematical model of cellular automata with variable cells size. The comparison of the developed mathematical model with the previous one has been done.

Keywords: mathematical modeling, cellular automata, modeling of dissolution

1. Introduction

During the search of new materials composition with a certain structure and certain physicochemical properties, the important task is to develop mathematical and computer models and their realization using high-performance parallel computing in order to significantly reduce the number of experimental researches. The modern generation of computers allows to carry out the mathematical modeling of various processes at different nano-, micro- and meso-levels. Mathematical and computer modeling allow to determine the search area for the developed compounds that could significantly accelerate the developing process and reduces its cost.
This paper presents the new mathematical model based on cellular automata with variable cells sizes.

2. Model of solid dissolution based on cellular automata

Currently there are several models describing the process of solid dissolution (J. Siepmann and F. Siepmann, 2013). The most widely used models are based on cellular automata (Laaksonen et al., 2009). At all previously known dissolution models based on cellular automata the cells had the fixed size that impose the certain restrictions on the model (Kimber et al., 2011). The proposed model for the solid dissolution based on cellular automata with variable cells sizes avoids the disadvantages of the previous ones.
The following assumptions have been accepted in the mathematical model:
1) the system is a set of cells;
2) the field has open borders; the substance is removed from the cells at the borders on each iteration;
3) each cell has three characteristics: the type of substance, the amount of substance (concentration) and aggregate state (solid, liquid);
4) the calculation is carried out iteratively (on each iteration dissolution and diffusion processes are occurred at the same time).
The model of dissolution is described by the Eq.(1):

$$\frac{dc}{dt} = D * F * (C_i - C_j) \quad (1)$$

where D is diffusion coefficient, F is surface of contact area while cells interaction, C_i, C_j are concentrations respectively in the i-th and j-th cells.

Next four figures present the possible states of the cells in the cellular automata. The initial state of the cell (relative to which it is considered by cellular automata) is shown on the left, the changed state of the cell is on the right.

In all cell «liquid – solid» pairs the border is shifted to direction of cell with solid, and it is accompanied by transfer of substance from solid to liquid state. It means that in cell with solid state the amount of substance is decreased, and in cells with liquid state the amount of dissolving substance is increased. The figure 1 presents a cell with solid surrounded by cells with liquid on four sides. Hence, the cell with «liquid-solid» borders is displaced with all sides and this cell is reduced in size.

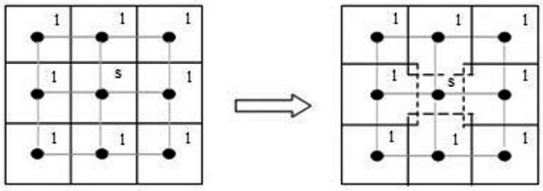

Fig.1. Cell with solid surrounded by cells with liquid

The figure 2 presents a cell with solid surrounded by three cells with liquid and one cell with solid, therefore, and only three sides of the «liquid-solid» cell border will be displaced.

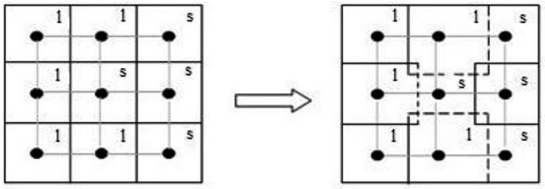

Fig.2. Cell with solid surrounded by three cells with liquid.

The figure 3 presents the cell with solid borders with two cells with liquid, so the shifting of the «liquid – solid» cell borders are only from two sides.

The figure 4 presents the case when the cell with solid has the left boundary with the cell with liquid, so the shifting of the «liquid – solid» cells borders are only between these cells.

While the calculation of dissolution the input data are linear size of the field - N cells and the maximum amount of each substance in the cell volume.

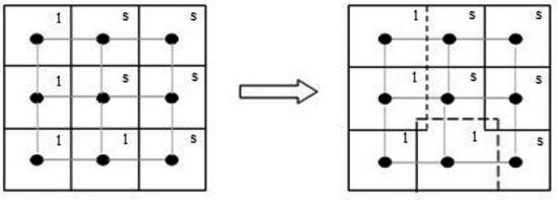

Fig.3. Cell with solid surrounded on two sides by cells with liquid

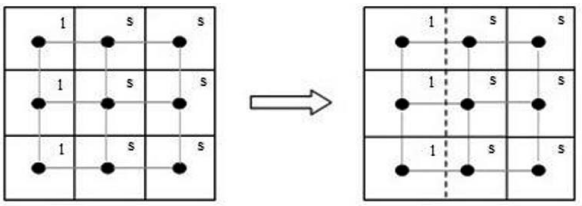

Fig.4. Cell with solid surrounded on one side by cells with liquid.

During dissolution the substance from cells with solid transfers to the cells with liquid, consequently, the substance amount in the cells is changed. On this basis one may assume that the distance between cells are changed too. In all pairs of the «liquid – solid» cells their boundaries are shifted toward cells with solid.
The values for all distances between the cells are stored in the linked matrix presented in the table 1.

Table 1. Linked matrix.

№ i-th cell	№ j-th cell	Distance i-j	Distance j-i
1	2	dl12	dl21
1	3	dl13	dl31
…	…	…	…

The symbols in the Table 1:
dl12 - distance from the cell 1 center to the border of cell 1 and cell 2;
dl21 - distance from the cell 2 center to the border of cell 1 and cell 2;
dl13 - distance from the cell 1center to the border of cell 1 and cell 3;
dl31 - distance from the cell 3 center to the border of cell 1 and cell 3.
The linked matrix contains the values of the distances between eight neighboring cells that allow to resize cells, or even to remove the cells (during substance transfer from solid to liquid state).
The figure 5 presents the interaction between two neighboring cells. In case a) it is seen the change of distance between the cells and the shifting of cell borders towards the cell with solid. In case b) there is a "shift of the center" when the substance from cell 2 transfers to cell 1, thus the volume of cell 2 is reduced (volume of cell 1 is increased respectively). The calculated distance dl2 becomes negative. In order to avoid this, the center of cell 2 is shifted and the distance dl2` becomes positive. If the "shift of the center" is not possible due to lack of substance in the cell, such cell is removed.

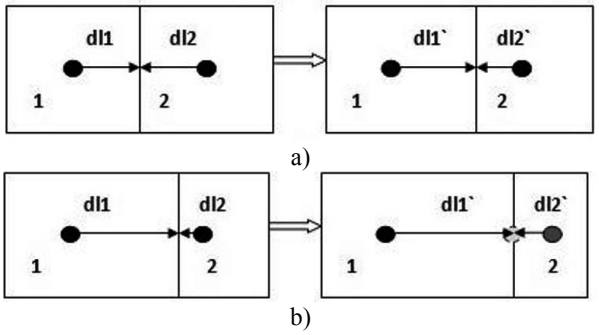

Fig. 5. Interaction of the neighboring cells: 1-liquid 2-solid;

a) change of distance between the cells during the dissolution;

b) "shift of the center".

The figure 6 presents the graphics of the density for the substance distribution from the selected iterations. As it is seen from the graphics in the iteration №1 the system has only two types of cells: the substance concentration is equal 0, and the maximum substance concentration (it is given in advance) is equal 255. In iteration №100 the number of cells with concentration 0 are decreased approximately by 4 times. On the graphics it is seen that while increasing of iterations, the cells concentration are gradually aligned.

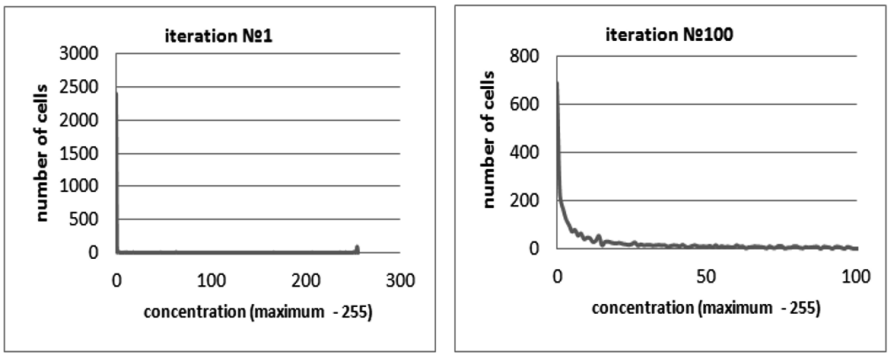

Fig.6. Graphics of the density of substance distribution

3. Discussion

The comparison of the proposed model by cellular automata presenting a set of cubic fields with linear size N cells with the solubility model developed before has been done (Ivanov et al., 2013).

The graphic illustration of the cellular automata is shown in figure 7.

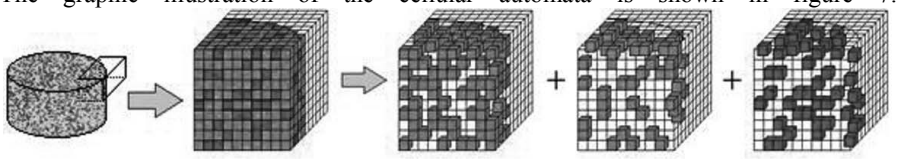

Fig.7. The graphic illustration of the cellular automata

Each iteration consists of three stages:

• calculation of dissolution (the transfer from solid to liquid state);
• calculation of diffusion (substance exchange in liquid state);
• calculation of substance transfer due to external factors.

During the calculation of dissolution the linear sizes of one cell and cellular automata fields are given as input data. The maximal possible amount of substance inside one cell depending on cell volume is determined.

After that, the substance amount corresponding to this substance-saturated solution is determined too for the one cell volume. Then the following assumption has been done: if the substance concentration in the cell is between the saturated solution concentration in one cell volume and possible maximal substance amount then the substance aggregate state is adopted as "solid". If the substance concentration is between zero and the saturated solution concentration in one cell volume, then the substance aggregate state is accepted as "liquid."

After input of initial data the iterative calculation process for substance dissolution takes place. The dissolution is calculated in all cells having the aggregate state "solid" to all neighboring cells and it is inversely to the concentration of the dissolved substances therein. The calculation of the substance amount transferred to the dissolved state is as

the following. The cell mass change where the substance is dissolved it can be calculated by the Eq.(2):

$$\frac{dM}{d\tau} = -kF(\mathrm{C}^* - \mathrm{C}) \tag{2}$$

where M is mass of solid, k is dissolution coefficient, F is dissolution surface, C^* is the saturated solution concentration, C is the current concentration in the solution. The expression for the dissolution coefficient (k) calculation in the stirred reactors has been obtained on the assumption that the decisive role in external mass transfer plays the destruction of the boundary layer by small-scale turbulent fluctuations:

$$k = e^{1/4} Sc^{-3/4} \tag{3}$$

$$e = \frac{N}{G} \tag{4}$$

$$Sc = \frac{\omega}{D} \tag{5}$$

e is the specific dissipation of mechanical energy; Sc is Schmidt criterion; N is power consumed for mixing; G - stirred volume mass.

New cell aggregate state is determined after the dissolution calculation in all possible cells that is based on new values of substance amount in the cells taking into account the rules mentioned above.

The diffusion calculation is based on Fick's equation. The substance diffusion coefficient in solution has been founded by molecular dynamics method using software NAMD, which allows to takes into account the interactions between the molecules of solvent and dissolved substance depending on the dissolution conditions.

Only cells having the aggregate state "liquid" are involved to diffusion calculation. For each cell with dissolved substance and its new neighbors new values of the cell substance amount are calculated based on previous ones.

The last part of the cellular automata iteration is the calculation of substance transfer due to the external factors impact.

The figure 8 shows the comparison of the calculated data on two computer models and the experimental researches.

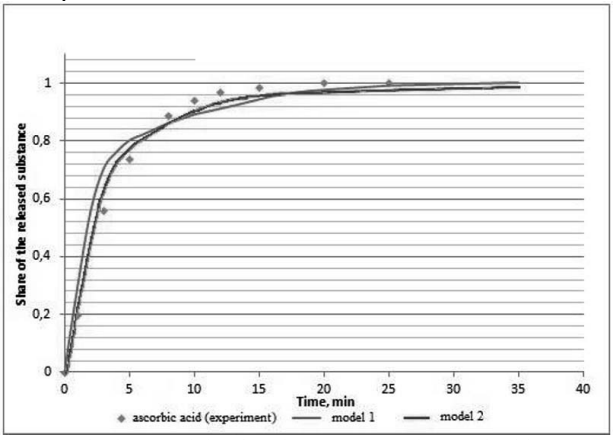

Fig.8. Calculation of the dissolution of ascorbic acid tablet. Comparison of the values calculated using the model with experimental data: model 1 - the cellular automata model for solubility made before; model 2 - the proposed model.

The comparison showed that the calculation accuracy for the proposed model is on 10-15% higher. This model based on cellular automata with variable cell size has several advantages:
• give the possibility of qualitative image of geometric shapes;
• the gradual reduction of the cells with solid reduces the number of the cellular automata elements that accelerate the calculating;
• allows to take into account the swelling process;
• give the possibility to calculate any body undergoing deformation as well as flexible body too.
The developed algorithm is enough resource-intensive in terms of time, but the removal of cells from solid during dissolution allows to accelerate the calculation process. However, the calculation productivity increasing is the priority task. Therefore, the apparent prospect is the use of parallel computing by means of CUDA technology.

4. Conclusions

In the future, it is planned to develop this mathematical model and to test it during the simulation of complex systems including a number of factors:
• substance dissolution;
• components swelling;
• solvent diffusion through the surface.
The study was supported by the Ministry of Education and Science of Russian Federation within the contract № 14.574.21.0111 «Creation of software and computer systems for the computer modeling of nanostructured sorbents based on organic and inorganic aerogels, including with embedded carbon nanotubes, and adsorption processes in its" 2014 .
In addition, during the model development in future it is planned to take into account the capturing film layer and polarization effects, in particular, the mutual influence of the soluble components.
In future the development of models based on cellular automata and their methodology will allow to transfer to more accurate and computing performance by using parallel computing. These mathematical and computer models can be used in such areas as pharmaceutics, agriculture, development of new materials and designs of its. The research is supported by the Ministry of Higher Education and Science within the framework of project component of the State Assignment №2.429.2014/K.

Abstract

In the Fluid Catalytic Cracking Units (FCCU) large hydrocarbon molecules are cracked into smaller molecules, generating high value products such as diesel, gasoline and useful petrochemical olefins. The control of these units is fundamental to maintain a satisfactory operation. Hence, the Real Time Optimization has proved an interesting strategy. A dynamic simulation of a FCCU was developed using a phenomenological industrial validated model. A Dynamic Neural Network (DNN) was trained with data from the FCCU model and gross and systematic errors were added to employ this system as a virtual plant. Data from this virtual plant were used to study strategies of online data processing, considering steady state identification (SSI) and gross error detection (GED), in order to eliminate measurement noise, as the initial steps into an RTO implementation.

Keywords: Fluid Catalytic Cracking Unit, Real Time Optimization, Data analysis, Virtual plant.

1. Introduction

The fluidized catalytic cracking unit (FCCU) is still a core operation in the modern fuel oriented refineries. In this unit, large hydrocarbon molecules are cracked into light high value products. Several studies have been performed on the modelling of a FCCU, such as the mechanistic model presented by Fernandes et al. (2005): a dynamic state model based on fundamental balance equations that include the riser, the stripper and the regenerator. Due to the satisfactory results, the mechanistic modelling has been extensively developed and reported.

Real Time Optimization is an operational strategy that tries to maintain the process close to the optimal operating conditions by means of adjusting a set point continuously. In that way, RTO requires measurements from the process to estimate its performance, an optimization procedure to estimate the optimal condition and a process control system to implement them. A special characteristic is that measurements from real plants are contaminated with errors; therefore, a denoising procedure is required.

In the present work, a dynamic simulation of a FCCU was developed using a phenomenological industrial validated model. A set of perturbations was applied to the model to obtain a large quantity of dynamic data. A parametric study of the input variables was developed in order to establish the most important ones for the system performance. Then, the selected variables were chosen as the inputs to design, train and test a Dynamic Neural Network (DNN) that will be considered as the virtual plant of

FCCU. Due to measurements in real systems are often corrupted with random noise, gross error and systematic errors; Gaussian error and gross error were added on simulated data from DNN. Finally, data from the virtual plant were employed to study strategies for the online data processing, considering steady state identification (SSI) and gross error detection (GED). For SSI, the wavelets method was the selected one, while for GED a strategy based on robust maximum likelihood estimator was employed. The advantage of using data from a virtual plant to study the strategies for online processing is that, due to real values are perfectly known, the performances of the strategies can be quantified without uncertainties. The developed virtual plant will be employed, in a next work, for studying Real Time Optimization (RTO) strategies.

2. Methodology

Considering that a DNN will be employed as the virtual plant of FCCU, a great quantity of data is necessary for training the network generated using a phenomenological industrial validated model. To define the input variables for the DNN a sensitivity analysis was developed and errors were added for simulating real plant data. The virtual plant data were employed to assess strategies for the data online processing.

2.1. FCCU base model and data generation

A dynamic simulation of the FCCU was developed using the industrial validated model proposed by Arbel et al. (1995). The FCCU model considers a quasi-steady state riser, a two phase regenerator and a stripper. In this model the dynamic behaviour is controlled by the residence time in the regenerator and it considers a detailed description of the cracking kinetics that occurs in the riser.

A set of modifications on the conditions was applied in the model for obtaining a large quantity of dynamic data that allows studying the system. These were systematically performed by using the control and disturbance variables, presented in the Table 1.

The oil composition bounds were in concordance with the range of stock compositions used in the model parameters in the fitting of the riser cracking kinetics, described by Arbel et al. (1995). For control variables a step type change was imposed. This is also true for the atmospheric and oil feed temperatures. The composition was changed by using a ramp type of blending between a pair of assays with a 0.05 blend fraction per minute.

Table 1. Control and disturbance variables for the FCCU dynamic model.

Variable name	Variable type	Lower bound	Upper Bound
Oil feed flow rate (kg/s), F_{of}	Control	29.7	89.1
Steam flow rate to the stripper (kg/s), F_{ss}	Control	1.6	4.8
Catalyst circulation rate (kg/s), F_{cat}	Control	178.3	534.8
Air flow rate to regenerator (kmol/s), F_{air}	Control	23.8	118.8
Atmospheric temperature (K), T_{atm}	Disturbance	302.2	330.2
Oil feed temperature (K), T_{feed}	Disturbance	338.6	505.2
Weight fraction of lumps in the oil feed (wt %)			
1) Heavy paraffins, Ph		2.45	14.79
2) Heavy naphtenes, Nh		4.05	19.61
3) Heavy aromatics substitution groups, Ah		1.74	12.83
4) Heavy carbons among aromatic rings, Rh	Disturbance	1.60	6.70
5) Light paraffins, Pl		6.15	37.11
6) Light naphtenes, Nl		10.15	49.19
7) Light aromatics substitution groups, Al		4.36	32.18
8) Light carbons among aromatic rings, Rl		4.00	16.80

2.2. Sensitivity Analysis

A sensitivity study on the input variables was developed for the FCCU in order to define the most important ones in the system performance. These variables were the input to design, train and test the Dynamic Neural Network (DNN). The analysis was performed by using the control and disturbances variables defined in the Table 1, keeping them within the upper and lower bounds of the analysis spectra.

The methodology of global sensitivity approach presented by Sobol (2001) was used to identify and calculate the effect of the coupled parameters in the performance of the gasoline yield (G), riser outlet temperature (T_{ris}), dense phase regenerator temperature (T_{rgn}) and CO/CO2 ratio.

2.3. Development of the Dynamic Neural Network (DNN)

The neural network was developed implementing the nonlinear autoregressive network with an exogenous inputs model (NARX), using the Levenberg-Marquadt training algorithm. A schematic representation of the DNN model is presented in the Figure 1 where, the inputs are consistent with the classification presented in the Table 1, and the outputs are the required measurements for RTO processing and assessing.

2.4. Error Addition

For simulating the behaviour of a real FCCU Gaussian error was added to outputs from Neural Networks with a Signal Noise Ratio of 40 (SNR=40). This ratio characterizes the detection quality of the signal of a measurement system. It compares the level of a desired signal to the level of background noise. Furthermore, a set of 20% of the overall output signal data was contaminated with randomly gross error at a magnitude from 0 to 5 % of the maxima values.

2.5. Wavelets de-noising

For denoising the output signals, the Short Time Fourier Transform (STFT) and Wavelets strategies were tested. Other strategies as the linear filter were discarded because their application is only in stationary signals. In the wavelet method, the signal is decomposed into low and high frequency components. The denoising was developed following the soft thresholding methodology that requires three steps which are decomposition of the signal, thresholding and reconstruction of the signal. The first one was carried out through wavelet transform, the second one by the universal thresholding or "sqtwolog" method proposed by Donoho (1995). The inverse wavelet transform and the retained coefficients were used for reconstructing the signal. Thresholding values are very important because they determine how much noise is removed from the signal. If the noise amount quantity is very small, some important features from the signal can be lost, and if it is very large, the noise will not be removed properly.

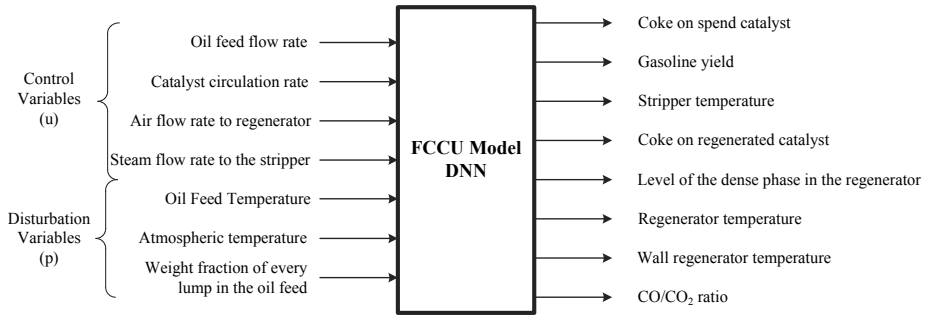

Figure 1. Input and output variables for the DNN model of the FCCU.

2.6. Steady state detection and gross error elimination

Steady State Detection (SSD) was carried out using the wavelet method proposed by Jiang (2003). The changes of an output signal of the system can be represented by means of the first order wavelet Wf(t). Then, when Wf(t)=0 the system is at steady state, but the zero crossing points through second order wavelet (WWf(t)), as proposed by Donoho(1995), are necessary to be considered.

Steady state is detected from the first and second wavelet transform with a steady state index β which is restricted between 0 and 1. β=0 indicates that an unsteady state is identified and β=1indicates that steady state is achieved. Jiang (2003) describes different conditions and restrictions associated to work out β value.

Gross error detection was done by minimizing the generalized maximum likelihood objective function with Hampel's redescending M-estimator which is a robust objective function that reduces the weight of data with higher difference against the estimation (Özyurt and Pike, 2004).

2.7. Methods efficiency estimation

For quantifying the ability of gross error detection into the steady state (SS) intervals, 24 SS (8000 data each) were evaluated. The criteria used for the evaluation were the ones reported by Özyurt Pike (2004) where, Overall Power (OP), Average number of Type I errors (AVTI) and Median Total Error Reductions (Mean TER) were employed. OP estimates the number of gross error correctly identified; while, AVTI measures the wrong gross error detection.

3. Results and discussion

The variables used as targets in this work are related to the main performance of the FCCU, such as the gasoline yield (G), riser outlet temperature (T_{ris}), dense phase regenerator temperature (T_{rgn}) and CO/CO2 ratio. The sensitivity analysis performed on the FCCU indicates that the control variables defined in the Table 1 have a high response factor for the targets, as shown in Table 2.

The global sensitivity indexes show that the rates of feed oil flow (F_{of}), catalyst circulation (F_{cat}) and air flow (F_{air}) have the highest sensitivities in relation to the targets. These values can be associated with high performance in the controllability since their changes will generate important gains.

Table 2. Global sensitivity indexes for the Input variable-target of the FCCU

Input Variable	Target			
	G	T_{ris}	T_{rgn}	CO/CO_2 ratio
F_{of}	0.859	0.740	0.414	0.385
F_{ss}	0.316	0.230	0.121	0.114
F_{cat}	0.810	0.690	0.510	0.501
F_{air}	0.780	0.124	0.890	0.910
T_{atm}	0.213	0.280	0.316	0.284
T_{feed}	0.529	0.750	0.521	0.312
Ph	0.560	0.310	0.425	0.389
Nh	0.682	0.412	0.589	0.403
Ah	0.520	0.254	0.412	0.321
Rh	0.280	0.678	0.789	0.704
Pl	0.551	0.241	0.469	0.341
Nl	0.740	0.128	0.236	0.209
Al	0.210	0.651	0.783	0.635
Rl	0.810	0.103	0.214	0.142

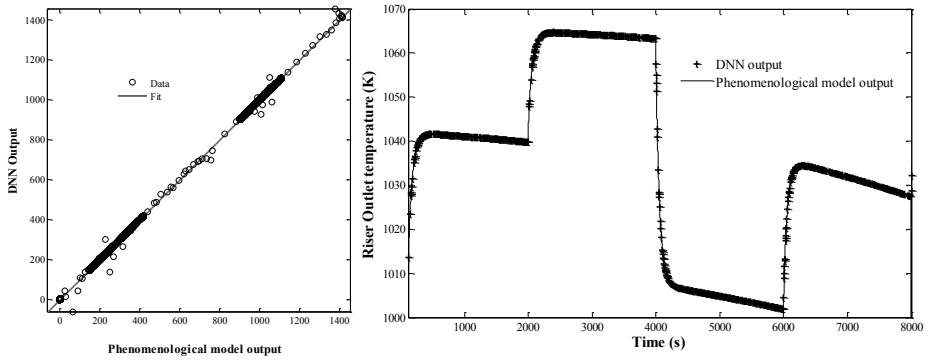

Figure 2. Regression and performance plots for the DNN

The DNN was developed using the NARX model, obtaining a network with 1 hidden layer, 17 hidden neurons, 14 input neurons and 8 output neurons. The performance of the DNN to correlate the behaviour of the phenomenological model is presented in the regression plots, Figure 2. The correlation coefficients (R^2 = 0.999 for the combination of all system outputs) and the visual comparison between DNN predictions and profiles from phenomenological model allows to affirm that the DNN achieves a good prediction of the FCCU behaviour.

For denoising and steady state identification wavelets generated satisfactory results and, based on their performance, it was selected. The DNN values are employed as the true value and the wavelets outputs will feed the next RTO steps. The comparison between them indicates that an efficient elimination of Gaussian error, still in presence of gross error, is attained when choosing the mother wavelet properly, Figure 3. In this case the most accurate wavelet family was Daubechies.

The indexes OP, AVTI and Mean TER are presented in Table 3. Mean TER value indicates that is possible to reach up to 69.8% total error reduction from a variable, and Figure 3 shows that the wavelets method proposed by Jiang (2003) is efficient for steady state detection. Due to slowly variations in signals, detection of SS based only on composition profiles, results non-presented in this work show an important quantity of type II error generating wrong steady state detections. The effect of error can be reduced by adjusting the λ_2 parameter defined by Jiang (2003).

Table 3. Parameters for gross error detection assess.

Parameter	Variable							
	C_{sc}	G	T_{sc}	C_{rgc}	L_{rgn}	T_{rgn}	T_{wall}	CO/CO_2 ratio
OP	0.847	0.856	0.721	0.845	0.789	0.701	0.711	0.804
AVTI	6.541	7.251	1.253	5.142	2.351	0.986	1.254	5.896
Mean TER	0.548	0.458	0.689	0.578	0.683	0.549	0.698	0.423

4. Conclusions

Considering that the fitted prediction of the steady states, trasient periods, and a minumium delay on calculations are fundamental characteristics for online analysis, the DNN trained with data from a validated phenomenological model is a good option to built a virtual plant for the RTO studies.

The denoising and steady state detection using the wavelets method were efficiently developed. Although the presence of type II error in signals with large time characteristic constant (τ)".

A Hybrid Discrete/Continuous Dynamic Model of Trayed Tower Hydraulics

David Pinilla-García and Santos Galán

Universidad Politécnica de Madrid, Department of Chemical Engineering (ETSII).
C/José Gutiérrez Abascal, 2. 28006 Madrid, Spain
santos.galan@upm.es

Abstract

A hydraulic model for trayed towers is presented that can reproduce the detailed behavior of the column in a wide range of operating conditions, including abnormal situations, while being simple, compact and flexible. As a subset of a complete one incorporating energy and material balances, it is designed to be implemented in modern dynamic simulation platforms using hybrid discrete/continuous formalisms.

Keywords: modeling, hybrid, dynamic, distillation, column, tray, hydraulics

1. Introduction

Modeling always implies a compromise between complexity and required detail. In distillation towers, hydraulics determines most of the important dynamic characteristics. Commercial dynamic simulators usually include tray and column modules conceived for the quite limited region of normal operation conditions, that can deal with regulatory control but, as Luyben (2012) points out, are inadequate for safety-related applications. Some cases in safety analysis as well as startup/shutdown simulation can be represented by the so-called high-fidelity models, such as those used in Operator Training Systems (OTS). A third class of models would be those that can reproduce abnormal situations for post-mortem and safety analysis, usually made on an *ad hoc* basis as in the BP Texas City refinery accident (Mogford, 2005). Computational fluid dynamics (CFD) models can go one step beyond, but they are still impractical (though possibly not for long). Increasing model complexity is paralleled by a lack of publicly available descriptions.

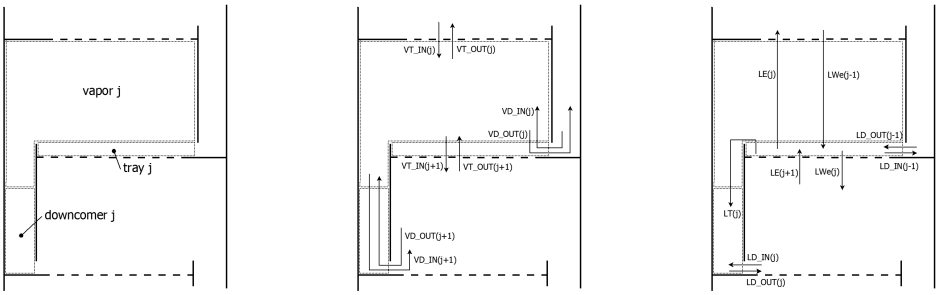
The main reference for high fidelity models is a not-so-recent paper by Gani et al. (1986). The model presented is compact and flexible, allowing the simulation of different types of towers and situations, including startup. It considers separate tray and downcomer dynamics, but it disregards vapor phase dynamics. Although it does consider some abnormal phenomena such as downcomer vapor blowing, it neglects others like downcomer liquid reverse flow. The paper also pays attention to the numerical solution, a key issue usually disregarded. More recent publications provide simpler hydraulic approaches. Some do not consider separate tray and downcomer holdups (and the important phenomena that derive from them) (Staak et al., 2011), others disregard vapor phase dynamics (Mahdipoor, 2006; Mahdipoor et al., 2007) and most neglect both (Cab et al., 2002; Chang et al., 1998). Taylor (2007) provides a comprehensive review of distillation modeling, focusing almost entirely on the development of rate-based models and, surprisingly, not discussing tray dynamics. Wittgens and Skögestad (2000) stress the importance (and the lack) of realistic and accurate hydraulic models, which have been pointed out by Kister (1997) as one of the main culprits for the increase in primary design malfunctions. The building and simulation of a compact first-principles hydraulic model that can handle abnormal situations is the aim of the present work.

2. Hydraulic model

The tower model is defined as a modular structure made of a succession of generic and special stages. The latter encompass feed and extraction trays and overhead and bottom sections and are modeled as variations of the generic stage. The former refers to the rest of conventional trays. Index j refers to the stage number for generic stages, counting from the top. Index T refers to the top stage and B to the bottom. This modular structure results in a highly flexible model that can easily reproduce different tower configurations with special features such as side strippers or pumparound refluxes.

Each stage is divided into three compartments: liquid in the tray, liquid in the descending downcomer and vapor (figure 1a). They account for the mass holdups and act as control volumes for the material balances. They are defined by the clear liquid heights, and some of them may even disappear if certain conditions are met. The model is built for generic one pass sieve trays with straight downcomer aprons. Complete mixing for both liquid and vapor phases and froth regime are assumed. Downcomer foaming, hydraulic gradient phenomena and mass-transfer derived fluxes (between different phases) are not considered.

Pressure difference across compartments drive the material fluxes. Most of the hydraulic correlations have been chosen following the recommendations of Kister (1992) and Perry and Green (2008). Other factors such as range of application and ease of implementation have also been taken into consideration. Feed and extraction stages are identical to a generic stage with the addition of the input or output streams to the corresponding mass balances. Overhead stage is similar to a generic stage. It consists of a generic tray and downcomer plus a larger vapor volume, the overhead vapor output and a liquid input, which is fed directly to the tray. Liquid entrained with the exiting vapor is not considered. Bottom stage consists of the bottom liquid and vapor holdups plus the liquid holdup on the last stage downcomer seal, the bottoms liquid output and a vapor input. It is assumed that no weeping falls into the downcomer seal. Liquid entrainment to the last stage is disregarded. Bottom liquid holdup is modeled assuming a flat bottoms geometry (measuring from the tangent line). Liquid flux to it from the downcomer seal is modeled through the standard weir correlation. Streams entering and exiting the tower depend on the characteristics of auxiliary equipment, and are thereby considered to be known variables. This hydraulic model is actually a subset of a more complete one where energy and material balances are incorporated under equilibrium or rated-based schemes.



(a) Stage compartments (b) Vapor fluxes (c) Liquid fluxes

Figure 1: Generic stage material fluxes

2.1. Vapor and liquid fluxes

The vapor streams considered are shown in figure 1b. They are defined as positive variables. Although the mass balance could be done allowing negative values, this would complicate the

addition of component and energy balances. V_D is the vapor blown through the downcomers when they are not sealed. The downcomer is considered to be sealed whenever downcomer or tray liquid height exceeds apron clearance: $\max\{h_{D,j}, h_{L,j+1}\} \geq H_a$. It is modeled using Kister's correlation 1979, including the change in space under the apron due to the presence of liquid. If the pressure difference is inverted, it can change direction and go from the downcomer to the tray. As an example, the resulting set of equations are provided below:

$$V_{D,j} = \begin{cases} 0 & \text{if } \max\{h_{L,j}, h_{D,j-1}\} \geq H_a \\ |P_j - P_{j-1}| = \frac{0.4977}{\rho_{V,j}} \left[\frac{V_{D,j}}{A_{dc}}\right]^2 \left[0.7 \frac{A_{dc}}{l_w(H_a - MAX\{h_{L,j}, h_{D,j-1}\}(j))} + 1.2\right] & \text{else} \end{cases} \quad (1)$$

$$V_{D_{OUT},j} = \begin{cases} V_{D,j} & \text{if } P_j >= P_{j-1} \\ 0 & \text{else} \end{cases} \quad (2)$$

$$V_{D_{IN},j} = \begin{cases} 0 & \text{if } P_j >= P_{j-1} \\ V_{D,j} & \text{else} \end{cases} \quad (3)$$

V_T, equal to the vapor load in regular operation conditions, is derived from the standard variation on the orifice equation for sieve trays. If pressure is higher on the tray above and there is no liquid in it, this vapor flux will go downwards. The mass balance is expressed as follows:

$$\frac{dM_{V,j}}{dt} = V_{T_{IN},j} + V_{T_{OUT},j+1} + V_{D_{IN},j} + V_{D_{OUT},j+1} - V_{T_{OUT},j} - V_{T_{IN},j+1} - V_{D_{OUT},j} - V_{D_{IN},j+1} \quad (4)$$

The liquid streams considered are shown in figure 1c. Liquid flow over the downcomer weir (L_T) follows the correlation of Bennett et al. (1997). Stream L_D is derived from the conventional correlation for head loss under the downcomer apron. It has been modified for the cases in which there is no liquid seal, according to the criteria explained above for stream V_D. This flow can either enter or leave the downcomer compartment, depending on the sign of the pressure difference. Weep rate is modeled through the Hsieh and McNulty (1993) correlation. Although it specifies that clear liquid height should be calculated according to Colwell's method, Bennett's has been used instead. Entrainment is generally negligible in the froth regime. However, L_E has been modeled using the Bennett et al. (1997) correlation. Separate mass balances are derived for the tray and the downcomer:

$$\frac{dM_{LT,j}}{dt} = L_{D_{OUT}j-1} + L_{We,j-1} + L_{E,j+1} - L_{D_{IN},j-1} - L_{E,j} - L_{T,j} - L_{We,j} \quad (5)$$

$$\frac{dM_{LD,j}}{dt} = L_{D_{IN},j} + L_{T,j} - L_{D_{OUT},j} \quad (6)$$

3. Simulation

The model presented above has been implemented and solved using Jacobian (RES Group, Inc.) simulation software, but it can be easily translated to other popular platforms such as gPROMS or Aspen Custom Modeler. Issues that arose during simulations (numerical singularities) called for modifications to be introduced in the implementation of the model equations. As an example, the code for flux V_D is provided below:

```
IF (P-P_s) >=1 THEN
        dP=SQRT(P-P_s);
ELSE
        IF (P-P_s) >=-1 THEN
                dP=(P-P_s);
        ELSE
                dP=-SQRT(P_s-P);
        END
END
```

```
K_VD^2=lw*ABS((Ha-MAX(h_L, h_D_s)))/(0.7*Adc+1.2*lw*ABS((Ha-MAX(h_L, h_D_s))));
IF h_L<Ha AND h_D_s<Ha THEN
    CASE traydown_head OF
        WHEN ZERO :
            trdow_head=0;
            VD_S_OUT=0;
            VD_S_IN=0;
            SWITCH TO NEGATIVE IF (P-P_s)<0;
            SWITCH TO POSITIVE IF (P-P_s)>0;
        WHEN POSITIVE :
            trdow_head=1;
            VD_S_OUT=Adc*dP*ABS(K_VD)*SQRT(rhoV/0.4977);
            VD_S_IN=0;
            SWITCH TO NEGATIVE IF (P-P_s)<0;
        WHEN NEGATIVE :
            trdow_head=-1;
            VD_S_OUT=0;
            VD_S_IN=-Adc*dP*ABS(K_VD)*SQRT(rhoV*K_VD/0.4977);
            SWITCH TO POSITIVE IF (P-P_s)>0;
        END #CASE
ELSE
        trdow_head=0;
        VD_S_OUT=0;
        VD_S_IN=0;
END #IF
```

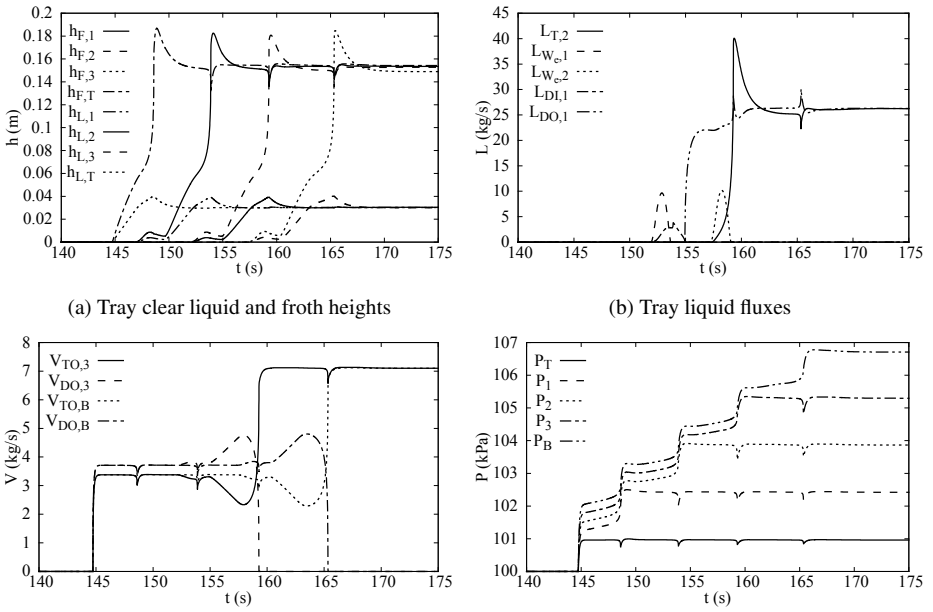
This flux is modeled using the square root of a pressure difference. This is problematic because it results in a numerical singularity when the radicand turns zero. Although this can be avoided explicitly, Newton iterations around this point still result problematic if the square root is maintained due to the change in the system of equations and the discontinuities in the derivative. The adopted solution, consisting in linearizing the flux for small absolute values of the pressure difference (1 Pa), has provided satisfactory results. The head loss constant, K_{VD}, is calculated in a separate equation to simplify its solving. Similar modifications have been introduced for all other equations. Linearization has been done for fluxes L_D, V_T, V_D and overhead vapor product. Reverse V_T flow is set to zero if clear liquid height is higher than 3 mm. Weep and entrainment rates are set to zero for tray liquid heights lower than 0.1 and 0.01 mm respectively.

4. Example: startup of a stripping tower

The following example reproduces tray behavior during the startup procedure, focusing on tray and downcomer sealing. Physical properties are those of the air/water system and vapor phase PVT relationships follow the ideal gas model. A constant temperature profile has been assumed. The tower has 4 trays with 21 in spacing and is 6 ft diameter. It has 0.5 in holes, 13.4% downcomer area, 10% hole/active area ratio, 2 in weir height and 1.5 in apron clearance. The simulated startup procedure is as follows: The tower is initially empty of liquid and with a constant pressure profile. Liquid is introduced in the overhead tray at a constant rate. Bottom Liquid output is set to zero until bottom liquid level reaches a height of 0.8 m. When liquid level reaches 1 m vapor is introduced into the bottom stage at a constant rate.

The following results have been obtained for the tower operating at 1 bar with a liquid rate of 25 kg/s and a vapor rate of 7.1 kg/s, which results in a flooding factor of about 0.84 (calculated using the Lygeros and Magoulas correlation). Figure 2a shows clear liquid (h_L) and froth (h_F) heights in trays. Opposite to what can be expected, rise to their steady state is not uniform, comprising an initial decrease and a strong overshoot. References to this have not been found in the published literature. When vapor is introduced the trays become completely sealed (figure 2b). The seal is temporarily lost later on (t=153s) and a ”pulse” of liquid weeps from above, starting to fill the tray. At this point liquid begins to flow from the tray to the downcomer of the stage above. This continues after the weeping has stopped, accounting for the small decrease in h_L. Shortly afterwards liquid flow under the downcomer acquires it’s normal sense and the tray steadily fills with liquid. When the froth reaches the outlet weir, liquid starts to fall into the downcomer. At the

same time a "pulse" of liquid weeps to the tray below.



(a) Tray clear liquid and froth heights

(b) Tray liquid fluxes

(c) Vapor fluxes exiting the two bottom stages

(d) Stage pressure

Figure 2: Tray behavior during startup (f=0.84)

Flow under the downcomer V_D (figure 2c) is initially higher than flow through perforations V_T. This difference increases initially as V_T decreases due to liquid beginning to accumulate on the tray above. This temporary decrease accounts for the weeping "pulses". As the liquid level on the tray increases the downcomer seals, causing a rapid fall in V_D until it reaches zero (and the seal is achieved) and an opposite increase in V_T towards it's steady-state value. As the downcomer seals pressure builds up in the stage and in those below (figure 2d). Pressure in the stages above initially decreases due to the decrease in V_D but it subsequently increases. This accounts for the observed anomalous peaks.

Even when a formal experimental validation with an industrial partner is still lacking, the model reproduces the expected behavior of a trayed column. Compared with the results presented in Gani et al. (1986) a reasonable agreement is observed. As an example, in figures 3a and 3b vapor through downcomers and liquid over weirs at startup are shown for both models. It can be seen that, for similar shapes of the trajectories, a more complex behavior is obtained in the proposed model due to the sealing pulses and other effects caused by the inclusion of vapor dynamics. This concordance is not surprising since, to some extent, the proposed model can be considered an upgrade for modern hybrid discrete/continuous dynamic simulators of Gani's model. At lower vapor rates an unexpected phenomenon is predicted by the new model. When the liquid rate is kept the same (25 kg/s) but the vapor rate is lowered to 6.4 kg/s (flooding factor of 0.77), vapor rate is not high enough for the bottom stage froth to reach the weir height and L_T flux never appears. Weeping from the bottom tray does not fall into the bottom downcomer seal pan, so V_D never decreases and V_T does not get high enough. Consequently, it appears that the last downcomer remains unsealed while the last tray remains in a situation of excessive weeping. Although it has not been explicitly reported in the literature and has to be confirmed experimentally, this situation

could be one of the common startup sealing problems mentioned by Kister (1990).

Figure 3: Results from Gani et al. (1986) (left) and the proposed model (right) at startup

5. Conclusions

A compact and simple hydraulic model that is able to represent abnormal operating conditions in trayed towers has been built and tested. Based in common correlations, key issues for performance are the appropriate definition of the flows and the adequate treatment of numerical singularities.

Abstract

Crystallization phenomena in stirred reactors are influenced by local hydrodynamic conditions and these must be taken into account for successful process scale-up and optimization. In this work, the available state of the art grid-based CFD methods and advantages and disadvantages of their application to mathematical modelling of batch crystallization processes were analyzed. The benefits of the Langrangian meshfree methods were discussed and the Smoothed Particle Hydrodynamics method proposed as an efficient method for a rapid prediction of the global mean flow in stirred reactors. Various aspects of the simulation results were assessed: quality of the fluid prediction, computational requirements, existence of numerical problems and availability of crystal size distribution. The developed Smoothed Particle Hydrodynamics CFD model was successfully coupled with discretised population balance equations to model a cooling batch crystallization process. It has been shown that 200 additional transport equations resulting from the discretisation of the population balance leads to only 50% decrease in computational performance while the same problem is still almost intractable from the computational point of view using the grid-based CFD methods.

Keywords: Crystallization, CFD, SPH, Population Balance.

1. Introduction

The population balance (PB) framework has been adopted as the most fundamental approach for modelling particulate multiphase systems (Ramkrishna, 2000). The population balance modelling framework provides a deterministic description of the dynamic evolution of the crystal size distribution (CSD) by forming a balance to calculate the number of crystals in the crystalliser. In order to take into account local hydrodynamics conditions in a stirred reactor a common approach is to couple the population balance equations with turbulent computational fluid dynamics (CFD) modelling to predict the key process performance indicators such as CSD, yield, recovery and reactor productivity (Barett et al., 2011). Although use of CFD for simulating particulate systems is becoming a standard approach, a number of issues still need to be addressed. One major problem is the computational expense of coupling a standard discretised population balance with a grid-based CFD code, as this approach requires a solution of an intractably large number of transport equations. Another, more feasible approach is to use a method of moments (Ramkrishna, 2000). However, even the methods of moments coupled with CFD do not provide a computationally efficient approach for scale-up and optimization due to a large difference in time resolution: a

time frame of a typical crystallisation process is several hours compared to a time step necessary to achieve reasonable accuracy of only few microseconds. CFD simulations cause the major problems requiring almost one day of simulation time for one second of real process on a standard desktop PC (Ali et al., 2015). The other common problem encountered with the method of moments is that the CSD is lost and needs to be reconstructed from its distribution moments. Several reconstruction techniques were developed, however, no unified technique for reconstruction of a complete distribution from a finite number of moments is available (John et al., 2007). There is also a number of problems that need to be addressed from the numerical perspective. So far CFD models of industrial crystallizers were exclusively implemented in Eulerian reference frame using grid-based methods (Rane et al., 2014). Those methods suffer from many problems: convective transport should be simulated and can influence the integration time step and cause numerical problems (LeVeque, 2002), cumbersome numerical mapping is required to handle complex geometries, determination of free or moving boundaries and material interfaces is rather difficult and causes various numerical problems (Hartmann et al., 2004), the computational requirements poorly scale with the size of the system and the numerical methods required to solve large systems of equations are typically not capable to fully take advantage of the modern parallelisation hardware and software systems. As a consequence, optimisation studies are computationally very expensive and, at the moment, not feasible in most cases.

2. Lagrangian meshfree methods

In this work the above-mentioned issues were addressed using the Lagrangian frame meshfree Smoothed Particle Hydrodynamics (SPH) method (Lucy 1977, Gingold and Monaghan 1977). The key idea of the meshfree methods is to provide accurate and stable numerical solutions for systems of partial differential equations with a set of arbitrarily distributed nodes (or particles) without using any mesh that provides the connectivity of these nodes or particles. SPH method offers a number of attractive features. The first is that pure advection is treated exactly. The advection term disappears from the Navier-Stokes equations and velocity partial derivative becomes an ordinary time derivative allowing the momentum dominated flows to be easily handled. For example, if the particles are given a colour, and the velocity is specified, the transport of colour by the particle system is exact (Liu and Liu 2003). The mass continuity equation is not necessary anymore since the mass balance is explicitly enforced using particles of a specified mass. Linear and angular momentum are explicitly conserved using the specially derived expressions for forces acting on particles (such as pressure, shear stress and surface tension). Population balance equations can now be applied to a smaller control volume (that is at a particle level) making the CSD available explicitly without reconstruction. Representation of multi-phase systems, free and moving surfaces is easy and not bound to the prescribed spatial grid like in grid-based methods. The fact that a fluid and crystals are represented by particles can be utilised to explicitly model phenomena relating to the solid phase such as secondary nucleation and breakage. Here, the local hydrodynamic conditions, particle size and velocity, and an angle of impact can be directly used to estimate the rate of secondary nucleation, with a direct linkage to experimental particle-wall collision measurements using the shadow imaging technique. The computational power required to integrate equations in time scales linearly with the size of the system (that is with the number of particles). Integration in time is typically performed using the explicit methods avoiding numerical problems common in grid-based methods. Grid-based

numerical methods such as finite element or finite volume methods always require a solution of a large system of (non)linear equations which is not relevant in SPH. Moreover, the use of weighted contributions rather than a linear system of equations allows for massive parallelisation, taking advantage of recent developments in CUDA GPU technology to significantly reduce simulation times. In a typical crystallisation model, the Navier-Stokes equations are coupled with a number of scalar transport equations such as temperature, concentration and the population balance equations (either moment equations or discretised number density function). In grid-based methods the additional transport equations lead to a significant increase in size of the numerical system and matrix storage while in SPH only to a marginal increase in memory and computational requirements. Large numerical systems typically solved on symmetric multiprocessor systems or computer clusters require some sort of communication and synchronization mechanisms. The only synchronisation technique used in SPH is primitive atomic operations used during calculation of forces between a pair of particles. Particle based SPH also offers much higher model reduction capabilities making lengthy optimization studies computationally feasible. Basically, the number of particles used to describe a system can be decreased having the superposition effect on execution speed: use of larger particles decrease the total number of particles and larger particles are allowed to move a larger distance in space during every time step, both effects causing the simulation speed-up.

3. Smoothed Particle Hydrodynamics

The essential formulation of SPH is that any field quantity can be determined through a weighted interpolation of surrounding field values (Gingold and Monaghan, 1977). This weighting is characterized by the smoothing length, h, it decays with distance and it is given by the following integral equation:

$$A(\mathbf{r}) = \int_{\Omega} A(\mathbf{r}')W(\mathbf{r}-\mathbf{r}', h)d\mathbf{r}' \tag{1}$$

where $A(r)$ is a field function at point r in space Ω, r is any point in Ω, and W is a smoothing kernel with h as its width. The numerical equivalent to Eq. 1 is obtained by approximating the integral interpolant by a summation interpolant:

$$A(\mathbf{r}) = \sum_j A_j \frac{m_j}{\rho_j} W(\mathbf{r}-\mathbf{r}_j, h) \tag{2}$$

where m_j is the mass of the particle j, r_j the position and A_j is the value of any quantity A at r_j. Basically, this equation states that any quantity can be represented by summation of quantities at nearby points multiplied by a weighting function, also known as a smoothing kernel. The gradient and the Laplacian of field functions can be obtained in a similar fashion (Lucy, 1977).

3.1. Navier-Stokes equations

The basic physical quantities of an isothermal, viscous fluid are velocity u, mass-density ρ, and pressure p and they are considered as continuous fields in the fluid. The classical formulation of the motion for incompressible fluid flow over time t is governed by the Navier-Stokes equations coupled with the mass continuity equation:

$$\rho\left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}\right) = -\nabla p + \mu\nabla\cdot(\nabla\mathbf{u}) + \rho g + \mathbf{f}$$
$$\nabla\cdot\mathbf{u} = 0 \tag{3}$$

where μ is the viscosity of the fluid and f is the sum of internal and external force-densities acting on the fluid such as buoyancy, surface tension and collisions with rigid bodies. In the Lagrangian formulation, particles completely define a fluid which implies that the particles move with the fluid. Compared to the Eulerian view this means that any field quantity now depends on time only. The particles carry mass, position and velocity, and will hold smoothed quantity approximations obtained from SPH. Thus, acceleration for the Lagrangian fluid particle becomes an ordinary time derivative of its velocity and the advection term in Eq. 3 disappears. Since the mass balance is explicitly enforced using particles of the specified mass the continuity equation is not necessary anymore. The basic Lagrangian formulation of the Navier-Stokes equations for an incompressible, isothermal fluid is therefore given by (Liu and Liu, 2003):

$$\rho\frac{d\mathbf{u}}{dt} = -\nabla p + \mu\nabla^2\mathbf{u} + \rho g + \mathbf{f} \tag{4}$$

More details about the smoothing kernels and expressions for the fluid density, pressure gradient, shear stress and surface tension forces can be found in Nikolic et al. (2014).

3.2. Implementation details

The model used in this work is based on the SPH model developed by Nikolic et al. (2014) and implemented in c++ using Fluidix software (MacDonald, 2014). Fluidix is NVidia CUDA-based parallel particle simulation platform which can be applied to practically any particle-based model and allows fully customized particle interactions with searches such as “each particle”, “each pair of nearby particles”, or “each particle colliding with a mesh”.

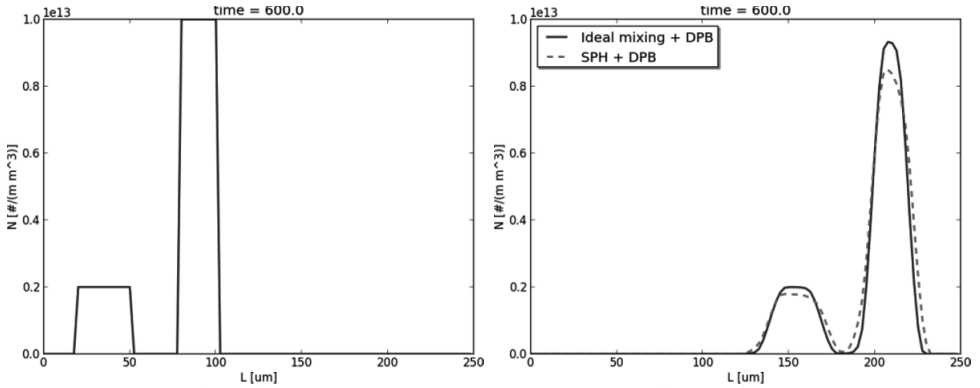
4. Applications

In the previous work (Nikolic et al., 2014) it has been shown that the SPH method can produce a very good prediction of the global mean flow in the reactor and that there is a trade-off between the number of particles used to represent the volume of the fluid in the reactor and the computational requirements. It has been presented that by decreasing the number of particles a satisfactory quality of the fluid flow description can be maintained while dramatically reducing the computational requirements for more than 30 times. In this work, the effect of the number of elements used to discretise the population balance on computational requirements was investigated.

4.1. Case study: coupling SPH with Population Balance

CFD model developed using the SPH method can easily be extended with additional transport equations by applying a similar methodology like one previously described. Three new scalar transport equations were added: heat balance, mass balance (concentration of dissolved crystals) and a set equations resulting from discretisation of the number density function (Discretised Population Balance method, DPB). In this study, the developed model was applied to growth-only cooling crystallisation of paracetamol from ethanol solution using the lab reactor and kinetics data from Mitchell et al. (2011). The initial supersaturation was set to 1.5667 and the initial temperature to 20^0C. The reactor is then cooled down to 0^0C through the reactor jacket. The population balance equation was discretised using the van Leer k-interpolation (with k=1/3) high resolution upwind scheme with Koren flux limiter (Qamar et al., 2006) using 100 intervals. The performance of the fine volume discretisation scheme was analysed using the seed with sharp discontinuities in its CSD as shown in Figure 1a. Since the process is growth-only the analytical solution for the ideal-mixing case is simply the initial CSD translated right by a distance $G{\cdot}t$ (growth rate multiplied by the time elapsed). The

simulation results after 600 seconds for the case where the DPB was coupled with the ideal mixing model and with the SPH model are presented in Figure 1b.



a) Inital CSD *b) CSD after 600s*

Figure 1. Simulation of the growth-only crystallisation using Discretised Population Balance method and van Leer high resolution finite volume scheme with flux limiter

The solid blue line in Figure 1b shows the performance of van Leer discretization scheme in an ideal mixing case. The scheme successfully suppressed oscillations in the solution and decreased the amount of the numerical diffusion present in all upwind schemes, although not completely. The dashed red line shows the CSD from the SPH model. Obviously, the nonidealities in the reactor cause that some fluid particles are well mixed while some other are located in poorly mixed zones (i.e. trapped in the zones around baffles or located in a poorly mixed top part of the volume) and contribute to the dispersion of the CSD. It can be observed that 100 elements are not enough to completely eliminate the numerical diffusion which is an indicator that a higher number of elements must be used. To determine the computational costs for different number of elements the same growth-only crystallisation problem was used again. Now the SPH model was coupled with the standard method of moments (SPH+MoM) keeping the first 6 moments only, and with the DPB equations (SPH+DPB) using a range of numbers of elements from 25 to 250. The simulation times were compared to the pure SPH simulations with the same number of particles. The simulation slowdown for all cases given in percents is presented in Figure 2.

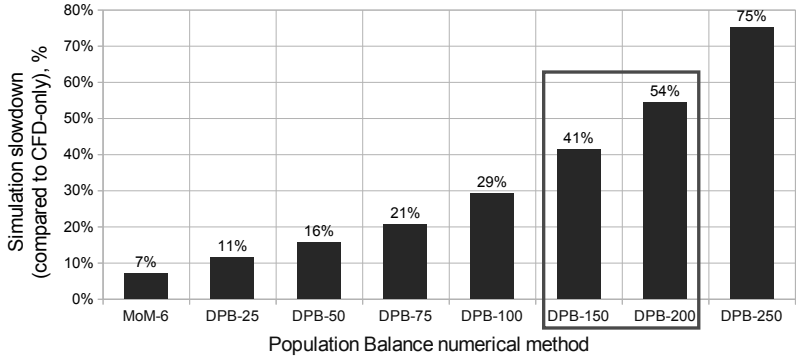


Figure 2. Computational requirements of coupled SPH and SMoM/DPB

5. Conclusions

The CFD model for a rapid prediction of the global mean flow in stirred tanks has been implemented using the Lagrangian meshfree Smoothed Particle Hydrodynamics method and its advantages for modelling of coupled hydrodynamics and crystallisation phenomena presented. The model offers an exact model of a convective transport, extreme parallelisation and model reduction capabilities, potential to directly utilize local hydrodynamics conditions for prediction of the secondary nucleation kinetics with a direct link to experimental particle-wall collision measurements using the shadow imaging technique, and the explicitly available CSD. Solution of the coupled system of Navier-Stokes and discretised population balance equations that is still almost intractable using the classical grid-based CFD methods can be efficiently solved now with only a marginal drop in performance (50% for 200 bins) compared to pure SPH simulations.

Model Reduction in Visual Modelling

Heinz A Preisig

Department of Chemical Engineering; NTNU; Trondheim, Norway
Heinz.Preisig@chemeng.ntnu.no

Abstract

Visual modelling redirects the users focus from writing model equations to the analysis if the structure and dynamics of the process model. This is enabled by having a highly structured approach to generating network models building an ontology for physical-chemical -biological processes. Visual modelling facilitates the generation of process model structures, their splitting into substructures based on time-scale assumptions and more generally model reduction. The operations can be done graphically, whilst the reduction algorithm provide the reduced models using an algorithm operating on the network representation extracted from the ontology.

Keywords: computer-aided modelling, code generation, design, control

1. Background

The main objective of the visual modelling project is to give the user a tool, which puts the focus on defining the structure of the model instead of coding the model equations. The user should be able to quickly implement his view of the process in terms of its dynamic behaviour and what is happening inside of the process, thus the reactions and phase changes, to mention the main ones. It should also enable to implement a set of consecutive simplifying assumptions making it possible to derive a group of simplified models that are tailored to specific model-based computational engineering problems that arise in the course of designing, realising and operating the plant. It is in this way, we put the model into the center of all the computational modelling tasks, thereby providing a maximum of compatibility and enable comparison of results on equal foots.

The graphical approach is simple and provides a visualisation of the initial assumptions made when generating the model in the first place. The mathematical representation is handled in the background by extracting them from an ontology that captures the behaviour of physical-chemical-biological systems comprehensively. The use of a systematically constructed ontology provides the security of structurally proper process models that are in the sequel compiled into code, thereby eliminating any transcript and interfacing errors. Implementing automatic model reduction methods on the generated mathematical models provides the means to implement the desired simplifying methods in the form of algorithms.

Visual modelling thus replaces mathematical model writing and manipulations with graphical manipulations that are easy to comprehend and provide a high-level of information concentration that provides an excellent platform for discussing the process model structure and the underlying assumptions. The whole process builds on a systematic representation of processes in the form of networks utilising basic graph-theoretical concepts and fundamental physics concepts.

2. Basice concept

The foundation is the ontology, which assumes that processes exist, operate and are represented in the frame of time and space. The process thus occupies a piece of the physical space and changes with time. The process is seen as an iteratively detailed hierarchical network of subprocesses thereby comprehending multi-scale process modelling (Preisig, 2010). Every model is thus first representing the process and its environment as hierarchical tree of volumes with the leaves of the tree being the most detailed, most granular representation of the modelled universe. This tree represents the physical containment in two sets: the process as a set of dynamic subprocesses and the environment as a static set of reservoirs. These subprocesses for an interacting network.

The defined subprocesses contain tokens that ”live” in them or make them up. In physical processes the behaviour of these tokens are described by the conservation principles, namely the conservation of mass, energy, linear and rotational momentum, and charges to mention the main ones. The tokens in the containment give raise to the definition of the state. If the tokens are continuous then the model is continuous whilst if they represent particles, the model will be discrete and is represented by population models. In both cases, the exchange of tokens is driven by differences in the potential fields associated with the different parts of the system. It is the intensive properties that are conjugates to the potentials that generate the driving forces, namely differences in the temperature, pressure, chemical potential that drive the process. Whilst these conjugates play a central role in the transport of the tokens, surprisingly the thermodynamic literature lacks a good term that comprehend these conjugates. It is the Bond-graph theory (Breedveld et al., 1991) that defines it as ”effort” variable, which appropriately characterises them as a group and it is the gradient in the effort variables that represents the driving force for the token transport. The tokens are transferred over the common boundary of adjacent systems, where the term ”system” is here used to represent a token-containing piece of the space, also simply called a capacity. The process-embedding environment consists of a set of infinitely large capacities, which provide and accept tokens.

The moving of tokens is the direct consequence of the capacities not being balanced with respect to the potentials. The process moves tokens between reservoirs driven by the reservoirs' imbalance of potentials, the process transports tokens due to an imbalance of the constituent subprocesses and the boarder subprocesses with the environment's reservoirs. It is thus the imbalances in universe that drive the processes.

Tokens may undergo transpositions inside the process, in fact this usually is the source of the term ”process”; change of phase and chemical/biological.

3. Mathematical framework

When modelling a process, the ”modeller” will make a first key assumption, namely a split of the universe into two parts: the process and its environment (Preisig, 2014). The split is intrinsically combined with a time scale assumption, namely that the most outer ring of the environment is formed by infinitely large capacities that exhibit constant intensive properties. This is a first underlying time-scale assumption.

The core element is the description of an individual capacity. Limiting ourself to continuous processes it is the conservation of extensive quantity Φ that represents the dynamic behaviour of the capacity.

$$\text{accumulation} \quad : \quad \dot{\Phi} = \int_0^S \hat{\phi}\, dS = \sum_{\forall i} \int_0^{S_i} \hat{\phi}_i dS_i \quad : \quad \text{sum of flows} \tag{1}$$

The common boundaries are characterised by a continuity condition for the effort variables π and a flux condition for the exchanged extensive quantity. Thus $\pi_{-\varepsilon} = \pi_{+\varepsilon}$ and $\hat{\phi}_{-\varepsilon} = \hat{\phi}_{+\varepsilon}$.

Connected capacities will thus form a network that can be described by a directed graph with the direction providing the reference co-ordinate for the respective connection: what is going out of one system is entering the other, according to the conservation principle. The global model of the process can be written as:

$$\underline{\dot{\hat{\Phi}}} = \underline{\underline{F}}\,\underline{\hat{\Phi}} \quad \text{where} \quad \underline{\hat{\Phi}} := \left[\hat{\Phi}_i\right]_{\forall i} \quad \text{and} \quad \hat{\Phi}_i := \int_0^{S_i} \hat{\phi}_i dS_i \tag{2}$$

3.1. Reactive systems

For reactive systems, the species are not conserved but species are transmuted into other species. So for species we can write the balance equations:

$$\underline{\dot{n}} = \underline{\underline{F}} \otimes \underline{\underline{S}}\,\underline{\hat{n}} + \underline{\tilde{\lambda}} \quad \text{with} \quad \underline{\tilde{\lambda}} := \underline{\underline{N}}^T V \underline{\xi}(\underline{c}) \tag{3}$$

and the $\underline{\xi}$ :: the extent of reaction vector, $\underline{\underline{N}}$ :: the stoichiometric matrix and V :: the volume, $\underline{c}$ :: the concentration vector. For the explanation of the $\otimes$ product and the matrix $\underline{\underline{S}}$ see Preisig (2010). If we multiply this equation with the vector of mole masses ($\underline{\lambda}$) the product with the transposition term becomes zero and we recuperate the total mass balance.

4. Model reductions

The core of the approach is in all cases the same: a complex part of the model is replace by a simpler surrogate model. Simplifications invariably remove information, thus the surrogate models are always going to contain less information than the original model. The process of generating surrogate models takes many different forms. Below we will discuss a common set of such replacement operations.

The most common operations are associated with time-scale assumptions in that parts of the model are either assumed to be constant or to be infinitely fast, thus are event-dynamic.

Approximating infinite-dimensional systems, namely distributed systems by finite-dimensional surrogate models is also a very common.

4.1. Event-dynamic assumptions

Any system can be assumed to be event dynamic. The mathematical method for handling event-dynamic assumption of any system is singular perturbation. Depending on the system, the singular perturbation parameter varies.

4.1.1. From distributed transfer to simple transfer

Applying the event-dynamic assumption to a individual distributed capacity the singular perturbation parameter is the token conductivity. As an example we take a one-dimensional heat transfer system. The dynamic description is based on the differential energy balance in the form of an enthalpy balance:

$$\dot{H} = -\frac{\partial}{\partial \underline{r}^T}\,\hat{q} \quad \text{assume one dimensional} \quad = -\frac{\partial}{\partial r_x{}^T}\,\hat{q} = k^q \frac{\partial}{\partial r_x{}^T}\,\frac{\partial}{\partial r_x{}^T}\,T \tag{4}$$

with k^q the heat conductivity, which serves as the singular perturbation parameter:

$$\lim_{k^q \to \infty} \frac{1}{k^q}\dot{H} = \frac{\partial}{\partial r_x{}^T}\,\frac{\partial}{\partial r_x{}^T}\,T = 0 \tag{5}$$

The temperature inside the system is thus a linear function defined by the temperatures at the two boundaries. The graphical operation is shown in Figure 1.

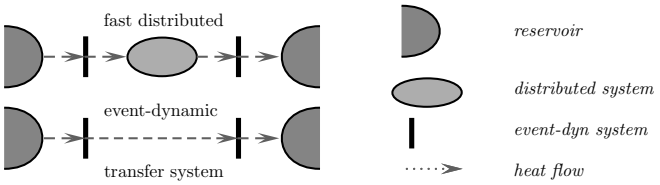

Figure 1: Simplifying a distributed transport system to a simple transfer

4.1.2. Small and large capacities

Often we design systems in which small and large capacities are combined. A sensor measuring the temperature in a fluid is such an example. The ideal design would make the sensor to have zero capacity. This is not possible, but one can aim at a very small sensor. This suggest to make a event-dynamic assumption about the temperature sensor, with the singular perturbation parameter being the capacity of the sensor.

$$\dot{H} = \hat{q} \quad \text{singularly perturbed} \quad \lim_{C_p \to 0} C_p \dot{T} = \hat{q} \quad = 0 \tag{6}$$

The time constant of the temperature sensor is inversely dependent on the heat capacity and direct dependent on the thermal conductivity. Thus we have a second possible reduction possibility, namely by choosing the thermal conductivity as the parameter for the singular perturbation.

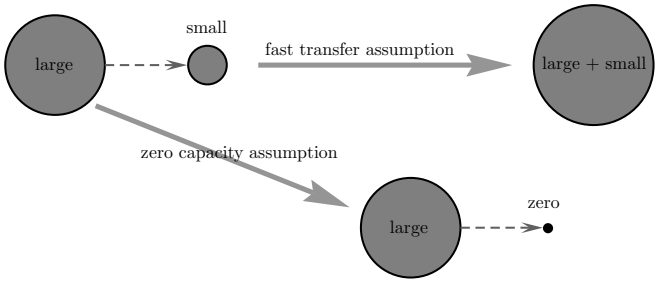

Figure 2: Approximating small capacities connected to a large capacity

$$\dot{H}_S = \hat{q} = -k^q(T_S - T_{fluid}) \quad \text{takes the form} \quad \lim_{k^q \to \infty} \dot{H}_S = -(T_S - T_{fluid}) = 0 \tag{7}$$

4.1.3. From distributed to low-order transfer

Distributed systems are infinite dimensional. Many different approximation methods are known and well documented. The one that is closest to our network approach is the finite volume approach in which the distributed spatial domain is split into a set of finite volumes for which the basic balances are applied. Key is the computation of the flows. One of the simplest methods assumed uniform conditions in each volume with the flows across the different boundary pieces being driven by the difference in the effort variables between the connected lumped systems. If we take the same heat transfer system as above, the simplification is shown in Figure 3.

The distributed system is replace by a network of lumped systems of the form Equation 2.

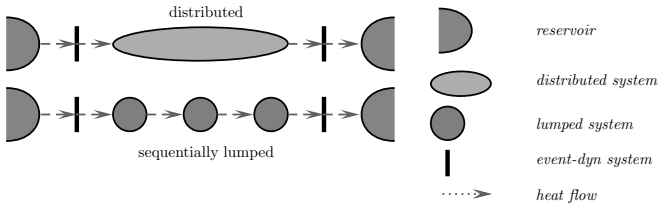

Figure 3: Distributed transfer to sequentially lumped transfer system

4.2. Reducing recycle networks

It is not uncommon to have a network in which a large amount of extensive quantity is moved in internal cycles. This is certainly the case in a stirred environment. With out any limitations, we analyse a model that consists of a generic dynamic part connected to a part that is forming a single cycle. The mathematical description for a generic extensive quantity Φ is given by:

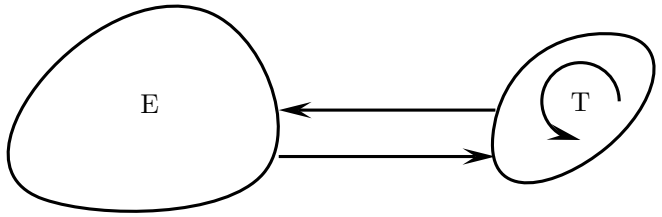

Figure 4: A cyclic network connected to a generic network

$$\dot{\underline{\mathbf{\Phi}}}_E = \underline{\underline{\boldsymbol{F}}}_{EE}\hat{\underline{\mathbf{\Phi}}}_{EE} - \underline{\underline{\boldsymbol{F}}}_{ET}\hat{\underline{\mathbf{\Phi}}}_{ET} \quad \text{and} \quad \dot{\underline{\mathbf{\Phi}}}_T = \underline{\underline{\boldsymbol{F}}}_{ET}\hat{\underline{\mathbf{\Phi}}}_{ET} + \underline{\underline{\boldsymbol{F}}}_{TT}\hat{\underline{\mathbf{\Phi}}}_{TT} \tag{8}$$

We focus on the second equation and formulate for the transfer[1] $\hat{\Phi}_m := \xi_m \hat{V}_m$ with $m \in \{ET, TT\}$. Without introducing a limitation, we assume that the cyclic process has only one cycle. We now make the order of magnitude assumption that the volumetric flow in the cycle is much larger than the flows connecting to the environment, thus $\hat{V}_{ET} << \hat{V}_{TT}$. If the process occupies a constant volume, then the volumetric flow rate is constant in the cycle. Using the large flow rate as the inverse of the singular perturbation parameter we get:

$$\lim_{\hat{V}_{TT}\to\infty} \frac{1}{\hat{V}_{TT}} \left(\dot{\underline{\mathbf{\Phi}}}_T = \underline{\underline{\boldsymbol{F}}}_{ET}\hat{\underline{\mathbf{\Phi}}}_{ET} + \underline{\underline{\boldsymbol{F}}}_{TT}\underline{\underline{\mathbf{\Psi}}}_{TT}\hat{V}_{TT} \right) \quad \text{yielding} \quad 0 = \underline{\underline{\boldsymbol{F}}}_{TT}\underline{\underline{\mathbf{\Psi}}}_{TT} \tag{9}$$

with $\underline{\underline{\mathbf{\Psi}}}_{TT} :: \mathbf{D}\left(\underline{\boldsymbol{\xi}}\right)$ the diagonal matrix of the intensive properties vector. With the process being a cycle, the properties of the inflow to each lump is equal to the outflow of the lump, thus all ξ_T are equivalent and thus the network behaves like a single lumped system with a network connection to the environment. Graphically this reflects into Figure 5.

5. Implementation issues

The implementation of the graphical editor consist of several components: a graph editor that supports the hierarchical structuring of the model. This primarily serves the purpose of administrating

[1] We use the notation *AB* for a reference co-ordenate pointing from *A* to *B*

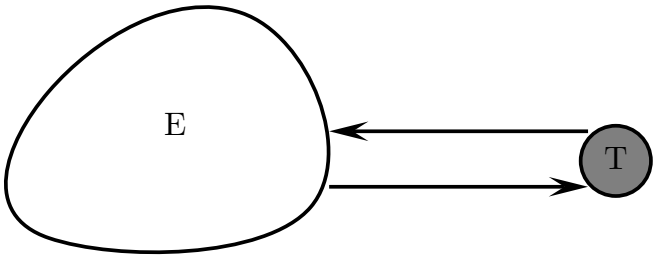

Figure 5: A cyclic network connected to a generic network

the model. The actual model is located at the leave nodes of the hierarchical decomposition tree, where also the connections are being implemented.

The graph editor has currently three inserts, one is plugging in two automata, one that defines the behaviour of the keyboard, the other define the graphical elements and the third makes the ontology with the list of model equations available. The ontology is also used to generate the automata and the graphics so as to have all elements consistent. Those operations are implemented as separate editors.

The model reduction methods, as described in this paper, are implemented over the ontology and so are the model reduction methods. One can also view the procedures as being a replacement of a complex model with a simplified surrogate model.

6. Conclusions

The algorithms for model reduction applying order-of-magnitude assumptions to individual model components, specifically distributed systems, have been presented. Large recycling rates yield a model reduction assuming very high recycling rates compared to other interactions. The order-of-magnitude assumptions are in essence all time-scale assumptions: fast vs low transfer rates, high vs small flow rates lead to short vs long residence times and thus enable a time-scale separation.

Singular perturbation theory in its basic form can be used to split the time domain and provide simplified models, of which the outer solutions - the larger time-sale solutions, are of particular interest.

The result is algorithmic and can be implemented to happen in the background automatically without the need of interference by the user. This provides a set of tools that enables the derivation of simplified models from a mother model, thus providing the desired feature of having consistent models within the context defined by the ontology.

Consecutive automatic code generation and splicing to match the target solver's code environment completes the integration of the model into the modelling suite.

Abstract

Unstructured meshes are widely used to delineate the complex geometry of blood vessels in computational fluid dynamics simulation. However, structured parametric meshes can better represent complex geometries with lower grid density thus enabling faster and more precise computations. Current mesh generation methods require user interaction and cannot be used for automatic generation of parametric mesh representations of vascular networks. Our aim is to present a fully automatic algorithm for parametric mesh representation of vascular networks from subject-specific medical images. The methodology requires no user interaction, can create volumetric meshes for non-planar bifurcations and offers full control over the local mesh resolution at the surface and the lumen of the blood vessels. We demonstrate the reliability of our algorithm in terms of mesh quality by evaluating scaled Jacobian and equiangular skewness. The novel method was applied in case studies to reconstruct real image data for the cerebral angioarchitecture. Accurate subject-specific representations of vascular trees are necessary to perform organ-wide hemodynamics for personalized surgical planning of vascular disease.

Keywords: Parametric mesh, vascular network, non-planar bifurcation, hexahedral elements, micro-circulation structure.

1. Introduction

Unstructured grids have been widely used to mesh complex geometric domains as they are readily available with many software packages (Somayaji et al 2008, Sweetman et al. 2011, Ghaffari et al 2014). Linear unstructured mesh tends to be stiffer and can be susceptible to shear-lock (Abaqus, 2008). In contrary, linear parametric meshes are more accurate in nonlinear or impact contact analysis and even more efficient than second order unstructured meshes (Songbai at al., 2011). Parametric meshes offer more accurate computational results even with lower-density grids thus accelerating speed. For the same number of elements, parametric meshes enhance the fidelity of geometrical reconstruction and numerical solutions. However, current methods for mesh generation have still required manual operations, which are time consuming and prohibit the fully automatic reconstruction of large vascular trees from subject-specific medical images.

In last decade, several research groups employed different methods to generate structured meshes for bifurcations and vascular trees. Antiga and Steinman (2002) applied the Cooper algorithm for hexahedral meshing to a single branch of bifurcation. Verma et al. (2005) produced natural coordinates from the Laplace's equation to create structured meshes for bifurcations. This methodology requires the numerical solution of three additional heat

conduction problems. Santis et al. (2011) proposed the manual construction of block structures inside and outside the vessel, whose projections on the lumen surface allows the generation of hexahedral meshes. Clearly, this manual technique is inadequate for large vascular networks. Our aim is to generate a fully automatic parametric mesh allows for better representation and a more computationally efficient patient-specific simulation of hemodynamic of the large vascular networks.

2. Methods

Microcirculation data were obtained as described by Linninger et al. (2013). For cerebral arterial trees, MR angiograms were acquired under Institute Review Board approval with a 3D Time of Flight pulse sequence from a 28 year old volunteer. An in-house image filter was applied to suppress signals from other tissues and enhance the vessels. The filtered image was imported into VMTK software Antiga et al. (2008) to acquire radius and connectivity information.

Parametric meshes of the entire vascular trees were generated using the five steps procedure shown in Fig. 1a, the creation of a parametric structured grid for bifurcations is discussed as follows.

In step 1, centreline point locations, radii, and connectivity information are extracted from VMTK. Cubic Bezier parameterization is applied to capture the curvature of the vessels as demonstrated in Fig. 1a. A cubic Bezier curve is a vector function in terms of the scalar parameter t with end points P_0 and P_1 and control points C_0 and C_1 as defined in Eq.(1). The endpoints bracket the space curve; the control points dictate the shape of the curve. Least square method is used to approximate the Bezier curve. Between two sequences of curves G^1 continuity is enforced as shown Fig. 1d.

In step 2, the Bezier network is categorized into bifurcations, outlet, and connecting segments. The initial decomposition is carried out by dividing the Bezier network into branches. That is, a branch is defined as an array of Bezier curves. Then, bifurcation regions are automatically detected and segmented as shown in Fig. 1c. In each bifurcation point, the branches were segmented where the arch length of branch is equal to twice the local radius.

In step 3, a separation plane and two Control Points (CPs) calculated to define bifurcation topology as shown in Fig. 1d. Firstly, bifurcation branches are indexed as i, j, k. Then, SP_{ij}, SP_{jk}, SP_{ki} are calculated between the branches of ij, jk, ki respectively by Eq.(2). The separation plane is defined by three separation points using Eq.(2). To complete the geometry of separation region, the length of the normal vector of the separation plane was extended by a magnitude equal to the mean radius.

In step 4, separation region with two CPs and three SPs was divided into 6 parts connecting each CP to a SP. Parametric radii are determined by Eq.(3). Then, a parametric curve equation has been developed to calculate surface nodes by using Eq.(4).

$$\vec{B}(t) = (1-t)^3 \cdot P_0 + 3t(1-t)^2 \cdot C_0 + 3t^2(1-t) \cdot C_1 + t^3 \cdot P_1 \quad (1)$$

$$SP_{ij} = (R_i \vec{V_j} + R_j \vec{V_i}) \cdot \sqrt{R_i{}^2 + R_j{}^2 + 2R_i R_j \cos \alpha_{ij}} \quad (2)$$

$$r(t) = t \cdot \|CP - BP\| + (1-t) \cdot \|SP - BP\| \ , t \in [0,1] \quad (3)$$

$$f(t,) = r(t)\cos() \ \vec{T} + r(t)\sin() \ \left|\vec{T} \times \vec{U}\right| + BP \quad (4)$$

Where ||.|| denotes the Euclidean norm and *BP* is bifurcation point. $\vec{U}$ is a unit vector from control point to bifurcation point; $\vec{T}$ denotes a unit normal vector to the plane of CP, SP and bifurcation point. α_{ij} is the angle between *i* and *j* branches.

Step 5 serves the generation of the interior volumetric mesh. First, the surface mesh points are sorted longitudinally within each cross-sectional group. Three integers a, b and c are employed to control the topology of butterfly grid generation and cross-sectional mesh resolution along radial axis, shown in Fig. 1e.

To increase the computational accuracy near the wall, where higher velocity gradients are expected, finer elements closed to arterial wall are recommended. To provide more realistic anatomical context computational meshes may be created with vessel walls, which can easily be created by extending the parametric lumen surface.

We can also control the mesh density in longitudinal direction. By increasing the number of longitudinal divisions in each segment, finer longitudinal mesh resolution can be achieved. The number of longitudinal divisions can also be correlated to segment radius thereby producing finer meshes for thinner vessels.

In step 6, we took advantage of regular surface mesh to create an optimal automatic algorithm to index mesh nodes and element to write a structured mesh in .msh format. Finally, mesh quality is assessed using ANSYS-ICEM CFD 15.

3. Results

This section presents the result of fully-automated parametric mesh generation to real world vasculature constructed from medical imaging data. We will apply our methodology to the parametric mesh generation for microcirculation and reconstruction of the entire arterial trees in mesh domain.

Fig. 2a-c show a result meshed of arteriolar tree of the microcirculation in the human cortex. Magnified views of its penetrating arterioles merging seamlessly into the capillary bed are displayed. The entire structure has 68,816 surface elements and 246,080 cells.

Fig. 2d illustrates parametric mesh for Circle of Willis with nine bifurcations with 9,456 surface element (Quad-4) and 35520 cells (Hexa-8). A magnified view of its outlet is also shown in Fig. 2e. Fig. 2f-g show a parametric mesh of a complete human cerebral vasculature from medical images. The parametric meshes for the entire arterial tree consist of 21,224 points, 21,471 connections, and 1,280 bifurcation segments. The full mesh of the brain vasculature contains of 8,838,816 hexahedral elements which is equally parameterized along local axial and radial coordinates.

The mesh quality was evaluated using scaled Jacobian and Equiangular skewness as shown in Table 1. A hexahedral cell is optimal if the skew is less than 0.4 and the scaled Jacobian is on average of 0.8. Mesh elements are increases from 14,836 to 150,580, categorized in coarse, medium and fine mesh size. The scaled Jacobian of the computational elements is about 0.86 on average with the minimum of 0.41, indicating that the shape quality of the elements is adequate for computations.

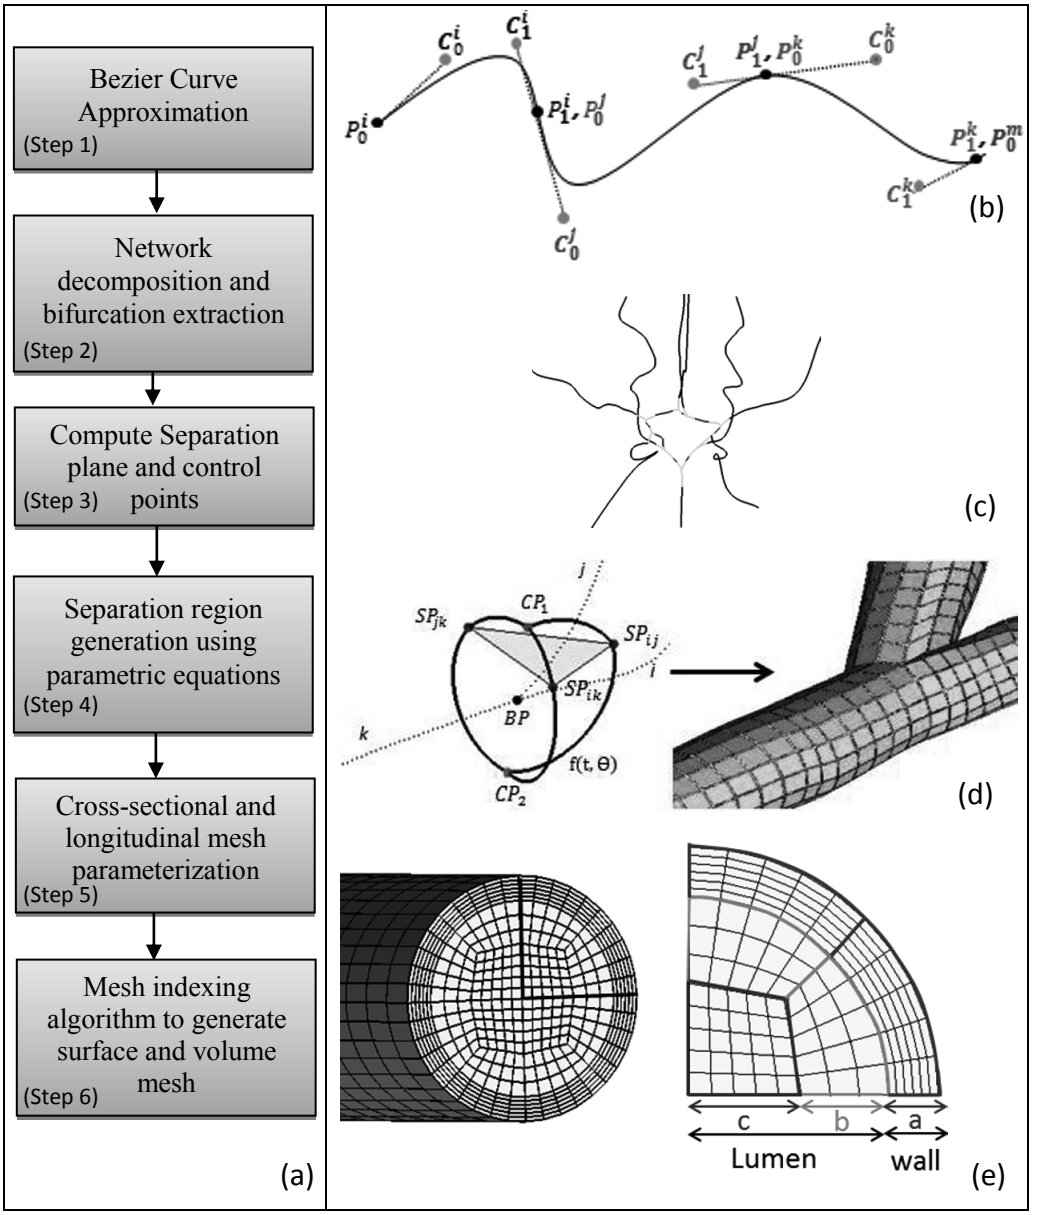

Figure 1. (a) A block diagram of stepwise generation of parametric mesh for bifurcations, (b) Bezier curve approximation, least square with cubic Bezier approximation has been used to represent tortuosity of vessel morphology. (c) Bifurcations is extracted in a position where the arch length of branch is quall to twice the relative radius, shown in green (or light grey) in Loop. (d) Separation plane is defined by SP_{ij}, SP_{jk}, SP_{ki}. Normal vector of the separation plane extends to find CPs. (e) Cross sectional mesh parameterization using butterfly grid. Parameter "a" describes the number of cells in vessel wall and "b, c" defines the mesh density in lumen area.

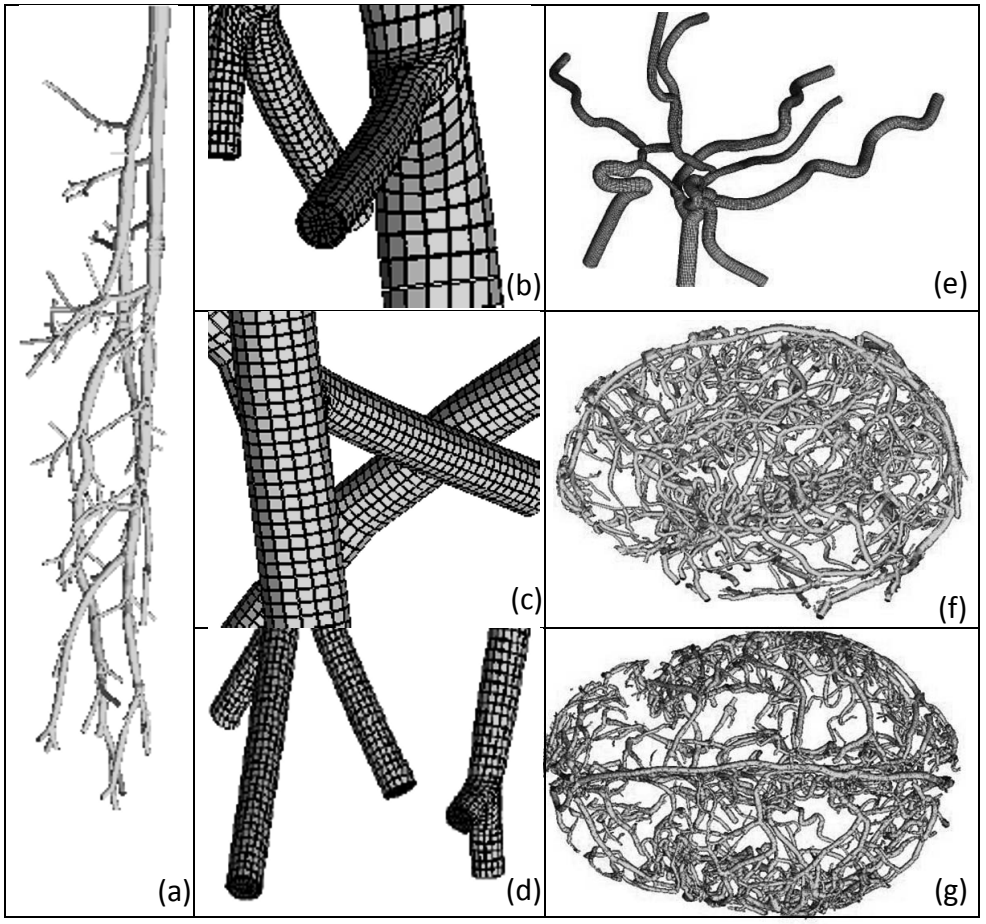

Figure 2. Result of the parametric mesh generation. (a) Schematic of micro-vessels in microcirculation structure (penetrating arteries). (b-c) Magnified view of the shrunken elements (%10) of micro-vessels. (d) Grid element generation of Circle of Willis as a local model of cerebral trees. (e) An outlet of Circle of Willis in magnified view (f-g) Full brain vasculature network.

Table 1. The mesh quality of the Loop with different resolutions is evaluated. The mesh resolution is determined by the longitudinal and cross sectional parameters.

Loop	Mesh resolution parameters (a, b, c, L)	#Elements, #nodes	Equiangular skewness (min, mean, max)	Scaled Jacobian (min, mean, max)
Coarse	3, 3, 4, 2	14836, 13898	0, 0.8, 0.79	0.41, 0.81, 1
Medium	3, 4, 8, 4	71938, 68297	0, 0.6, 0.8	0.5, 0.89, 1
Fine	4, 6, 10, 5	150580, 144804	0, 0.15, 0.8	0.61, 0.89, 1

4. Conclusion

Our novel method allows a robust and fully automatic generation of parametric meshes suitable for large vascular trees. The method does not require user input and can handle non-planar bifurcations. In our methodology all elements are oriented along the blood flow direction, thus allowing the alignment of the gridlines with the physiological velocity direction in the vessels. Such alignment will reduce numerical diffusion error occurring during the integration of the flow equation, thereby providing higher accuracy of the results, Vinchurkar et al. (2008).

3D geometric vascular models have important applications in diagnosis and investigation vascular malformations, such as aneurism, stenosis and atherosclerosis. Moreover, subject specific meshes with physiological boundaries can be used in personalized surgical planning for subject-specific hemodynamic simulations of the entire cerebral circulation.

Abstract

In recent years, advances in mathematical modeling techniques, algorithms for solving mathematical equations and computational power have all combined to make the study of complex phenomenon with large number of inputs possible, which could otherwise have been unattainable with physical experiments. Particularly excellent computational tools for models on the small scale have opened a new avenue for replacing physical experiments by computational experiments. Often, it is physical/chemical properties that are the target, because they are used in a multitude of models. But since the computational experiments are often of very large scale and high complexity, they require significant computational resources, not least of which is time. Hence, a direct coupling of the codes is not feasible and one has to take refuge in simpler models that are approximating the behaviour of the complex model, called the surrogate models. Naturally the objective is to generate surrogate models that approximate the complex behaviour as well as possible within a given domain. But since computational experiments are not contaminated with stochastic noise, classical design of experiment methods like blocking, randomization and replication are irrelevant (Fang et al., 2005) - the gap is all due to lack of fit. So the maximum acceptable gap in a given domain is usually the essential measure that the application of the surrogate model defines. The goal is clear, one aims at computationally cheap approximations that are sufficiently good as defined by the application. Surrogate models are commonly used in multiscale simulations for bridging the gap between the finer and the coarser scales. We discuss the approach on an illustrative example where the Redlich-Kwong equation of state is approximated by linear surrogate models.

Keywords: surrogate models, design of experiments, multiscale modeling

1. Introduction

Surrogate models are simple analytical models that mimic the input/output behaviour of complex systems. Developing such models requires performing computationally expensive simulations at a set of carefully selected sample points. These models approximate the behaviour of the underlying complex simulations to a reasonable precision while also being computationally cheaper to evaluate. Surrogate models can thus be seen as a simple representation of a complex system with relaxed accuracy in a given domain. The trade-off between the accuracy and the computational time is an important consideration during the construction of these models.

Surrogate models are constructed with the use of computer experiments where the design parameters cover a carefully chosen range of values within the design space. These values are selected according to certain specifications or patterns using a technique known as the design of experiments (see sec. 2.1) The computationally expensive simulation is carried out at these selected

points and the responses are recorded. Using this input/output data, the behaviour of the complex simulation is then approximated by simple functional relations, which we call the surrogate models. The exact nature of the complex simulation thus becomes irrelevant and only the surrogate model that approximates the behaviour of the complex simulation becomes important. These surrogate models can be based, for example, on equations where higher order terms are neglected, or on assumptions of lumped systems instead of distributed ones (Koziel et al., 2011).

The use of surrogate models is most evident in multi-scale modeling. The conventional view of modeling has been to focus on a particular scale of a system. The effects of the other scales in the system are usually neglected by making assumptions about their behaviour or by using constitutive relations. On the other hand, multi-scale modeling involves simultaneous consideration of the different scales of a system, as well as the combination of these scales into an overall model for the system. The objective is to achieve the efficiency of a higher scale and the accuracy of a lower scale. In this context, the interactions between different scales play a significant role in determining the quality of the overall model.

Suppose that in a system, a model A on a particular scale of the system requires some data from some model B on the same or a different scale. To provide this information to model A, model B might itself require some data from some model C in the system. Furthermore, simulations at the lower scale are generally more complex than those at the higher scale. In such multi-scale systems, the propagation of data from one model to another might be computationally very expensive and hence infeasible. This is where surrogate models come into the picture. They provide a computationally cheap and efficient way of linking the different models in a multi-scale system. For example, when a higher scale model calls for some data from a lower scale complex simulation, the required data can be computed using a surrogate model instead of the complex simulation. Moreover, surrogate models easily integrate with computer codes even when they are written in different programming languages, which is often the case in multi-scale modelling. In the subsequent sections, we describe the framework for constructing surrogate models, followed by an illustrative example (Giunta et al., 2003).

2. Framework of Constructing Surrogate Models

2.1. Design of Experiments

Design of experiments (DOE) constitutes the different techniques of determining the locations of the sample points in a design space (see Fig.1). The samples chosen through the DOE should give a good representation of the entire design space so that the surrogate model that is constructed from these sample points can provide a good prediction of the responses from the complex simulation. In addition to that, the number of samples chosen through the DOE should be relatively small compared to the actual design space. In general, a DOE method should be able to provide maximum information about the design space with minimum possible samples. The DOE method to be used depends on various factors like the dimensionality of the problem, the structure of the surrogate model to be used, the error tolerance criteria for the construction of the surrogate model and the existence of random error in the complex model.

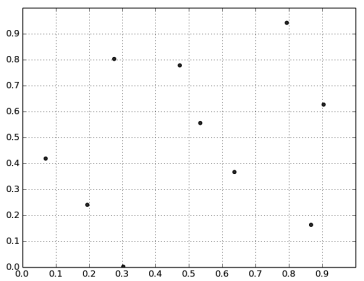

Figure 1: Latin hypercube sampling for 10 points in the design space $[0,1]^2$

The DOE methods can be broadly classified into two categories: classical and modern. In case

of laboratory experiments where the random error exists, i.e. each new run of the experiment results in a different error, the classical DOE methods are preferred. The classical methods tend to generate sample points at the extremes of the design space in order to adequately represent the design space even in the presence of this random error. Examples of the classical DOE methods are the Box-Behnken design, the Central Composite design, etc. On the other hand, in case of deterministic computer simulations, the modern DOE methods are used. The underlying assumption in case of these computer simulations is that each run of the simulation results in exactly the same responses. Examples of the modern DOE methods include the Monte-Carlo sampling, Latin-Hypercube sampling and the Orthogonal Array sampling

It might happen that the design space is extremely large and that a single surrogate model cannot sufficiently represent the complex simulation over the entire design space. In such cases, dividing the design space into smaller divisions might be feasible. The DOE is performed separately on each of these divisions and separate models are fit to each of the sampled data. In other words, local approximations for the complex simulation are found over the design space. However, if in these cases the continuity over the entire design space is a necessity, then appropriate boundary conditions have to be applied at the boundaries of the divisions.

2.2. Forward Mapping

The basic idea of forward mapping is to use the input-output data from an unknown black box function $y = f(x)$ to make the best guess $\hat{y} = \hat{f}(x)$ for this unknown function. Thus, if $y = f(x)$ represents a complex simulation, $\hat{y} = \hat{f}(x)$ represents the corresponding surrogate model. The objective is to minimize the gap between y and $\hat{y}$. The general way to do this is to define a measure for this error, and then to minimize this measure of error so that y and $\hat{y}$ are 'close enough'. There are various ways in which surrogate models can be predicted, like the response surface methodologies, kriging, etc. We present a brief overview of one common technique for constructing polynomial response surface models (Han and Zhang, 2012).

The polynomial model is constructed using least-squares regression. Suppose we have an n-dimensional design space in which the complex simulation is performed at m different points (selected using the design of experiments), leading to the generation of m sampled points. This method is demonstrated for the case of quadratic polynomials, but it can very well be used for linear models or higher order polynomials. The quadratic model, in comparison with the complex simulation, can be represented as:

$$f(x) = \hat{f}(x) + \varepsilon, x \in \mathbb{R}^n, \tag{1}$$

where $\hat{f}(x)$ is the quadratic model and ε is the random error assumed to be normally distributed with zero mean. The error at each point is assumed to be independent and identically distributed. The quadratic model $\hat{f}(x)$ for an n dimensional design space can be represented as:

$$\hat{f}(x) = \beta_0 + \sum_{i=1}^{n} \beta_i x_i + \sum_{i=1}^{n} \beta_{ii} {x_i}^2 + \sum_{i=1}^{n} \sum_{j=1}^{n} \beta_{ij} x_i x_j, \tag{2}$$

where β_0, β_i, β_{ii} and β_{ij} are unknown coefficients to be determined. In the above equation there are a total of $p = \dfrac{(n+1)(n+2)}{2}$ unknown coefficients to be determined. Thus we need at least p equations and thus p sample points to construct a quadratic model for an n-dimensional problem. Suppose that $\beta \in \mathbb{R}^p$ is the vector that contains these p unknown coefficients, the least-squares estimator of β is given by:

$$\beta = (U^T U)^{-1} U^T f_S, \tag{3}$$

where:

$$U = \begin{pmatrix} 1 & {x_1}^{(1)} & \cdots & {x_n}^{(1)} & {x_1}^{(1)}{x_2}^{(1)} & \cdots & {x_{n-1}}^{(1)}{x_n}^{(1)} & \left({x_1}^{(1)}\right)^2 & \cdots & \left({x_n}^{(1)}\right)^2 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ 1 & {x_1}^{(m)} & \cdots & {x_n}^{(m)} & {x_1}^{(m)}{x_2}^{(m)} & \cdots & {x_{n-1}}^{(m)}{x_n}^{(m)} & \left({x_1}^{(m)}\right)^2 & \cdots & \left({x_n}^{(m)}\right)^2 \end{pmatrix} \in \mathbb{R}^{m \times p} \tag{4}$$

The unknown coefficients in β are determined using eq. 3 and eq. 4. Then, using eq. 2, which will be the resultant surrogate model, the approximate response $\hat{f}$ at any point in the design space can be calculated.

2.3. Backward Mapping

The sensitivity analysis of the surrogate model obtained from the forward mapping is performed in the backward mapping. Based on the results of the analysis, it is decided whether or not to update the surrogate model. If the surrogate model needs to be updated, the DOE is performed once again, followed by the forward mapping. This process is repeated till an acceptable surrogate model is obtained. The backward mapping thus introduces a loop in the overall framework. It is also worth noting that the backward mapping procedure is computationally less expensive than the forward mapping procedure.

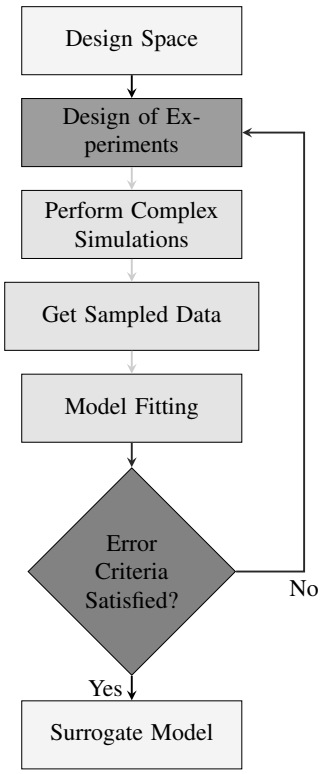

Figure 2: Overall framework for developing a surrogate model.

The traditional way of performing the sensitivity analysis of a surrogate model is with the use of the Fisher information matrix. The inverse of the Fisher information matrix is the covariance matrix. Depending on the uncertainties present in the experiment, the Fisher information matrix can be used to find the limits on the variances of the surrogate model parameters (Atkinson et al., 2014). Since in contrast to physical experiments, computational experiments are not contaminated by noise, the Fisher information provides solely a measure of the 'lack of fit' of the surrogate model. The traditional interpretation of the measure for the variance associated with the estimate is not applicable. Hence, in deterministic systems, it becomes necessary to perform the sensitivity analysis using measures that quantify the error between the outputs of the complex simulation and the surrogate models at the sampled points. An error tolerance criteria is thus defined and the algorithm is iterated till this criteria is met (see Fig.2).

In the context of multi-scale modeling, the selection of the error tolerance criteria depends not only on the model of interest but also on its interaction with other models, on same or different

scales in the system. Even a small error at one scale of a system can propagate and result in large errors at some other scale. Hence, it is important that the error tolerance criteria be defined by the model that is ultimately going to use results obtained from some other model in the system. For example, if model A requires some data from a complex model B and the surrogate model is approximating the complex model B, then the error tolerance criteria used in the construction of this surrogate model should be be defined by model A.

3. An Illustrative Example

To demonstrate the overall framework for constructing surrogate models, we consider a multi-scale system where a macroscopic model requires pressure of one mole of ammonia as an input. The macroscopic model asks for this pressure data from a lower scale model, which we consider to be the Redlich-Kwong equation of state for one mole of ammonia, $P = \dfrac{RT}{(V-b)} - \dfrac{a}{\sqrt{T}V(V+b)}$, where P is the pressure in atm. Our objective is to find local linear approximations (surrogate models) for the Redlich-Kwong equation. Each of the linear models should be of the form $\hat{P} = \beta_0 + \beta_1 T + \beta_2 V$, where β_0, β_1 and β_2 are the unknown coefficients to be determined.

Table 1: Ammonia information used in the simulation

Constant/Variable	Value/Range	Units
T	(420, 600)	K
V	(0.25, 1.00)	$L\ mol^{-1}$
R	0.082	$L\ atm\ mol^{-1}\ K^{-1}$
a	85	$atm\ K^{1/2}\ L^2\ mol^{-2}$
b	0.025	$L\ mol^{-1}$

We thus have a 2-dimensional design space with the design variables being temperature and volume (the inputs to the Redlich-Kwong equation). The ranges of temperature and volume are arbitrarily chosen above their respective critical values for ammonia. Note that we do not include very low values of volume in our demonstration because a linear surface is a very poor approximation of the Redlich-Kwong equation at very low values of volume. The values and ranges of the constants and the variables used in our simulation are shown in Table 1. The design space is divided into 5 subintervals each along the temperature and the volume axes. This results in 25 equally sized subregions in the design space. Then the Latin hypercube sampling (DOE) is performed for 20 points in each of the subregions. For a particular subregion, the pressure at each of the 20 selected points is calculated using the complex model (Redlich-Kwong equation) to get the input/output data. Then, the linear surrogate model is fit to this input/output data using the least squares regression method of the response surface methodology as described in sec. 2.2. The same procedure is applied for all the 25

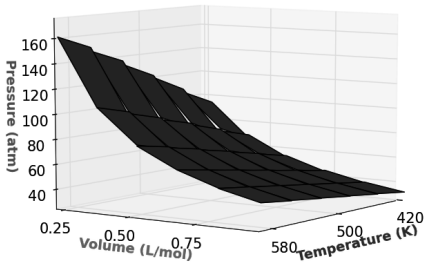

Figure 3: The linear surrogate model surfaces in the 25 subregions.

subregions to obtain a linear surrogate model for each. The maximum error between the complex and the surrogate model at the selected points in the subregion is chosen to be the measure for error. We assume that the macroscopic model's error tolerance criteria corresponds to a maximum error tolerance of 3 atm in the surrogate model. Thus, the simulation (beginning at the DOE) is run until the maximum error does not exceed 3 atm in any of the subregions. Furthermore, to rectify the discrepancies in the results at the borders of these subregions, an average value of the result obtained from the models in the bordering subregions is considered. The surface plot of the surrogate models resulting from one such simulation are shown in Fig.3. As can be seen from Fig.3, the surface profile of the surrogate model is a reasonably good approximation of the PVT surface profile of the Redlich-Kwong equation. In this particular simulation run, it took 10 iterations in the framework before the error tolerance criteria was satisfied. The values of the surrogate model coefficients for 5 random subregions are shown in Table 2.

Table 2: Surrogate model coefficients for 5 subregions.

Coefficients	β_0	β_1	β_2
Subregion 1	28.308	0.215	-125.941
Subregion 2	49.295	0.189	-143.373
Subregion 3	53.621	0.195	-159.288
Subregion 4	32.671	0.152	-79.299
Subregion 5	40.356	0.147	-87.522

4. Conclusion

The computational cost of applications involving complex simulations can be greatly reduced with the help of surrogate models. They also provide an efficient way for handling scale interactions in a multi-scale system. Usually, local surrogate models provide better approximations rather than a single surrogate model spanning the entire design space. In deterministic computer experiments without any stochastic noise, the surrogate models are better validated by defining a tolerance criteria for the gap between the responses of the complex and the surrogate model. The common variance-based arguments are only giving a measure for the lack of fit and the standard statistical arguments do not apply, so the computations are deterministic and free of stochastic contaminations. The tolerance criteria should be defined by the application using the surrogate model so as to avoid the large errors caused by error propagation from the model to the application. In the illustrative example considered, the local linear surrogate models provide a good approximation of the Redlich-Kwong equation (the exceptions being at very low values of volume). When dealing with divided design spaces, the issue of discrepancies in the results at the borders of the subregions can be addressed by using statistical techniques like averaging or interpolating.

Systematic Development of Kinetic Models for Systems Described by Linear Reaction Schemes

Carolina S. Vertis, Nuno M.C. Oliveira and Fernando P.M. Bernardo

CIEPQPF; Dep. Chemical Engineering; University of Coimbra; Coimbra, Portugal
nuno@eq.uc.pt

Abstract

A phased approach for generation of linear reaction schemes, i.e., schemes where each reaction has only one reactant and one product as principal species, is proposed in this work. Exhaustive generation of all stoichiometric consistent chemical reactions and enumeration of all possible reaction schemes (based on mass flux analysis), is considered. A graph approach is used for representation of the reaction schemes, and a network model used to elucidate the structure of alternative models at a given level of complexity. After the selection of plausible model structures, determination of possible model parameters is performed in a later step, through regression of the experimental data available. We consider the application to a relevant case study, capable of evidencing the gains and advantages resulting from this systematic analysis.

Keywords: reaction schemes, identification, kinetic model development, discrete optimization.

1. Introduction

Kinetic models of chemical reaction systems provide fundamental information for chemical process design and optimization. The traditional approach to develop these models is to postulate a reaction scheme (network of chemical reactions) based on observed species, their concentrations and eventually some theoretical or heuristic considerations on plausible reaction pathways. On top of this reaction scheme, kinetic laws for each reaction step are established, and regression of experimental data is used to determine the corresponding kinetic parameters. If reasonable statistical adjustment is achieved, the overall kinetic model, comprising the initially postulated reaction scheme and the estimated kinetic parameters, is accepted. If not, modifications are introduced, either in the kinetic models and/or in the reaction scheme used to describe the system. Due to the nonlinear nature of the regression problems, the required modifications are often not prominent (or unique), and tend to be dependent on the expectations of the modeler relative to the behavior of the system. Clearly, this is not a systematic procedure and, as such, it does not guarantee that the most plausible schemes are examined. This is especially true when the number of species and consequently the total number of possible reaction schemes is high. In these cases, a successful approach for kinetic model development requires a substantial integration between different phases such as thorough enumeration of alternatives structures, discrimination between competing models and planning of new experiments, identification of the reaction network structure, selection of the kinetic laws that describe each individual step, regression of kinetic parameters, and finally the validation of the overall results.

The identification of reaction schemes is a topic addressed in the literature under different contexts, such as the analysis of biological metabolic networks and chemical systems with catalytic and non-catalytic reactions. A recent review of existent methods for reaction-pathway identification

separates these in two major groups: methods based on linear algebraic analysis and others based on graph theory (Bertók and Fan, 2013). All of these techniques consider a steady state approach, starting from an overall reaction (formed only by terminals species), and considering elementary steps that can be incrementally combined to produce the desired global reaction. These methods usually address the generation of direct (cycle-free) mechanisms, which are composed by a set of linearly independent reactions. Sellers (1984) proposed a combinatorial method to identify chemical mechanisms using linear algebraic analysis, describing a chemical system by an integer matrix which express the incidence relations between all chemical species and all elementary reactions in the system. The graph theoretic approach provides a different approach, following a list of axioms of feasible reaction pathways and feasible reaction networks to identify mechanisms at steady state, starting from a global reaction. It relies on a graph representation with several types of graphs, including bipartite graphs (P-graphs) (Seo et al., 2001; Fan et al., 2002).

Despite these contributions, a systematic and well-structured kinetic model development approach is still missing, in particular one that fully incorporates experimental data when examining alternative reaction schemes. This paper proposes a methodology that addresses these needs, organized in sequential steps, which include: (i) the exhaustive search of the space of possible reaction schemes, in order of increasing complexity, (ii) the selection of the most plausible reaction schemes in face of the available experimental data, and (iii) detailed kinetic modelling of each reaction step. In the present work, only linear reaction schemes are considered, i.e., reaction schemes where each reaction has only one reactant and one product (Temkin et al., 1996). Nevertheless, the structure of the methodology can be adapted to more general situations. Compared with the more traditional approach, an important advantage of the proposed method is the separation of the tasks of elucidation of the reaction scheme from the determination of the kinetic laws for each reaction scheme. This avoids the use of nonlinear regression in the initial development phases, eliminating their associated numerical problems, e.g., the presence of multiple local optima, which often complicate the model development task.

2. Description of the methodology

The main structure of the proposed methodology is described in Figure 1. In the first step (s1), the list of possible chemical reactions between the species present in the system is identified. In the present case only linear chemical reactions are considered; moreover, the list of possible reactions is generated solely based on stoichiometric considerations. Other useful criteria for this step include thermodynamic and energetic issues (Fishtik et al., 1999; Fishtik and Datta, 2000). The generation algorithm is based on a MILP (mixed integer linear programming) formulation and exhaustive enumeration of feasible solutions (corresponding to possible reactions), using integer cuts. The set of solutions found in this step forms a *superstructure* for the individual reaction schemes considered in the next steps.

The second step (s2) corresponds to the generation of reaction schemes through combination of reactions enumerated in step 1. Since only linear reactions were considered, the schemes generated are also linear. Each reaction scheme is represented by a graph, where nodes correspond to principal chemical species and arcs to chemical reactions. The generation methodology is presented in more detail in Section 3 and is based on a structural flux analysis, ensuring that only connected schemes are generated. The mathematical formulation corresponds to a MILP problem, whose solutions represent candidate reaction schemes.

In the third step (s3), the available experimental data is considered; it is assumed that this corresponds to concentration profiles obtained in non-stationary conditions. Continuous approximations of these profiles are obtained through orthogonal collocation on finite elements, obeying appropriate global mass conservation constraints, e.g., for closed systems. The coefficients of the approximating polynomials are calculated as the solution of a quadratic optimization problem, in-

cluding regularization constraints as needed, to avoid undesired oscillations in the approximated profiles. The smoothed profiles thus obtained are used to calculate reliable estimates of the derivatives dC/dt, for calculation of the reaction rates in the next step.

The fourth step (s4) involves the use of the time derivatives of the concentration profiles to establish a detailed flux analysis for each reaction network considered. This enables a first selection of the plausible reaction schemes from the entire list of possible schemes generated in step 2, as the ones where positive or null (net) reaction rates are observed, for each reaction. The actual analysis performed on this phase depends on the *redundancy index* (IR) of the network considered. This is defined as the number of additional pathways (chemical reactions) in the network compared with the minimum number of pathways ($\mathtt{nrx}_{\mathtt{min}}$) that allow a network to remain fully connected, with a fixed number of nodes, where $\mathtt{IR} \geq 0$. The minimum number of pathways among species that ensure a connected network is equal to the number of species minus one (Meyer, 2000; Marin and Yablonsky, 2011). For schemes with $\mathtt{IR} = 0$, the calculation of the instantaneous reaction rates can be done through the solution of a linear system of equations $Ar(t) = dC(t)/dt$, where A is the incidence matrix, and $r(t)$ the vector of reaction rates at time t. For schemes with $\mathtt{IR} > 0$ the calculation of the instantaneous reaction rates cannot be performed as in the previous case, since the above linear system is underdetermined; in this case the flux analysis requires the use of additional data sets and the correlation between fluxes in consecutive time intervals. However, even in this situation, a max-min methodology can be used to eliminate clearly infeasible reaction schemes. Due to space limitations, the complete analysis of this case is outside the scope of the present paper, where the application example considered has only $\mathtt{IR} = 0$.

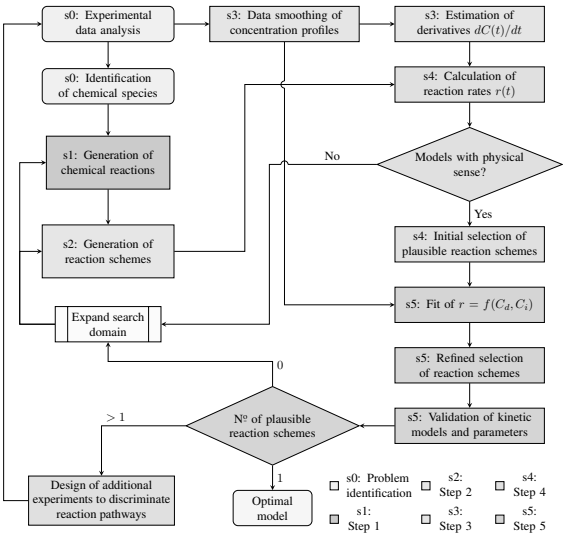

Figure 1: Structure of the methodology for development of kinetic models.

The fifth and last step (s5) of the methodology allows a finer selection of reaction schemes, now based on the regression analysis of the individual reaction rates calculated in step 4 with the concentrations of each reactant and reaction product. This task is now much simplified, since the structure of each candidate reaction network can now be considered fixed. If a good correlation between each reaction rate and the corresponding species reactant and product species is found, the scheme is considered a good plausible candidate to explain the kinetic data. If either steps 4 or 5 result in an empty set, this means that neither of the considered reaction schemes is a reasonable model for the observed data. Therefore, one should go back to steps 1 or 2 and expand the search space, considering other chemical reactions and/or more complex schemes. If, on the other hand, too many alternative schemes are equally good and remain at the end of step 5, then further experimental studies are recommended, to discriminate between competing reaction schemes, or properly identify still unclear partial pathways. In this analysis, the uncertainties inherent to the experimental data used can also be considered.

3. Generation of linear reaction schemes

The starting point for the generation step of reaction schemes is the superstructure that represents the reaction scheme with maximum complexity, by incorporating all possible reactions identified in step 1 (Figure 2). Alternative schemes contained in this superstructure are generated through a structural flux analysis with mass balances for each node. The structure has nodes corresponding to each participating species, plus two additional (fictitious) nodes: a *supersource* node, that injects the quantity X into the network, and the *supersink* node, that receives quantities Y, Z, V and W from each of the nodes. These quantities are determined depending on the desired complexity (IR) for the reaction scheme, and are such that only connected graphs are generated, thus avoiding isolated subgraphs.

The following sets are defined: c — chemical species (nodes), rx— chemical reactions (arcs), c1 and p1— subsets of c that contain the principal components and product species; p1 has the same species as c1 except the initial reactant(s). The auxiliary sets exd and exi are conditional sets used to denote that a given reaction occurs in the direct or reverse form in the scheme considered. In the superstructure of Figure 2 the supersource node is only connected to components initially present in the reacting mixture, and injects the amounts $\mathtt{ss}_i$:

$$\mathtt{ss}_i = \begin{cases} \mathtt{IR} + \mathtt{nrx}_{\mathtt{min}}, & \forall i \in \mathtt{c1} \backslash \mathtt{p1} \\ 0 & \forall i \in \mathtt{p1} \end{cases}$$

The supersink node is connected to all node species in the network, and absorbs the amount $\mathtt{ni}_i$ from each node, where $\mathtt{ni}_i$ represents the number of incident arcs in the respective node, i.e., the number of pathways that have that node as a product. Binary variables $\mathtt{ycpr}_{i,j}$ are used to represent the fact that chemical species $i \in \mathtt{c1}$ is a product in the reaction $j \in \mathtt{rx}$ (or not). In this case:

$$\mathtt{ni}_i = \sum_{j \in \mathtt{rx}} \mathtt{ycpr}_{i,j}, \qquad \forall i \in \mathtt{c1}$$

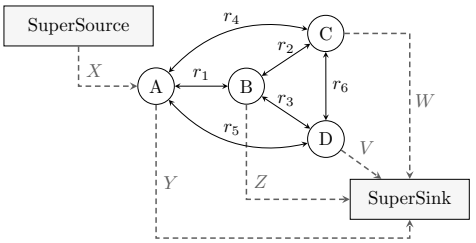

Figure 2: Reaction network superstructure representation.

A generic mass balance for each node can be written as equation (2), where $F_{i,i'}$ corresponds to the flux between the specie i to i', and am is the adjacency matrix which identifies the connections between species, with $\mathtt{am} \equiv [\mathtt{am}_{i,i'}], \forall i, i' \in \mathtt{c1}$. The formulation uses binary variables to choose the direction of the pathways, according to the reaction pathways in the corresponding network; in this case $\mathtt{yrxd}_j$ represents a direct pathway and $\mathtt{yrxi}_j$ a reverse one. Each of the reactions can be considered only in a given direction for the purpose of generation of the reaction scheme, as given by equation (3), since reversible reactions occur predominantly in a given direction, until equilibrium is reached. Additional constraints ensure that if a reaction exists in the scheme, the structural flux cannot be zero, while other constrains establish upper limits in this flux — equations (4).

The stoichiometric coefficients calculated in step 1 are stored in parameters $\mathtt{nsre}_{i,j}$ and $\mathtt{nspr}_{i,j}$, with $i \in \mathtt{c1}$, $j \in \mathtt{rx}$. These parameters are used to define equations (5–7), linking variables $\mathtt{ycpr}_{i,j}$, $\mathtt{yrxd}_j$ and $\mathtt{yrxi}_j$. Enforcing network connectivity, all products have to be generated at least once, up to a limit of $\mathtt{II}_{max}$ times, where $\mathtt{II}_{max} = \mathtt{IR} + 1$, as given by equation (8). Finally, a constant objective function is adopted, equal to the number of chemical reactions in the network (equation 1). Each feasible reaction scheme is sequentially generated through the solution of the optimization problem (1–9), corresponding to a MILP network problem with integer coefficients. The complete enumeration of all possible reaction schemes can be achieved either through incremental addition of integer cuts to the formulation (and resolving it) or, more efficiently, through the use of a MILP

solver that allows the direct enumeration of all feasible solutions at once.

$$\min_{\substack{F,\mathtt{yrxd},\\ \mathtt{yrxi},\ \mathtt{ycpr}}} \quad n_{\mathtt{rx}} = \sum_{j\in\mathtt{rx}} \mathtt{yrxd}_j + \mathtt{yrxi}_j \tag{1}$$

$$\text{s.t.} \quad \mathtt{ss}_i + \sum_{i'\in\mathtt{c1}} F_{i',i}\,\mathtt{am}_{i',i} - \sum_{i'\in\mathtt{c1}} F_{i,i'}\,\mathtt{am}_{i,i'} - \sum_{j\in\mathtt{rx}} \mathtt{ycpr}_{i,j} = 0, \quad \forall i \in \mathtt{c1} \tag{2}$$

$$\mathtt{yrxd}_j + \mathtt{yrxi}_j \le 1, \quad \forall j \in \mathtt{rx} \tag{3}$$

$$\begin{aligned} &F_{i,i'} \ge \mathtt{yrxd}_j, \quad \forall (i,i',j) \in \mathtt{exd} \qquad F_{i,i'} \ge \mathtt{yrxi}_j, \qquad \forall (i,i',j) \in \mathtt{exi} \\ &F_{i,i'} \le \mathtt{yrxd}_j N, \quad \forall (i,i',j) \in \mathtt{exd} \qquad F_{i,i'} \le \mathtt{yrxi}_j N, \qquad \forall (i,i',j) \in \mathtt{exi} \end{aligned} \tag{4}$$

$$\mathtt{yrxd}_j = \mathtt{ycpr}_{i,j}, \quad \forall i \in \mathtt{c},\ j \in \mathtt{rx}, \qquad \text{if } \mathtt{nspr}_{i,j} \ne 0 \tag{5}$$

$$\mathtt{yrxi}_j = \mathtt{ycpr}_{i,j}, \quad \forall i \in \mathtt{c},\ j \in \mathtt{rx}, \qquad \text{if } \mathtt{nsre}_{i,j} \ne 0 \tag{6}$$

$$\mathtt{ycpr}_{i,j} = 0, \quad \forall i \in \mathtt{c},\ j \in \mathtt{rx}, \qquad \text{if } \mathtt{nsre}_{i,j} = 0 \wedge \mathtt{nspr}_{i,j} = 0 \tag{7}$$

$$\sum_{j\in\mathtt{rx}} \mathtt{ycpr}_{i,j} \ge 1, \quad \forall i \in \mathtt{p1}, \qquad \sum_{j\in\mathtt{rx}} \mathtt{ycpr}_{i,j} \le \mathtt{II}_{max}, \quad \forall i \in \mathtt{c1} \tag{8}$$

$$F_{i,i'} \in \mathbb{N}_0^+, \quad \forall (i,i') \in \mathtt{c1}, \quad \mathtt{yrxd}_j,\ \mathtt{yrxi}_j,\ \mathtt{ycpr}_{i,j} \in \{0,1\}, \quad \forall i \in \mathtt{c},\ j \in \mathtt{rx} \tag{9}$$

4. α-pinene case study

This methodology is illustrated by the application to the thermal isomerization of α-pinene (Fuguitt and Hawkins, 1945; Stewart and Sørensen, 1981). This system comprises 5 chemical species: α-pinene (AP), limonene (LIM), allo-ocimene (AO), β-pironene (BP) and a dimer (D). We fixed the chemical reaction $r_9 : 2\,\mathrm{AO} \longrightarrow \mathrm{D}$ in all generated schemes, since its presence is known previously. Two data sets from isothermal batch experiments at different temperatures are used (T1 and T2). In this case 50 reaction schemes were generated, and 31 (and 34) schemes were selected as plausible in step 4, for data sets T1 and T2, respectively. In step 5 of the methodology, regression of the corresponding reaction rates considering simple homogeneous kinetics for each reaction rate in each plausible reaction scheme were considered, and used to discard most of the candidates. Figure 4 and Table 1 present the structure and numeric values of the parameters found for the best candidate, after the termination of the selection procedure. Significant differences in the regression results relative to the additional alternatives were found; together with the fact that the same solution was found for each data set considered individually, this provides additional confidence that the reaction scheme depicted in Figure 4 is the most adequate to describe the experimental data available, at this level of model complexity ($\mathtt{IR} = 0$).

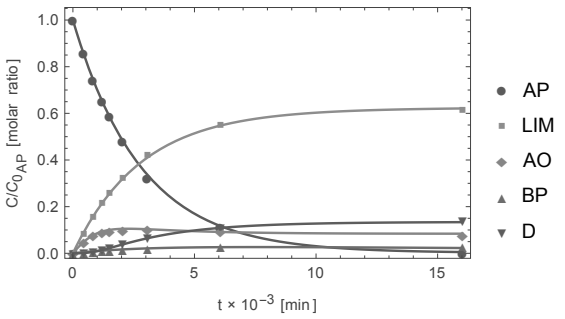

Figure 3: Experimental isothermal data T2 and simulation with the fitted kinetic parameters.

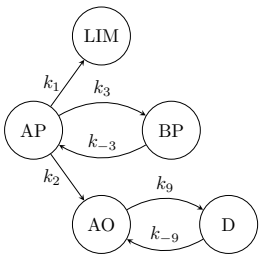

Figure 4: Reaction scheme proposed in this work for the thermal isomerization of α-pinene.

Table 2 compares the results of this model with the equivalent results provided by the model identified by Stewart and Sørensen (1981). The underlying reaction schemes are significantly

different, and the later model uses a larger number of chemical reactions. However, given the experimental data available, the proposed model is able to provide a lower sum of squared errors (SSE). This illustrates the importance of systematic evaluation of model alternatives, and the need of extra experimental or theoretical information to justify more complex model structures.

Table 1: Reaction rates and kinetic parameters, in min^{-1} for first order reactions and $\text{min}^{-1}\,\text{C}^{-1}$ for second order reactions (data set T2).

rx	Model	$k_d \times 10^3$	$k_i \times 10^3$
r_1	$k_d C_{AP}$	0.220	–
r_2	$k_d C_{AP}$	0.124	–
r_3	$k_d C_{AP} - k_i C_{BP}$	0.012	0.030
r_9	$k_d C_{AO}^2 - k_i C_D$	3.167	0.165

Table 2: Comparative results of objective function value for data sets T1 and T2.

Model	T1	T2
Stewart and Sørensen (1981)	0.00710	0.01337
This work	0.00288	0.00075

5. Conclusions

A sequential methodology for the development of chemical reaction kinetic models, which explores the space of possible reaction schemes and gradually selects the simplest schemes able to satisfactorily explain the available experimental data, is proposed. The determination of kinetic parameters through nonlinear regression is left to the final stage of the methodology where only the most plausible schemes arrive. Therefore, the confidence in the estimated kinetic parameters is likely to be higher than the one obtained using the traditional approach to kinetic modeling (based on a postulated reaction scheme with no guarantees that others may better explain the observed data). The methodology was applied to one case study, illustrating that even for relatively simple systems the number of plausible reaction schemes may be high, and that alternative reaction schemes could be found. Moreover, the methodology also illustrates that in some cases the available data is not enough to completely identify a reaction scheme; in such cases this model development should be complemented with directed additional experiments, to elucidate specific uncertain pathways.

Abstract

A model and solution strategies are investigated for the optimization of a Dividing Wall Batch Reactive Distillation Column (DWBRC). In order to accomplish this objective, we describe a dynamic model that involves tray-by-tray calculations for the time varying column profiles. In order to compare the simultaneous solution of the system of differential and algebraic equations, two different approaches are used: equation oriented based on orthogonal collocation implemented in GAMS, and control vector parameterization (CVP) as implemented in gPROMS.

Keywords: Reactive batch distillation, dynamic optimization, Dividing Wall Columns

1. Introduction

Reactive Batch Distillation Columns (RBC) have been studied as a promising technology due to its dual functionality: separation and reaction. Modeling, simulation, and optimization of batch distillation processes rely on dynamic models. A number of different solution approaches for this kind of systems, described by a set of differential and algebraic equations (DAEs) have been proposed in the literature. One of these approaches has been developed by Biegler (1984), in which the dynamic optimal control problem is approximated by a finite dimensional nonlinear program (NLP) through the discretization of all variables using finite elements with orthogonal collocation points. This equation oriented approach can then be solved with GAMS (General Algebraic Modeling System 24.2.2) as an NLP problem to simultaneously perform the optimization while converging the DAEs. The other solution method is the Control Vector Parametization (CVP) proposed by Vassiliadis et al. (1994) which relies on the iterative solution of DAEs in the space of the control variables in order to perform the optimization with a Successive Quadratic Programming (SQP) method.

In this study we propose the optimal design and operation of a Dividing Wall Batch Reactive Distillation Column (DWBRC). We propose an esterification reaction for the production of ethyl acetate (as the distillate product). This study investigates with the two solution approaches how the parameters such as vapor flow rate (V, $kmol/hr$) and optimal control variable reflux ratio ($RR = R/V$) are to be adjusted to maximize the productivity in the column for a given product specification. First, we provide the problem statement followed by the proposed mathematical model in section 3. The model was solved using two different approaches presented in section 4 for the production of ethyl acetate. The column configuration and operational conditions are

presented in section 5. The results are shown in section 6 followed by the conclusions in section 7.

2. Problem statement

In a general form the problem can be stated as follows:

≪ Given a feed consisting of a mixture of NC components, the column configuration, and product purity specification for a key distillate component. The goal is to maximize an objective function by manipulating the column reflux ratio RR(t) and vapor flowrate V to purify a given mixture until an NC pure component is obtained (inside some pre-specified tolerance). ≫

The specific dynamic optimization problem can then be described as:

Given:	Column configuration, feed mixture, vapor flow rate, product purity and batch time.
Determine:	Optimal reflux ratio.
To maximize:	The amount of distillate product.
Subject to:	Equality and inequality constraints.

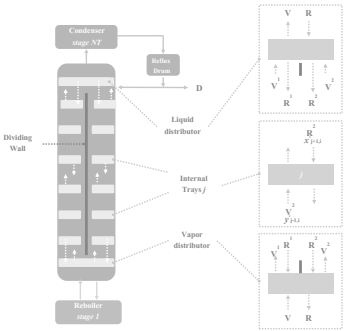

Figure 1: Batch Reactive Distillation Column (BRC)

The reflux ratio $RR(t)$ is considered the control variable in the optimization problem. A general profit function P that combines the minimum time and the maximum distillate problem is given by Mujtaba (2004) and is used in this study:

$$P = \frac{C_1 D - C_2 M_{B_0}}{t_B + t_S} - C_3 \tag{1}$$

where P is the profit ($\$/hr$), D is the amount of distillate product ($kmol$), C_1 is the sales value of the distillate product ($\$/kmol$), M_{B_0} is the initial raw material charge ($kmol$), C_2 is the cost of raw material ($\$/kmol$), C_3 is the fixed operating cost (energy, wages, depreciation, etc., $\$/hr$), t_B is the batch time (hrs) and t_S is the set up time (charging and cleaning time between batches, hrs). In mathematical terms, the optimization problem can be represented as:

$\mathbf{max}_{RR(t)}$	**D**	
s.t.	Dynamic process equations	(equality constraints)
	$x_{product}(t) \geq x_{desired}$	(inequality constraint)
	Bounds on Q_{REB} *and* $D_{product}$	(inequality constraint)

3. Dynamic Process Equations

In order to solve the optimization problem shown in the previous section, it is necessary to develop a rigorous model to successfully predict the behavior of the variables with respect to time. Two basic assumptions are applied in the formulation of the model:

1. The vapor phase holdup is assumed to be negligible compared to the liquid phase holdup on each plate.
2. Chemical reactions in the vapor phase are neglected.

The proposed set of differential and algebraic equations (DAEs), can be decomposed into different equations: mass balances, energy balances, equilibrium equations (chemical, physical and thermodynamic) and other equations such as reaction rate, summation of compositions, etc. The set of equations that constitutes the proposed model is presented in the set of Equations 2-19, which are derived from the distillation column on Figure 1. The heat of reaction in the energy balance equations is omitted because heat of formation at the standard conditions is used as a base for enthalpy calculations. The notation for the variables is given in Figure 2. The stages are numbered from bottoms to top of the batch column, stage 1 being the reboiler and condenser the stage 10. More details about the column are given in Section 5.

Total mass balances

Reboiler: $j = 1\text{n}$

$$\frac{dM_B}{dt} = -D + \Delta n_1 M_B \tag{2}$$

Distributors: $j = NT - 1$ and Tray 2

$$\frac{dM_j}{dt} = R^1_{j+1} + R^2_j - R_j + V_{j+1} - V_j + \Delta n_j M_j \tag{3}$$

Internal Trays: $j = 2$ and $NT - 2$

$$\frac{dM^1_j}{dt} = R^1_{j+1} - R^1_j + V^1_{j-1} - V^1_j + \Delta n^1_j M^1_j \tag{4}$$

Component mass balances

Reboiler: $j = 1$

$$M_B \frac{dx_{B,i}}{dt} = R_2 x_{2,i} - R_B x_{B,i} - V_B(x_{B,i} - y_{B,i}) + r_{B,i} M_B - \Delta n_i M_B \tag{5}$$

Distributors: $j = 2 and j = NT - 1$

$$\frac{d(M_j x_{j,i})}{dt} = R^1_{j+1} x^1_{j+1,i} + R^2_{j+1} x^2_{j+1,i} - R_j x_{j,i} + V_{j-1} y_{j-1,i} - V_j y_{j,i} + r_{ji} M_j \tag{6}$$

Internal Trays (section 1 and 2): $j = Distributor + 1, ..., NT - 2$

$$\frac{d(M^1_j x^1_{j,i})}{dt} = R^1_{j+1} x^1_{j+1,i} - R^1_j x^1_{j,i} + V^1_{j-1,i} y_{j-1,i} - V^1_j y^1_{j,i} + r^1_{ji} M^1_j \tag{7}$$

$$\frac{d(M^2_j x^2_{j,i})}{dt} = R^2_{j+1} x^2_{j+1,i} - R^2_j x^2_{j,i} + V^2_{j-1,i} y_{j-1,i} - V^2_j y^2_{j,i} + r^2_{ji} M^2_j \tag{8}$$

Condenser: $j = NT$

$$\frac{d(M_{NT} x_{NT,i})}{dt} = V_{NT-1} y_{NT-1,i} - (V_j + \Delta n_{NT} M_{NT}) x_{NT,i} + r_{NT,i} M_{NT} \tag{9}$$

Energy balance

Reboiler: $j = 1$

$$0 = Q_{REB} + R_2 h^L_2 - R_B h^L_B + V_B(h^L_B - h^V_B) \tag{10}$$

Distributors: $j = NT - 1$ and Tray 2

$$R^1_{j+1} h^{L_1}_{j+1} - R^2_{j+1} h^{L_2}_{j+1} - R_j h^L_j + V_{j-1} h^V_{j-1} - V_j h^V_j = 0 \tag{11}$$

Internal Trays: $j = Distributor + 1, ..., NT - 2$

$$R^1_{j+1} h^{L_1}_{j+1} - R^1_j h^{L_1}_j + V^1_{j-1} h^{V_1}_{j-1} - V^1_j h^{V_1}_j = 0 \tag{12}$$

Condenser: $j = NT$

$$Q_{COND} - V_{NT-1} h^V_{NT-1} + (V_{NT-1} + \Delta n_{NT} M_{NT}) h^L_{NT} = 0 \tag{13}$$

Equilibrium relationship and vapor and liquid summations

$$y_{j,i} = K_{j,i} x_{j,i} \quad and \quad y_{j,i}^{1,2} = K_{j,i} x_{j,i}^{1,2} \qquad , \qquad \Sigma y_{j,i} = 1 \quad and \quad x_{j,i} = 1 \tag{14}$$

Vapor-Liquid Equilibrium constant

$$K_{j,i} = K_{j,i}(x_{j,i}, T_j, P_j) \quad and \quad K_{j,i}^{1,2} = K_{j,i}^{1,2}(x_{j,i}^{1,2}, T_j^{1,2}, P_j) \tag{15}$$

Enthalpy

$$h_{j,i}^{L} = h_{j,i}^{L}(x_{j,i}, T_j, P_j) \quad and \quad h_{j,i}^{L_{1,2}} = h_{j,i}^{L_{1,2}}(x_{j,i}^{1,2}, T_j^{1,2}, P_j) \tag{16}$$

$$h_{j,i}^{V} = h_{j,i}^{V}(y_{j,i}, T_j, P_j) \quad and \quad h_{j,i}^{V_{1,2}} = h_{j,i}^{V_{1,2}}(y_{j,i}^{1,2}, T_j^{1,2}, P_j) \tag{17}$$

Reaction and Reaction Terms

$$\underset{(acetic\,acid)}{AcOH} + \underset{\text{(ethanol)}}{EtOH} \leftrightarrow \underset{\text{(ethyl acetate)}}{EtOAc} + \underset{\text{(water)}}{H_2O} \tag{18}$$

$$\Delta n_j = \Sigma r_{j,i} \quad when \quad r_{j,i} = r_{j,i}(k_{j,i}, x_{j,i}) \tag{19}$$

j and i are the number of trays and components, respectively
$x_{j,i}$ is the liquid mole fraction for tray j and component i
$y_{j,i}$ is the vapor mole fraction for tray j and component i
D is the distillate flowrate
R_j is the liquid flowrate in tray j
V_j is the vapor flowrate in tray j
M_B and M_{NT} are the reboiler and distillate holdup, respectively
Q_{REB} is the energy consumed in the reboiler
Q_{COND} is the energy consumed in the condenser
h_j^L is the liquid enthalpy in tray j
h_j^V is the vapor enthalpy in tray j
superscript 1 and 2 represent left side (*section* 1) and right side (*section* 2) of the dividing wall batch column, respectively

Figure 2: Notation used on the dynamic model

4. Solution approaches

In order to determine the optimal solution of the dynamic model presented in the previous section, we summarize below some of the issues that arise in the two approaches used in this study.

4.1. Solving the optimization problem by an Equation Oriented Approach

In this approach the set of DAEs (Equations 2 - 19) is discretized into a set of algebraic equations by applying finite elements and the orthogonal collocation method developed by Cuthrell and Biegler (1987). These equations are then used in a large-scale NLP model. The use of finite elements and collocation points provides more flexibility but the error in the discretization cannot be easily controlled. The proposed DAE system involves a complex set of equations that leads to an index 2 problem. To be solved, the index should be reduced to 1 by differentiating the equation $\sum_{i=1}^{NC} x_{j,i} = 1$. This leads to a new algebraic equation that substitutes the internal trays mass balances given in Equation 7 for one component.

4.2. Solving the optimization problem by Control Vector Parameterization Approach

To formulate the optimal control problem as a reduced NLP problem, the control variable RR(t) is approximated by a finite dimensionally equation. The time interval is divided into a finite number of subintervals, each involving a finite number of parameters for the control variables to be optimized. This new problem is subjected to the constraints of the model and can be solved using a Succesive Quadratic Programming (SQP) algorithm. This approach has the advantage of providing a direct control of the discretization error by adjusting the size and order of the integration steps using integration techniques.

5. Case study

The reaction-separation is carried out using a 10 tray Dividing Wall Batch Reactive Column (DWBRC). The operational conditions are given in Table 1. An amount of 100 kmol is fed into the reboiler at the start of the operation with the next composition in mole fraction: 0.45 acetic acid, 0.45 ethanol and 0.10 water. The distillate product must achieve a purity of at least 0.70 in mole fraction of ethyl acetate in the distillate with a fixed batch time of 1 hour. The performance is modeled assuming a constant molar holdup for each tray (a total column holdup of 4% of the initial feed where 50% is taken as the condenser hold up and the rest is equally divided in the plates). Constant relative volatilities, calculated using NRTL are used for the various components for modeling the phase equilibrium. The initial values for the system variables are calculated at total reflux in the steady state. The reaction zone extends from tray 1 to 9. The production of ethyl acetate by the esterification of acetic acid with ethanol is accomplished by the stoichiometric equation 18.

Table 1: Operational conditions for the batch reactive column: acetic acid esterification

Number of Trays	
(including reboiler and condenser)	10
Feed, M_{B_0}, kmol	100
Vapor, V, kmol/h	Variable
Vapor and Liquid Distributors	$\beta_1 = 0.70$
	$F_1 = 0.70$
Composition Feed, x_i^0, mole fraction	
Acetic Acid	0.45
Ethanol	0.45
Ethyl Acetate	0
Water	0.10
Activity coefficients (NRTL), α_i	
Acetic Acid	0.98
Ethanol	0.99

Condenser	0.283
Internal trays	0.071
Column Pressure, P, bar	
Condenser	1.05
Internal Trays	1.12-1.08
Reboiler	1.2
Reaction equations given in Mujtaba (2004)	
r = $k_1C_1C_2$ - $k_2C_3C_4$	
$k_1 = 4.76x10^{-4}$	
$k_1 = 1.63x10^{-4}$	

6. Results

The optimization problem is solved by discretizing the differential equations using the two approaches presented in section 4 with the next specifications: the CVP approach implemented in gPROMS and the equation oriented approach with 10 finite elements and 3 collocation points implemented in GAMS (24.2.2) using CONOPT as the NLP solver. The objective is to maximize the productivity by converting the maximum profit problem in a maximum productivity problem when $C_1 = 1$ and $C_2 = C_3 = t_S = 0$ in Equation 1. The reflux ratio is used as the control variable. Five different cases with different vapor flowrates were studied. All examples were solved on a Workstation with 8 GB RAM memory and Intel®CoreTM i7 CPU (2.20 GHz).

The CVP approach results in a system of 530 equations and 600 variables. The optimization problem is solved in 40 seconds. From the results presented in Table 2(a). The fixed batch time is 1.0 *hour*, while the optimal reflux ratio is piecewise as shown in Figure 3(c) for all vapor flowrates. It is clear that the maximum amount of distillate product $D_{ethylacetate}$ $(kmol)$ is achieved for the maximum vapor flowrate $V = 90\ kmol/hr$. The equation oriented approach results in a system of 532 equations and 698 variables. The optimization problem is solved in 318 seconds. The results are presented in Table 2(b). As in the CVP approach, the batch time is 1.0 *hour*. The maximum amount of distillate product $D_{ethylacetate}$ $(kmol)$ is achieved for the maximum vapor flowrate $V = 80$ $kmol/hr$. In both approaches, the amount of distillate and the energy consumption were directly proportional to increases in vapor flowrate. Therefore, any higher purity would require higher energy consumption. A comparison between the calculated reboiler energy shows that the EOA needs a better initial point for the temperatures in the trays. The accumulated distillate composition profiles for the maximum distillate product for the two approaches are shown in Figures 3(a) and 3(b).

Table 2: Results for the productivity maximization

(a) Results for the CVP approach

Vapor (kmol/hr)	Q_{REB} (kJ)	D_{EtOAc} (kmol)

7. Conclusion

In this work, a model for the optimization of a dividing wall batch reactive distillation column when the esterification of ethanol using acetic acid to produce ethyl acetate is studied. A maximum productivity optimization problem is solved under fixed distillate product purity (ethyl acetate concentration higher than 0.70 in mole fraction). The results show that the problem is solved using the two different approaches: the finite elements with collocation points implemented in GAMS (24.2.2), and the control vector parametization implemented in gPROMS (2004) with no major differences on the calculated variables values. These differences are due to the discretization error carried out during the discretization. Also, the results show that significantly more CPU time is required with the EOA approach.

Abstract

The representation and graphical visualization of the chemical components in the composition space is a powerful tool for the analysis and interpretation of process systems behaviour. Reactive distillation is a relatively new technique combining reaction and separation by distillation. Numerous applications are reported in literature, giving details on process design. However, no commercial software is providing tools for representation of reactive residual curve maps. Reasonable explanation can be provided by complex reaction kinetics which is not easy to implement in software. In this study, liquid vapour equilibrium in (non)reactive systems is calculated to build (non) reactive residual curve maps, using SIMULIS® Thermodynamics (from ProSim, France) as database and server for with different thermodynamic models and MATLAB to solve the mathematical model aimed to build (non)reactive residual curve maps. The communication between those software applications is ensured by a MATLAB toolbox provided by ProSim. Graphical facilities of MATLAB allow making suggestive representations. The work consists in setting up the methodology and the mathematical models for (non)reactive residue curve maps for non-reactive and kinetically controlled scenarios.

Keywords: reactive distillation, residual curve maps, feasibility analysis
