The main objective of this work is to theoretically simulate Reactive Curve Maps for the production on TAME (tert-amyl-methyl-ether), in order to check the feasibility of the reactive distillation process. Two theoretical models are used for this process: a non – reactive process where the RCM's are created for the Isopentane – Methanol – TAME system and a kinetically controlled process for the Isoamylenes – Methanol – TAME system.

In this respect MATLAB® – SIMULIS® Thermodynamics communication facility is used to calculate liquid vapor equilibrium in (non) reactive systems. In this way,

MATLAB powerful calculating tools are used to integrate the high complexity thermodynamic models implemented in SIMULIS® Thermodynamics.

2. Case study

The increased interest for using tertiary ethers as additives intensified the research to study thermodynamic and kinetic aspects of the chemical reactions involved in their synthesis. Most of the models published so far to characterize the process for tertiary ethers synthesis were focused only on the main reaction. The prime process involves three simultaneous reversible reactions, two etherification reactions of isoamylenes with methanol (MeOH) and the isomerization between 2M1B (2-Methyl-1-Butene) and 2M2B (2-Methyl-2-Butene), over an acidic ion-exchange resin. The networks for the reactions are presented in equations 1-3. in which the reaction pairs shown establish the reaction equilibria.

$$MeOH + 2M1B \underset{k-1}{\overset{k+1}{\Longleftrightarrow}} TAME \tag{1}$$

$$MeOH + 2M2B \underset{k-2}{\overset{k+2}{\Longleftrightarrow}} TAME \tag{2}$$

$$2M1B \underset{k-3}{\overset{k+3}{\Longleftrightarrow}} 2M2B \tag{3}$$

These are the main reactions used in most of the studies of modelling the kinetics of the reaction (Kirivanta –Paakkonen, 1998) and the chemical reactor (Su and Chang, 2000).
Mathematically, the residue curves can be calculated for any number of chemical compounds. Unfortunately, only three components can be represented in a bi-dimensional surface using a Gibbs diagram. For calculating the reactive residual curves, the isoamylenes are lumped in order to have three components in the system (Isoamylenes, Methanol and TAME). This method was proposed by Thiel et al. (1997). This is possible because the two isoamylenes components which are part of TAME synthesis – 2 methyl 1 butene and 2 methyl 2 butene – are chemically and thermodynamically similar and usually are fed in equilibrium in the column. Equations (1) and (2) are therefore lumped together and are treated as one component *IA* (isoamylene):

$$MeOH + IA \underset{k-1,2}{\overset{k+1,2}{\Longleftrightarrow}} TAME \tag{4}$$

For the three reactions taking place simultaneously, thre coupled chemical equilibrium constants are considered. Rihko et al. (1994) is proposed the following equilibrium expressions (T in K):

- TAME synthesis from 2M1B: $K_{a,1} = 1.057 \cdot 10^{-4} \exp(4273.5/T)$
- TAME synthesis from 2M2B: $K_{a,2} = 1.629 \cdot 10^{-4} \exp(3374.5/T)$
- Isoamylenes isomerization: $K_{a,3} = K_{a,1}/K_{a,2}$

The kinetic model of the global reaction is formulated according to Oost and Hoffman (1996):

$$r_{1,2} = r_1 + r_2 = k_{f,12} \cdot \left(\frac{a_{2M1B}}{a_{MeOH}} - \frac{1}{K_{a,3}} \cdot \frac{a_{TAME}}{a_{MeOH}^2} \right) \tag{5}$$

Using the following reaction rate constant:

$$k_{f,12} = \left(1 + K_{a,3}(T)\right) \cdot 2.576 \cdot exp\left[-10.764 \cdot 10^3 \left(\frac{1}{T} - \frac{1}{331.15}\right)\right] [\frac{mol}{s}] \tag{6}$$

3. Methodology

The equations systems described for the non-reactive (7) and reactive (8) residue curve models are nonlinear algebraic and differential equations. The residue curves can be obtained by integrating the models forward and backwards from an initial liquid composition. As solver, ode45 implemented in MATLAB is used in this work. The function gives a numerical solution to DAE system based on variable step size Runge – Kutta integration routines. The backward integration is performed transforming the DAE system into its inverse.

$$\begin{aligned} &\frac{dx_i}{d\tau} = x_i - y_i && i \in [1, n-1] \\ &y_i = f(P, T, xi), && i \in [1, n] \\ &\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i = 1 \end{aligned} \tag{7}$$

$$\begin{aligned} \frac{dx_i}{d\tau} = x_i - y_i + Da \frac{1}{k_{ref}} \Bigg[& \sum_{k=1}^{n_{rx}} \nu_{i,k}\, r_k \\ & - \left(\sum_{k=1}^{n_{rx}} \nu_{total,k}\, r_k \right) X_i \Bigg] \end{aligned} \qquad \begin{aligned} &i \in [1, n-1], \\ &k \in [1, n_{rx}] \end{aligned}$$

$$\begin{aligned} &y_i = f(P, T, x_i, x_{i+1}, \dots, x_{n-1}) && i \in [1, n] \\ &r_k = f\left(k, K_{eq}, a_i, a_{i+1}, \dots, a_{n-1}\right) && k \in [1, n_{rx}] \\ &\sum_{i=1}^{n} x_i = \sum_{i=1}^{n} y_i = 1 \end{aligned} \tag{8}$$

MATLAB 2010b and SIMULIS® Thermodynamics are used together to solve the equations (7) and (8). To call SIMULIS in MATLAB, a SIMULIS Calculator is created, using the function: *stCALCreate*. Next different functions are used to calculate system VLE characteristics: *stCALFlashWP* (Figure 1)- liquid-vapor flash at given pressure and vaporization ratio, *stCALDewTemperature* – calculation of the dew temperature, *stCALBubbleTemperature* – calculation of the bubble temperature.

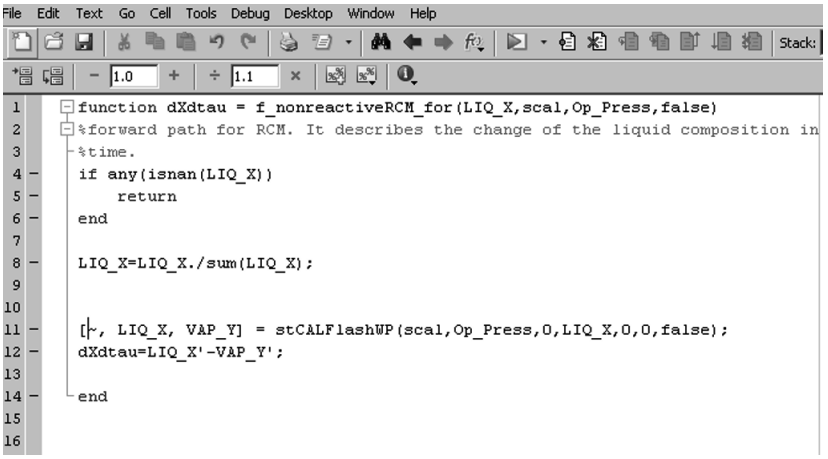

Figure 1. Generating residual curves in MATLAB using SIMULIS functions

4. Results

In Figure 2 it can be observed the trajectories of non-reactive mixture of IA / MeOH / TAME Calculations were made using *UNIFAC - Dortmund* activity model with the method presented in Chapter 2. Two azeotropes exist for the studied pressure: between IA and MeOH, an unstable node, and between TAME and MeOH, a saddle point. These points are linked by a distillation boundary. Two stable nodes are found on pure MeOH and TAME.

In the diagrams presented in Figures 3 and 4 the trajectories of the reactive IA / MeOH / TAME mixture are plotted. Four singular points are observed, as for the non-reactive mixture. The Damkohler number *Da* is enhanced starting with the value 10^{-4} until 10^{-1}. It can be observed that the TAME stable point is enriched by MeOH and by olefins for higher values of *Da*. The binary saddle point (MeOH/TAME) gets enriched with MeOH at small *Da* numbers. Increasing *Da* 10^{-1} leads to ternary saddle points.

The unstable node is leaving the physically relevant composition space by the influence of the chemical reaction at higher values of *Da*.

Bonet-Ruiz (2012), obtained different profiles for the RCMs for Da = 0.1. In the work presented by Bonet-Ruiz (2012) at 4 bar a different topology is obtained. In this case, the ternary stable node is not present. Because of this, the saddle point and the corresponding boundary lines are also not present. Thiel et al. (1997) report the same behaviour for Da = 1 and 1 bar, where the stable node disappears and every trajectory runs into the collecting trajectory which is the only remaining separatrix in the composition space. The difference between the reported values can be explained by the

different interaction parameters used by SIMULIS Thermodynamic which are used in this study.

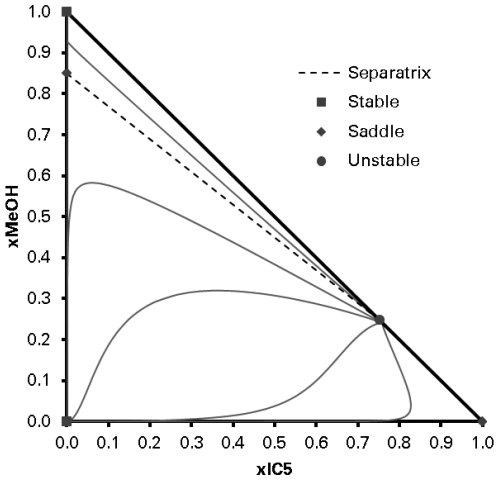

Figure 2. RCM – iC5-MeOH-TAME- P = 4 Bar Da = 0

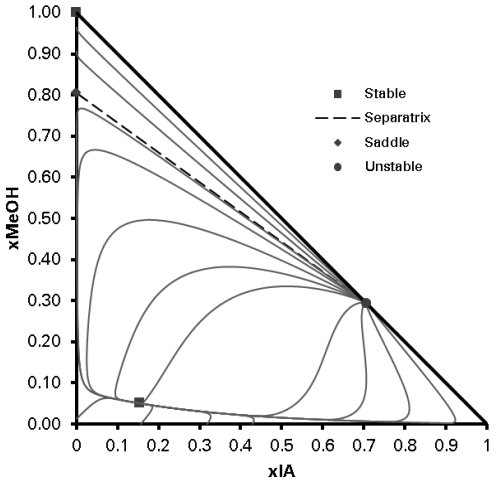

Figure 3. RCM – IA-MeOH-TAME- P = 4 Bar Da = 0.0001

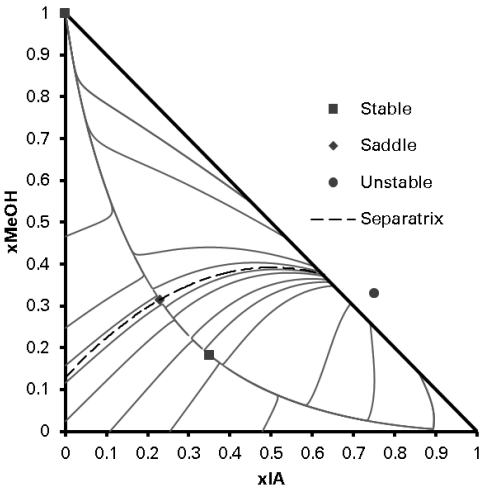

Figure 4. RCM – IA-MeOH-TAME - P = 4 bar Da = 0.1

5. Conclusions

In this work, the implementation of SIMULIS® Thermodynamics communication facility with MATLAB® is successfully done, calculating liquid vapor equilibrium with different thermodynamic models. Based on these thermodynamic properties, (non) reactive residue curve maps are generated for TAME synthesis system which involve the following components: *2 – methyl-1-butene, 2-methyl-2-butene, Isopentane, Methanol, TAME*.

For building the residual curve maps, a kinetic model where the two isoamylenes are lumped together is used, in order to have a three components system (*Isoamylenes, Methanol and TAME).*

Different topologies for the reactive residual curves are obtained compared to similar studies. This can be explained due to different interaction parameters used by SIMULIS® Thermodynamics UNIFAC Dortmund model used here.

Abstract

Effective accident prediction is needed in the chemical process industries to facilitate risk management during plant operations. This is however hampered by the unavailability of data needed for accident modelling purposes, and models that are based on distribution theory are used as they require the least amount of data. This article discusses the application of grey modelling approach and its combination with Bayesian network. The models are applied to two case studies, i.e. a process vessel and an LNG facility. The results obtained are compared to that of Poisson model. Results show that the hybrid first-order grey model with Bayesian network BG(1,1) is most accurate, followed by the grey models G(1,1) and G(2,1), with the Poisson model trailing behind. The results illustrated the potentials of grey modelling approach in dealing with scarce data conditions.

Keywords: CPI accident prediction, Poisson–Gamma model, grey model, Bayesian network, hybrid model.

1. Introduction

One promising strategy to facilitate risk reduction efforts is by using information obtained from accident modelling. Using a few of the available techniques, accidents are predicted in terms of their likelihood to happen, the location at which they are likely to occur and the anticipated failures of relevant components. An example of this methodology is the SHIPP model (Rathnayaka *et al.*, 2011), which has the ability to identify the location of an expected failure source and predict the likelihood of an accident. Because accident data are difficult to gather, accident prediction techniques that require the least amount of data are favoured. A stochastic model has become a preferred option as it requires only one data point and a prior distribution function that represents the system's behaviour. For this reason, stochastic approach such as the Poisson model has received considerable applications in accident modelling in the CPI (e.g., Meel *et al.*, 2007; Al-shanini *et al.*, 2014b). However, this model has the tendency to underestimate and is lacking in sensitivity (Rathnayaka *et al.*, 2012; Al-shanini *et al.*, 2014a).

This paper explores an alternative strategy by adopting grey modelling approach, which has found more applications in other industries including agricultural, environmental, and

electronics due to its simplicity and capability of reasonably forecasting events using as few as four data points (Tseng *et al.*, 2001; Hsu, 2003; Lin and Yang, 2003; Deng, 1989; Chang and Tseng, 1999). The performances of this model, along with an improved version configured by combining it with Bayesian network are compared to the Poisson model.

2. Prediction Models for a Data-Scarce Environment

2.1. Stochastic Poisson-Gamma Model

Poisson-gamma model belongs to stochastic forecasting approach that is often used to predict the number of unwanted consequences in the CPI. The model offers good predictions when the mean and the variance of the data are in close proximity. A conjugate pair of distribution functions of gamma (as prior function) and Poisson (as likelihood function) is used. Once data is observed, the likelihood function updates the prior distribution to its posterior. The mean value of the probability mass function represents the number of the predicted events as shown in Figure 1. Details on Poisson model can be found in (Al-shanini *et al.*, 2014b).

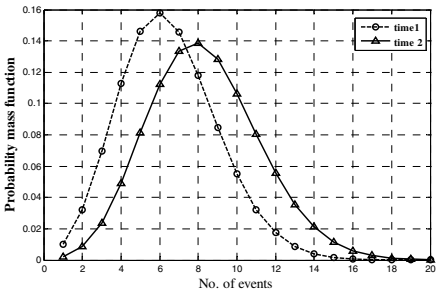

Figure 1: Poisson predictive probability mass function change for two time intervals

2.2. Time Series Grey Models

The grey model of M-order partial differential equation of N variables belongs to a time series forecasting family, referred to as G(M,N) is first introduced by Ju-Long (1982). The term "grey" represents the fact that the model contains both white and black parts. The white part has theoretical supports, while the black part depends on empirical data. Grey modelling approach assumes that the process can be represented by certain generic partial differential equation according to the order of the process. Then using accident data, the model parameters are estimated. This modelling strategy requires only four data points to predict the future event. The ratios σ = [σ(2), σ(3),…, σ(n)], where $\sigma(k) = x^{(0)}(k-1) \,/\, x^{(0)}(k)$ for $k = 2,3,\ldots,n$ and x(0) is the original data points, have to fall within the range 0.1345–7.389. Two grey models of a single variable are the most applied in literature which are the first and second orders G(1,1) and G(2,1). Table 1 briefly discusses their implementation steps.

2.3. Improving Parameters Estimation Using Bayesian Network

Another alternative is also proposed by adopting Bayesian network (BN) to improve parameters estimation in G(1,1). In this case, BN is used as a regression method of the new sequence data produced from AGO to determine model coefficients instead of OLS method normally used in the grey model. The combination of enlargement of original data provides an advantage to model's predictability especially with data containing outliers (Hsu and Wang (2007)). Bayesian analysis is used to build a statistical model that relates prior knowledge (y) and observables (x), and then estimates the conditional posterior probability p(y\x). In BN, the observed data are assumed to follow a normal distribution as shown in the following Eq. 1:

Y[i] ~ normal(mu[i],tau) (1)

where, $mu[i] = -u + a \times x[i]$, (a) and (u) are normal distributions with means and precisions in the range (0, 1.0E-6), and (tau) is a non-informative beta distribution with shaping distribution parameters of (0.01, 0.01). Other systems may require another distribution functions that better fits the observed data. Once models' coefficients are estimated, they are substituted in the partial differential equation to predict the future events.

Markov Chain Monte Carlo (MCMC) simulation software (WinBUGS), that uses the Gibbs Sampling technique, is used to compute the BN for estimating the coefficients. This is done by setting a joint posterior distribution using MCMC as the target distribution, and simulates the parameters to converge to the targeted values.

3. Case studies

Two case studies data sets are used. The first is a process vessel adopted from Kalantarnia *et al.* (2009) and the second is an LNG liquefaction and exporting facility. The data sets are summarised in table 2.

Table 2: Historical real time data of the case studies

Time interval	System 1 Vessel precursor data	System 2 LNG facility precursor data
1	7	7
2	7	6
3	8	12
4	8	11
5	5	11
6	12	13
7	14	12
8	16	-

4. Result and discussion

Four models, i.e., Poisson, G(1,1), G(2,1) and BG(1,1) are applied to the case studies, and results that are shown in table 3 and 4 are obtained. For the BG(1,1), the BN model is tested with 1000 burn samples followed by 1000 iterations for each chain. For grey models, iterative population increase configuration is applied to the case studies data in which the first four data points are used to estimate models' coefficients and predict the fifth one. Next, one more data is considered and so on.

The results show that the BG(1,1) provides the best accuracy with average absolute mean percentage error (AMPE) for the two case studies of 18.24, followed by G(1,1) with average AMPE of 21.9, G(2,1) with 21.95, and Poisson with 26.36. Figure 2 shows the validation of the four prediction models. Note that in this case the first order grey model performed better that the second order. This is probably due to the process dynamics and requires further investigations.

Table 1: G(1,1) and G(2,1) implementation steps

Sequence	G(1,1)	G(2,1)
Generation of new sequence from the original data	$X^{(1)}=\{x^{(1)}(1),x^{(1)}(2),\ldots,x^{(1)}(n)\}$, where $X^{(1)}(1)=X^{(0)}(1)$, and $X^{(1)}(k)=\sum_{i=1}^{k}x^{(0)}(i)$ for $k=2,3,\ldots,n$. the sequence mean generated of consecutive neighbours $X^{(0)}(k)=-aZ^{(1)}(k)+u,\ k=2,3,\ldots,n$, where a is the developing coefficient, u is the grey input, and $z^{(1)}(k)=\alpha X^{(1)}(k)+[1-\alpha]X^{(1)}(k-1)$, for $i=2,3,\ldots,n$.	$X^{(1)}=\{x^{(1)}(1),x^{(1)}(2),\ldots,x^{(1)}(n)\}$, where $X^{(1)}(1)=X^{(0)}(1)$, and $X^{(1)}(k)=\sum_{i=1}^{k}x^{(0)}(i)$ for $k=2,3,\ldots,n$. With inverse accumulated generator operator IAGO sequence $\alpha X^{(0)}$ of $X^{(0)}$ as $\alpha^{(1)}X^{(1)}=\{\alpha^{(1)}x^{(0)}(1),\alpha^{(1)}x^{(0)}(2),\ldots,\alpha^{(1)}x^{(0)}(n)\}$ where $\alpha^{(1)}x^{(0)}(k)=x^{(0)}(k)-x^{(0)}(k-1)$ the sequence mean generated of consecutive neighbours of X(1) is $Z^{(1)}=\{z^{(1)}(1),z^{(1)}(2),\ldots,z^{(1)}(n)\}$ where $z^{(1)}(k)=\frac{1}{2}\left[x^{(1)}(k)+x^{(1)}(k-1)\right]$

Figure 2: Validation of prediction models for case studies with iterative population increase configuration

Conclusion

The study on scarce data prediction models based on two case studies has demonstrated the capability of the grey model in surpassing Poisson-gamma model in predicting accidents in the CPI. The results show that BG(1,1), which is the hybrid of BN and G(1,1) has the highest prediction accuracy, followed by other grey models and the Poisson. However, grey models and their hybrids require at least four observed data points, while the Poisson-gamma model needs only one data point to predict the next event. The results from this work also support previous findings on the prediction based on Poisson-gamma model that are reported to underestimate the actual data. In conclusion, this study has proved the potentials of the grey-based modelling in providing prediction capability in data-scarce environment. It is anticipated, with further enhancement, this modelling strategy would be able to effectively support risk-based decisions in plant operation and maintenance.

Multi-objective Optimisation of Atmospheric Crude Distillation System Operations Based on Bootstrap Aggregated Neural Network Models

Funmilayo N. Osuolale*, Jie Zhang

School of Chemical Engineering and Advanced Materials, NewcastleUniversity, Newcastle upon Tyne, NE1 7RU, UK
f.n.osuolale@newcastle.ac.uk ; fnosuolale@lautech.edu.ng

Abstract

This paper presents a new methodology for optimising the energy efficiency of a crude distillation unit without trading off the product quality and process throughput. It incorporates the second law of thermodynamics which indicates how well a system is performing compared to the optimum possible performance and hence gives a good indication of the actual energy use of a process. Bootstrap aggregated neural networks are used for enhanced model accuracy and reliability. In addition to the process operation objectives, minimising the model prediction confidence bound is incorporated in multi-objective optimisation to improve the reliability of the optimisation results. The economic analysis of the recoverable energy (sum of internal and external exergy losses) reveals the energy saving potential of the method. The proposed method will aid the design and operation of energy efficient crude distillation columns.

Keywords: crude distillation, exergy, optimisation, neural networks.

1. Introduction

Distillation process has always attracted the interest of researchers and quite a number of work in the literatures are focused on improving its energy efficiency either for binary systems (Osuolale and Zhang, 2014) or multi component systems (Ochoa-Estopier et al., 2012). In recent years optimisation of crude distillation system has received considerable research interest. This is because major cost of operation second only to the cost of crude in a refinery is energy and 35% of these is consumed in the crude distillation unit. Rather than large scale expansion, most industries will maximise available resources for maximum profitability.

Thermodynamic analysis of a crude distillation unit gives insight into its second law efficiency. Past work on the second law analysis reveals low efficiency of the system with an efficiency of 0.27-0.43 for the ADU (Al-Muslim and Dincer, 2005). This could imply that improvement of the efficiency of the column will be better off when it is based on the second law. The challenge therefore is to develop optimization procedures based on second law analysis aimed at minimising the inefficiencies without compromising the quality of the product.

In this regard, determining the thermodynamic conditions of the inlet and outlet streams for every considered possibility is of paramount importance. Rigorous, empirical and simplified models of crude distillation systems are widely publicised in the literatures. Rigorous models are however computationally demanding and might not be feasible for

real time optimisation. Also, the complexity of rigorous models often limits networking the crude distillation system with other heat integrated systems. Simplified model was implemented in the optimisation of a distillation system in a related work (Valleriote et al., 2012). Though simplified models are more robust than rigorous models, they are however sensitive to initial guesses. To overcome these problems, data driven models such as artificial neural network (ANN) models can be utilised. The computation time in ANN model evaluation is very short making them ideal for real-time optimisation. Bootstrap aggregated neural networks are used in this study for enhanced model accuracy and reliability. Neural network models for exergy efficiency and product quality are developed from simulated process operation data and are used to maximise exergy efficiency while satisfying product quality constraints.

2. Methods of Analysis

2.1. Description of Systems

The atmospheric distillation system considered in this study is presented in Fig. 1. The crude to be processed was Venezuela Tia Juana light crude (Watkins 1973). The crude was characterised using experimental assay that includes the bulk crude properties, light end volume percent, ASTM distillation, API gravity and TBP distillation. The assay data was fed into the data bank of the simulator software HYSYS. The result of the characterisation is a set of pseudo-components and a detailed chemical composition of the identified light ends components. The column processes 100,000 barrel/day of crude at 25psia and 690 ^{o}F into 6 products: light naphtha, heavy naphtha (HN), kerosene, diesel, atmospheric gas oil (AGO) and residue.

2.2. Exergy analysis

For an open system, the mass, energy and exergy balance equations are

$$\sum M_{in} = \sum M_{out} \tag{1}$$

$$\sum E_{in} + Q = \sum E_{out} + W \tag{2}$$

$$\sum Ex_{in} + \sum_{j=1}^{n}(1 - \frac{T_0}{T_j})Q = \sum Ex_{out} + W + I \tag{3}$$

where M_{in} and M_{out} are mass flow rate in and out of the system respectively, E_{in} and E_{out} are inlet and outlet energy rates respectively, Q is heat transfer rate, W is the work rate, Ex_{in} and Ex_{out} are exergy rates in and out of the system respectively and I is the irreversibility rate of the system.

The total exergy of a stream is given as

$$Ex = Ex_{phy} + Ex_{chem} + Ex_{mixing} \tag{4}$$

$$Ex_{phy} = m[h - h_0 - T_0(s - s_0)] \tag{5}$$

where m is the mass flow rate, h and s are the enthalpy and entropy at stream conditions respectively, h_0 and s_0 are, respectively, enthalpy and entropy at reference conditions of $T_0 = 298.15\ K$ and $P_0 = 101.3\ kPa$. For the crude stream considered, standard molar chemical exergy Ex_{chem} is calculated from the standard molar chemical exergies of all identified components and pseudo-components as

$$Ex_{chem} = m\left[\sum b_{qi} + \sum b_{chi} + RT_0 \sum lna_i\right] \tag{6}$$

where b_{chi} is the chemical exergy for component, b_{qi} is the chemical exergy for pseudo component, and a_i is the activity coefficient of component i. The standard chemical exergy for pseudo-compoentns can be determined from heuristic empirical expression as a function of the elementary composition and their heating values (Szargut et al., 1988).

$$B_{qi} = \varphi_i C_i \tag{7}$$

where φ_i is the regression equation to express the ratios H/C, N/C, O/C and S/C for pseudo-component i, C_i is the net calorific heating value of the pseudo-component i. The exergy efficiency and the irreversibility rate definitions are given by Eq(8) and Eq(9) respectively:

$$\varphi = \sum Ex_{out} / \sum Ex_{in} \tag{8}$$

$$I = \sum Ex_{in} - \sum Ex_{out} \tag{9}$$

2.3. Economic Analysis

Basically the economic analysis is based on the operating profit of the column and expressed mathematically as

$$Profit = \sum_{j=1}^{n} M_j C_j - [M_{crude} C_{crude} + M_{steam} C_{steam} + \sum_{x=1}^{n} Q_x C_x] \tag{10}$$

where M_j and C_j are the flow rate and cost of product *j* respectively, M_{steam} and C_{steam} are the flow rate and cost of steam respectively, Q_x and C_x are the heat requirement and the cost of utility respectively. The calculation is based on the assumption of 8600 h per year. Table 1 gives the prices of the feed, products and utility (Energy information administration, 2014).

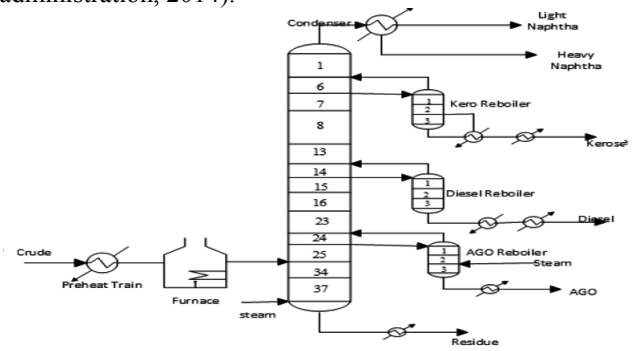

Figure 1. Schematic diagram of an atmospheric distillation unit

3. Multi-Objective Optimisation Using Bootstrap Aggregated Neural Network Models

3.1. Bootstrap aggregated neural network

In order to improve the generalisation capability of neural netwroks, several networks are developed on bootstrap resampling replication of the training data and combined. A bootstrap aggregated neural network (BANN) can be represented mathematically as

$$f(X) = \sum_{i=1}^{n} w_i f_i(X) \tag{11}$$

where $f(X)$ is the aggregated neural network predictor, $f_i(X)$ is the *i*th neural network, w_i is the aggregating weight for combining the *i*th predicted neural network, n is the number of neural networks, and X is a vector of neural network inputs. BANN can also give model prediction confidence bounds from individual network predictions (Zhang 2004). The standard error of the *i*th predicted value is calculated as

$$\sigma_e = \left\{\frac{1}{n-1}\sum_{b=1}^{n}[y(x_i;W^b) - y(x_i;)]^2\right\}^{\frac{1}{2}} \quad (12)$$

where $y(x_i) = \sum_{b=1}^{n} y(x_i;W^b)/n$ and n is the number of neural networks. The 95% prediction confidence bounds can be calculated as $y(x_i;) \pm 1.96\sigma_e$.

Table 1. Feed, products, and utility prices

Item	Crude	LN	HN	Kero	Diesel	AGO	Res	Heat duty	Cooling water	steam
Price	80	44.3	136	122.7	121.75	95.29	89.71	150	5.25	0.14
Unit	$/bbl	$/bbl	$/bbl	$/bbl	$/bbl	$/bbl	$/bbl	$/kJ	$/kJ	$/kmol

3.2. Modelling of the atmospheric distillation unit

In this study, simulated process operational data were generated from HYSYS and were divided into training (50%), testing (30%), and unseen validation (20%) data sets. A BANN containing 30 neural networks was developed to model exergy efficiency and product quality using product flow rates as inputs. The network giving the lowest mean squared errors (MSE) on the testing data is considered as having the appropriate number of hidden neurons.The Levenberg-Marquardt trainning algorithm was used to train the network. Fig. 2 shows the BANN model performance on the unseen validation data.

Fig. 3 shows the MSE of the individual networks and BANN containing different number of networks on the training and unseen validation data sets. It can be seen that individual networks give inconsistent performance on the training and unseen validation data indicating the non-robust nature of single networks. BANNs give consistent and more accurate prediction performance on the training and unseen validation data sets.

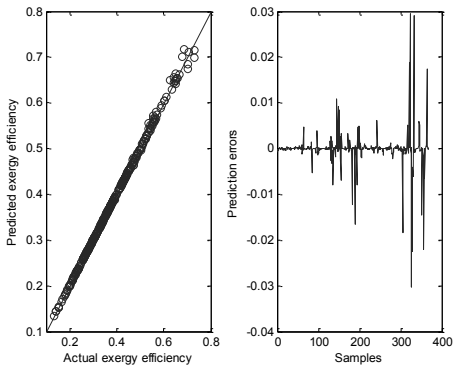

Figure 2. BANN predicted vs. actual exergy efficiency (left) and prediction errors (right)

3.3. Multi-objective optimisation

The objective of the optimisation is to maximise the exergy efficiency of the distillation unit while satisfying product quality constraints. To improve the reliability of the optimum, an additional objective of minimising the standard error of individual network

predictions was introduced and formulated using the goal attainment multi-objective optimization procedure as

$$J = \begin{bmatrix} -y \\ \sigma \end{bmatrix} \qquad (13)$$

$$min_{x,\delta}\ \delta$$

s.t. $J(y) - W_i\delta \leq F$

$[y, m] = U(x)$

$m_{lb,k} \ll m_k \ll m_{ub,k} \qquad k = 1, 2, \ldots, 5$

where J is the objective function, y is the exergy efficiency, U is the BANN model of the ADU, $x = [x_1, x_2, \ldots x_8]$ is a vector of decision variables containing 5 product flow rates and 3 pump around flow rates shown in Table 3, m is a vector of the product oil quality, σ is standard prediction error, F is the desired goal, and W is a vector of weighting parameters which controls the degree of goal achievement and introduces a measure of flexibility that allows for trade off the conflicts among objectives. A narrow confidence bounds indicate the reliability of the prediction and gives a measure of assurance of the process attaining the predicted exergy efficiency. The relative error of the multi-objective optimisation and simulation results for minimizing the confidence bounds are given in Table 2. The effect of incorporating the confidence bounds in the multi-objective optimization can be revealed in that the exergy efficiency of the HYSYS validated process is close to that predicted by the model.

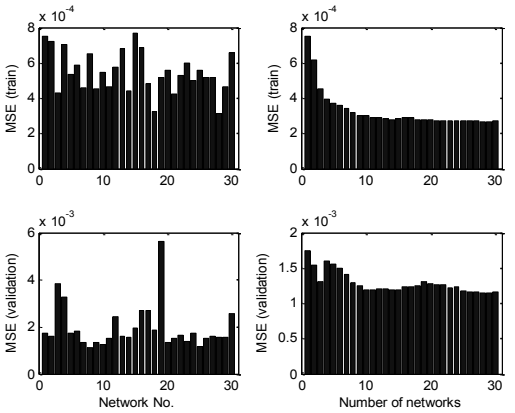

Figure 3. MSE of individual networks (left) and BANN (right) for the crude distillation unit

Table 2. Optimisation and simulation results

Hysys validated	Optimum 1 (Eff)	Optimum 2 (cb)	Goal 1 (Eff)	Goal 2 (cb)	Weight 1 (Eff)	Weight 2 (cb)	Relative error
73.86	79.62	0.3883	0.8	0.01	0.01	1	0.07798
71.90	78.12	0.1982	0.8	0.01	0.1	1	0.08650
71.68	75.34	0.0566	0.8	0.01	1	1	0.05106
61.62	65.56	0.0244	0.8	0.01	1	0.1	0.06394
50.84	53.18	0.0127	0.8	0.01	1	0.01	0.0458

Table 3 shows the base case and the optimum results of the decision variables. The products qualities are within the expected bound range. Table 4 shows the corresponding thermodynamic and economic analysis. The optimisation results in 29.6% increment of the exergy efficiency. This translates to 68% decrease in

irreversibility loss and 46.5% reduction in energy costs of the column with reference to their initial values. Every real process has an element of irreversibility which often degrades the engineering performance. With the methodology proffered from this study ways of considerably decreasing the irreversibility of the system as well as determining the efficiency of the process is made easy.

The total profit is increased by $\$38\times10^6$/year through optimally adjusting product flow rates. The increment is mainly due to the optimum operating conditions from the exergy based analysis of the column. The reduction in the cost of energy contributed to about 10% in the total profit. The results show that considerable economic benefit of the column can be achieved at no additional cost of equipments.

Table 3. Optimisation results (decision variables)

	HN	Kerosene	Diesel	AGO	Residue	PA1	PA2	PA3
Base case	517	508	952	267	1296	943	1132	943
Optimum	511	511	1000	267	1348	946	1127	940

Table 4. Optimisation results (efficiency and profit)

	Exergy (%)	Irreversibility (kJ/hr)	Energy cost ($/yr)	Profit ($/yr)
Base case	42.10	1.913×10^8	7.655×10^6	2.360×10^9
Optimum	71.68		4.095×10^6	2.398×10^9

4. Conclusions

Multi-objective optimisation for improving the exergy efficiency of a crude distillation system using bootstrap aggregated neural network model is presented. By incorporating model prediction confidence as additional optimisation objective, the reliability of optimisation is enhanced. Application to a simulated crude distillation unit shows that the proposed technique can significantly improve the second law efficiency of the system leading to an additional economic advantage. The method can aid in the operation and design of energy efficient distillation columns.

Abstract

This paper presents an optimization study of a distillation column for methanol and aqueous glycerol separation in a biodiesel production plant. Considering the available physical data of the column configuration, a steady state model was built for the column using Aspen-HYSYS as process simulator. Several sensitivity analysis were performed in order to better understand the relation between the variables of the distillation process. With the information obtained by the simulator, it is possible to define the best range for some operational variables that maintain composition of the desired product under specifications and choose operational conditions to minimize energy consumptions.

Keywords: Simulation, optimization, distillation, biodiesel process

1. Introduction

Many industrial companies struggle to survive in a competitive market and are looking for additional strategies to increase processes efficiency. Some companies have been operating for many years with the pre-established conditions provided by the process's licensor. However, since processes first startup, changes may have occurred which would require a new tuning of the control variables not only to achieve process specifications but also to run it with energy minimization cost. Testing different conditions in running processes may not be acceptable due to restrict timetables for goal production quantities to be achieved, and to avoid products out of specification. The growing use of process simulators by research groups has allowed a greater deepening of process knowledge without disturbing the usual operation (Seider et al., 2009).

Optimization studies for efficiency increase can be performed to the whole process, or on large energy-consuming units which is the case of distillation columns (Jobson, 2014). Creating distillation columns' models in process simulators allows performing optimization without disturbing the process, which is a good tool to improve energy efficiency. In the existing columns several former design variables may not be susceptible to be modified. Some examples are the number and type of stages, feed location and pressure drop along stages. Others remain available for optimization such as reflux ratio, supplied heat in the reboiler and feed stream temperature.

This work addresses the study of the operating conditions of an existing distillation column for methanol/water/glycerol separation, operating in a biodiesel production process. The objectives of the study were to establish a better relation between the

distillation process variables, to accomplish a more energy efficient operation. The distillation column is responsible for 35 % of total thermal energy consumption of the process (Palmeira et al., 2010), which results that any energy saving will have a significant economic impact in the operating costs.
A comprehensive Aspen-HYSYS model based on thermodynamic and physical data of the distillation column was developed. The relation between column temperatures and composition specification in outlet streams were studied. The optimal reflux ratios for different reboiler's temperature and the influence of feed temperature in the column energy consumption were also investigated.

2. Methods

Based on physical dimensions of the distillation column and packing characteristics, a steady state model was developed in Aspen-HYSYS software. The rectification section of the distillation column is composed by 26 plates and the stripping section by particle packing. The column was simulated with pressures of 1.1 atm in column bottoms and 1 atm at the top. The feed stream to the column is composed by 21 % methanol, 51 % water and 28 % glycerol at 75 °C. The composition limits in outlet streams are 1000 ppm methanol in aqueous glycerin in the bottom and 300 ppm of water in distillate. NRTL thermodynamic model was used for properties estimates.
Two degrees of freedom were found in the model using all physical characteristics of the column. In the real column, the two degrees of freedom correspond to variables that can be controlled, which are reflux ratio and supplied heat in the reboiler. In the simulation model, input data could correspond to numerical values for these two real control variables. However, the simulator allows choosing desired values for other two variables (always respecting the two available freedom degrees) and will iteratively search for the correspondent solution. Depending on the studies performed, the input specifications were: water composition in distillate, methanol composition in bottoms, reflux ratio, reboiler and feed temperature.

3. Sensitivity Analysis

Several sensitivity analysis between the column variables were performed, to provide a better understanding to control the distillation process in a more effective way.

3.1. Vapor Liquid equilibrium of Methanol/Water mixture

One of the distillation specifications is the maximum of 300 ppm of water present in the distillate. Since there isn't any direct measure of water content in the real column, the water content control is obtained by indirectly measuring of the column temperatures. For that, the rectification section of the column is equipped with four temperature sensors in 1st, 5th, 8th and 13th stages (referred as T1, T2, T3 and T4, respectively). Assuming that the glycerol content in distillate is negligible, it is considered that this stream is composed exclusively by methanol and a small fraction of water. As a result, the water composition of the 1st stage vapor phase can be obtain from the dew curve in the methanol/water VLE phase diagram, when the temperature in that stage is known. Because, the vapor phase of the 1st stage and distillate compositions are effectively the same, the precise temperature measure in the 1st stage could be considered the most important because it allows precise water content determination in distillate.
VLE data extracted from the simulation model (Figure 1) shows that temperature in 1st stage has low sensitivity with water content variation. For example, when considering a temperature variation of only 0.1 °C above 64.5 °C (corresponding to 300 ppm), we obtain 64.6 °C that corresponds to 2000 ppm which is way out the allowed limit.

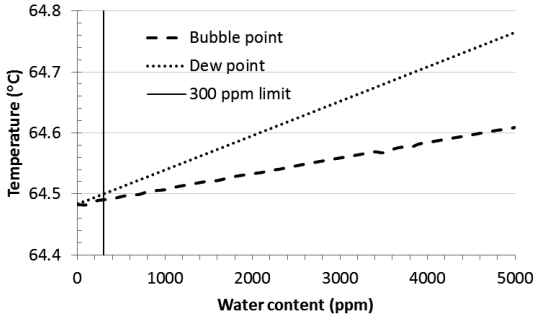

Figure 1 - VLE for methanol/water mixture for 0-5000 ppm of water for P=1 atm.

Due to intrinsic measuring error of temperature sensors which is of this magnitude order, any water content reading based exclusively in this parameter will be far from being accurate. Nevertheless, accurate and high precision temperature sensors should be used in these measures.

3.2. Column temperature profile for different water content in distillate

Due to lack of precision in water content determination based exclusively in 1st stage temperature, additional points of temperature measure in other column stages are taken in consideration. The measured temperature in each stage can be dependent not only from the distillate composition but also from feed composition and temperature, and reflux and reboiler temperatures. Assuming constant values for the latest referred variables, the temperature dependence of stages with distillate composition was investigated. Figure 2 shows the expected temperature profile for different water contents at distillate, considering the reboiler at 105.4 °C. It can be observed that there is an increase sensitivity of stage temperature to water content when descending in the column. This information is highly precious when controlling the column because water content in distillate can be estimated based in the set of stages temperatures.

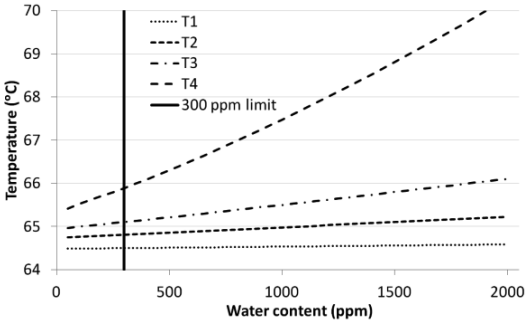

Figure 2 – Stage temperatures dependence with water content (for $T_{reboiler}$=105.4 °C).

3.3. Reflux ratio influence on distillate composition

The influence of reflux ratio and reboiler temperature in distillate water content can be observed in Figure 3. The results show that water content is reduced dramatically to values around 300-500 ppm with an increase of reflux ratio to values around 1.5. From this point forward, reflux ratio increase will have a lower impact in water content reduction. These results indicate that column control is quite sensitive when operating with reflux ratios near the optimal point, because a small decrease in this value will result in a sharp increase of water content in distillate. This will be easily detected by an

increase in temperature profile in stages, as seen in previous section. This study also shows that lower reboiler temperatures favour water content reduction in distillate, however this will increase methanol presence in bottoms, which in undesirable.

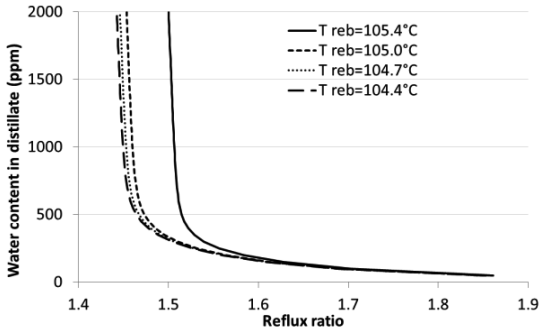

Figure 3 – Water content in distillate dependence with reflux ratio and reboiler temperature.

3.4. Methanol content in column bottoms with stripping section temperatures

In addition to water content limitation in distillate, there is also a methanol maximum of 1000 ppm in column bottom. As in the previous case, there is no direct measurement of this component composition in outlet stream so control is currently based on temperature measures in reboiler and middle of stripping section (referred as T6). As it can be observed in Figure 4, there is a correlation between reboiler temperature and methanol content that is almost independent of the reflux ratios used.

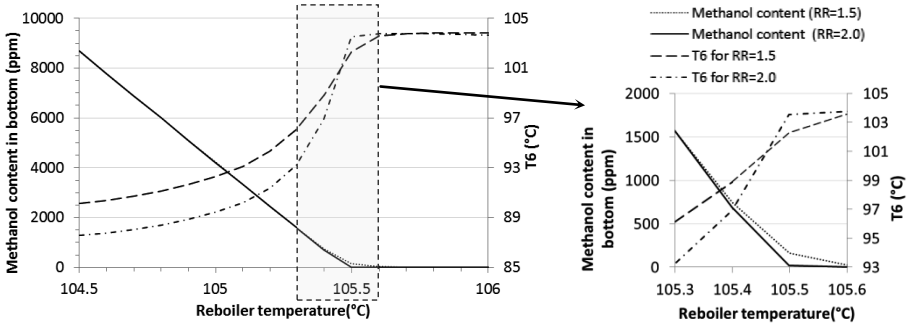

Figure 4 – Methanol content in bottom for different stripping section temperature profiles (reboiler and middle section T6) considering reflux ratios of 1.5 and 2.0.

There is a threshold temperature value of about 105.35 ºC. Below this value it is not possible to obtain aqueous glycerine with methanol content within specification limit. Temperature in middle section (T6) is highly sensitivity to methanol composition, however its absolute value depends on reflux ratio. Higher reflux ratios will decrease T6 temperature for the same methanol content. Because reboiler temperature has low sensitivity to methanol content, T6 is an important parameter to determine if the composition limitation is accomplished.

3.5. Variables control range where composition limits are observed

The real distillation column is controlled exclusively by the reboiler temperature (using a PID control loop that changes vapor rate fed to reboiler) and reflux rate (which when related to distillate rate give us reflux ratio). In section 3.3, it was established a relation between water content in distillate and reflux ratio and reboiler temperature. In

section 3.4, the same relation was made between methanol content in column bottom and the same variables. Assembling these two relations we can establish in which values range of the control variables, both composition specifications will be respected. The region in Figure 5 between the lines showed corresponds to the feasible solutions.

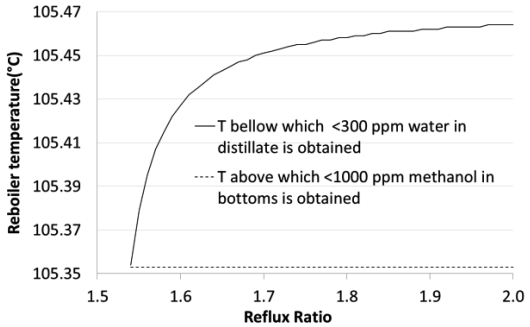

Figure 5 – Reboiler temperature and reflux ratio ranges where composition limits are respected.

It is also possible to observe that even for a higher reflux ratio of 2, the column will only be working with compositions under control if the reboiler temperature is kept between about 105.35 °C and 105.46 °C, which is a very low operational range. For this reason, the knowledge of the temperature in the middle of stripping section is of great importance as a complement of reboiler temperature. A similar study to the previously presented can be observed in Figure 6, where temperature T6 range is obtained for specifications fulfilment. This is information is of great help because the T6 range is much greater than temperature measure error of sensors.

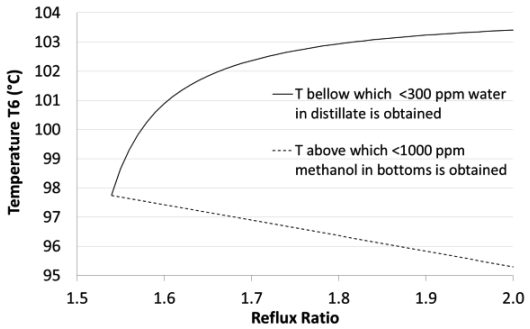

Figure 6 – T6 and reflux ratio ranges where both composition limits are observed.

The optimal operational conditions would be the contact point between the two lines at Reflux Ratio=1.54 and $T_{reboiler}$=105.35 °C, because this is where reflux ratio have lowest value corresponding to the lowest power removed in condenser. When the column is operating with higher reflux ratios, this allows a more comfortable distillation control because there is wider range of reboiler and T6 temperatures where the process is still within specifications boundary. However this advantage is achieved with greater energy expenses in condenser and reboiler.

3.6. Feed temperature influence in power consumption

Before entering in the column, the feed stream is heated from 66 °C to 75 °C in a heat exchanger that uses steam as utility. From simulation results (Figure 7a) it is observed that considering exclusively the column energy optimization, higher feed temperatures

favour the reduction of energy consumed in the reboiler and will result in higher energy consumption in condenser as a result of optimal reflux ratio increase. When the feed temperature increase is obtained at expenses of hot utility, this energy should also be accounted when searching optimal feed temperature. Observing Figure 7b, where heat power includes the power consumed in the external heat exchanger and in the reboiler, we can conclude that from energetic point of view, higher feed temperature is undesirable. Suppressing the actual feed heating with utility will result in a 1.3 % reduction in heat energy consumption and 1.5 % reduction in cooling energy. A reduction of the feed temperature to 66 °C represents an increase of the supplied thermal power into the reboiler of about 4 %. This issue must be taken in consideration since heat transfer rate capability in the reboiler is limited.

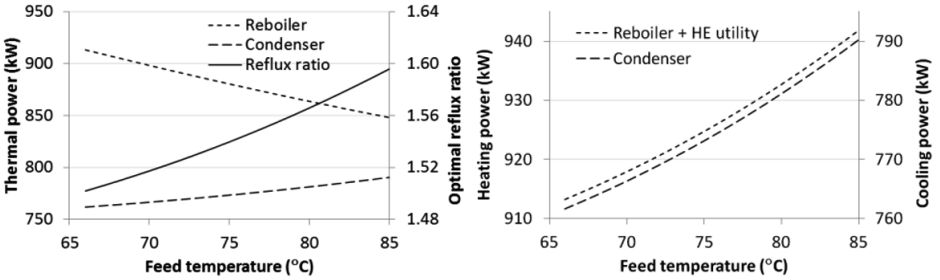

Figure 7 – Feed temperature influence in heat and cold thermal power consumption a) considering only column energy streams, b) accounting with supplied external heat.

4. Conclusions

This paper showed studies using an Aspen-HYSYS model simulation of a real industrial distillation column. After careful parameterization of the model, important information was retrieved without performing any testing in the real process. Because the mentioned methanol/water/glycerol distillation column doesn't have online composition analysis, the obtained results from these studies are of great importance in order to establish the operation conditions that correspond to the minimum thermal energy consumption subject to the composition restrictions.

In this case it was concluded that, the knowledge of temperatures measured in other stages of the column are crucial to maintain the outlet compositions within limits. The performed simulation studies showed how these temperature variables are related with outlet compositions and what are the admissible ranges.

The feed temperature study showed that the actual feed heating that uses steam utility should be suppressed since it increases total heat and cold energy supply to the process. A dynamic model of the distillation column should be the next step analysis to simulate some other perturbations in the process and determine the correction steps to maintain the process running in optimal conditions.

Abstract

The ultimate goal of bioprinting is the production of living and functional tissue and organs for transplantation in a reasonable time scale. To achieve this goal, the best process would be organ printing. It enables creation of tissue with a high level of cell density; can solve the problem of vascularization in thick tissues; organ printing can be done *in situ*.
Organ printing is a computer-aided 3D tissue engineering of living organs with layer-by-layer deposition of tissue spheroids compounded by pre-sorted cells and hydrogel with principles of self-assembly. This process can be divided in 3 technological steps: i) Development of the design files (blueprint) for the organs; ii) Actual printing; iii) Post processing or organ conditioning and accelerated tissue and organ maturation.
This work presents an initial study about the post-processing concerning the maturation phase. It was adopted a clinical image of computer tomography (CT) of a human heart. A branch of this heart was selected and handled. This image was converted into a 3D virtual mesh able to be used in the simulations. Two conditions were considered: a 3D branch formed by spheres analogously to the tissue spheroids representing a fresh organ bioprinted and the second one taking into account the surface of the branches representing a more maturated structure.
Some analysis were executed to verify the fusion process among the tissue spheroids when the spheres are under fusion to each other and the distance between them decreased at long the time. Velocity and pressure were analyzed through four selected sections in the vascular branch where there is fluid flow through the spheres that form threedimensionally the structure as a fresh organ bioprinted by a 3D bioprinter.

Keywords: 3D Bioprinting, modeling, computer simulation, vascular segment.

1. Introduction

Organ printing is a computer-aided robotic layer by layer additive biofabrication of 3D human tissues and organs constructs using tissue spheroids as building blocks (Mironov et al., 2003; Mironov et al., 2009; Mironov et al., 2011). Tissue spheroids closely placed layer by layer in supporting hydrogel can fuse in horizontal and vertical directions and form 3D tissue and organ constructs.

Tissue fusion is a natural ubiquitous process occurring during embryonic development of tissues and organs (Pérez-Pomares and Foty, 2006). In organ printing technology, tissue fusion is a fundamental biological process which enables biofabrication of 3D tissue and organ constructs. Mathematical modeling and computer simulation methods have been successfully used for predictive modeling of postprinted tissue fusion process (Yang et al. 2012; Sun et al., 2014; McCune et al., 2014).

Bioprinted 3D tissue and organ constructs must be vascularized in order to maintain their viability (Visconti et al., 2010). It has been demonstrated that bioprinting of build in intraorgan branched vascular system could be accomplished using solid and lumenized vascular tissue spheroids (Kasyanov et al., 2011; Gentile et al., 2008) which also undergo process of tissue fusion. The branched vascular tree is suitable for intravascular perfusion. It is crucial to study the fluid behavior during the tissue maturation of the cells, so the simulations help to understand which range of parameters values should be used to ensure the optimal condition for cell maturation.

For this propose, the aim is to quantify the stresses caused by the passing fluid, and it is also important to quantify the fluid velocity between the tissue spheroids.
These two parameters are important for the study because it is necessary to ensure the structural integrity of the printed organ and it is necessary to ensure a perfect cell metabolism. Several steps were executed for each fusion stage.

2. Modeling of the scenario

This part was started by reconstructing a random vain ramification located near to the hearth. This ramification came from a Computed Tomography (CT) scan. Software InVesalius originally created in the Renato Archer Information Technology Center (CTI) is able to import CT images (and also Magnetic Resonance MRI) and generate a 3D digital model. So, CT from a human heart (Figure 1 left) was imported into InVesalius.

The aim is to get a part of the 3D model – whole structure analyses requests much computer efforts and it was not the goal of this work – to segment it (treat it), generate a 3D mesh in such way the mesh could be take into a computational fluid dynamics simulation software. In order to be possible simulating the mesh, it was needed to modulate the surfaces for assembling the 3D model as presented in Figure 1 (right). Only some segments of the heart were selected and a modulation of the surfaces was performed on the reconstruction of the model.

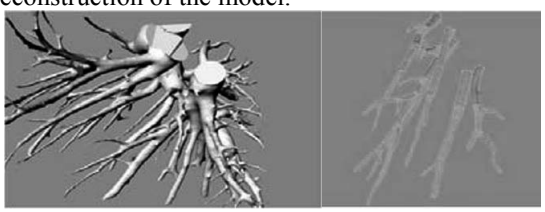

Figure 1 – Processed CT with InVesalius (left) and Surface modeling of the vascular segments (right).

After the reconstruction of the model, a little part of the vain which had a section of around 3mm was cut off. A zone with a bifurcation (Fig. 2) was selected, i.e., a zone

that had a fork-like geometry. This zone was selected because of being a branch and possibly present a higher stress area segment.

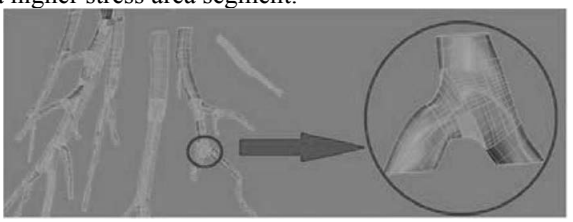

Figure 2 –Selected vascular branch for the simulation.

After selecting the zone, the structure was modeled using spheres as an analogy to tissue spheroids. Basically, a tissue spheroid is a microtissue composed by cell aggregates that will be enveloped by some type of hydrogel. Tissue spheroids contain high density of cells (Rezende et al., 2013) and undergo a natural process of fusion by surface tension when the 3D printer dispenses them onto a platform. Therefore, tissue spheroids have been considered as a special type of material. Thus, the vascular branch was 3D modeled using layers of small spheres (Fig. 3).

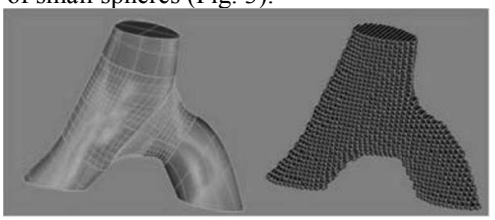

Figure 3 – Representation of printed tissue spheroids.

With the vain section of 3mm, the spheres of 2µm diameter were modeled. Two different stages of fusion were analyzed: 1% and 20% (Fig. 4).

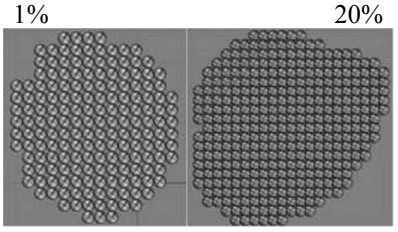

Figure 4 – Design of different tissue spheroids fusion stages.

Computational Fluid Dynamics (CFD) software developed by ANSYS CFX (version R15.0) has been used in our simulations. Each spheroid represented in the simulation was considered as a sphere of alginate. In this work, it was chosen an alginate concentration of 3%, where k = 6 Pa.s and n = 0.84 with density equals to 1.4 g/cm^3 and a shear rate range from 0.01 to 100 s^{-1} and an average viscosity in the range of 2.8 to 12.5 Pa.s (Rezende et al., 2009).

3. Results and discussions

After the mesh has been built, CFD simulations were initiated. To simplify the results and to get more concise information, four different sections (Fig. 5) specifically located on the model were created to get a term of comparison between all configurations.
A flow of fluid passing among the spheres was considered entering at the top before S1 of the structure and leaving after S4. Two different fusion stages (1% and 20%) and two different flow velocities (40 cm/s and 100 cm/s) simulations are presented in this paper. Moreover, it was set an outlet pressure of zero Pascal and temperature equals to 37˚C.

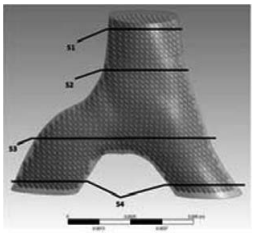

Figure 5 – Locations of the 4 sections analyzed.

Figure 6 shows the profile of velocity and pressure values at sections S1 and S4.

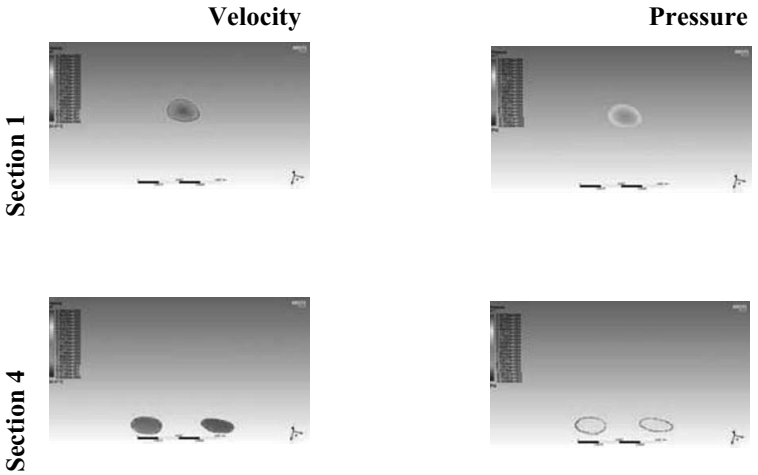

Figure 6 – Profile (color distribution) of velocity and pressure for 1% fusion and input velocity 40cm/s.

Analysing the impact of the velocity variation on the model, both velocities were compared and the following conclusions were pointed as presented in Table 1. For 1% fusion and both inlet velocities, it was observed that the velocity has a logarithmic behavior, which tends to zero. One finding is that both simulations are directly proportional each other. The fact that the velocity is high in the inlet and it's almost zero in the outlet shows that the pressure will be much higher in the inlet which can be a problem to the spheroids.

In the simulations of the 20% fusion (Table 1) with inlet velocity of 40 cm/s, the velocity was constant trough the model. For 100 cm/s, the same results were observed however with a little higher velocity trough the model. This allows having a better control in the spheroids environment guaranteeing that the spheroids have the same conditions.

Table 1 shows the relation between the velocities inside the geometry with both fusions 1 and 20%. The inlet velocities were 40 and 100 cm/s:

Table 1 – Velocities at each section.

Inlet Velocity		40 cm/s		100 cm/s	
Fusion		1%	20%	1%	20%
Section1	Min.	112,6	0	142,8	0
	Max.	140,8	33,1	285	148,1
Section 2	Min.	56,3	0	71,39	0
	Max.	84,47	33,1	142,8	148,1
Section 3	Min.	0	0	0	0
	Max.	28,16	33,1	142,8	148,1
Section 4	Min.	0	0	0	0
	Max.	28,16	33,1	142,8	148,1

Concerning the pressures, on the fusion stage of 1%, it could be verified that the pressure on the lower velocity is lower relatively to the pressure on the model with higher velocity. On both models the pressure is higher in the inlet and it tends to zero until it reaches the outlet, so this translates in a high pressure gradient. The only difference between the models with different velocities is that on the model with higher velocity the pressure will be higher on the entire model when compared to the model with the lower velocity. Table 2 presents the relation of pressure between the fusion stages with inlet velocities of 40 and 100 cm/s:

Table 2 – Pressures at each section.

Inlet Velocity		40 cm/s		100 cm/s
Fusion		1%	20%	1%
Section1	Min.	10,92	44,91	49,6
	Max.	12,52	55,85	56,81
Section 2	Min.	7,77	30,5	35,3
	Max.	9,33	34,12	42,5
Section 3	Min.	2,96	12,4	6,6
	Max.	6,14	23,26	20,95
Section 4	Min.	0,226	1,53	-0,6
	Max.	1,37	8,78	6,6

4. Conclusions

A 3D structure representing a fresh human organ obtained from a 3D bioprinter has been studied *in silico*. Computer simulations have been done to study the behaviour of fluids through tissue spheroids under fusion process. Many parameters have been analyzed. In this work, two ones were verified: velocity and pressure. Four different sections were traced in a vascular branch modeled from a computer tomography image which was imported by software InVesalius and then a 3D model and mesh were generated. The model was carried out into computational fluid dynamics simulation

software to analyze the two parameters – velocity and pressure – which demonstrated to be very critical to the fresh organ if not very well controlled.

Abstract

The elimination by selective adsorption of nitrogen-heterocyclic compounds (NHC) in diesel may be considered as a strategic step prior to hydrodesulphurization (HDS), to achieve ultra-low sulfur diesel (ULSD). NHC compete favorably with sulfur-heterocyclic molecules (SHC) for sites in $CoMo/Al_2O_3$ and $NiMo/Al_2O$ catalysts at typical HDS operating conditions. It is also known that NHC and SHC adsorb favorably on various solids supports at mild conditions. These encourage the design of a process for the adsorption of both NHC and SHC contained in diesel prior to HDS to achieve ULSD. To this goal, a detailed process model has been developed for the simulation of the transient non-isothermal operation of a pilot-scale fixed-bed for the continuous adsorption and desorption stages treating a diesel with 500 ppm of a mixture of NHC and SHC. Model simulations of a continuous three-stage adsorption-desorption operation shows that the process can be successful, if an adequate combination of adsorbent, solvent and temperature is found, and best performance is achieved when using small microporous particles with large pore diameters.

Keywords: ultra-low sulfur diesel, multicomponent adsorption, process modeling.

1. Introduction

The elimination of nitrogen and sulfur heterocyclic compounds in diesel is one of the most important issues that refineries face to meet the existing stringent environmental regulations against NOx and SOx emissions. Current deep hydrodesulphurization (HDS) at high temperatures and pressures may not be able to reduce sulfur content by less than 15 ppm (ULSD), not only because of the known difficulties to remove alkyl derivatives of dibenzothiophene compounds, but also because nitrogen-heterocyclic compounds (NHC) in HDS compete favorably with sulfur-heterocyclic molecules (SHC) for sites in $CoMo/Al_2O_3$ and $NiMo/Al_2O$ catalysts (Lesermann, et al. 2007; Wen, et al. 2010).

On the other hand, it is known that not only NHC can adsorb on various solids supports, but also SHC adsorb on the same type of supports (Aude, 1979; Kim, 2006; Wen, 2010), which has resulted in the development of a process for the selective removal, by adsorption, of NHC and SHC in diesel prior to HDS (Lesermann, et al. 2007). Moreover, the selective adsorption of NHC and SHC can be performed at mild conditions in temperature and pressure, and with no use of Hydrogen. However, to

achieve the above, the right combination of solid adsorbents, and solvent mixtures and temperatures for desorption and regeneration stages should exist.

The aim of this work is to show that the adsorption process could be successful if three conditions are met, although only the first two are considered here. The first condition is related to the existence of solid sorbents to perform the adsorption, which according to the published literature they already exist. The second one is the availability of the right combination of solvent mixtures that make desorption to be effective to cope with diesel production in the refinery. The third and perhaps the determining condition is solvent regeneration. Additional considerations to the success of this process are to seek for the best sorbents physical and chemical characteristics like particle and pore dimensions, and the right amount and strength of active sites, to which this work is mainly focused. It is clear that a battery of packed-beds is required to satisfy the continuous production of diesel in a refinery, so that this process could be implemented accordingly.

2. The adsorption-desorption process

Typical solid adsorbents for NHC and SHC are zeolites (Audeh, 1970), Ni/SiO2-Al2O3 (Kim, et al. 2006), activated carbon (Wen, et al. 2010), and alumina and silica xerogels containing Zr, Ti; preferably with large amounts of acid sites (Ns), in pores with diameters ranging from 2-10 nm, and particle sizes between 0.6-1.5 mm, and specific surface areas (Sg) in the range 150-750 m^2/gr (Lesemmann, et al. 2007). Typical NHC molecules are Carbazole, Quinoline and Indole, whereas for SHC the alkyl derivatives of dibenzothiophene (4,6-dimetil, C2-, C3-, C4-DBT) are the target. Desorption could be accomplish using mixed solvents containing alcohols, ethers and ketones (Lesemmann, et al. 2007), and solvent regeneration seems to be the key for an economically successful process.

3. The process model

Packed-bed multicomponent adsorption is described at two levels. At the inter-particle fluid level mass and heat balances are given by convective and dispersive terms. At the intra-particle level diffusion is assumed to be Fickean at the (cylindrical) pores of the solid adsorbent, and multicomponent adsorption and desorption are assumed to follow Langmuir kinetics under no-equilibrium conditions, using a wide range of kinetic parameter values to characterize the multicomponent mixture, and to evaluate the robustness of the model.

At the inter-particle level in the fluid-phase, mass and heat balances are:

$$\varepsilon\left[\frac{\partial Cn}{\partial t}+\langle u\rangle\frac{\partial Cn}{\partial z}\right]-D_A\frac{\partial^2 Cn}{\partial z^2}-D_R\left(\frac{\partial^2 Cn}{\partial r^2}+\frac{1}{r}\frac{\partial Cn}{\partial r}\right)=\varepsilon k_L a_V\left(Cns-Cn\right) \tag{1}$$

$$\varepsilon\rho c_P\left[\frac{\partial T}{\partial t}+\langle u\rangle\frac{\partial T}{\partial z}\right]-k_{tA}\frac{\partial^2 T}{\partial z^2}-k_{tR}\left(\frac{\partial^2 T}{\partial r^2}+\frac{1}{r}\frac{\partial T}{\partial r}\right)=\varepsilon h a_V\left(Ts-T\right) \tag{2}$$

With boundary conditions:

At r=0: $\frac{\partial Cn}{\partial r} = \frac{\partial T}{\partial r} = 0$; at r=Rt: $\frac{\partial Cn}{\partial r} = 0$; $-k_{effR}\frac{\partial T}{\partial r} = h_W\left(T - T_W\right)$ (3)

At z=0: $\varepsilon\langle u\rangle Cn\big|_{O-} = \varepsilon\langle u\rangle Cn\big|_{O+} - D_A\frac{\partial Cn}{\partial z}\Big|_{O+}$; at z=Lt: $\frac{\partial Cn}{\partial z}\Big|_{Lt} = 0$ (4)

At z=0: $\varepsilon\rho c_P\langle u\rangle T\big|_{O-} = \varepsilon\rho c_P\langle u\rangle T\big|_{O+} - k_{tA}\frac{\partial T}{\partial z}\Big|_{O+}$; at z=Lt: $\frac{\partial T}{\partial z}\Big|_{Lt} = 0$ (5)

The Darcy equation is used to account for the flow velocity in the fixed-bed

$$\langle u\rangle = \frac{K_b}{\mu}\frac{\Delta P}{L_t} \tag{6}$$

Mass balances at the intra-particle level are, for the liquid in pores:

$$\varepsilon_P\frac{\partial Cns}{\partial t} = D_{eff}\left(\frac{\partial^2 Cns}{\partial\lambda^2} + \frac{\partial^2 Cns}{\partial\sigma^2} + \frac{1}{\sigma}\frac{\partial Cns}{\partial\sigma}\right) \tag{7}$$

With boundary conditions at the pore radius (σ), and pore length which is equal to the radius of the particle (λ):

At $\sigma = 0$: $\frac{\partial Cns}{\partial\sigma} = 0$; at $\sigma = R_P$: $-\varepsilon_P D_{eff}\frac{\partial Cns}{\partial\sigma} = \left(1-\varepsilon_P\right)\rho_P R_n$ (8)

At $\lambda = 0$: $\frac{\partial Cns}{\partial\lambda} = 0$ at $\lambda = L_P$: $-\varepsilon_P D_{eff}\frac{\partial Cns}{\partial\lambda} = \varepsilon k_L\left(Cns - Cn\right)$ (9)

The heat balance assumes that the solid temperature Ts remains uniform in the whole particle, and the heat of adsorption is assumed to be negligible.

$$\left(1-\varepsilon_P\right)\frac{\partial Ts}{\partial t} = \varepsilon h a_V\left(T - Ts\right) + Q_{ads} \tag{10}$$

The net rate of adsorption Rn (moles/g cat-s) for the species nis given in terms of the specific surface area (Sg- m^2/g) and the concentration of active sites (Ns- sites/m^2)

$$R_n = k_n S_g N_S\left[Cns\left(1 - \sum_{m=1}^{NComp}\theta_m\right) - \frac{\theta_n}{K_n}\right] \tag{11}$$

The adsorbed species θ*n* followsa the Langmuir expression and it is free to move by surface diffusion.

$$\frac{\partial \theta_n}{\partial t} = D_{surf} \frac{\partial^2 \theta_n}{\partial \lambda^2} + \frac{\rho_P R_n}{N_S} \tag{12}$$

However, boundary conditions state that:

At λ =0 and λ=Lp $$\frac{\partial \theta_n}{\partial \lambda} = 0 \tag{13}$$

Desorption kinetics in the presence of the mixture of solvents is assumed to be first order with respect to the adsorbed species, in which desorption dominates, and it is given as follows:

$$R_{nDes} = k_{ndes} S_g N_S \theta_n \tag{14}$$

Similar expressions of this model have been used previously to describe the isothermal adsorption of multicomponent mixtures (Kaczmarski, et al. 1997), however not with the same detail, and in none of them diffusion and adsorption in the solid adsorbent are given in terms of the (cylindrical) pore in the particle (average pore length Lp and diameter Rp). The model is used to assess the key importance of using small microporous particles (Lp) with large pore diameters (Rp),and the roles of the specific surface area (Sg) and the concentration of active sites (Ns).

Numerical Solution: The model is solved numerically using the method of orthogonal collocation on finite elements for both, the inter-particle fluid phase (axially using 20 elements of equal size with 4 interior points, and radially with one internal collocation point), and the intra-particle solid phase where diffusion and adsorption take place inside the cylindrical pore (3 elements axially, using 4 interior points with elements of different size, and one internal collocation point radially) (Villadsen and Michelsen, 1977). Other used methods are the tri-diagonal matrix, and a 4th order Runge-Kutta.

4. Results and Discussion

To analyze process feasibility for the multicomponent selective adsorption of NHC and SHC, the model is used to simulate the transient non-isothermal operation for the continuous three-stage adsorption-desorption of a pilot-scale fixed-bed (Length=3 m; Diameter=0.30 m; liquid flow rate=0.36 m^3/h), for the treatment of a diesel containing 500 ppm of a mixture of NHC and SHC species, at 333 K and 2.3 bar (adsorption), 373 K and 1.25 bar (desorption). For this, it is assumed that the right solvent exists, and we seek for the best characteristics of the solid adsorbent like: concentration of acid sites (Ns), specific surface area (Sg), average particle radius (Lp) (equivalent to the pore length), and average pore radius (Rp), which are key parameters for the success of the process. The selection of a continuous three-stage adsorption-desorption operation was chosen to show the operability of this process in terms of an efficient elimination of adsorbed species between stages. Figures 1 and 2 show respectively the sequential stages of adsorption and desorption during 50 h of continuous operation. The time-on-stream used for each of the 3-stage operation in other simulations is 10 h per each adsorption and desorption stage.

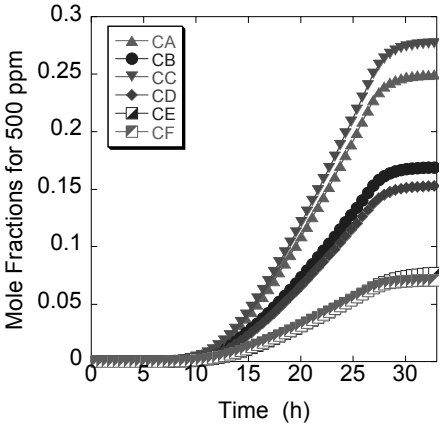

Figure 1. Breakthrough curves during bed adsorption of 500 ppm (particle radius Lp= 0.25 cm, with pore radius Rp = 9 nm) at 333 K. Sg=250 m^2/g; Ns=1.0x10^{-12} sites/cm^2.

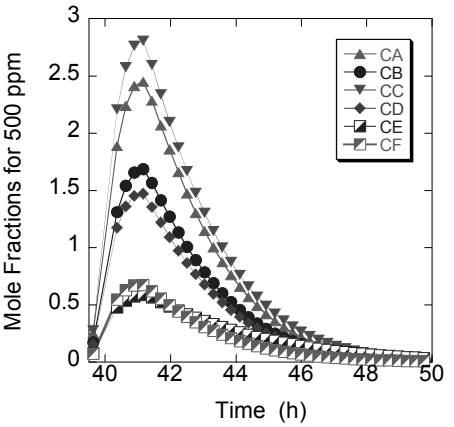

Figure 2. Desorption stage (starting at t=40 h) of NHC and SHC (particle radius Lp= 0.25 cm, with pore radius Rp = 9 nm) at 373 K.Sg=250 m^2/g; Ns=1.0x10^{-12} sites/cm^2.

4.1. Role of particle size specific surface area and active sites concentration

Figure 3 shows the base case at same conditions of Figure 1 for a continuous three-stage adsorption-desorption process of 500 ppm of NHC and SHC species in diesel.Figures 3 and 4 show thatprocess performance is enhanced when using smaller microporous particles with same porous radius (Rp), as bed dispersion of mass is smaller for the smaller particle radius. Figures 5 and 6 show the corresponding responses for larger values of specific surface areas (Sg) and concentration of active sites (Ns), showing again that for both cases a better performance is achieved as compared to that shown in Figure 3.

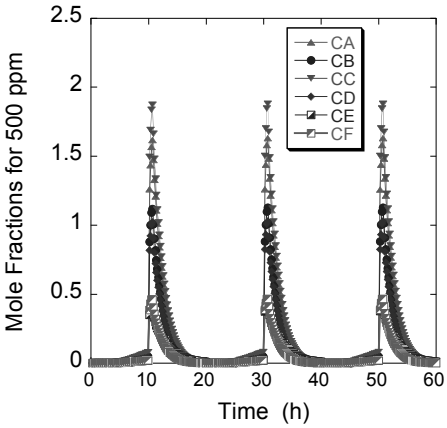

Figure 3. Particle radius Lp= 0.25 cm.

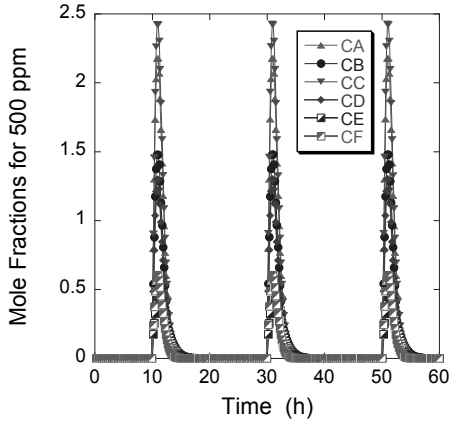

Figure 4. Particle radius Lp= 0.125 cm.

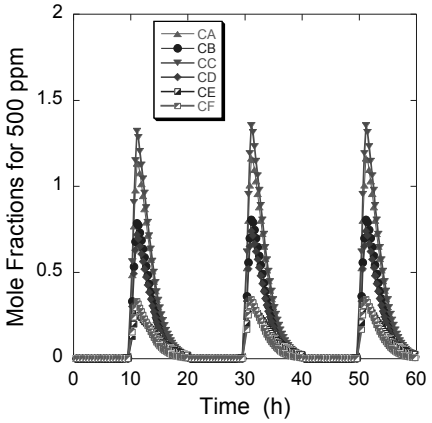

Figure 5. Continuous three-stage using Sg=400 m^2/g; Lp= 0.25 cm.

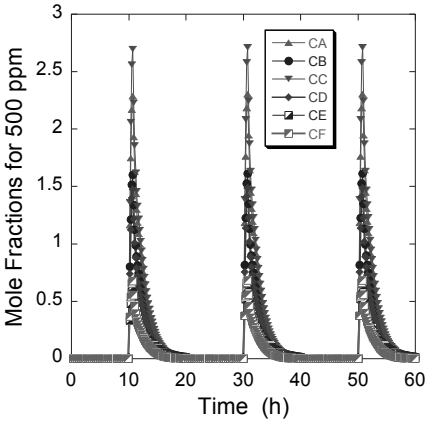

Figure 6. Continuous three-stage using Ns=2.50x10^{-12}sites/cm^2; Lp= 0.25 cm.

5. Conclusions

Multicomponent adsorption of Nitrogen and Sulphur heterocyclic compounds in diesel prior to hydrodesulphurization for ultra-low sulfur diesel can be successfully accomplished by the proper selection of adsorbents (definitely zeolites), solvents and operating conditions. Best performance is obtained when using small microporous particles with large pore diameters, but not very large specific surface areas or large concentration of active sites; these two properties should be optimized. Finally, the regeneration and solvent recovery (not treated in this work) is very important, since large volumes of solvent may be required together with a large demand of energy, making this stage the key for an economically successful process.

Abstract

Hydrodynamics of gas-solid in the fast fluidization regime were investigated by a combination of experiment and computational fluid dynamics (CFD) simulations. A two-dimensional (2D) numerical simulation of gas-solids flow in a circulating fluidized bed riser was performed based on the two-fluid model (TFM). The effect of some essential parameters, namely, specularity coefficient (φ), and particle-particle restitution coefficient (e_{ss}), was examined for one set of operating condition. A range of specularity coefficients from 0.1 to 0.0001 were investigated. When specularity coefficient is set to values of 0.001 and above gives axial solid holdup profiles that reasonably agree with the experimental data. It was found that the specularity coefficient has substantial effect on bulk flow. Moreover, the effect of the elasticity of particle collisions showed that the high particle-particle restitution coefficients gave good quantitative agreement. Further extensive validations were carried out to investigate the validity of screened model parameters for different solid circulation rate and gas velocity. Simulation results for different operating condition were able to predict the qualitative trend. Although the model under-predicted the solid holdup at a high solid circulation rate, but was able to capture axial heterogeneity. The 2D results presented in this work will provide a useful basis for the future 3D simulation work of a current CFB system.

Keywords: Kinetic theory of granular flow, circulating fluidized bed riser, Two-fluid model

1. Introduction

Circulating fluidized bed (CFB) reactors are widely applied in many industrial-scale operations because of several advantages, such as improved contact between gas and solid particles, good turndown capability and operation flexibility (Berruti et al., 1995; Grace and Bi, 1997). In general, CFB can be operated under different fluidization regimes; the most common is Fast Fluidization (FF) and present studies were carried out on this regime. In recent years, computational fluid dynamic (CFD) has become a useful tool to study and predict the hydrodynamics of multiphase flows. The approaches that

are used in the simulation of multiphase flows are the two-fluid model (TFM) and discrete element method (DEM). To model large industrial riser systems, Eulerian-Eulerian (TFM) method with the kinetic theory of granular flow (KTGF) framework are more suitable (Jiradilok et al., 2006). Despite several previous studies, the selection of proper wall boundary condition (BC) and appropriate closure model for given flow condition remains inconclusive (van Wachem et al., 2001). For the CFD simulation of a CFB riser, free-slip, partial-slip and no-slip wall boundary condition has been adopted in the literature. The partial-slip boundary condition was used by Jiradilok et al. (2006), the no-slip boundary condition was used by Lu et al. (2009) and Benyahia et al. (2005) suggested free-slip BC in the simulation of a dilute pipe. Researcher found that choosing the correct value of specularity coefficient is critical for most validation. In contrast, the varying particle-wall restitution coefficient (e_w), doesn't affect the characteristic trends (Neri and Gidaspow, 2000). Hence, an assessment of the appropriate specularity coefficient is important for accurate prediction. Further, the particle-particle restitution coefficient (e_{ss}) also plays an important role in gas-solid flow. The particle-particle restitution coefficient value represents the elasticity of particle collisions between two particles; its value ranges from zero for perfectly plastic to one for a perfectly elastic collision. It has served as a tuning parameter for matching experimental results (Cloete et al. 2011), therefore in the current work three different values of the coefficient of restitution i.e. e_{ss}–0.99, 0.9, 0.8 were examined. Among the works in the literature, most of the researchers have investigated the model parameter at one operating condition. Whereas in the current work, we evaluate the validity of these model parameters for different solid circulation rate and gas velocity in the fast fluidization regime.

2. Experimental Setup

Experiments were carried out in a cold-mode dual circulating fluidized bed (CFB) reactor, as shown in Figure 1a. The CFB system is made of plexiglas and composed of 7 m long riser, 75 mm in diameter and with a L-shape exit configuration. The riser and the downcomer are equipped with several pressure transducers for measuring the pressure profile. Solid circulation rate (G_s) was measured once the system has reached steady state using a ball valve in the downcomer. Silica sand was used as a bed material, with an averaged diameter of 249 µm and density of 2353 kg/m^3. In the present experimental work four sets of operating conditions were considered in the fast fluidization regime. With increasing solids mass flux, at constant superficial gas velocity (U_g = 3 m/s and G_s = 19, 48.9 kg/m^{2}s) and increase in superficial gas velocity, at constant solids mass flux (U_g = 3.0, 4.0 m/s and G_s = 43.7 kg/m^{2}s).

3. Model description and implementation

3.1. Numerical Model

The governing equations were solved using the finite volume approach in FLUENT. Two-fluid model was used for simulating the flow behavior in the CFB riser. A dispersed k-ε turbulence model with standard wall function was adopted to account for the gas phase turbulence effect. The interphase momentum exchange between the two phases was provided through the drag coefficient. For the present case, the Gidaspow drag model (Gidaspow, 1994) was employed. For solving solid phase, kinetic theory of granular flow was employed to compute shear stress. Kinetic energy associate with particle velocity fluctuation is represented by a "granular temperature (Θ)".

3.2. Simulation Setup

Three-dimensional (3D) geometry consumes high simulation time, two-dimensional (2D) riser simulation were performed to keep the computational workload at a reasonable level. The schematic geometry of the 2D riser used in the simulation study is shown in Figure 1b. At the bottom inlet, only the gas velocity is specified; the inlets for solid phase are located at the two sides of the riser at the height 0.6 m; at the top outlet, atmospheric pressure is prescribed.

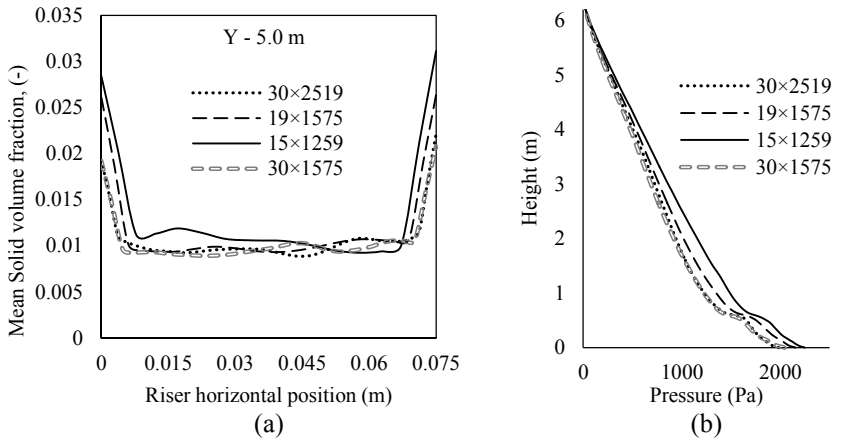

Figure 2: Effect of different grid resolutions (a) Time-averaged radial solid volume fraction (b) Time-averaged axial pressure (U_g = 3.0 m/s, G_s = 43.7 kg/m^{2}s)

To achieve an acceptable grid independent solution four different grid resolutions of 30×2519, 19×1575, 15×1259 and 30×1575 were applied to this simplified geometry. The radial profiles of mean solid volume fraction at the height of 5.0 m were presented in Figure 2a. For the 19×1575, 15×1259 grid resolution, solid volume fraction transition from wall to core quite sharp and the profile predicted by the 30×2519 and 30×1575 computational cells were similar. The effect of grid size on the axial solid holdup was also tested in the simulation, as shown in Figure 2b. Grid resolutions of 30×2519 and 30×1575 predict similar pressure along the height of a riser. However, the simulation with 19×1575, 15×1259 grid resolution predicts somewhat higher pressure than with the other two simulations. Therefore the grid resolution of 30×1575 was selected to conduct further simulation. Transient CFD simulations were carried out using a time step size of 0.0003 s with 100 iterations per time step. Transient behavior of solid mass flux was

monitored dynamically at the outlet of riser to ensure a pseudo-steady-state has achieved before any data analysis.

4. Results and Discussion

In the Johnson and Jackson, (1987) wall boundary condition theory, the specularity coefficient (φ) represents the frictional contact between the solid phase and wall, and the particle-wall restitution coefficient (e_w) quantify the dissipation of solid phase kinetic energy by collision with the wall. As discussed above, the specularity coefficient is an important parameter, in contrast, the varying particle-wall restitution coefficient has no significant effects. Therefore, in the present work, a wide range of the specularity coefficients from 0.1 to 0.0001 were investigated.

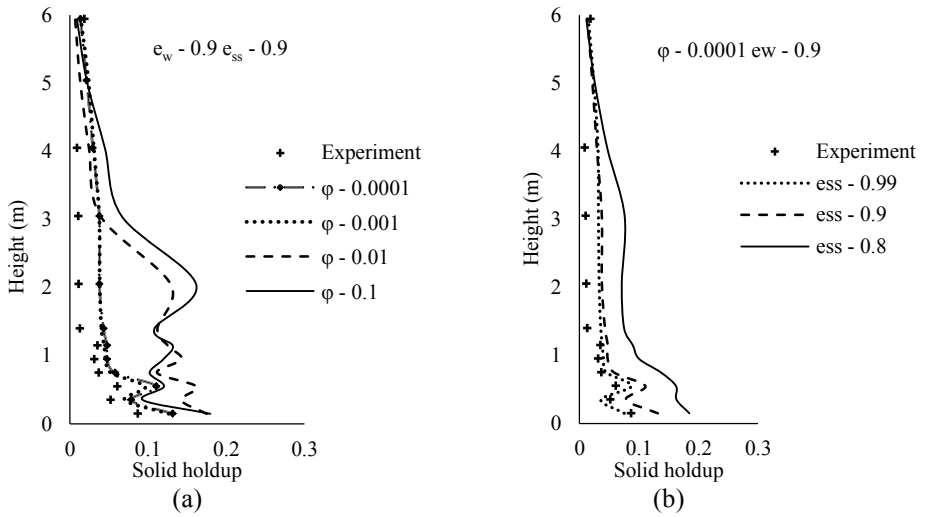

Figure 3: Effect of (a) Specularity coefficients, (b) Particle-particle restitution coefficients on the axial solid holdup profile (U_g = 3.0m/s, G_s = 43.7 kg/m^{2}s)

Figure 3a demonstrates the effect of the specularity coefficient on the axial solid holdup profile. The specularity coefficient of 0.1 predicts significantly high values of the solid holdup then the experimental data in the mid and bottom section of riser, whereas for same specularity coefficient value results in low solid holdup along 5–6 m of riser height. For the specularity coefficient of 0.01, the solid holdup for a height of 0 and 3 m is also considerably high than the experimental value, but after 3 m, the predicted values reasonably agree with the experimental data. The high value of specularity coefficient results in higher flow resistance for particles moving in an upward and downward direction result in a high solid holdup. For specularity coefficient value of 0.001 and above gives reasonably qualitative agreement with experimental data throughout the height of the riser. Thus, the lowest specularity coefficient value (φ–0.0001) will be used for remainder of the study.

As discussed in the earlier section three different values of the coefficient (e_{ss}–0.8, 0.9 and 0.99) were examined. From Figure 3b it can be clearly seen that for e_{ss}–0.8 model over predict the solid holdup in most axial locations. The computed results show a significant improvement in the axial solid holdup as the coefficient of restitution

increased from 0.8. The simulation results using particle-particle restitution coefficients of 0.99 were successfully able to predict typical flow characteristics. Comparatively at 0.9 particle-particle restitution, over predicts the solids holdup at the bottom section of a riser. A higher coefficient of restitution means no dissipation of kinetic energy resulting in more particles leaving the riser. Therefore, the solid holdup distribution in the riser declined.

Validity of above screened model parameters were further evaluated at various solid mass fluxes and superficial gas velocities. From Figure 4a it can be clearly seen that the best agreement with the experimental data observed for low solid mass flux (19.2 kg/m^{2}s). However, for increased solid flux bottom dense regions were under-predicted. One possible reason for this discrepancy is that the conventional Gidaspow drag model cannot account for the reduction in drag due to formation of clusters in the gas-solid riser flow (Shah et al. 2011). To overcome the short comings of the conventional drag correlation multiscale approaches such as the sub-grid scale (SGS) and the energy minimization multiscale (EMMS) models are expected to lead better predictions (Shah et al. 2015). Similarly, for high gas velocity (U_g = 4m/s) the model was unable to predict quantitatively, but show reasonable qualitative agreement. These discrepancies could be due to 2D simplification of the solids inlet and outlet configurations. Recent work by Li et al. (2014) has shown that the 2D simulation can only be used as an effective tool for qualitative studies and 3D simulation is required to accurately capture the quantitative flow behavior in CFB risers. The 2D results presented in this work will provide a useful basis for the future 3D simulation work of a current CFB system.

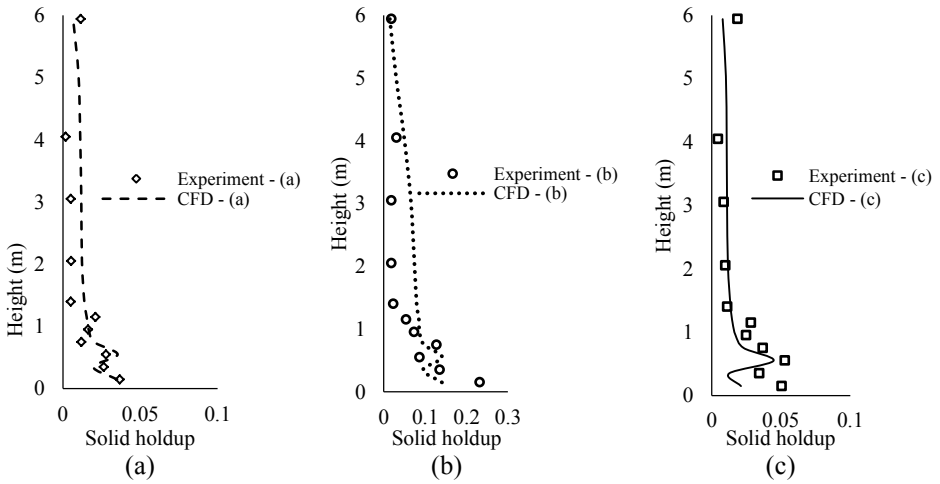

Figure 4: Model prediction at various operating conditions (φ–0.0001 e_w–0.9 e_{ss}–0.99) (a) U_g = 3.0 m/s, G_s = 19.2 kg/m^{2}s, (b) U_g = 3.0 m/s, G_s = 48.9 kg/m^{2}s, (c) U_g = 4.0 m/s, G_s = 43.7 kg/m^{2}s

5. Conclusion

In this work, the hydrodynamics of CFB riser were investigated using two-fluid model (TFM) coupling with the kinetic theory of granular flow. A lower specularity coefficient (0.001 and above) and high particle-particle restitution coefficients (e_{ss}–0.99) gives a reasonable agreement between the predicted axial solid holdup profiles and

experimental data. In the present study, specularity coefficient values significantly affects the riser bulk flow. Particle-particle restitution coefficients express the amount of the energy dissipation by collisions and were used as a tuning parameter in the present study. Particle-particle restitution coefficient (e_{ss}) was tuned to fit the overall experimental profile of axial solid holdup. With the evidence of results it was observed that the model prediction improves as the coefficient of restitution increases. Finally, the validity of screened model parameters were further evaluated for different operating conditions. The model was capable of predicting the main features of the complex gas-solids flow operated in the fast fluidization regime. However, the model showed some discrepancy in predicting the bottom dense regions particularly operating at high solid circulation rate. This study reveals that the one setup of model parameter and boundary condition can be used to predict system operating at the same flow regime. The 2D results presented in this work will provide a useful basis for the future 3D simulation work of a current CFB system.

Abstract

Phase transfer catalyst (PTC) is used to transfer the desirable active form of an anion from the aqueous phase to organic phase where the reaction occurs. One of major challenges for process design of the PTC system is to establish a reliable thermodynamic model capable of describing phase behaviours of all components including water, organic solvents, inorganic salts, and the PTC. In this work, a new electrolyte model based on the KT-UNIFAC group contribution approach has been developed by adding the Debye-Hückel theory and a second virial coefficient-type term into the KT-UNIFAC model. The temperature-dependent parameters of the new model are introduced to improve the description of phase equilibria in temperature ranges between 273.15 and 373.15 K. The proposed model has been successfully applied to the predictions of phase behaviours of alkali halide aqueous solutions that are usually found in PTC systems, thereby, extending the application range of the PTC-system model. The solubility of PTC in organic solvents, which is a key factor for strategy of PTC and solvent selection, has been calculated using the e-NRTL-SAC model.

Keywords: phase transfer catalyst, PTC, electrolyte model, UNIFAC

1. Introduction

1.1. PTC system

Since Basolo et al. (1973) introduced the concept, biphasic reaction systems have been increasingly considered as promising organic synthesis options due to possibilities of identifying novel synthesis routes that are flexible, easier to operate and give higher production yields. Phase transfer catalyst (PTC) as an application of the biphasic system is employed to obtain higher yields and substitute hazardous or expensive solvents.

As shown in Figure 1, active anion (Y^-) is transferred via PTC cation (Q^+) from aqueous phase into organic phase where the reaction occurs with organic raw material (R-X) to produce a desirable product (R-Y). Inactive form of the PTC (QX) dissolved in aqueous phase from organic phase reacts with active inorganic salt (M^+Y^-) to complete the cycle. Mathematical models on the PTC systems, including physical and chemical equilibrium, reaction mechanism and unit operation, have been generated in our previous works (Anantpinijwatna et al., 2014; Piccolo et al., 2012) and are further developed in this work to analyse the PTC-based process.

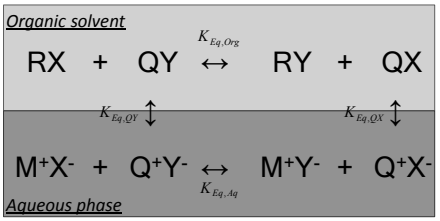

Figure 1: Reaction mechanism for a generic PTC system.

1.2. Thermodynamic model

The key information for the successful design of a PTC-based process is the solubility of active and inactive forms of the organic catalytic cations in aqueous or organic phases and the partitions between these two phases, which are calculated from the activity coefficients of the PTC as a function of compositions of all species for each phase and the system temperature. Therefore, reliable thermodynamic models capable of describing the phase behaviours of all the species presented in the PTC system are required. Due to lack of available measured data for a reactive system, predictive models based on molecular structural parameters, like UNIFAC or segments like eNRTL-SAC (Chen and Song, 2005) are preferred. With respect to thermodynamic modelling, the PTC system can be decomposed into four subsystems (A – D) consisting of:

Subsystem A (organic solvent – water): describes the mutual solubilities between organic solvent and water using NRTL or KT-UNIFAC models

Subsystem B (inorganic salt – water): describes the behaviour of inorganic salt (M^+X^- and M^+Y^-) in aqueous phase using e-NRTL, e-NRTL-SAC, or **e-KT-UNIFAC** models

Subsystem C (organic solvent – PTC): describes the behaviour of PTC (QX and QY) in organic solvent using NRTL, **e-NRTL-SAC**, or UNIFAC-IL thermodynamic models

Subsystem D (water – PTC): describes the behaviour of PTC (Q^+X^- and Q^+Y^-) in aqueous phase using e-NRTL, e-NRTL-SAC, or e-UNIQUAC models

Thermodynamic descriptions of subsystem A are well-established with existing models, whereas the models needed for subsystem D was presented in our previous work (Anantpinijwatna et al., 2014). In this work, a new electrolyte model (e-KT-UNIFAC) is developed and initially applied to the subsystem B, where some representative alkali halide salts can be used as a donor of reacting anions or an acceptor of inactive anions. Solubilities of various PTC species in various organic solvents for subsystem C are determined using the eNRTL-SAC model, reporting new parameters of the PTCs fitted to experimental data. The calculated results are compared with literature data.

2. Model and Parameters

2.1. Reactor model

The framework for the modelling of biphasic reaction systems was proposed and applied to the PTC system with a biphasic reactor model (Anantpinijwatna et al., 2014). The model is composed of 8 balance equations (Eqs. 1-8) and 4 equilibrium conditions (Eqs. 9-12) as shown below.

$$N_{X^-,Aq} = N^0_{X^+} + \xi_{Aq} \quad (1)$$

$$N_{Y^-,Aq} = N^0_{Y^-} - \xi_{Aq} \quad (2)$$

$$N_{RX,Org} = N^0_{RX} - \xi_{Org} \quad (3)$$

$$N_{RY,Org} = N^0_{RY} + \xi_{Org} \quad (4)$$

$$N^T_{QX} = N^0_{QX,Aq} + N^0_{QX,Org} - \xi_{Aq} + \xi_{Org} \quad (5)$$

$$N_{QX,Org} = N^T_{QX} + N_{QX,Aq} \quad (6)$$

$$N^T_{QY} = N^0_{QY,Aq} + N^0_{QY,Org} + \xi_{Aq} - \xi_{Org} \quad (7)$$

$$N_{QY,Org} = N^T_{QY} + N_{QY,Aq} \quad (8)$$

$$0 = X_{RY,Org}X_{QX,Org} - K_{Eq,Org}X_{QY,Org}X_{RX,Org} \quad (9)$$

$$0 = X_{X^-,Aq}X_{QY,Aq} - K_{Eq,Aq}X_{Y^-,Aq}X_{QX,Aq} \quad (10)$$

$$0 = X_{QX,Org} - K_{Eq,QX}X_{QX,Aq} \quad (11)$$

$$0 = X_{QY,Org} - K_{Eq,QY}X_{QY,Aq} \quad (12)$$

where N_i and X_i are mole number and mole fraction of component *i*, respectively, and ξ are extent of reaction. $K_{Eq,Org}$ and $K_{Eq,Aq}$ are equilibrium variables in organic and aqueous phases, while $K_{Eq,QY}$ and $K_{Eq,QX}$ are partition variables of active and inactive PTC, which are calculated by appropriate thermodynamic models.

2.2. e-KT-UNIFAC

In the proposed model the activity coefficient (γ_i) of group *i* is calculated by a sum of three different terms, a long-range (LR) for direct effects of charge interactions, a middle-range (MR) term for indirect effects of charge interactions, and a short-range (SR) term for contribution of noncharge interactions.

$$\ln \gamma_i = \ln \gamma_i^{LR} + \ln \gamma_i^{MR} + \ln \gamma_i^{SR} \quad (13)$$

The long-range term is derived from Debye-Hückel theory (Debye and Hückel, 1923) and given by Macedo et al. (1990). For the middle-range a second virial coefficient-type term from the Pitzer model (Pitzer, 1973) is added to give better description at high salt concentrations up to their solubilities. Working equations are given in Mohs and Gmehling (2013) but, in this work, the middle-range interactions between water and ions were assumed to be negligible and additional temperature-dependent coefficients were introduced for application in a wide range of temperatures. The middle-range interaction parameters (B_{ij}) between cation and anion are expressed as

$$B_{ij} = \left[b_{ij,1} + b_{ij,2}(T - T_0)\right] + \left[c_{ij,1} + c_{ij,2}(T - T_0)\right]\exp\left(-\sqrt{I} + 0.125I\right) \quad (14)$$

where T_0 is reference temperature of 298.15 K and *I* is molal ionic strength (mol/kg). The short-range contributions are calculated using KT-UNIFAC (Kang et al., 2002) composed of combinatorial and residual parts. Group volume and surface area parameters, R_i and Q_i, of ions needed for KT-UNIFAC were estimated from ionic radius with new standard segment radius for physically correct representation of the combinatorial part, $Q_i/R_i \leq 1$ (Cheng, 2003). Temperature dependence of group-interaction parameters (a_{ij}) are represented in the residual part of KT-UNIFAC.

$$a_{ij} = a_{ij,1} + a_{ij,2}(T - T_0) \quad (15)$$

All parameters for binary interactions of water-ion and ion-ion were fitted to experimental data such as mean ionic activity coefficients, osmotic coefficients, vapour-liquid equilibria, and solid-liquid equilibria and the values are listed in Table 1.

Table 1: Model parameters for middle-range and short-range interactions

2.3. e-NRTL-SAC

The e-NTRL-SAC model (Chen and Song, 2005) is based on the segment contribution concept where each molecule can be characterized by four conceptual segments (X, Y-, Y+, and Z). The working equations are given in the original paper and the parameters of water and organic solvents are obtained from published papers (Chen et al., 2001; Song and Chen, 2009). The conceptual segment numbers for eleven PTCs are newly determined from solubility data in twelve organic solvents. The parameter values are reported in Table 2 with their corresponding average deviations.

Table 2: Segment numbers of PTC for NRTL-SAC model

PTC	No. of Exp.	X	Y-	Y+	Z	σ*

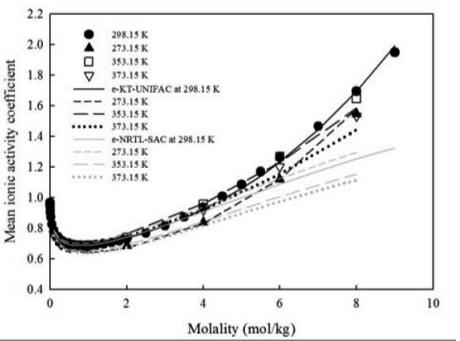

Figure 3: Comparisons of calculated mean ionic activity coefficients of NaBr with data (Hamer & Wu, 1972; Archer, 1991)

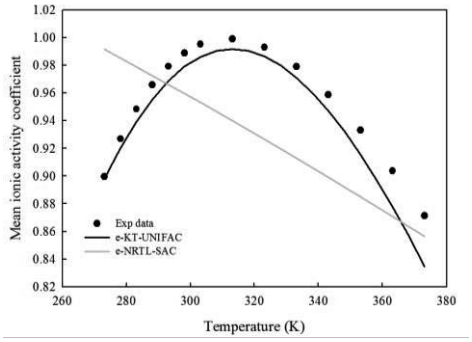

Figure 4: Comparisons of calculated mean ionic activity coefficients of NaCl with data (Clarke & Glew, 1985) at 6 molality

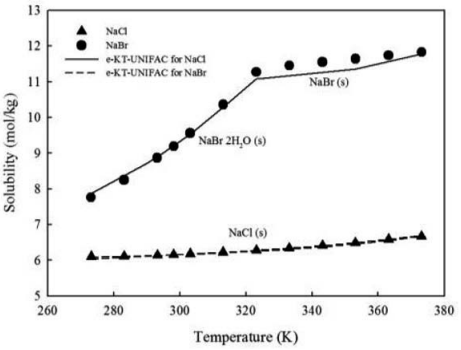

Figure 5: Comparisons of calculated solubility of NaCl and NaBr with data (Haynes et al., 2015)

3. Results and Discussions

3.1. e-KT-UNIFAC with subsystem B

Calculated mean ionic activity coefficients are compared with literature data and eNRTL-SAC model results (Chen and Song, 2005) for NaCl and NaBr in Figures 2 and 3, respectively. These calculations are found in good agreement with the experimental data and more accurate than those of eNRTL-SAC in the temperature range between 273.15 and 373.15 K. With increasing temperatures at a fixed molality, the mean ionic activity coefficients increase, reach a maximum, and decrease again as shown in the Figure 4 for NaCl. The model successfully describes the behaviour, whereas the eNRTL-SAC model shows a continuous decrease with the temperature. The model gives better description of the PTC process, where reactions may take place at temperature other than 298.15 K.

In addition, salt solubilities in water were calculated using the new model. The salt solubility is determined at a given temperature, where the equilibrium constant calculated using activity coefficients is equal to the value calculated using standard thermodynamic properties. As shown in Figure 5, the results show good agreement with the data.

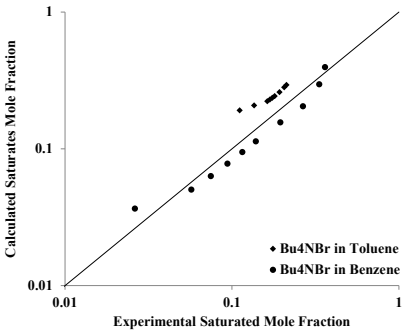

Figure 6: Comparisons of calculated solubility of Bu4NBr PTC by e-NRTL-SAC model with experimental data; ▲ in benzene; ● in toluene. (Abraham, 1970)

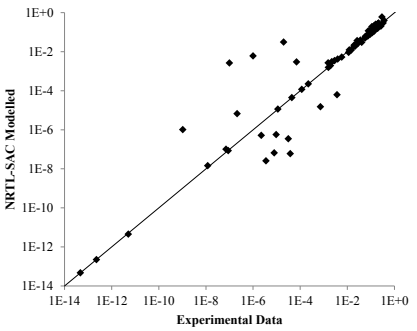

Figure 7: Comparisons of calculated solubility of 11 PTCs in 12 solvents by e-NRTL-SAC model with experimental data. (Abraham, 1970, 1972, 1971)

3.2. e-NRTL-SAC with subsystem C

The e-NRTL-SAC model (Chen and Song, 2005) has available parameters for the interactions of water and PTCs; this is subsystem D (Anantpinijwatna et al., 2014). Here the model is applied to calculate activity coefficients and the solubility of eleven PTCs in organic phases listed in Table 2. The results show an acceptable agreement between the measured experimental data and model predictions as shown in Figure 6 and 7. The modelling results on subsystems C and D are employed to calculate partitions of the PTC between aqueous and organic solvents.

Conclusions

For accurate design of the PTC-based process, complex phase behaviours need to be analysed using the thermodynamic model for systems of water, organic solvents, inorganic salts, and PTC. New electrolyte model based on KT-UNIFAC was established and applied to the PTC system. As initial step the model was found to successfully describe various thermodynamic properties of alkali halide aqueous solutions. The systematic model framework provides possibilities of extension to other systems involving the PTC. The e-NRTL-SAC model has also been used to model the PTC system. In this work solubilities of various PTCs in organic solvents were calculated using this model with good agreement. The results give a good fundamental basis for study of PTC system and the developed model can be fundamentally used to determine systematic strategies for selection of the PTC and the organic solvent.

As future works the model will be extended to other subsystems and employed for the simulation of the overall PTC-based process.

Abstract

The automated construction of physical laws from raw experimental measurements poses a great challenge in modern modelling and remains an open question. The work here presents a novel generalized Mixed-Integer Nonlinear Programming (MINLP) approach, which constitutes a rigorous theoretical formulation that best fits the given data. The proposal is based on the use of generic representation of analytical functions as binary evaluation trees which are Directed Acyclic Graphs (DAG) utilized to allow the construction of a superstructure out of which the optimal fitting model can be identified by solving the resulting (non-convex) MINLP problems. The trees are constructed in a way that their nodes are comprised of a linear combination of basic atomic functions, either arithmetic or unary, weighted by binary decision variables. Both single-input single-output (SISO) and multiple-input multiple-output systems are considered, as well as more complex models comprised of differential equations or even described by series summation of algebraic terms. The aim and contribution proposed methodology in this paper is to present the most general theoretical formulatioon of how models are constructed for systems quantification via analytical function forms, irrespective of the source of data. The constructed formulation is shown to contain all formulations thus far presented in the open literature, comprising a starting point either for direct fitting or for the derivation of simplified approaches.

Keywords: Directed Acyclic Graph; Function Evaluation Tree; Model Automated Construction; Mixed-Integer Nonlinear Programming;

1. Introduction

Mathematical modelling constitutes a fundamental aspect of all applied sciences and engineering, and is usually based in theoretical knowledge of underlying mechanisms to be effected. The automation of such model construction in analytical form is a highly-desirable aim, which to this date has not had a general theory behind it. In the past few decades, different approaches, such as Kriging (Oliver and Webster, 1990), Gaussian Processes (Williams and Barber, 1998), Artificial Neural Networks (Nandi and Azzouz, 1998) and Sub-model regression (Gatu et al., 2007) have been developed towards this goal. Recently, a paper claiming a similar approach has appeared in the open literature (Schmidt and Lipson, 2009). The approach in the latter article follows the lines of a customized construction technique, presented more along the context of algorithm design and relying heavily on heuristic optimization procedures ("Genetic Algorithms"). While an

interesting approach, it lacks the mathematically rigorous understanding presented in this paper, which generalizes completely the approach by setting it as a proper Mixed-Integer Mathematical Programming problem. Recently, Cozad et al. (2014) proposed automated learning of algebraic models for optimization (ALAMO) by summing algebraic terms to fit the models.

Unlike other approaches, our proposal is based on the use of a generic representation of analytical functions as binary evaluation trees (Directed Acyclic Graphs, DAG) . The trees are constructed in such a way that their nodes are comprised of a linear combination of basic atomic functions, either arithmetic or unary, which are weighted by binary decision variables. Allowing only one of the nodal binary variables to attain the value of one forces the construction of a standard representation of any analytical function. It is theoretically demonstrated that as the tree expands, it is possible to encapsulate any analytical form a noiseless function may have, and given enough measurements to establish a unique fitting. For noisy data, as for example with measurements from experiments, suitable tolerance constraints can be included to ensure adequacy and reliability of the models extracted. The approach is generalized to capture the cases of dynamic models, *e.g.* models described by ODE right hand sides, as well as models that are described by series summations of terms. The premise to guarantee the solutions obtained is that deterministic global optimization methods be used, otherwise with local optimization techniques it is only possible to guarantee a sufficiently good fitting but not the absolutely best functional structure, nor the best model parameter values, corresponding to the given data.

2. Analytical function representation as binary trees

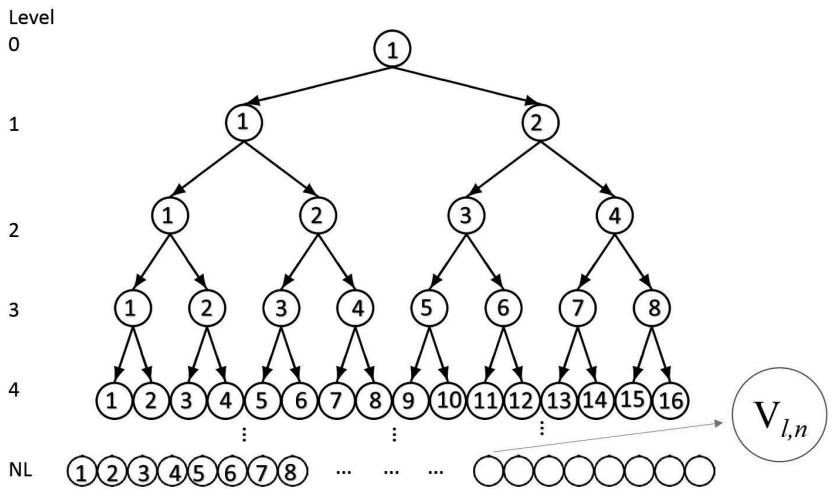

Figure 1: DAG tree representation of analytical functions

The Directed Acyclic Graph (DAG) description of analytical algebraic functions will be used throughout this work. A *superstructure* balanced binary tree is proposed to be constructed for the representation of any function. The superstructure is a term implying the inclusion of more elements in a decision making process than a final solution will contain, and their presence is to be decided automatically via the optimization process. In this way, all the possible combinations allowed in a design can be considered and the optimal one to be identified. The structure and number of nodes in a 4-level balanced binary tree is shown in Figure 1.The formulation presented

in the next sections uses the following index sets are: (a) number of layers in the superstructure tree: $l \in \{0,1,2,\ldots,NL\}$, (b) bivariate and univariate functions $f_k(\cdot)$ considered: $k = \{1,\ldots,NF\}$, and (c) the top layer of the tree is layer 0 which contains exactly 1 node (the root of the function tree). All layers have n_l nodes given by $n_l = 2^l, \quad l = 0,1,2,\ldots,NL$.

2.1. Bivariate operations

The bivariate operations correspond to arithmetic operators and are summarized in Table 1 below. These are sufficient for the description of a DAG representing the evaluation of an analytical function by assigning appropriately what the left offspring, $V_{l+1,2n-1}$, and right offspring, $V_{l+1,2n}$, are for each node, respectively. It is noted that the division and power operations have to be safeguarded against evaluations outside their domain of definition. It is also noted that the first to operations are simply assignment of either the left or right node value to the current node, thus bypassing this node without any function description.

Table 1: Arithmetic bivariate tree operations

#	$f_k(\cdot)$	#	$f_k(\cdot)$
1	$V_{l+1,2n-1}$	5	$V_{l+1,2n-1} \times V_{l+1,2n}$
2	$V_{l+1,2n}$	6	$V_{l+1,2n-1} \div V_{l+1,2n}$
3	$V_{l+1,2n-1} + V_{l+1,2n}$	7	$V_{l+1,2n-1} \hat{} V_{l+1,2n}$
4	$V_{l+1,2n-1} - V_{l+1,2n}$		

The nodal value can be represented by the inclusion of bivariate operations weighted by binary parameters, by the combination of both the left offspring $V_{l+1,2n-1}$ and right offspring $V_{l+1,2n}$ as input:

$$V_{l,n} = \sum_{k=1}^{NF} \delta_{l,n,k} f_k(V_{l+1,2n-1}, V_{l+1,2n}) \tag{1}$$

This equation will be the same as the one presented generally in the next section, with the latter being the more general description.

2.2. Univariate functions

Each node may also carry a function within it and its choice again is to be made by a suitable binary decision variable to be chosen optimally. Functions $f_k(\cdot)$ can be: $\log(\cdot)$, $\exp(\cdot)$, $\sin(\cdot)$, $\cos(\cdot)$, $\tan(\cdot)$, $\sqrt{(\cdot)}$, *etc.* It is noted that if these are to be included they have to be safeguarded against evaluations outside their domain of definition, if applicable. The nodal value can be expanded thus by the inclusion of univariate function operations weighted by additional binary decision variables, by considering only the right offspring nodal value $V_{l+1,2n}$ as input:

$$V_{l,n} = \sum_{k=1}^{NF} \delta_{l,n,k} f_k(V_{l+1,2n-1}, V_{l+1,2n}) \tag{2a}$$

$$\sum_{k=1}^{NF} \delta_{l,n,k} = 1, \quad \delta_{l,n,k} \in \{0,1\} \tag{2b}$$

$$k = 1,2,\ldots,NF; \quad n = 1,2,\ldots,2^l; \quad l = 0,1,2,\ldots,NL-1 \tag{2c}$$

2.3. Enriching the basis set of nodal functions

It is clear by the way the nodal value is represented that it comprises a linear summation of either univariate or bivariate elementary operations or functions. Unlike other approaches which use extensive sets of functions as a basis, the proposed approach requires comparatively very few terms per node. To increase the applicability and compactness of the tree representations it is thus advantageous and highly desirable to include a richer set of functions, particularly if the approach is to be used to fit or predict physical laws from data using standard forms. The extended functions may be either available in the computer system (or programming platform) used, or they will have to be input as direct approximations in the nodal value constructs.

3. Optimization problem

3.1. Formulation of the fitting optimization problem

The presented nodal expressions so far allow the construction of a general binary tree representation of any analytical function, and for any number of variables via an appropriate Mathematical Programming (MP) formulation. The fitting problem results in a Mixed-Integer Nonlinear Programing problem (MINLP) which will be hard to solve in general, being generally expected to be non-convex. Nonetheless, it is clear that the formulation presented in this work is the most rigorous representation of any analytical functional form.

Node per level equations:

The equations defining how the information (values) propagate from one level to the next is presented here going downwards in the tree from level 0 to level $NL-1$. Level NL, the final level in the tree, is handled in a different way as explained later. Some reordering and restructuring of the node value parameters is carried out to have uniformity in the presentation.

Level 0 to NL − 1 equations:

$$\begin{aligned} V_{l,n} \;=\;& \delta_{l,n,1}V_{l+1,2n-1}+\delta_{l,n,2}V_{l+1,2n}+\delta_{l,n,3}(V_{l+1,2n-1}+V_{l+1,2n})+\delta_{l,n,4}(V_{l+1,2n-1}-V_{l+1,2n}) \\ & +\delta_{l,n,5}V_{l+1,2n-1}\cdot V_{l+1,2n}+\delta_{l,n,6}\frac{V_{l+1,2n-1}}{V_{l+1,2n}}+\delta_{l,n,7}\left(V_{l+1,2n-1}\right)^{V_{l+1,2n}} \\ & +\ldots+\delta_{l,n,NF}f_{NF}(V_{l+1,2n-1},V_{l+1,2n}) \qquad (3a) \\ & \sum_{k=1}^{NF}\delta_{l,n,k}=1;\quad \delta_{l,n,k}\in\{0,1\} \qquad (3b) \\ & k=1,2,\ldots,NF;\quad n=1,2,\ldots,2^l;\quad l=0,1,2,\ldots,NL-1; \qquad (3c) \end{aligned}$$

There is a total of $2^{NL}-1$ nonlinear constraints and $2^{NL}-1$ linear constraints introduced by the equations above, and there are $NF\times(2^{NL}-1)$ binary variables in total.

Level *NL* equations

The assignment of values to the last layer of the binary tree which is comprised only of leaf nodes follows a special logic. This assigns values from the variable set of the system being modelled as well as a tunable parameter set with parameters $\boldsymbol{p}=[p_j]$, $j=1,2,\ldots,NP$, which are continuous decision variables. We assume that we have input variables $\boldsymbol{x}=[x_i]$, $i=1,2,\ldots,NX$ in the system. For a single realization (measurement point) of these variables we wish to assign them via an optimization constraint formulation that will automatically allocate them in all possible ways to the leaves of the binary tree.

$$V_{NL,n} = \sum_{i=1}^{NX} \zeta_{n,i} x_i + \sum_{j=1}^{NP} \xi_{n,j} p_j \tag{3d}$$

$$\sum_{i=1}^{NX} \zeta_{n,i} + \sum_{j=1}^{NP} \xi_{n,j} \leq 1 \tag{3e}$$

$$\zeta_{n,i} \in \{0,1\}; \quad \xi_{n,j} \in \{0,1\}; \quad p_j^L \leq p_j \leq p_j^U \tag{3f}$$

$$n = 0,1,2,\ldots,2^{NL}; \quad i = 1,2,\ldots,NX; \quad j = 1,2,\ldots,NP; \tag{3g}$$

The constraints are chosen as above, as the purpose of parameters $\zeta_{n,i}$ and $\xi_{n,j}$ is to include or cancel the presence of a single associated variable x_i or parameter p_j in a leaf of the tree, while the continuous parameters p_j are bounded below and above by fixed bounds p_j^L and p_j^U, respectively. This introduces two 2^{NL} vectors of decision variables $\zeta_{n,i}$ and $\xi_{n,j}$ respectively. The above equations introduce 2^{NL} linear constraints and 2^{NL} linear constraints. It is noted that the constraints above allow the inclusion of either a parameter or a variable at the leaf nodes.

3.2. Objective function choice

The choice of objective function beyond the simple direct fitting using least squares, is desired to be such that it minimizes the number of nonzero coefficients in the resulting evaluation tree formulation. This is in accord to the idea of the automatic derivation/identification of "physical laws" directly from data. A physical law is in effect a data-compression method, in that with a very limited number of parameters and initial conditions one is able to predict entire series of data.

Based on the idea of compression of information, and that this is in effect what a good model or "physical law" is intended to do, then it is natural that one should consider information-theoretic criteria to measure how good a model is in terms of not only fitting the data, but also in compressing information. This is simplistically done by LASSO-like approaches (Tibshirani, 2011), which aim to minimize also the number of nonzero parameters used (or in terms of linear regression, to minimize the number of regressors). Information theoretic criteria for fitting are numerous and their diversity is a result of the philosophy of how information content is measured and encapsulated mathematically. Generally, the underlying principle in all these is the Minimum Description Length (MDL) for example string length when compressing data, or algorithm steps required to compute a given calculation task, *etc.* (Foster and Stine, 1999). Some of these criteria, like the Akaike Information Criteria (Hurvich and Tsai, 1993) and Bayesian Information Criteria (Burnham and Anderson, 2004), when applied to data regression contain measures of the variance of fitting the full model. This might be acceptable in the case that there is always more data than parameters, however one has to be careful with such measures of information content in the case where the potential number of regressors is much larger (*e.g.* basis functions used in linear regression) than the data available. These criteria are very much more useful in the sense that they do not require a multiobjective approach nor do they require penalty schemes. However, they are highly nonlinear and potentially nonconvex functions which would make direct minimization even harder.

4. Conclusions and future directions

The proposed theory in this work outlines a generic representation of any analytical function form constructed by DAG, which can be used for model identification within the scheme of minimizing the number of nonzero parameters, and hence general nonlinear terms that can arise as operations in the definition of a mathematical model. The formulation presented in this paper can be seen

to be the most general one that captures and explains all previous attempts/formulations and approaches for this problem. It is thus therefore worth exploring the proposed methodology as well as committing effort to make it work – even if for limited applications to begin with. The major task is that the problem as formulated is a global optimization MINLP in order to guarantee the solutions obtained (best possible model construction and fitting to available data). Future work will be the solution of the resulting MINLP problem to global optimality, and consideration of relaxations. For impact, one should explore innovative and surprising applications in areas that would give credence to our proposed methodology and theory. The applications of this approach are envisaged to have significant impact in many diverse areas of interest: aside from physicochemical and biological systems, where for example one would be seeking to discover new interactions as well as their kinetic functional forms, it is possible to use this methodology in systems whose nature is not mechanistic, such as social and financial systems, and offer quantification via novel model construction. We believe that our approach to construct phenomenological models, even for partially defined or understood systems, will lead to a significant advancement both in modelling approaches as well as revealing interactions that otherwise could not be discovered by heuristic trial-and-error, or mere observation of these systems. Relevant applications will demonstrate the potential of the proposed approach.

Abstract

Aqueous two-phase systems (ATPSs) are a promising downstream separation technology in the production of biopharmaceuticals. Understanding the fundamentals of protein separation is challenging due to the large experimental space that must be explored. To tackle this, experimental liquid-liquid equilibria and protein partitioning data is combined with a process model to explore the dynamic operation of a semi-batch aqueous two-phase extraction process for the separation of enzyme α-amylase in a PEG 4000 – phosphate ATPS containing NaCl. The semi-batch system can be readily implemented into existing biopharmaceutical production processes. Interaction parameters for chemical potential equations are estimated from tie-line data. Running multiple extraction cycles, where the bottom phase is replaced with fresh phosphate rich, protein free material, increases the purity of α-amylase while reducing the yield. The influence of the phase ratio on α-amylase purity and yield is also investigated.

Keywords: aqueous two-phase extraction, modelling, amylase, semi-batch

1. Introduction

The market for therapeutic proteins is currently increasing at a remarkable pace. In many cases, therapeutic proteins, such as monoclonal antibodies, must be administered in relatively large dosages. This large dosage requirement (> 100 mg dose^{-1}) (Shire et al., 2004), coupled with the high demand for these drugs, has resulted in an increased pressure on pharmaceutical companies to deliver high quality drugs at sufficient quantities. As a result, there has been an increasing amount of research & development (R&D) aimed at improving upstream efficiency, which has resulted in increased cell titres during the cell culture/fermentation stage of protein production. To date, improvements in upstream technology have, however, not been matched by improvements in downstream technology. Consequently, expensive chromatography columns must be scaled accordingly to cope with the increasing amounts of material generated, which is proving to be a process bottleneck due to the limitations in their capacity, but also their cost, and has highlighted the need for a re-evaluation of downstream separation methodologies.

Aqueous two-phase extraction has been shown to be a promising alternative downstream separation technology for biopharmaceutical separations (Rito-Palomares, 2004). Its method of action is the differential partitioning of proteins and other components between two established aqueous phases. Understanding the fundamental characteristics of protein separation in ATPSs is of paramount importance as the process design is to a large extent determined by the partitioning of material between the two phases of the system. Factors such as charge, hydrophobicity, solute affinity, polymer molecular weight and concentration, all play an important role in partitioning in

aqueous two phase extractions (Asenjo and Andrews, 2011). In addition, there are many different possible process configurations to explore such as batch, co-current and counter-current operations. Exploring all of the above factors and configurations manually is very resource intensive. To date, process modelling of ATPSs has been limited and focuses on continuous-operations (Mistry et al., 1996, Ahmed Samatou, 2012, Ahmed Samatou et al., 2007).To tackle this issue, we present an approach that integrates already available experimental liquid-liquid equilibria data with dynamic process models that describe aqueous two-phase extractions. The approach permits a fast, yet systematic, investigation of both process design and operation. In this work, the approach is demonstrated by considering a semi-batch extraction system operated in cycles. The semi-batch system can be readily implemented into existing biopharmaceutical production facilities.

2. Process modelling framework

2.1. Liquid-liquid equilibria modelling

There are many thermodynamic models that describe the liquid-liquid equilibria of ATPSs (Cabezas, 1996). In this work, a simple thermodynamic model based on osmotic virial expansions is used to calculate the chemical potential of the polymer (component 1), salt (component 2) and water (component 3) in terms of molality of polymer and salt (Edmond and Ogston, 1968, Zafarani-Moattar and Sadeghi, 2001):

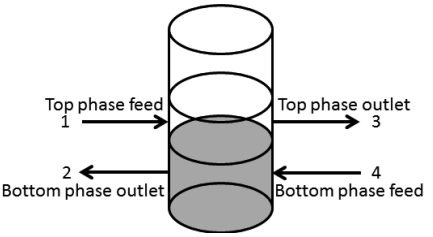

Figure 1: A single separation stage

$$\mu_1 = \mu_1^0 + RT(\ln(m_1) + \beta_{1,1}m_1 + \beta_{1,2}m_2) \quad (1)$$

$$\mu_2 = \mu_2^0 + RT(\ln(m_2) + \beta_{2,2}m_2 + \beta_{1,2}m_1) \quad (2)$$

$$\mu_3 = \mu_3^0 - RTV_3(m_1 + m_2 + \frac{\beta_{1,1}}{2}m_1^2 + \frac{\beta_{2,2}}{2}m_2^2 + \beta_{1,2}m_1m_2) \quad (3)$$

At equilibrium, the chemical potential of each component in each phase is the same:

$$\mu_i^{Top} = \mu_i^{Bottom} \qquad for\ i = 1 \ldots 3 \quad (4)$$

2.2. Estimation of interaction parameters

Interaction parameters for Eq.(1)-(3) were estimated using experimental tie-line data for a polyethylene glycol (PEG) 4,000 – phosphate ATPS at different NaCl concentrations obtained from Mistry et al. (1996).

2.3. Partition coefficient correlations

In this work, the partition coefficient of α-amylase and impurities was empirically correlated to NaCl mass fraction using experimental data obtained from Mistry et al. (1996), and the correlations obtained are similar to those already presented by the same authors:

$$ln(K_{alpha-amylase}) = 0.04874(100 \times x_{NaCl})^2 + 0.3043 \times 100 \times x_{NaCl} - 2.731 \quad (5)$$

$$ln(K_{Impurities}) = 0.01412 \times 100 \times x_{NaCl} - 0.01341 \quad (6)$$

2.4. *Process model*

A simple first principles tank model with two inlets and two outlets was used to model a batch process, i.e. a single stage (See Figure 1). Stages can also be linked together to

form a counter-current train. The relative amount of top and bottom phase is determined by integrating the equilibrium equations with the following tank model describing protein partitioning in a polymer-salt ATPS:

$$\frac{dM_p}{dt} = F_{1V}C_{1,p} - F_{2V}C_{2,p} - F_{3V}C_{3,p} + F_{4V}C_{4,p} \qquad for\ p = 1 \dots \#\ proteins \tag{7}$$

$$M_p = C_{Top,p}V_{Top} + C_{Bottom,p}V_{Bottom} \qquad for\ p = 1 \dots \#\ proteins \tag{8}$$

$$C_{Top,p} = K_p C_{Bottom,p} \qquad for\ p = 1 \dots \#\ proteins \tag{9}$$

$$C_{3,p} = C_{Top,p} \qquad for\ p = 1 \dots \#\ proteins \tag{10}$$

$$C_{2,p} = C_{Bottom,p} \qquad for\ p = 1 \dots \#\ proteins \tag{11}$$

$$M_p = initial\ value \qquad for\ p = 1 \dots \#\ proteins\ at\ t = 0 \tag{12}$$

The following mass balances were conducted for phase forming components (polymer (component 1), salt (component 2) and water (component 3)):

$$\frac{dM_i}{dt} = F_1 x_{1,i} - F_2 x_{2,i} - F_3 x_{3,i} + F_4 x_{4,i} \qquad for\ i = 1 \dots 3 \tag{13}$$

$$M_{i,O} = M_{i,Top} + M_{i,Bottom} \qquad for\ i = 1 \dots 3 \tag{14}$$

$$x_{3,i} = x_{Top,i} \qquad for\ i = 1 \dots 3 \tag{15}$$

$$x_{2,i} = x_{Bottom,i} \qquad for\ i = 1 \dots 3 \tag{16}$$

$$x_{Top,i} \times \sum M_{Top,i} = M_{Top,i} \qquad for\ i = 1 \dots 3 \tag{17}$$

$$x_{Bottom,i} \times \sum M_{Bottom,i} = M_{Bottom,i} \qquad for\ i = 1 \dots 3 \tag{18}$$

$$x_{O,i} \times \sum M_{O,i} = M_{O,i} \qquad for\ i = 1 \dots 3 \tag{19}$$

$$M_i = initial\ value \qquad for\ i = 1 \dots 3\ at\ t = 0 \tag{20}$$

It was assumed that after mixing and settling the composition of top and bottom phases is equal to the outlet concentrations as shown in equations Eq.(10), (11), (15) and (16).

2.5. Software

All process simulations and parameter estimation tasks are conducted using gPROMS ModelBuilder 3.5.3 (Process Systems Enterprise, 2014). Tie-line data was obtained by digitising phase diagrams in OriginPro 8.6 (OriginLab, Northampton, MA).

3. Interaction parameter estimation

Using gPROMS, the model parameters were estimated based on published experimental data, taking into account uncertainties in experimental measurements (see Table 1). As actual experimental error was unknown, a conservative standard deviation of 0.02 was assumed for experimental phase composition data obtained from Mistry et al. (1996) allowing for standard deviations in parameter values to be obtained.

Table 1: Estimated interaction parameters for Eq.(1), (2) and (3).

$\beta_{i,j}\ (kg\ mole^{-3})$	PEG 4,000		Phosphate	
	Value	Standard Deviation	Value	Standard Deviation
PEG 4,000	-21.131	14.35	6.2	2.343
Phosphate	-		-1.327	0.1734

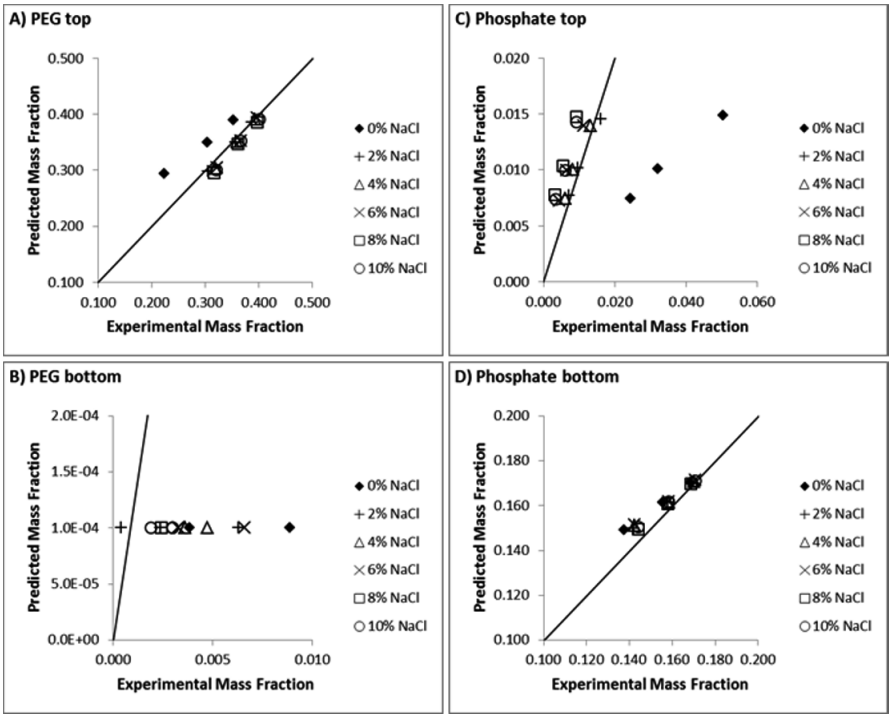

Figure 2: Parity plots comparing model predictions (y-axis) with experimental data (x-axis) from Mistry et al. (1996).

The chemical potential equations (Eq. (1), (2) and (3)) used do not take into account the presence of NaCl which influences phase equilibria. The presence of 2 wt% NaCl shifts the phase equilibria significantly; this is most noticeable in parity plots A and C in Figure 2.

For PEG 4,000 – phosphate ATPSs containing NaCl concentrations above 2 wt%, the phase equilibria predictions are sufficient for process simulations as the experimental phase diagrams for these systems are very similar. The PEG 4,000 mass fraction in the bottom phase is usually very small, therefore a constant mass fraction of 0.001 was assumed in the simulations, this also increased the robustness of the simulations. The presence of NaCl can be taken into account by extending the chemical potential equations to a 4 component system; however, this would require more parameters to be estimated.

4. Process simulations

Dynamic batch simulations were conducted as most biopharmaceutical operations are either batch or semi-batch. The streams profiles are shown in Table 2 and are based on Figure 1. The influence of the phase ratio (mass of top phase to mass of bottom phase) on yield and purity was also investigated by varying the mass flow rate of stream 4 during initial loading.

Streams 1 and 4 feed the PEG rich top phase and phosphate rich bottom phase, respectively. The following operating protocol was used (streams numbers correspond to Figure 1):

Table 2: Stream conditions.

Stream #	Operating flow rate (kg s^{-1})	Amylase concentration (kg m^{-3})	Impurity concentration (kg m^{-3})	PEG (wt%)	Phosphate (wt%)
1	1.00	1.00	1.00	57.37	0.08
2	1.00	N/A	N/A	0.10	22.94
3	N/A	N/A	N/A	N/A	N/A
4	1 to 4.00	N/A	N/A	N/A	N/A

1. Streams 1 & 4 are turned on until the mass in the tank is greater than 300 kg. (Stream 1 contains the protein).
2. Allow 10 minutes for mixing and 15 minutes for settling. (Mixing and settling is not modelled).
3. Drain the bottom phase (containing protein) via stream 2 until the mass in the bottom phase is less than 5 kg.
4. Fill with fresh phosphate rich bottom phase via stream 4 until the mass in the tank is greater than 300 kg. Go to step 2.
5. Repeat steps 2 to 4 for multiple extraction cycles.

The steps in Figure 3 at 30 minute intervals correspond to the extraction cycles outlined in the operating protocol.

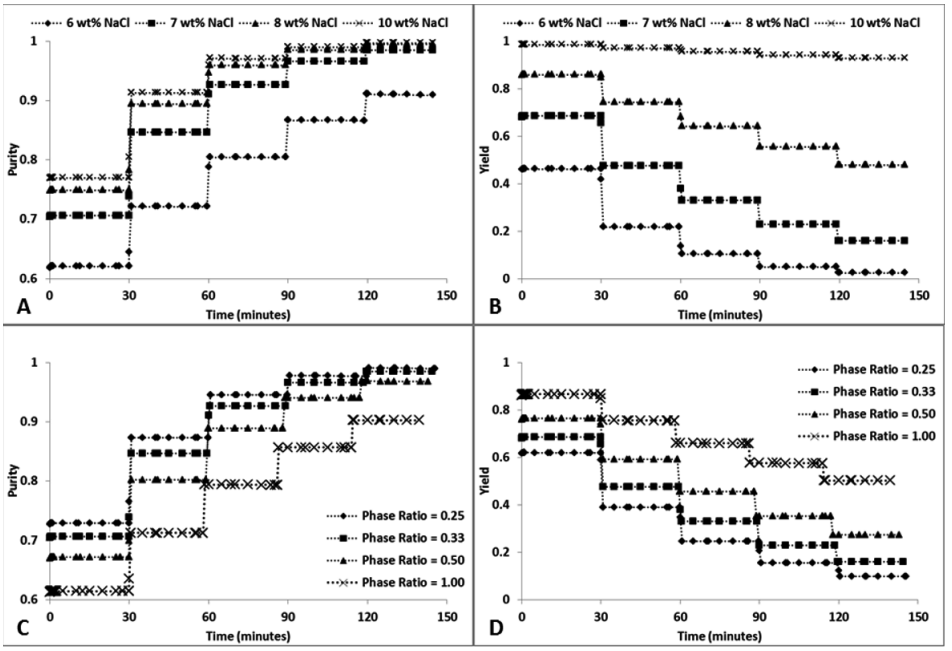

Figure 3: α-amylase yield and purity plots. A & B) influence of NaCl concentration (phase ratio = 0.33). C & D) influence of phase ratio (7 wt% NaCl).

Increasing the number of extraction cycles results in higher purity, however, the yield of α-amylase is reduced. Figure 3 shows that increasing the NaCl concentration from 6 wt% to 10 wt% will cause the purity and yield to increase. This is because the partition coefficient of α-amylase is increased almost 90-fold while the partition coefficient of the impurities is relatively constant. Operating using 10 wt% NaCl would see a purity and yield of 0.91 and 0.97 after two extraction cycles, respectively. At low NaCl

concentrations, the α-amylase partition coefficient is less than 1, meaning that the operating protocol could be adapted to replace the top phase instead of the bottom phase.

Figure 3 shows how the phase ratio can be manipulated to alter purity and yield. A smaller phase ratio (C & D) results in higher purity because, relative to α-amylase, more impurities partition into the bottom phase. Unfortunately, the amount of α-amylase in the bottom phase is also increased when the phase ratio is decreased, hence resulting in a lower yield.

5. Conclusions

Interaction parameters for chemical potential equations were estimated from experimental phase equilibria data. Phase equilibria model predictions were found to be sufficient for ATPSs containing more than 2 wt% NaCl, although future work would include extending phase equilibria models to take into account the presence of electrolytes. Phase equilibria models were then integrated with first principle mass balance models to describe the dynamic operation of a semi-batch aqueous two-phase extraction process to purify enzyme α-amylase. Multiple extraction cycles improved the purity of α-amylase but reduced yield. Although 5 extraction cycles were simulated, at a NaCl concentration of 10 wt%, a purity and yield of 0.91 and 0.97, respectively, was achieved with only two extraction cycles. It was also found that changing the phase ratio greatly influenced purity and yield. A lower phase ratio, corresponding to a larger bottom phase, resulted in a higher purity, but a lower yield.

6. Nomenclature

M_p	Mass of protein p in tank (kg)	$C_{k,p}$	Conc. of protein p in stream k (kg m^{-3})
$x_{k,i}$	Mass fraction of component i in steam k (-)	F_{kV}	Volumetric flow rate of stream k (m^3 s^{-1})
$\beta_{i,j}$	Interaction parameter between components i and j, respectively (kg $mole^{-3}$)	V_3	Molar volume of water (m^3 $mole^{-1}$)
μ_i	Chem. potential of component i (J $mole^{-1}$)	m_i	Molality of component i (mole kg_{water}^{-1})
T	Temperature (K)	K_p	Partition coefficient of protein p (-)
F_k	Mass flow rate of stream k (m^3 s^{-1})	$M_{i,O}$	Total mass of component i in tank (kg)
$M_{i,}$	Mass of component i in top or bottom phase (kg)	$x_{O,i}$	Overall mass fraction of component i in tank (-)

Abstract

In this paper we present a framework for the development of hybrid multi-parametric model predictive controllers applied to intravenous anaesthesia. A step-by-step procedure is described featuring a piece-wise model for anaesthesia describing the induction and maintenance phase, a recently developed multi-parametric mixed-integer quadratic programming solver and a novel hybrid control strategy tested for a set of 12 patients.

Keywords: multi-parametric/explicit model predictive control, multi-parametric mixed-integer quadratic programming, hybrid systems

1. Introduction

In most biomedical systems the mathematical model contains pharmacodynamic models which usually include strong nonlinearities. In particular the Hill curve representation is often used as an approximation for the description of such nonlinearities. This is a common feature that can be also found in other branches of science (Demetriou, 2012), economy (Porter, 1985) and engineering (Lindley, 1985, Gonzalez and Wintz, 1987). For the case of infusion of anaesthetic agents, the nonlinear Hill curve approximation has been used in both volatile (Krieger et al., 2014) and intravenous (Nascu et al., 2012, Nascu et al., 2014) anaesthesia and it describes the relation between the concentration of the drug and the effect observed on the patient.

In this paper we first generate a piece-wise linearization of the Hill curve. The main advantage of this procedure is that the parameter space is linearized and that the uncertainty in some key parameters of the Hill curve is compensated for. As a result of the linearization, the anaesthesia model is described by a piece-wise affine system, the control of which results in a hybrid model predictive control (hMPC) problem (Bemporad and Morari, 1999) and thus a mixed-integer quadratic programming (MIQP) problem formulation. However, the online implementation of hMPC involves the online solution of the MIQP problem, which introduces a high computational burden. Thus in this paper, we present a step-by-step procedure for the development of explicit hMPC controllers via a multi-parametric MIQP algorithm. This development is part of PAROC, a comprehensive framework and software solution for the general design, operational optimization and control of process systems (Pistikopoulos et al., 2014). The framework includes a high-fidelity model of the system which is approximated using discrete time models in state space form via model order reduction techniques.

The reduced model is then used to formulate an optimization problem subject to the state space model and constraints. The resulting multi-parametric programming problem is solved with state-of-the-art techniques. In the last step, the solution is validated against the original high fidelity model, thus closing the loop.

2. Framework Description

2.1 Intravenous Anaesthesia Mathematical Model

For the automatic regulation of depth of anaesthesia (DOA) the anaesthetic agent, in our case Propofol, is the input and the Bispectral Index (BIS) the output of the system. Because of its pharmacological profile, Propofol is applicable for both induction and maintenance of hypnosis during anaesthesia and intensive care sedation.(Ionescu et al.). The BIS is a signal that is derived from the electro-encephalogram (EEG) used to assess the level of consciousness during anaesthesia. A BIS value of 0 equals EEG silence, while a BIS value of 100 is the expected value of a fully awake and conscious adult, 60-70 and 40-60 range represents light and moderate hypnotic condition, respectively. The target value during surgery is 50, providing a gap between 40 and 60 to guarantee adequate sedation (Bailey and Haddad, 2005, Absalom et al., 2011).

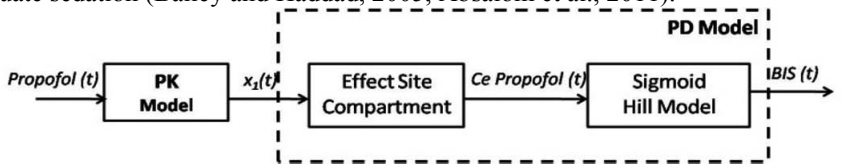

Figure. 1. Schematic representation of the NONLINEAR SISO patient model

In Figure 1 the pharmacokinetic (PK) – pharmacodynamic (PD) blocks denote compartmental models used to represent the distribution of drugs in the body, i.e. the mass balance. The pharmacokinetic model represents the relation between the drug administration and the drug concentration in the body, whereas the pharmacodynamic model represents the relation between the concentration of the drug and the effect.
The PK-PD models most commonly used for Propofol are the 4th order compartmental model described by (Schnider et al., 1999) and (Minto et al., 1997), respectively and are presented in Table 1.

Table 1. Mathematical model for intravenous anaesthesia

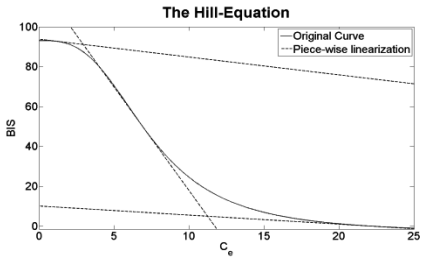
Intravenous Anaesthesia	
PK model	$\dot{x}_1(t) = -[k_{10} + k_{12} + k_{13}] \cdot x_1(t) + k_{21} \cdot x_2(t) + k_{31} \cdot x_3(t) + u(t)/V_1$ $\dot{x}_2(t) = k_{12} \cdot x_1(t) - k_{21} \cdot x_2(t)$ $\dot{x}_3(t) = k_{13} \cdot x_1(t) - k_{31} \cdot x_3(t)$ $\dot{x}_e(t) = -k_{e0} \cdot x_e(t) + k_{1e} \cdot x_1(t)$
Effect site compartment	$\dot{C}_e(t) = k_{e0} \cdot (C_e(t) - C_p(t))$
PD model (Hill curve)	$BIS(t) = E_0 - E_{\max} \cdot \frac{C_e(t)^\gamma}{C_e(t)^\gamma + EC_{50}^\gamma}$

In the PK model x_1 represents the drug concentration in the central compartment [mg/l]. The peripheral compartments 2 (muscle) and 3 (fat) model the drug exchange of the blood with well and poorly diffused body tissues. The concentrations of drug in the fast and slow equilibrating peripheral compartments are denoted by x_2 and x_3

respectively. The parameters k_{ij} for $i \neq j$, denote the drug transfer frequency from the i^{th} to the j^{th} compartment and $u(t)$ [mg/min] is the infusion rate of the anaesthetic or analgesic drug into the central compartment. The parameters k_{ij} of the PK models depend on age, weight, height and gender and can be calculated for Propofol. Notice that in the model used in this paper $C_e = x_e$, E_0 denotes the baseline value (awake state - without drug), which by convention is typically assigned a value of 100, E_{max} denotes the maximum effect achieved by the drug infusion, EC_{50} is the drug concentration at 50% of the maximal effect and represents the patient sensitivity to the drug, and γ determines the steepness of the curve.

2.2 Piecewise linearization

Due to the nonlinearity of the Hill curve, we propose a piecewise affine representation which divides the BIS into three partitions, where each partition i is associated with a different linear function $BIS = C_i C_e + e_i$ (see Figure 2).



$$BIS = \begin{bmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \end{bmatrix} \left(\begin{bmatrix} C_1 & C_2 & C_3 \end{bmatrix} C_e + \begin{bmatrix} e_1 \\ e_2 \\ e_3 \end{bmatrix} \right)$$

$$\delta \in [0,1]^3$$

Figure 2. Schematic of hybrid mp-MPC control

The binary variables δ thereby denote whether a certain partition is active. As a result, this system belongs to the class of hybrid systems, i.e. systems which are described by continuous as well as discrete dynamics and/or logical constraints. Thus, the problem of designing a hybrid model-predictive controller can be reformulated as a mixed-integer quadratic programming (MIQP) problem (Bemporad and Morari, 1999), i.e.

$$\begin{aligned} \min_{x,y,u} J = {} & x'_N P x_N + \sum_{k=1}^{N-1} x_k Q_k x_k + \sum_{k=1}^{N-1} (y_k - y_k^R)' Q R_k (y_k - y_k^R) + \\ & + \sum_{k=0}^{N_u-1} (u_k - u^R)' R_k (u_k - u^R) + \sum_{k=0}^{N_u-1} \Delta u_k R1_k \Delta u_k \\ s.t. \; & \mathrm{x}_{t+1} = A x_t + B u_t \\ & \mathrm{y}_t = C x_t \\ & \mathrm{BIS}_{\min} \le y \le BIS_{\max} \\ & \Delta \mathrm{u}_{\min} \le \Delta u \le \Delta u_{\max} \end{aligned} \tag{1}$$

$$x_t \in X \subseteq \Re^p, u_t \in U \subseteq \Re^s$$

where x are states, y outputs and u controls, all (discrete) time dependent vectors. The subsets of output variables that get tracked have time-dependent set points y^R. Finally Δu are changes in control variables, $\Delta u(k) = u(k) - u(k\text{-}1)$. The prediction horizon is denoted by N and control horizon by N_u. X, U are the sets of the state and input

constraints that contain the origin in their interior. Both $Q>0$, the objective coefficient for the states and $P>0$, the terminal weight matrix for the states, are symmetric semi-positive definite matrices. The quadratic matrix for manipulated variables $R>0$ is a symmetric positive matrix, QR is the quadratic matrix for tracked outputs and $R1$ is a weight matrix for the control action changes Δu. Thus, if a certain combination of integer variables is fixed, problem (1) results in a convex QP.
In classical MPC, problem (1) is solved as soon as the nominal value of the initial state x_0 is available. In case of hybrid systems, this requires the online solution of a MIQP problem, which might be computationally prohibitive. One way to overcome this computational burden is multi-parametric programming, where the initial states are treated as parameters and the optimization problem is solved as a function thereof (Pistikopoulos, 2009). For the case of problem (1) this requires the solution of a multi-parametric mixed-integer quadratic programming (mp-MIQP) problem, for which recently novel solution procedures have been described (Oberdieck and Pistikopoulos, 2014).

2.3 Multi-parametric Model Predictive Control

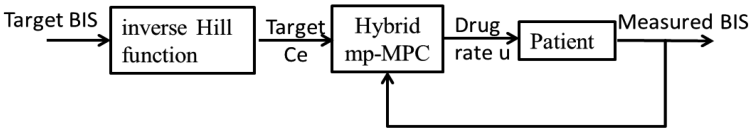


Figure 3. Schematic of hybrid mp-MPC control

The Patient block is composed of the pharmacokinetic part (linear) and the pharamacodynamic part, the Hill curve which introduces the nonlinearity in the system. Dealing with this nonlinearity and the inter- and intra- patient variability is one of the main challenges in the anaesthesia process. Due to the characteristic S-shape of the Hill curve a linearization around three points was performed.
For the implementation of mp-MPC, the problem is reformulated as a MIQP problem. The structure of the control scheme is presented in Figure 3.

3. Results

The closed loop control tests are performed on a set of 12 virtually generated realistic patients (Ionescu et al., 2008). Their performances are tested by means of the BIS index and the corresponding Propofol infusion rates. The Propofol infusion rates are limited to 10 mg/s due to pump restrictions.

3.1. Induction phase

The induction of the patient should be performed as fast as possible, such that little time is lost before the surgeon can start operating. It is therefore desirable that the patient reaches the BIS = 50 target and remains within the target value without much undershoot or overshoot.
Figure 4 shows the simulation results of the controllers for the BIS index and the corresponding control action, i.e. the Propofol infusion rates. Note that the states of the patients are considered as parameters. The controller shows good performances, with no significant undershoot and fast settling time of approximately 4 minutes. In common practice the operation procedure does not start until the patient reaches an adequate DOA, usually taking up to 15 min. Thus, a rise time between 5 min and 7 min gives good performance.

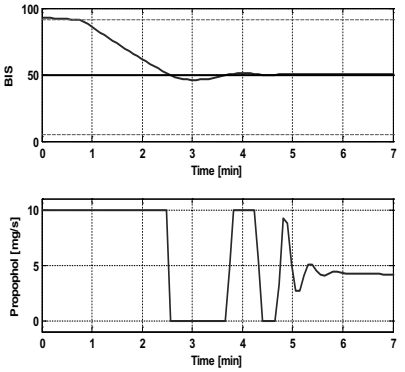

Figure 4. BIS output and corresponding infusion rates for the induction phase (the dashed lines denote the points of transition between the linearized sections of the Hill curve)

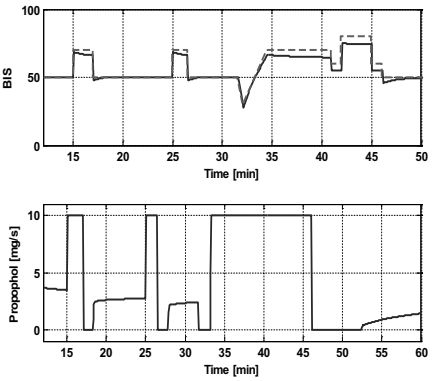

Figure 5. BIS output and corresponding infusion rates for the maintenance phase

3.2. Maintenance phase

During the maintenance phase, it is important that the controller rejects the disturbances occurred during surgery as fast as possible and bring the patient to the BIS target value. In this phase, typical disturbances can be applied additively to the output of the process in order to check the controller's ability to reject them (Dumont et al., 2009). The standard stimulus profile used for simulation is presented in Figure 5 and each interval denotes a specific event in the operation theatre (Yelneedi et al., 2009). Figure 5 also shows the performance of disturbance rejection of the hybrid controller and the corresponding infusion rates. This aspect presents the most challenging part of the disturbance rejection tests, and we can observe that the controller is able to achieve good performances even when subject to strong disturbance signal and restriction of the pump.

4. Conclusions

In this paper we present a framework for the design of hybrid multi-parametric model predictive controllers. The framework is applied to the intravenous process of anaesthesia for the induction and maintenance phase. The anaesthesia process is described by a piece-affine system via a linearized version of the Hill function. For the maintenance phase, a realistic disturbance signal was considered and applied. A simulation study is performed on a set of 12 virtually generated patients.

The results show good performances with a fast settling time and no significant overshoot or undershoot, a high-efficiency, optimal dosage and robustness of the model predictive control algorithm to induce and maintain the desired Bispectral Index reference while rejecting typical disturbances from surgery. The controller is also able to deal with the high inter- and intra- patient variability.

Some of the most important challenges in the control of anaesthesia is inter- and intra-patient variability and significant disturbances during the maintenance phase. In order to deal with these problems, future work will focus on extending the developed algorithm to simultaneous multi-parametric hybrid moving horizon estimators and model predictive control.

Dynamic Chance-Constrained Optimization under Uncertainty on Reduced Parameter Sets

David Müller[a], Erik Esche[a], Sebastian Werk[a] and Günter Wozny[a]

[a]*Department of Process Dynamics and Operation, Technische Universität Berlin, Str. des 17. Juni 135, D-10623 Berlin*
david.mueller@tu-berlin.de

Abstract

Uncertainty is a crucial topic for the decision making process in almost every scientific field. Therefore, the correct implementation into optimization problems is vital. Herein, the chance-constrained optimization approach is applied and compared with a standard Monte Carlo optimization on a CSTR model. The two approaches are expanded by limiting the number of uncertain parameters in the system with according subset selection strategies from parameter estimation studies. The idea here is that a high number of uncertain parameters does not add to a better description of a system. The uncertainty can be represented by a subset of uncertain parameters, which suffice to describe the system behavior. In this contribution, it is shown that the results, both for the chance constrained and Monte Carlo optimization approaches, are improved regarding result stability and control action indication. Additionally, it is discussed how the chance-constrained approach yields even better results regarding the objective function of the optimization problem and it is shown that the solution time is drastically reduced.

Keywords: Chance Constraints, Optimization under Uncertainty, Subset Selection

1. Motivation and Introduction

The consideration, proper handling, as well as the correct implementation of uncertainty are still some of the most challenging issues in process optimization today. On an industrial level, conservative measures are often applied to compensate for uncertainty, which of course lead to losses of potential profit. To minimize these, different approaches in stochastic process optimization exist. Of interest in this contribution is the chance-constrained optimization approach. Herein, a deterministic result for a stochastic optimization problem is obtained, while process constraints are adhered to with a certain probability. Independent of the way that uncertainties are implemented into an optimization problem, it can generally be said that with a higher number of uncertain parameters, the computational complexity for solving the optimization problem for certain approaches increases. Additionally, poorly estimated parameters can add unrealistic behavior to the system.

Nevertheless, it is possible to support engineers in selecting the most relevant uncertain parameters for optimization under uncertainty using a strategy proposed in (Müller et al., 2014). Core features of the algorithm presented therein are an identifiability analysis of parameters and respective subset selection as well as a sensitivity analysis of parameters towards all states and a user-defined objective function. The remaining uncertain parameters are those that are relevant for optimization under uncertainty. Therefore, the novelty in this contribution is the combination of subset selection strategies for the selection of relevant uncertain parameters with two stochastic optimization approaches: Monte-Carlo-Optimization (MCO) and chance-constrained optimization (CCO).

2. Chance-Constrained Optimization

The chance-constrained approach has intensively been studied by Charnes and Cooper (1959), Wendt et al. (2002), Li et al. (2008), Arellano-Garcia and Wozny (2009), and Werk et al. (2012). The concept is briefly revisited in the following.

2.1. Optimization Problem Formulation

The objective function of the stochastic optimization problem is formulated as shown in Eq. (1). Hereby f is the objective function. The minimization is to be achieved by manipulating the controls u. The states are the vector x and the uncertain parameters the vector ξ. For the purpose of this contribution, a multivariate normal distribution of ξ is assumed. Hereby, μ is its expected value and Σ the covariance matrix. In order to cope with the uncertain factors, the vector of inequality constraints h of the optimization problem is written as shown in Eq. (2).

$$\min_{u} \; E\,[f(x,u,\xi)] \qquad \xi = \mathcal{N}(\mu,\Sigma) \tag{1}$$

$$s.t.\; Pr\{h(\dot{x},x,u,\xi) \geq 0\} \geq \alpha \tag{2}$$

The probability of adhering to a certain constraint with a certain percentage α is of relevance. Thus, a relaxation of the inequality constraint is performed.

2.2. Optimization Problem Implementation

The optimization problem is implemented as shown in Fig. 1 and is solved in six steps. In **Step 1**,

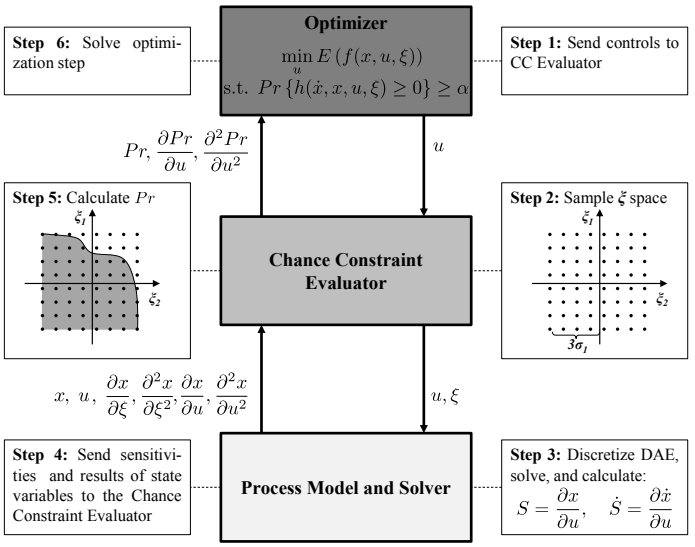

Figure 1: Complete framework for solving the chance-constrained optimization problem.

the controls u are sent to the chance constraint evaluator. In our case, this is the dynamically optimized chance constraint evaluator (DoCCE). In **Step 2**, the DoCCE performs a sparse sampling of the uncertain parameters ξ. The user has the possibility to set the grid width (e.g. 3σ), the grid resolution (number of samples within the width), as well as the grid depth of the sample. In **Step 3**, the samples of ξ and the controls u are passed down to the process model and solver. The solver discretizes the DAE into an AE and solves the model with given controls and parameters.

Hereby, the sensitivity matrix of the states regarding the controls is determined. In **Step 4**, based on the implicit function theorem, the sensitivity of the states regarding the parameters and regarding the controls is sent back to the DoCCE. Afterwards, in **Step 5**, an integration to calculate the probability *Pr* of adhering to the constraints is carried out. For this purpose, a root-finding problem is solved and the course of the constraints h is determined. Finally, the optimizer obtains the probability (1), the sensitivity of the probability regarding the controls (2), as well as its second derivative of the sensitivity regarding the controls (3). For our case, the optimization problem is implemented in Python using a framework for the chance constraint calculation presented in Werk et al. (2012) and Wendt et al. (2002). Ipopt is used as an NLP solver for the optimization problem. For the simulation part of the framework, a sparse DAE solver with automatic sensitivity generation (sDACl, developed by Barz et al. (2011)) is used in combination with an NLE solver (NLEQ1s, developed by Nowak and Weimann (1991)).

3. Case Study

The case study by (Müller et al., 2014) of a continuously stirred tank reactor (CSTR) with several reactions is further explored by comparing the results of four different optimizations under uncertainty: The first being a basic Monte Carlo-based stochastic optimization as well as a Chance-Constrained optimization on all initially uncertain parameters of the CSTR model, the third being a Monte Carlo-based stochastic optimization on a reduced set of uncertain parameters, and the fourth a chance-constrained optimization using the same subset. The calculations are performed on an intel 7 - 3770 CPU @ 3,50 GHz x 8 with 16 GB RAM running on Ubuntu 14.04 (64 Bit).

3.1. Task Description and Optimization Problem Formulation

The CSTR has one entering and exiting mole flow $\dot{F}$. The inlet stream has two relevant concentrations c_{A0} and c_{B0} at a temperature of T_0. In the CSTR, two reactions take place: A is reacted to product C and B is reacted to A. The reactor is heatable or coolable via the jacket with the heating temperature T_j. The CSTR and its reactions can be described with Eq. (3) to (5). The flow leaves the reactor at temperature T with concentrations c_A and c_B. The objective is to minimize the concentration of c_A leaving the reactor.

$$\frac{dc_A}{dt} = \frac{\dot{F}}{V} \cdot (c_{Ao} - c_A) - k_{Ao} \cdot c_A \cdot e^{\frac{-E_A}{R \cdot T}} + k_{Bo} \cdot c_B \cdot e^{\frac{-E_B}{R \cdot T}} \tag{3}$$

$$\frac{dc_B}{dt} = \frac{\dot{F}}{V} \cdot (c_{Bo} - c_B) - k_{Bo} \cdot c_B \cdot e^{\frac{-E_B}{R \cdot T}} \tag{4}$$

$$\begin{aligned} \frac{dT}{dt} = &\frac{\dot{F}}{V} \cdot (T_o - T) - \frac{U \cdot A}{\rho \cdot c_p \cdot V} \cdot (T_j - T) + \frac{-\Delta H_A}{\rho \cdot c_p} \cdot k_{Ao} \cdot c_A \cdot e^{\frac{-E_A}{R \cdot T}} \\ &+ \frac{-\Delta H_B}{\rho \cdot c_p} \cdot k_{Bo} \cdot c_B \cdot e^{\frac{-E_B}{R \cdot T}} \end{aligned} \tag{5}$$

The constants in the process are the volume of the reactor V = 1 m^3, the heat of reaction ΔH_A = $4.5 \cdot 10^4$ J/mol and ΔH_B = $-5.5 \cdot 10^4$ J/mol for reaction A and B respectively, and the incoming stream $\dot{F}$ = $6.5 \cdot 10^{-4}$ m^3/s. The applied expected values and variances of the parameters for the three optimizations are obtained from (Müller et al., 2014) and are displayed in Tab. 1 and Tab. 2.

3.2. Results and Discussion

Four cases are analyzed in greater detail, to analyze the effect of optimization under uncertainty using reduced parameter subsets. The objective is displayed in Eq. (6).

$$\min_u E\ [f(x,u,\xi)] = -c_A \text{ with } \xi \sim N(\mu, \Sigma) \tag{6}$$

$$s.t.\ g(x,u,\xi) = 0 \text{ and } h(x,u,\xi) = T \leq 340K \tag{7}$$

Table 1: Expected parameter values for uncertain parameters from (Müller et al., 2014).

	E_A [J/(molK)]	E_B [J/(molK)]	k_{Ao} [1/s]	k_{Bo} [1/s]	ρ [kg/m]	c_p [J/(kgK)]	U·A [W/K]
Real val.	$6.90 \cdot 10^4$	$7.20 \cdot 10^4$	$5.0 \cdot 10^6$	$1.0 \cdot 10^7$	$8.00 \cdot 10^2$	3.5	1.40
Full set	$6.94 \cdot 10^4$	$7.62 \cdot 10^4$	$6.1 \cdot 10^6$	$4.0 \cdot 10^7$	$5.50 \cdot 10^2$	5.0	1.37
Subset	$6.94 \cdot 10^4$	$7.62 \cdot 10^4$	$6.1 \cdot 10^6$	$4.0 \cdot 10^7$	$5.54 \cdot 10^2$	5.0	1.38

Table 2: Parameter variances for the full set and subset from (Müller et al., 2014).

	E_A	E_B	k_{Ao}	k_{Bo}	ρ	c_p	U·A
Full set	$4.0 \cdot 10^3$	$3.3 \cdot 10^3$	$7.8 \cdot 10^6$	$4.2 \cdot 10^7$	$3.2 \cdot 10^3$	$3.0 \cdot 10^1$	$1.0 \cdot 10^{-1}$
Subset	$8.4 \cdot 10^1$	$7.9 \cdot 10^1$	0	0	0	0	$1.2 \cdot 10^1$

Monte Carlo Optimization - Full Set: The first case of interest is a MCO using the whole set of estimated parameters including their determined variances. 10,000 MCOs are performed to obtain a reliable result. The differential algebraic equation system describing the CSTR is stiff and shows a tight feasible area for control and parameter combinations. Fig. 2 displays the determined control actions. The MCO shows an erratic behavior and gives no clear indication on how to operate the controllable reactor. Whilst the feed of c_{A0} reaches its lower bound (7 mol/m^3), the results for T_0 and T_j are widely spread and the feed c_{B0} jumps to both bounds. For an operator, this result is not desirable.

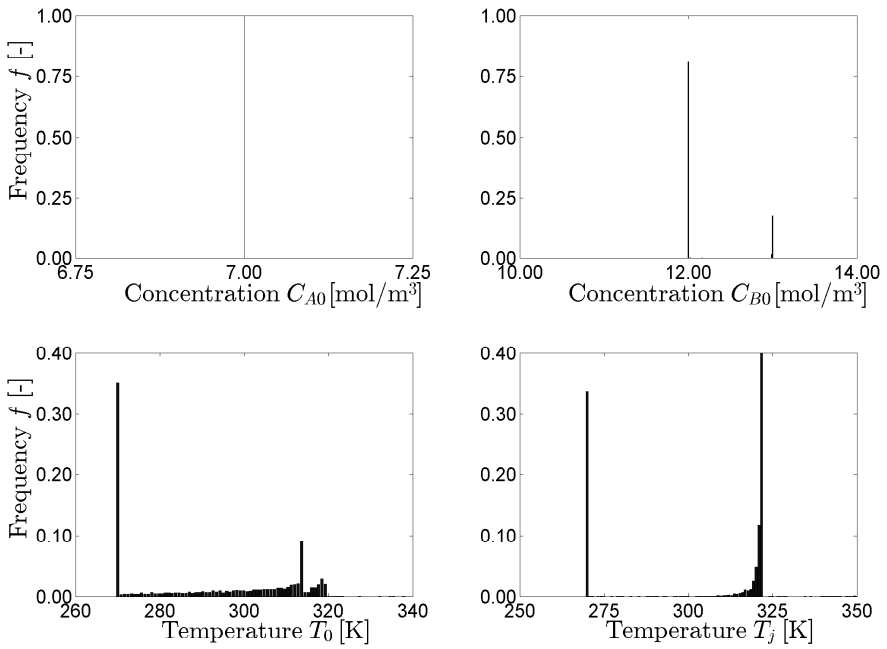

Figure 2: MCO result for the control actions using the full set of uncertain parameters.

Chance-Constrained Optimization - Full Set: The same optimization problem is then solved using chance-constrained optimization. As for the chance-constraints, a probability of $\alpha = 98\%$ is required for the upper bound on the reaction temperature. The optimization problem shown above

is expanded to Eq. (8).

$$s.t.\ g(\dot{x},x,u,\xi) = 0 \text{ and } Pr\{h(\dot{x},x,u,\xi) = T \leq 340K\} \geq \alpha \tag{8}$$

For this case, no result could be obtained within any reasonable amount of time compared to the MCO (2 days). This result strengthens the statement that if this approach is used for optimization, the uncertainty in a model must be focused on a smaller set of uncertain parameters.

Monte Carlo Optimization - Subset: The second MCO, using the reduced parameter set, shows a less erratic behavior with more than 92% of all 10,000 Monte Carlo samples leading to an optimal solution. The used subset of uncertain parameters is shown in Tab. 2. The parameters with a variance of 0 are the fixed parameters, while the others are the uncertain parameters. In all MCO cases, the value of the objective function is almost the same proving the controllability of the process. The objective function value lies at 6.6 mol/m^3. Furthermore, the range of valid control actions is not as wide as in the case of the first MCO with the full set of uncertain parameters. The control actions are displayed in Fig. 3. The result for the final temperature is shown in comparison to the result of the chance-constrained optimization result in Fig. 4. Here it is obvious, that the optimization results in control actions keeping the final temperature far away from the temperature bound of 340K. This of course means a loss of profit.

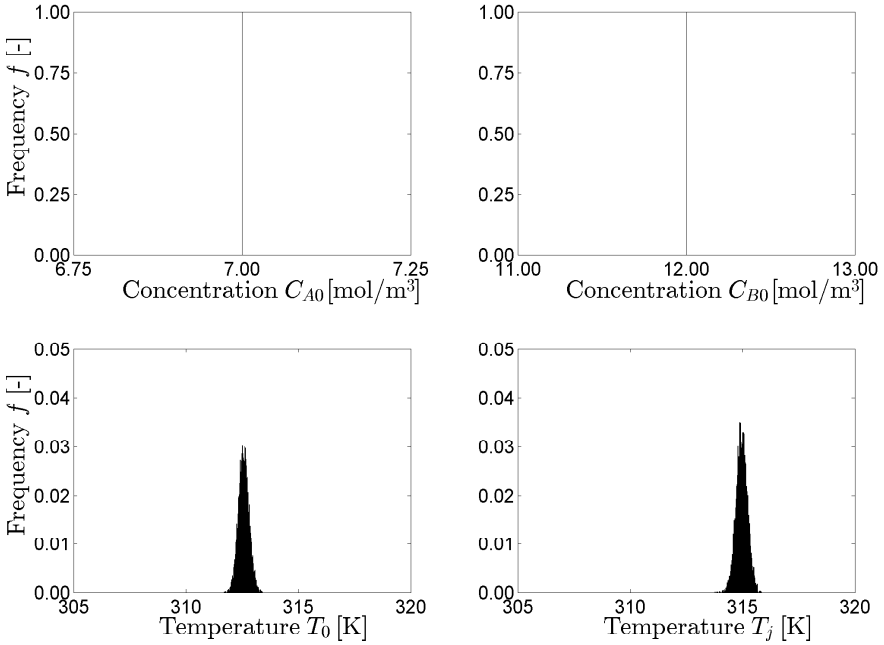

Figure 3: MCO result for the controls using the subset of estimated parameters.

Chance-Constrained Optimization - Subset: Finally, a chance-constrained optimization is carried out for the reduced subset with the same probability bound for the reaction temperature. A solution to the optimization problem can be found in less than 120 seconds as opposed to over 6 hours for the Monte Carlo optimization. A further Monte Carlo analysis of the thus found result with respect to the parameter uncertainty shows a desirable stability. The expected value of the objective function lies at 6.58 mol/m^3. Thus, a clear indication for an operator is obtained, on how the reactor should be operated and a slightly higher objective function value is achieved.

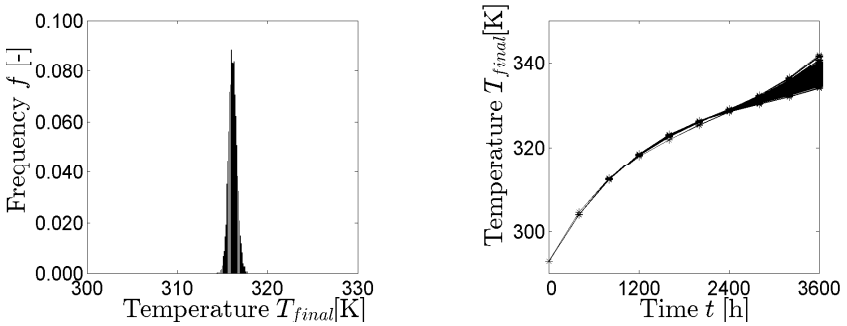

Figure 4: MCO result (left) and CCO result (right) for the subset of estimated parameters.

4. Conclusions and Outlook

Among other things, the results indicate, that implementing too much uncertainty into a process model, no sensible result for a Monte Carlo optimization as well as for the chance-constrained optimization is obtained. Secondly, the described method of using the parameter reduction algorithm combined with chance-constrained optimization is a suitable path towards comprehensive process optimization under uncertainty. This is the case both for Monte Carlo and chance constrained optimization. Thirdly, the latter yields clear, easily interpretable, and implementable optimization results as only one deterministic result is obtained. Additionally, the objective function value of the CC result is higher, as a minor constraint violation is allowed. As an outlook, the chance-constraint optimization approach will be implemented into the open source modeling environment MOSAIC (Kuntsche et al., 2011). Thus, the acceptance of the approach can be improved.

Abstract

Thermal membrane distillation (TMD) is a promising separation technology which involves simultaneous heat and mass transfer through a hydrophobic semi-permeable membrane. Studies of this technology have focused on the performance of individual modules. However, due tospecific purity and recovery requirements in some processes, multiple TMD modules have to be used in different configurations such as series, parallel, and combinations, which might require to reroute streams from one module to another or to recycle a stream to the same unit. This paper presents a systematic approach to synthesize an optimal TMD network. All the potential configurations are embedded within a structural representation of the problem which is then formulated as an MINLP optimization model, in which the objective function is the minimization of the total cost of the system.The advantages of the presented approach over conventional design procedures is shown through a case study dealing with the desalination of water (i.e,. integrated TMD modules yield better results with respect to usual configurations).

Keywords: Process Synthesis; Membrane Distillation; Separation Networks; Seawater Desalination; Optimization.

1. Introduction

Thermal membrane distillation (TMD) is becoming an attractive alternative as a separation method owing to several compelling features such as high rejection of ions, macromolecules, colloids and cells, along with low energy requirements (Khayet and Matsuura, 2011) due to mild operation conditions (i.e., relatively low pressure and low temperature). The driving force for the mass transfer in this technology is the partial vapor pressure difference across a microporous hydrophobic membrane. This vapor pressure difference is usually a function of the temperature difference (Kim, 2013). Despite the fact that TMD units can reach high separation levels, seldom single stage modules are not enough to satisfy these requirements (either in quality or quantity). In these cases staging of permeate and/or retentate might be required in diverse configurations such as series, parallel or combinations (it should be noted that this issue has not been addressed in the literature, and this is the main contribution of the present work), Nevertheless,several works have focused on the synthesis of other desalination systems, for example in RONs (Reverse Osmosis Networks). Karuppiah et al. (2012)

presented an optimization approach for synthesizing water treatment systems accounting for RO units. Abejón et al. (2012) proposed the use of RO units for ultra-purification of chemicals. Alnouri and Linke (2012; 2013) proposed a systematic process synthesis and optimization approach that takes into consideration multiple water quality parameters for the design of RO desalination networks. Du et al. (2014) proposed a multi-objective optimization approach for synthesizing RO networks for seawater desalination. Almansoori and Saif(2014) presented an optimal integrated RO system and a pressure retarded osmosis (PRO) for seawater desalination and power generation. Saif et al. (2014) presented an approach for the optimal design of RO networks considering variations in the streamproperties. Dahdah and Mitsos(2014) introduced a methodology to identify improved thermal-based desalination structures, the model considers either a multi-effect distillation system (MED) or a stage in a multi-stage flash system (MSF) to determine the best configuration. However there have not been works about the synthesis of integrated TMD networks. Thus, in this work a novel approach for the systematic designof a TMDN based on a new superstructure and a mathematical programming formulation is presented.

2. Design approach

The network configuration was represented through a source-sink approach (El-Halwagi et al., 1996). A source is a process stream that is rich in the constituent(s) that has to be removed in the separation task. Here, it is assumed that each TMD module represents a building block. The feed is preheated in the TMD module. Enough heat should be provided to induce the evaporation at a moderate temperature. The amount of heat and the inlet temperature of the stream fed to the TMD unit are optimization variables. Water vapor passes across the membrane and is condensed on the permeate side using a recirculating permeate-sweeping liquid which is colder than the feed. The size of each element is an optimization variable (including a zero size, which indicates that the element does not exist). Each TMD unit produces two streams (permeate and reject). Either one or both may be rerouted back to the network to be assigned to new sinks.The feed may be split into several fractions and assigned to the different TMD units. The proposed superstructure for the design of an integrated TMDN is shown in **Figure 1**. The problem consists in determining the optimum network configuration, unit sizes, stream allocation, and operating conditions.

3. Mathematical model

First the indices used in this model are defined: i represents the number of TMD units connected in parallel arrangement, k indicates the number of units connected in series, and i' is used to indicate a subsequent line of TMD modules. The model is constituted by mass, solute and energy balances in the mixers and splitters in the network and additional equations to calculate the permeate flux passing through the membrane, temperature polarization coefficient and membrane area.The heating for each TMD unit is provided by external utilities and this is equal to the feed flow rate ($w_{i,k}^{TMD}$) times the heat capacity for this stream ($\mathrm{Cp}_{\mathrm{i,k}}^{\mathrm{TMD}}$) and the temperature difference ($t_{i,k}^{TMD} - t_{i,k}^{mix}$). Only a fraction of this heat is used in vaporizing the permeate. The fraction is given by the efficiency factor ($\eta_{i,k}$). Hence, the heat balance for the TMD unit is given by:

$$\eta_{i,k} w_{i,k}^{TMD} \mathrm{Cp}_{\mathrm{i,k}}^{TMD} (t_{i,k}^{TMD} - t_{i,k}^{mix}) = w_{i,k}^{perm} \Delta h_{vw_{i,k}}, \quad \forall i \in I, \forall k \in K \tag{1}$$

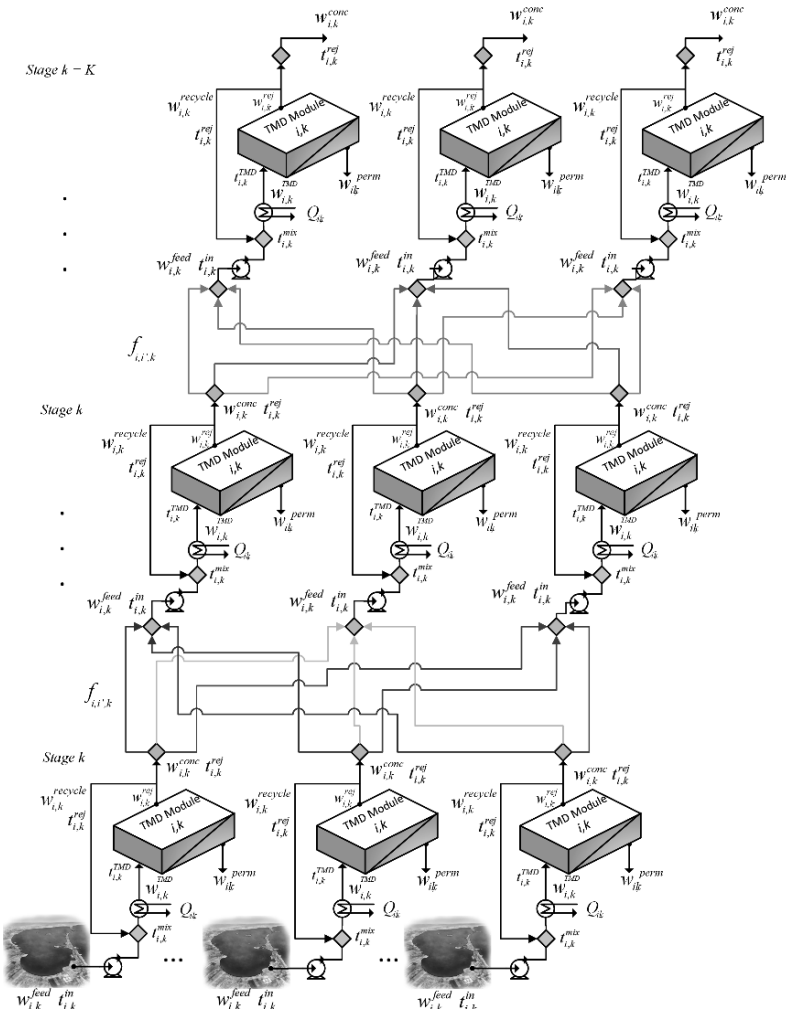

Figure 1. Superstructure for synthesizing a TMDN.

The permeate flux passing through the membrane ($j_{w_{i,k}}$) is calculated with equation (2)

$$j_{w_{i,k}} = b_{w_{i,k}} \left(p^{vap}_{wfeed_{i,k}} \gamma_{wfeed_{i,k}} x_{wfeed_{i,k}} - p^{vap}_{wperm_{i,k}} \right), \quad \forall i \in I, \forall k \in K \tag{2}$$

Where $x_{wfeed_{i,k}}$ is the mole fraction of water in the feed, $p^{vap}_{wfeed_{i,k}}$ is the vapor pressure in the feed side and $p^{vap}_{wperm_{i,k}}$ is the vapor pressure in the permeate side of the membrane, $b_{w_{i,k}}$ is a parameter for the molecular diffusion of water in air and $\gamma_{wfeed_{i,k}}$ is the activity coefficient.

A set of logical relationships are required to determine the components of the network required in the optimal solution. This depends on several factors such as the amount of recovered water, final concentration of permeate, and the impact of the total cost (capital and operating). Therefore, binary variables are used to indicate the existence or absence of such units ($y_{i,k} = Unit\ existance, \{0,1\}$).

$$\mathrm{W}^{\min} \cdot y_{i,k} \le w_{i,k}^{feed} \le \mathrm{W}^{\max} \cdot y_{i,k}, \qquad \forall i \in I, \forall k \in K \tag{3}$$

Where $\mathrm{W}^{\max}$ and $\mathrm{W}^{\min}$ are upper and lower limits for the flow rate of the feed that can be used in a TMD unit. When the inlet flow rate to the unit *i* in the stage *k* ($w_{i,k}^{feed}$) is greater than zero, then the associated binary variable ($y_{i,k}$) must be one. On the other hand, when the binary variable $y_{i,k}$ is zero (i.e., the associated TMD unit does not exist), the treated flow rate ($w_{i,k}^{feed}$) must be zero.

The total annual cost for the TMDN takes into account the fixed cost for the TMD units as a function of the membrane area ($\mathrm{C}_{\mathrm{F1}}^{\mathrm{TMD}}$) for TMD modules and as a function of the flow rate of the stream to be fed ($\mathrm{C}_{\mathrm{F2}}^{\mathrm{TMD}}$) for non-membrane elements, the installation costs of the TMD unit ($\mathrm{C}_{\mathrm{inst}}^{\mathrm{TMD}}$), and the operating cost for the TMD units ($\mathrm{C}_{\mathrm{Op1}}^{\mathrm{TMD}}$; $\mathrm{C}_{\mathrm{Op2}}^{\mathrm{TMD}}$; $\mathrm{C}_{\mathrm{Op3}}^{\mathrm{TMD}}$). In equation (4), the exponent $\beta_{\mathrm{k}}^{\mathrm{TMD}}$ is a factor used to account for the economies of scale. The heating and cooling utilities are also accounted in the terms $\mathrm{Cost}^{\mathrm{Heating}}$ and $\mathrm{Cost}^{\mathrm{Cooling}}$. Furthermore, the investment is annualized through the factor k_{F}, and H_{Y} is the operating time per year of the process. Notice that the fixed charge for the units is only added when the units exist through the use of the binary variables ($y_{i,k}$). Thus, total annual cost is stated as follows:

$$TAC = \left[\begin{array}{c} \mathrm{k_F} \sum_i \sum_k \left[\left(\mathrm{C}_{\mathrm{inst}}^{\mathrm{TMD}} \cdot y_{i,k} \right) + \left(\mathrm{C}_{\mathrm{F1}}^{\mathrm{TMD}} \cdot A_{m_{i,k}} \right)^{\beta_2} + \left(\mathrm{C}_{\mathrm{F2}}^{\mathrm{TMD}} \cdot w_{i,k}^{TMD} \right)^{\beta_3} \right] \\ + \mathrm{H_Y} \sum_i \sum_k \left[\mathrm{C}_{\mathrm{Op1}}^{\mathrm{TMD}} \cdot y_{i,k} + \mathrm{C}_{\mathrm{Op2}}^{\mathrm{TMD}} \cdot \left(1 - \xi_{\mathrm{i,k}} \right) w_{i,k}^{feed} + \mathrm{C}_{\mathrm{Op3}}^{\mathrm{TMD}} \cdot w_{i,k}^{TMD} \right] \\ + \mathrm{H_Y} \sum_i \sum_k \left[\mathrm{Cost}^{\mathrm{Heating}} \cdot Q_{i,k}^{Heating} \right] \end{array} \right] \tag{4}$$

It is worth notice that the nonlinearities and nonconvexities are included in the solute balances and energy balances for the mixers, energy balances in the heaters, in the equations for the TMD modules(i.e., solute balance, energy balance, the equation to calculate the permeate flux through the membrane, the temperature profile and the membrane area), as well as the equation of the total annual cost.

4. Results

A seawater desalination process is presented to show the applicability of the proposed approach for designing TMDN. The problem was coded using the software GAMS (Brooke et al., 2014). Where the solver DICOPT was used to solve the associated mixed-integer nonlinear programing (it should be noted that DICOPT does not guarantee to get the global optimal solution). To solve the problem, a computer with an Intel® Core TM i7-4700MQ processor at 2.40GHz and 8 GB of RAM was used.

4.1. Case Study. Seawater desalination process.

A brackish water desalination process in the coast of Saudi Arabia is considered. For this process, a feed of 3456kg/h with a concentration of 0.1% (1,000 ppm) of dissolved NaCl is processed. The maximum allowable membrane area for each module is 100 m^2/module. The objective consists in maximizing the annual gross profit obtained from the sales of permeate minus the total annualized cost of the system. The optimal

solution is shown in **Figure 2**. It involves two units in series. A total recovery of 95.90% of water as permeate was obtained. The feed temperature for the first unit (1,1) is 300 K and the feed temperature for the second unit (1,2) is 359 K. The first unit has a membrane area of 92.4 m^2 which represents 83.2% of the total required area of membrane and produces a permeate flow rate of 2,764 kg/h which is 83.4% of the total permeate of the TMDN. The total permeate is 3,316 kg/h, which yields an annual revenue of $212,340/y. The total annual cost is $170,347/y and the annual gross profit for the optimal solution is $41,993/y.Furthermore, six additional configurations were analyzed (either parallel or series arrangements) to show the advantages of the proposed approach. In scenario 3, were only a single unit is presented, the annual gross profit reaches $40,306/y which is 4% lower than the optimal solution. Scenarios 3 and 4 present parallel arrangements in which the total permeate is 16.5% lower than the optimal solution, also the total cost is affected by the installation cost of each unit in both cases. In scenario 5, although the total permeate is 2.1% greater than the optimal solution, the total annual profit is affected by the installation of 3 units in series. Scenarios 6 and 7 have similar permeate flow rates to the optimal solution, however, the total annual cost increased because of the multiple modules. **Table 1** shows the main economic results for the optimal configuration and for other analyzed scenarios.

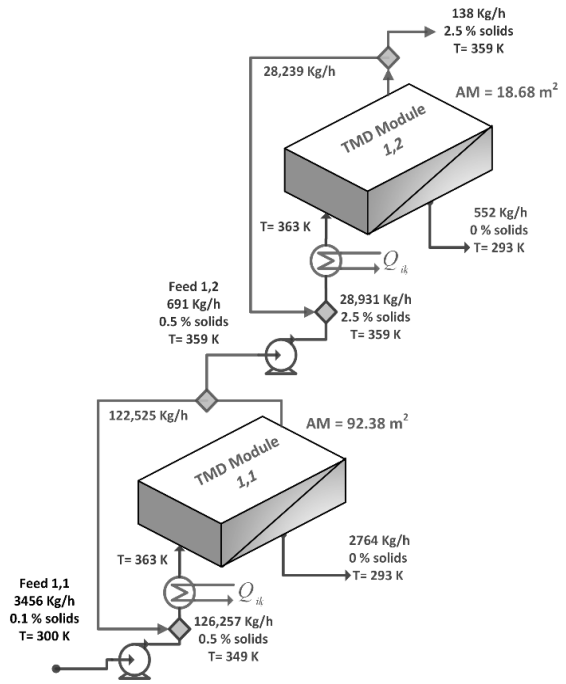

Figure 2. Optimal TMDN for the Case Study.

5. Conclusions

An optimization model for the synthesis of TMDN has been presented. The model is based on a superstructure that embeds all the possible configurations for the network. The proposed model incorporates modelling equations as well as technical and design constraints used to determine the optimal configuration and operating conditions of the process.A case study from Saudi Arabia was solved, in which the results show that two TMD modules in series arrangement yield better results than single, parallel and hybrid

configurations, based on the total permeate flow rates, total annual cost and annual profit. The on-going and future research should focus on the integration with various desalination processes in order to satisfy various water qualities that reduce the cost of desalination, also it is essential to incorporate clean energy technologies which will have a significant benefit in the desalination cost.

Table 1. Optimal results for the Case Study and comparison with six other scenarios.

		Scenario						
Concept	Unit	Optimal	2	3	4	5	6	7

Multicolumn-multicut cross decomposition for stochastic mixed-integer linear programming

Emmanuel Ogbe[a] and Xiang Li[a]

[a]*Department of Chemical Engineering; Queen's University; Kingston, ON, Canada*
xiang.li@queensu.ca

Abstract

This paper proposes a multicolumn-multicut cross decomposition method for stochastic mixed-integer linear programming problems. In this method, multiple columns or multiple cuts are added to the Dantzig-Wolfe restricted master problem or the Benders relaxed master problem, in one iteration. We demonstrate the advantage of the proposed method in comparison with single cut and multicut Benders decomposition methods and a single column single cut cross decomposition method, through the case study of a bio-product supply chain problem.

Keywords: Stochastic programming; Mixed-integer linear programming; cross decomposition.

1. Introduction

Mixed-integer linear programming (MILP) paradigm has been applied to a host of problems in process systems engineering literature. Typical applications include supply chain optimization, process network design and operation, production planning and scheduling, etc. These applications often involve factors that are usually not known with certainty before some decisions are made, which result in uncertain parameters in the MILP model. Using the classical scenario approach, the stochastic MILP problem can be formulated into a two-stage stochastic programming problem (Birge and Louveaux (2010)) as follows:

$$\begin{aligned} \min_{\substack{x_0,\\ x_1,\ldots,x_s}} \; & c_0^{\mathrm{T}} x_0 + \sum_{\omega\in\Omega} c_\omega^{\mathrm{T}} x_\omega \\ \text{s.t. } & A_{0,\omega} x_0 + A_\omega x_\omega \le b_{0,\omega}, \quad \forall \omega \in \Omega, \\ & x_\omega \in X_\omega, \quad \forall \omega \in \Omega, \\ & x_0 \in X_0, \end{aligned} \tag{P}$$

where $x_0 \in X_0 = \{x_0 = (x_{0,b}, x_{0,c}) \in \{0,1\}^{n_{x_{0,b}}} \times \mathbb{R}^{n_{x_{0,c}}} : B_0 x_0 \le d_0\}$ denotes the first-stage decisions, $x_\omega \in X_\omega = \{x_\omega \in \mathbb{R}^{n_x} : B_\omega x_\omega \le d_\omega\}$ denotes the second-stage decisions, and the subscript $\omega \in \Omega = \{1,2,\ldots,s\}$ indexes each scenario. We assume that sets X_0 and x_ω are nonempty and bounded.

Problem (P) is computationally challenging when the number of scenarios involved is large, but its structure can be exploited by a decomposition strategy for efficient solution. Classical decomposition methods for Problem (P) include Dantzig-Wolfe decomposition (DWD) (Dantzig and Wolfe (1960)), Benders decomposition (BD) (Benders (1962)), Lagrangian decomposition (LD) (Carøe and Schultz (1999)), and cross decomposition (CD) (Van Roy (1983)) (Mitra et al. (2014)).

Recently, a new CD method has been developed through the integration of the classical DWD and BD methods, which has significant advantages over the classical DWD and BD methods for

solving Problem (P) (Ogbe and Li (2014)). In this CD method, only a single column or a single cut is added to the DWD or Benders master problem in one iteration. This paper proposes a variant of the new CD that adds multiple columns or cuts in one iteration to achieve an improved convergence rate, as it is well-known that the multicolumn and multicut strategies can accelerate the convergence of classical DWD and BD (Lasdon (1970))

The remaining part of the article is organized as follows. In section 2, we briefly introduce the new CD method. Then in section 3, the multicolumn-multicut CD is presented together with its convergence property. Case study results for a bio-product supply chain problem is presented in section 4 to demonstrate computational advantage of the proposed method. The article ends with conclusions in section 5.

2. The cross decomposition method

The CD method recently developed by the authors synergizes DWD and BD by solving the subproblems from each decomposition method in a unified framework (Ogbe and Li (2014)). On the one hand, two subproblems from DWD, called **DWD restricted master problem** and **DWD pricing problem** in this paper, are solved in the CD. They are constructed through vertex representations of bounded polyhedral sets. Specifically, set $X = \prod_{\omega\in\Omega} X_\omega$ in Problem (P) can be represented as:

$$X = \{x = (x_1,...,x_s) \in \mathbb{R}^{s\cdot n_x} : x_\omega = \sum_{j\in J} \theta^j x^j_\omega, \omega \in \Omega, \sum_{j\in J} \theta^j = 1, \theta^j \geq 0, \forall j \in J\}, \tag{1}$$

where set J includes indexes for all extreme points of X and possibly other points in X as well (Ogbe and Li (2014)). Each point used for defining X is called a *column*. The following set, used in the lth DWD iteration in the CD method, is a subset of X,

$$X^l = \{x = (x_1,...,x_s) \in \mathbb{R}^{s\cdot n_x} : x_\omega = \sum_{j\in J^l} \theta^j x^j_\omega, \omega \in \Omega, \sum_{j\in J^l} \theta^j = 1, \theta^j \geq 0, \forall j \in J^l\}, \tag{2}$$

where $J^l \subset J$. When using X^l instead of X, Problem (P) is restricted into the DWD restricted master problem, which can be written in the following form:

$$\begin{aligned} obj_{DWRMP^l} = \min_{x_0,\theta^j} \; & c_0^{\mathrm{T}} x_0 + \sum_{\omega\in\Omega} c_\omega^{\mathrm{T}} \left(\sum_{j\in J^l} \theta^j x^j_\omega \right) \\ \text{s.t. } & A_{0,\omega} x_0 + A_\omega \left(\sum_{j\in J^l} \theta^j x^j_\omega \right) \leq b_{0,\omega}, \quad \forall \omega \in \Omega, \\ & \sum_{j\in J^l} \theta^j = 1, \quad \theta^j \geq 0, \quad \forall j \in J^l, \\ & x_0 \in X_0. \end{aligned} \tag{DWRMP^l}$$

As a result, Problem (DWRMP^l) provides an upper bound for Problem (P). Let π^l_ω be Lagrangian multipliers for the first group of constraints in Problem (DWRMP^l), then a DWD pricing problem can be solved to generate an extra point for set X^l. This problem can be decomposed over the scenarios; for scenario ω, the subproblem is:

$$\begin{aligned} obj_{DWPP^l_\omega} = \min_{x_\omega} \; & (c_\omega^{\mathrm{T}} + \left(\pi^l_\omega\right)^{\mathrm{T}} A_\omega) x_\omega \\ & x_\omega \in X_\omega. \end{aligned} \tag{DWPP$^l_\omega$}$$

On the other hand, two subproblems from BD, called **BD primal problem** and **BD relaxed master problem** in this paper, are also solved in CD. The BD primal problem is constructed at the kth BD iteration by fixing $x_0 = x_0^k$. The resulting problem provides an upper bound for Problem (P), and it can be decomposed over the scenarios. For scenario ω, the subproblem can be written as:

$$\begin{aligned} obj_{\mathrm{PP}_\omega^k} = \min_{x_\omega}\ & c_0^{\mathrm{T}} x_0^k + c_\omega^{\mathrm{T}} x_\omega \\ \text{s.t. } & A_{0,\omega} x_0^k + A_\omega x_\omega \le b_{0,\omega}, \\ & x_\omega \in X_\omega. \end{aligned} \tag{BPP$_\omega^k$}$$

Using the principles of projection and dualization (Geoffrion (1972)), Problem (P) can be equivalently formulated into a master problem that includes a finite number of duality-based constraints called *cuts*. When including a subset of the cuts, the problem becomes the following BD relaxed master problem:

$$\begin{aligned} \min_{x_0,\eta}\ & \eta \\ \text{s.t. } & \eta \ge \sum_{\omega\in\Omega} obj_{BPP_\omega^j} + \sum_{\omega\in\Omega} \left(c_0^{\mathrm{T}} + (\lambda_\omega^j)^{\mathrm{T}} A_{0,\omega}\right)\left(x_0 - x_0^j\right), \quad \forall j \in T^k, \\ & \eta \ge \sum_{\omega\in\Omega} obj_{DWPP_\omega^j} + \sum_{\omega\in\Omega} \left(c_0^{\mathrm{T}} + \left(\pi_\omega^j\right)^{\mathrm{T}} A_{0,\omega}\right) x_0 - \left(\pi_\omega^j\right)^{\mathrm{T}} b_{0,\omega}, \quad \forall j \in U^l, \\ & x_0 \in X_0, \end{aligned} \tag{BRMP^k}$$

where T^k includes indexes of Lagrangian multipliers generated from previously solved Problem (BPP$_\omega^k$) before the kth BD iteration, and U^l includes indexes of Lagrangian multipliers generated from previously solved Problem (DWPP$_\omega^l$).

The CD method solves the above four subproblems iteratively to yield a sequence of upper bounds and lower bounds of Problem (P), and the algorithm can converge in a finite number of iterations to an optimal solution. Figure 1 illustrates the algorithmic framework. More details about the CD algorithm can be found in Ogbe and Li (2014).

Remark 1. *The CD method is advantageous over the classical BD method, because it generates better upper and lower bounds via using (a) the better one of the upper bounds provided by DWD and BD upper bounding problems and (b) the better one of the lower bounds from DWD and BB lower bounding problems. Note that in Problem (BRMP^k), the cuts generated by DWD subproblems do not necessarily dominate the Benders cuts, and vice versa.*

3. The multicolumn-multicut cross decomposition method

In the multicolumn-multicut (MCMC) CD, a multicolumn DW restricted master problem instead of Problem (DWRMP^l), and a multicut BD relaxed master problem instead of Problem (BRMP^k), are solved. The multicolumn DW restricted master problem restricts set X using the following set X_{MC}^l instead of X^l:

$$X_{MC}^l = \{x = (x_1, ..., x_s) \in \mathbb{R}^{s \cdot n_x} : x_\omega = \sum_{j\in J^l} \theta_\omega^j x_\omega^j, \sum_{j\in J^l} \theta_\omega^j = 1, \theta_\omega^j \ge 0, \forall j \in J^l, \forall \omega \in \Omega\}. \tag{3}$$

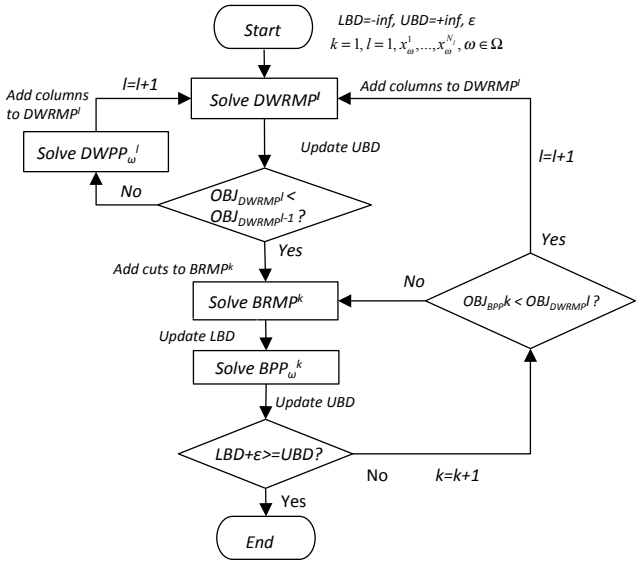

Figure 1: The cross decomposition algorithm flowchart

As a result, the problem can be written as:

$$
\begin{aligned}
obj_{DWRMP-MC^l} = \min_{x_0,\theta_\omega^j}\ & c_0^{\mathrm{T}}x_0 + \sum_{\omega\in\Omega} c_\omega^{\mathrm{T}}\left(\sum_{j\in J^l}\theta_\omega^{\mathrm{j}}x_\omega^{\mathrm{j}}\right)\\
\text{s.t. } & A_{0,\omega}x_0 + A_\omega\left(\sum_{j\in J^l}\theta_\omega^{\mathrm{j}}x_\omega^{\mathrm{j}}\right) \le b_{0,\omega}, \quad \forall\omega\in\Omega, \qquad \text{(DWRMP-MC}^l\text{)}\\
& \sum_{j\in J^l}\theta_\omega^{\mathrm{j}} = 1,\ \theta_\omega^j \ge 0, \quad \forall\omega\in\Omega,\ \forall j\in J^l,\\
& x_0\in X_0.
\end{aligned}
$$

The multicut BD relaxed master problem for the CD can be written as:

$$
\begin{aligned}
\min_{x_0,\eta_1,\ldots,\eta_s}\ & \sum_{\omega\in\Omega}\eta_\omega\\
\text{s.t. } & \eta_\omega \ge obj_{\mathrm{BPP}_\omega}(x_0^j) + \left(c_0^{\mathrm{T}} + (\lambda_\omega^j)^{\mathrm{T}}A_{0,\omega}\right)\left(x_0 - x_0^j\right), \quad \forall j\in T^k,\ \forall\omega\in\Omega,\\
& \eta_\omega \ge obj_{DWPP_\omega^j} + \left(c_0^{\mathrm{T}} + \left(\pi_\omega^j\right)^{\mathrm{T}}A_{0,\omega}\right)x_0 - \left(\pi_\omega^j\right)^{\mathrm{T}}b_{0,\omega}, \quad \forall j\in U^l,\ \forall\omega\in\Omega,\\
& x_0\in X_0.
\end{aligned}
\qquad \text{(BRMP-MC}^k\text{)}
$$

Proposition 1. *(DWRMP-MC^l) is a better restriction of Problem (P) compared to (DWRMP^l).*

Proof. $\forall x = (x_1,\ldots,x_s)\in X_{MC}^l$, consider x_ω in this vector ($\forall\omega\in\Omega$). As x_ω is a convex combination of points in the convex set X_ω (according to Eq. (1)), $x_\omega\in X_\omega$. So $x\in\prod_{\omega\in\Omega}X_\omega = X$. Therefore, $X_{MC}^l\subset X$, and Problem (DWRMP-MC^l) is a restriction of Problem (P).

On the other hand, $\forall x = (x_1, \ldots, x_s) \in X^l$, according to Eq. (2), $\exists \theta^j \geq 0$, x_ω^j ($j \in J^l$, $\omega \in \Omega$) such that $\sum_{j \in J^l} \theta^j = 1$, $x_\omega = \sum_{j \in J^l} \theta^j x_\omega^j$. According to Eq. (3) this implies that $x \in X_{MC}^l$. So $X^l \subset X_{MC}^l$, which means that the feasible set of Problem (DWRMP-MC^l) is closer to the feasible set of Problem (P) and therefore Problem (DWRMP-MC^l) is a better restriction of Problem (P). □

Proposition 2. *(BRMP-MC^k) is a better relaxation of Problem (P) compared to (BRMP^k).*

Proof. This has been proved (in the context of multicut Benders decomposition) in the literature (Birge and Louveaux (1988)). □

Theorem 1. *if Problem (P) is feasible, and all the subproblems can be solved to ε-optimality in a finite number of steps, the MCMC CD algorithm terminates in a finite number of steps with an ε-optimal solution of Problem (P).*

Proof. The CD algorithm in proved to be finitely convergent in Ogbe and Li (2014). Propositions 1 and 2 show that the multicolumn and the multicut reformulations of the master problems even improves the upper and lower bounds generated at each iteration, so the MCMC CD method is finitely convergent. □

4. Case Study

4.1. Case Study Problem and Implementation

We compare BD, multicut BD (MC BD), CD and MCMC CD through a bio-product supply chain optimization problem. This problem was originally presented in Čuček et al. (2010), and later modified into a two-stage stochastic MILP formulation by McLean and Li (2013). The stochastic MILP model contains 18 binary variables and 1876*s* continuous variables, where s is the number of scenarios.

The case study was implemented on a virtual machine running Linux with 3.2GHz CPU and 6 GB memory installed on a Windows host system. MATLAB 2013 was used to program all algorithms. All subproblems were modeled in GAMS 24.1.1 and interfaced with MATLAB using the interface GDXMRW provided by GAMS. CPLEX 12.5 was used as the LP and MILP solver for all implementations.

4.2. Results and Discussion

Figure 2 summarizes the times used to solve the case study problem with different numbers of scenarios using the four approaches. It can be seen that BD is the slowest among the four, and with the multicut formulation, the performance of BD is significantly improved. The multicolumn-multicut formulation also significantly improves the efficiency of CD, and the MCMC CD method achieves the best performance.

Why MCMC CD is the fastest algorithm among the four can be explained with Figure 3. This figure illustrates how the bounds obtained by the four algorithms change during the solution procedure. It can be seen that the bounds generated by MCMC CD converge the fastest, which is because MCMC CD not only updates the bounds using subproblems from both DWD and BD, but also uses better restricted and relaxed subproblems (through multicolumn and multicut formulations). The number of iterations for MCMC CD to converge is about half of that for MCMC BD, less than a third of that for CD, and less than a fourth of that for BD. The fact that MCMC CD is faster than MCMC BD may be due to two reasons. One is that in MCMC CD, the upper bound is the better one of the upper bounds yielded from BD and DWD upper bounding problems. The other is that the solutions of DWD pricing problems provide extra cuts for the Benders relaxed master problem, some of which can be better than the Benders cuts.

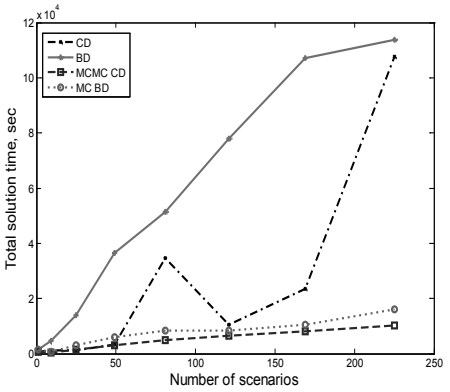

Figure 2: Summary of computational times

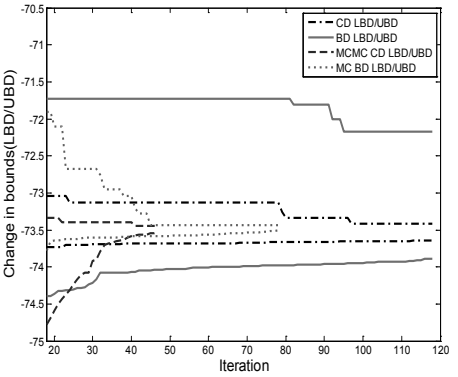

Figure 3: Bound evolution (for 9 scenarios)

5. Conclusions

A MCMC CD algorithm is developed solve stochastic MILPs in form of Problem (P). Tighter upper and lower bounds are derived for the MCMC CD through the multicolumn and multicut reformulation and the reformulation does not hurt the finite convergence of the algorithm. Case study results show that, the MCMC CD is faster than the classical BD method by an order of magnitude when the number of scenarios is large, and it is also significantly faster than CD and MC BD for all cases.

Abstract

Efficient ant colony optimization (EACO) is a new metaheuristic optimization algorithm for tackling linear, nonlinear and mixed integer nonlinear(MINLP) programming problems. In this work, a solvent selection optimization problem modeled based on a novel computer-aided molecular design (CAMD) methodology is optimized using an EACO algorithm. The molecular design problem is formulated as an MINLP model where a solvent solute distribution coefficient is maximized subject to structural feasibility, property and process constraints. The capability of the proposed methodology is illustrated through a case study of an extraction of acetic acid from waste process stream by liquid-liquid extraction. Environmentally benign new solvents with better targeted properties are proposed.

Keywords: Efficient Ant Colony Optimization, Group contribution method, CAMD, Hammersley Sequence Sampling, Solvent selection.

1. Introduction

Solvents are extensively used as process materials, extracting agents and process fluids in the process, pharmaceutical and solvent based industries. Environmental awareness, strict legislation and the need of high performance solvents have lead in the search for environmentally benign and high performing solvents. In many cases, the search for solvents is done through experiments, and database searches. These methods are usually expensive and time-consuming. Computer aided molecular design (CAMD), which is the reverse method of the group contribution method, is a systematic tool that generates solvents of high performance, economical, and with better environmental performance. The existence of a combinatorial search space in molecular design poses a challenge for traditional deterministic optimization methods. In this work, we propose a new approach to solvent design problem by implementing anefficient ant colony optimization (EACO) algorithm. By combining the CAMD and EACO algorithm, large numbers of solvent molecules are generated from a small set of building blocks (given in Table 1.) that satisfy target solvent properties. In the forward problem, the proposed EACO algorithm generates solvent molecules that satisfy the model constraints and the group contribution method predicts properties from the molecular structure and facilitates the solution of the CAMD problem.

ACO is a metaheuristic class of optimization algorithm inspired by the foraging behavior of real ants (DorigoandStutzle, 2004). Natural ants randomly search food by

exploring the area around their nest. If an ant locates a food source, while returning back to the nest, it lay down a chemical pheromone trail that marks its path. This pheromone trail will indirectly communicate with other members of the ant colony to follow the path. Over time, the pheromone will start to evaporate and therefore reduce the attraction of the path. The routes that are used frequently will have higher concentration of the pheromone trial and remain attractive. Thus, the shorter the route between the nest and food source imply short cycle time for the ants and these routes will have higher concentration of pheromone than the longer routes. Consequently, more ants are attracted by the shorter paths. Finally, the shortest path will be discovered by the ant colony. In ACO algorithms, artificial ants are stochastic candidate solution construction procedures that exploit a pheromone model and possibly available heuristic information of the mathematical model. The artificial pheromone trails are the sole means of communication among the artificial ants. Pheromone decay allows the artificial ants to forget the past history and focus on new promising search directions. The pheromone values are updated according to the information learned and the algorithmic procedure leads to very good and hopefully, a global optimal solution. It was originally introduced to solve combinatorial optimization problems, in which decision variables are characterized by a finite set of components. However, in recent years, its adaptation to solve continuous and mixed variable Socha(2004) programming problems has received an increasing attention.

In recent years, there has been a significant research interest in developing and implementing for different applications, however, to the authors knowledge, there is no work in the literature that implement ACO algorithm to solve the MINLP CAMD problems. The proposed algorithm combines CAMD and EACO algorithm proposed by (Gebreslassie & Diwekar, 2015a) as shown in Figure 1. The algorithm parameters, the UNIFAC building block groups and their properties such as the volume and surface area parameters, and the interaction parameters between building blocks are first introduced. These UNIFAC groups are uniquely designed to generate all possible molecules by exploring all possible combinations. For example, as shown in the algorithm, ethanol (CH_3CH_2OH) is generated from the CH_3, CH_2, and OH groups. The number of combinations can be reduced by introducing constraints from physical and chemical properties, structural feasibility as well as those from regulatory restrictions. Once molecules are generated, the properties of the molecules are predicted based on the properties of their building blocks using the UNIFAC model.

2. Solvent Selection Model Formulation (Case Study)

Acetic acid is commonly used as a process solvent and it is produced as a byproduct. Because acetic acid can be a pollutant as well as a valuable solvent, it is important to minimize or possibly avoid the discharge of acetic acid to the environment. To recycle or remove acetic acid from waste process streams, liquid-liquid extraction is commonly

used. For absorption process, one can either use high-boiling solvents or low-boiling solvents depending on the process considered. Ethyl acetate, isoamylacetate, and isopropyl acetate are widely used in industries to extract acetic acid. Ethyl acetate, which is one of the common solvents for acetic acid extraction, has high solute distribution coefficient (m=0.3156), unfortunately it also has high solvent loss (S_L =0.0560). The high solvent loss property indicates the need alternative environmentally benign solvents. The molecular design problem is formulated as an MINLP model Eq. 1in which a solute distribution coefficient is maximized subject to structural feasibility,

\end{aligned}
$$

property, and process constraints. The UNIFAC, the solute distribution coefficient, the solvent selectivity and the solvent loss models can be viewed in (Gebreslassie and Diwekar 2015b)

The bounds on the constraints are taken from the properties of the commonly practiced solvent for acetic acid extraction (Kim & Diwekar, 2002).Normal boiling point (T_{bp}) is estimated using the linear prediction model. $b_i$is the number of free attachments in a group index *i*. In this problem, the discrete decision variables are the number of groups N_1 involved in a solvent molecule and the building block index N_2^i; $i \in \{1, ..., N_1\}$of that molecule. From these groups a unique solvent molecule that has high solute distribution coefficient and the model constraints are generated. As shown in Table 1, the total numbers of groups used in this work are *24* and a maximum of *10* groups per molecule are allowed, therefore, the total combinatorial space is composed of $24^{10}(6.34 \times 10^{13})$ combinations. The three UNIFAC parameters, surface area, volume, and interaction parameters, as well as boiling point parameters, group free attachments and the molecular weights can be viewed in (Gebreslassie & Diwekar, 2015b).

3. Efficient Ant Colony Optimization (EACO) Algorithm

One of the simplest and most widely used methods for sampling is the Monte Carlo method which is based on the pseudorandom number generator. The pseudorandom number generator produces samples that may be clustered in certain regions of the population and does not produce uniform samples. Therefore, in order to reach high accuracy, larger sample sizes are needed, which adversely affects the computational efficiency (Diwekar & Kalagnanam, 1997). (Gebreslassie & Diwekar, 2015a) proposed EACO algorithm that improves the performance of the conventional ACO algorithm for combinatorial, continuous and mixed variable optimization problems by introducing the Hamersley sequence sampling (HSS). The initial solution archive diversity for continuous and mixed-variable optimization problems plays an important role in the performance of ACO algorithm. The uniformity property of the HSS technique is exploited to avoid clustering of the initial solution archive in a small region of the potential solution space. Moreover, ACO algorithm is a probabilistic method, several random probability functions are involved in the algorithm procedure. For example, in combinatorial ACO algorithm, the random number for the transition probability test and for continuous and mixed-variable optimization problems, the random number to test the probability of choosing ant guide from the solution archive. The distribution of these random numbers affects the performance of the ACO algorithm. At this stage, the multidimensional uniformity property of HSS is introduced to improve the computational efficiency of the ACO algorithm. The algorithm proposed in this work combines CAMD and EACO algorithm and it is given in Figure 1.

4. Results and Discussions

The algorithm terminates when it reaches maximum number of iterations (MaxIter), or if the tolerance (eps) that is the relative difference between solutions found in two consecutive iterations is lower or equal to a parameter *eps*for a set of consecutive number of iterations (*ICON)*. The parameters used for the EACO algorithm are archive sizes *K=1500*,number of antsnAnts = 30, *q=1E-3* and *eps=1E-6*, evaporation parameter ρ*=0.75*.

An attractive solvent has a high solute distribution coefficient, selectivity and low solvent loss. The EACO algorithm generated more than 30 solvents with higher m value than Ethyl acetate, which is one of the common practice of solvent for acetic acid extraction (m = 0.3156). The first top 5 solvents for high and low boiling temperature solvents are summarized in Tables 2&3, respectively. As shown in the tables, most of

the high ranked solvent molecules are ethers, alcohols and aldehydes. A high value of m reduces the size of extraction equipment and the amount of recycling solvent. In other words, these high m solvents will reduce the investment cost and the operational cost related to the energy consumption for solvent recovery. From Tables 2&3, it can be concluded that the EACO algorithm generate a set of candidate solvents with better solute distribution coefficient and low solvent loss properties.

Table 2. High boiling point temperature candidate solvents

Rank	Solvent	m	β	S_L	T_{bp}
1	$2CH_2$,C,CH_2=CH,CH=CH,CH_3OH,CH_3O	0.691	8.85	0.010	517.7

1	CH_2=CH,CH_2=C, CH_3O, CH_2O	0.751	7.79	0.033	374.9
2	CH_2=CH,CH=CH, CH_3O	0.709	9.25	0.019	337.2
3	CH_3, CH_2=CH,$2CH_2O$	0.666	7.58	0.044	355.4
4	CH_3,CH2=C, CH_3CO	0.612	14.59	0.052	364.4
5	CH_3, CH=CH, CH_3CO	0.610	16.10	0.048	372.0

Comparing the results from EACO algorithm shown in Tables 2&3 and the results reported by Diwekar and co-workers (Kim & Diwekar, 2002b) obtained using Efficient Simulated Annealing (ESA), the best solvent molecule found by EACO algorithm with configuration (*$2CH_2$,C,CH_2 =CH,CH= CH,CH_3OH,CH_3O*) has values of m =0.691, which exceeds the optimal solvent (*CH_3, $6CH_2$,OH*) found by ESA with m = 0.6074. Moreover, the EACO algorithm has also found a set of candidate solvent molecules with better solute distribution coefficients than the first ranked solvent molecule found by ESA. There are two reasons for this phenomenon: (1) the EACO algorithm finds a set of solutions equal to the number of ants used by the algorithm instead of one as in the simulated annealing, and this property enables EACO algorithm the ability to cover the search space easily and gives a better chance to find the global optimum; and (2) in simulated annealing, an infeasible solution is accepted or discarded randomly according to the Metropolis criterion. The disadvantage of this constraint violation handling strategy is that there is no standard for accepting or discarding solutions. Therefore, some infeasible solutions that have more chances to reach the optimum may be discarded and, consequently, some good patterns are lost in the process. In EACO algorithm the selection of q parameter is carefully chosen in such a way to focus initially at exploration and when the quality of the solution is improved to focus on exploitation.

Table 4.Results compared with decomposition methods.

Method	Solvent	m	β	S_L	T_{bp}
Karunanithi et. al. (2005)	1CH3,3CH2,1CH3CO	0.491	11.0	0.0038	404.1

Karunanithiet. al. (2005) proposed a new CAMD methodology where the general molecule/mixture design problem was decomposed into an ordered set of sub-problems such that the solution of the decomposed set of sub-problems is equivalent to that of the

original MINLP problem. In this approach, sub-problem is solved and a large portion of the infeasible part of the search space is deleted, thereby leading to a final sub-problem that is significantly manageable MINLP or NLP problem. Because all the sub-problems except the final sub-problem are constraint satisfaction, global optimality can be guaranteed. The proposed candidate solvent from Karunanithiet. al. (2005) is shown in Table 4. The candidate solvents from EACO algorithm have better solute distribution coefficient for both high (Table 2.) and low (Table 3.) boiling temperature solvents. However, the authors want to mention that the work by Karunanithiet. al. (2005) considers 15 building blocks while we consider 24 building blocks.

5. Conclusions

We propose a new solution strategy based on EACO algorithm for solving solvent selection CAMD problem. The proposed methodology involves formulating the solvent selection molecular design problem as an MINLP model and solution method for identifying candidate solvents.The capability of the proposed approach is illustrated through a case study of solvent selection for acetic acid extraction from waste process stream. The UNIFAC model is used to estimate the mixture properties and the EACO algorithm generateenvironmental benign new solvents with better targeted properties. The EACO algorithm has found a set of candidate solvent molecules with better solute distribution than the first ranked solvent molecules proposed using ESA optimization strategies

Optimisation of Process Parameters with Simultaneous Consideration of Energy Efficiency Measures

Timo Bohnenstaedt,[a] Kristina Zimmermann,[a] Georg Fieg[a]

[a]*Institute of Process and Plant Engineering, Hamburg University of Technology, Schwarzenbergstraße 95, D-21071 Hamburg, Germany*

Abstract

Sustainable process design and energy efficiency evaluation are major topics for recent process engineering. Process integration by the means of heat recovery is a powerful approach to reduce the need for additional heating or cooling. Usually a heat exchanger network is applied to utilize waste heat within a process directly, while a super ordinated utility system is applied for indirect heat transfer between different processes. The aim of this work is to point out the possibilities of multi-objective optimisation in order to implement the design of heat recovery measures at an early stage of process design. Similar to the well-known pinch technology this new combined optimisation procedure can be best described as an advanced targeting step. Pareto-optimal solutions are generated using a genetic algorithm. The mathematical background will be described within this work.

Keywords: Multi-objective optimisation, Process design, Energy efficiency

1. Introduction

The general concept of the incorporation of heat recovery analysis into the optimisation procedure of process design is outlined by Figure 1.

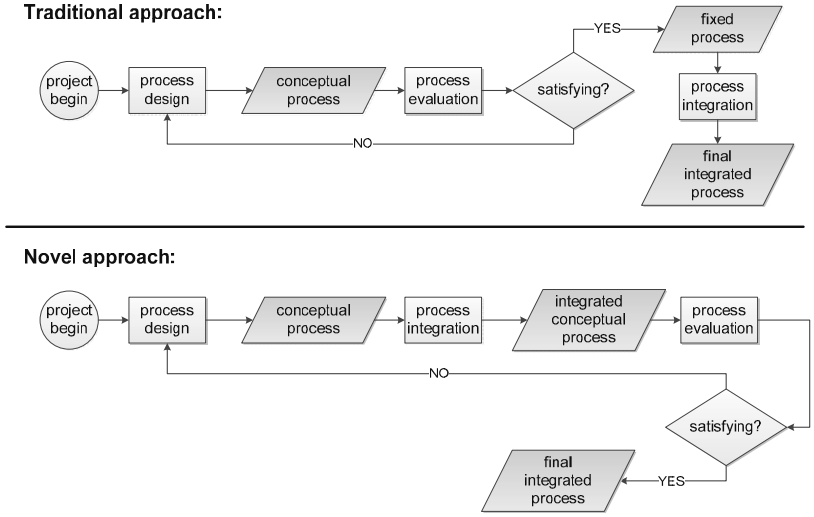

Figure 1: New optimisation approach

The concept is based on two scientific advancements: pinch analysis and multi-objective optimisation. Pinch analysis may be considered as a standard among modern analysis approaches. The development goes back to Linnhoff and Vredeveld (1984). Especially the graphical analysis approach based on the Composite Curves is an essential part of almost all recent analysis approaches. The concept of pinch analysis was extended to the level of site-wide energy analysis by Dhole and Linnhoff (1993), as well as Raissi (1994) and Klemeš et al. (1997) for the graphical methodology. The most recent developments in heat integration techniques are focusing on a wide-spread field of possible secondary objectives for the targeting and design of heat exchanger networks. Escobar et al. for example is investigating flexibility and controllability considerations (2013). Nam Sun et al. is proposing a new optimisation approach for the case of different types of utilities and heat exchanger designs (2013). Another objective of current research is the implementation of systems with heat losses or heat gains investigated by Wan Alwi et al. (2013).

Common for these state-of-the-art advancements in heat recovery methodologies is a fixed and already parameterised process layout defining the desired target temperatures, heat duties and heat capacity flow rates. Traditionally, this is following the idea of a hierarchical, sequential process design approach described by Douglas and Stephanopoulos (1995). Nevertheless does the chosen complexity of heat integration affect investment as well as operating costs just as the determination of process apparatuses or recycle streams do. Taking this reason into account it is very promising to include heat integration into the earlier steps of process design via a multi-objective evaluation.

2. Background foundation for optimisation

As already mentioned in the introduction the chosen approach for the incorporation of heat recovery measures into the procedure of process design is done by the analysis of investment and operating costs. In order to do so a typical multi-objective optimisation problem with constraints is mathematically formulated according to Equations 1 to 4.

$$f_o(\boldsymbol{x}) \qquad o = 1, 2, \dots, O \tag{1}$$

$$g_j(\boldsymbol{x}) \geq 0 \qquad j = 1, 2, \dots, J \tag{2}$$

$$h_k(\boldsymbol{x}) = 0 \qquad k = 1, 2, \dots, K \tag{3}$$

$$x_l^{LB} \leq x_l \leq x_l^{UB} \qquad l = 1, 2, \dots, L \tag{4}$$

A solution to this multi-objective optimisation is given by a vector of decision variables $\boldsymbol{x} = (x_1,\ x_2, \dots, x_L)^T$ that minimizes the dimensions o of the objective function $f_o(\boldsymbol{x})$. The solutions have to be subject to each inequality constraint $g_j(\boldsymbol{x})$ and each equality constraint $h_k(\boldsymbol{x})$. The solution space for each decision variable x_l is restricted to values within its lower bound x_l^{LB} and upper bound x_l^{UB}.

For the approach described by this work $f_1(\boldsymbol{x})$ would be a representation of the investment costs and $f_2(\boldsymbol{x})$ would be a representation of the operating costs. Both objective functions are dependent on the process parameterisation $\boldsymbol{x}$. In accordance to the aim of heat integration the vector of decision variables has to consist of all process variables that affect process temperatures, heat duties or heat capacity flow rates. Both objective functions have to be minimized for optimal solutions as shown in Figure 2.

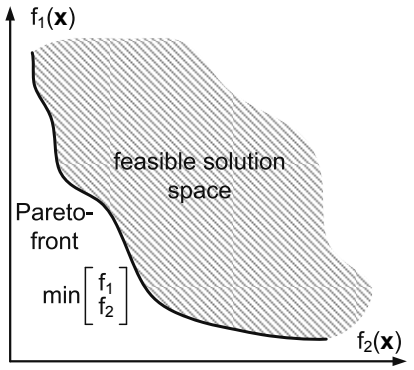

Figure 2: Illustration of a Pareto-front

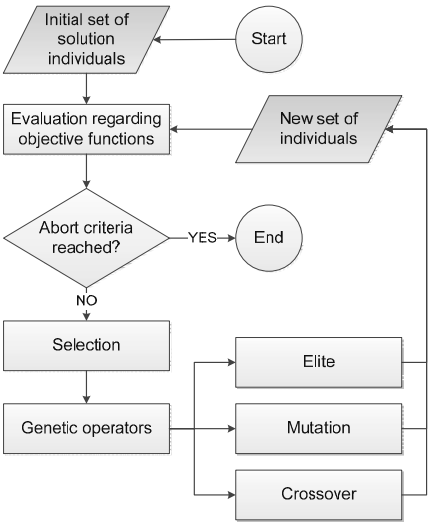

Figure 3: Flow chart for a genetic algorithm

3. Scientific implementation

The optimisation approach stated in Chapter 2 leads to a non-linear mixed integer problem type. It is obvious that rather than a single solution, multiple process design have to be evaluated for generating a Pareto-front consisting of the best solutions found. Proven methods for solving such kind of task are population-based stochastic algorithms. For the terms of this work a genetic algorithm was developed. A basic scheme for the method of operation is illustrated by Figure 3. Each solution candidate of the genetic algorithm is represented by a set of decision variables $\boldsymbol{x}$. A set of decision variables is directly related to a corresponding set of input variables of a computer aided flowsheet. The flowsheet calculation of each individual is used to complete the necessary data for the evaluation regarding the objective functions. A simplified example for a single reactor system is given by Figure 4.

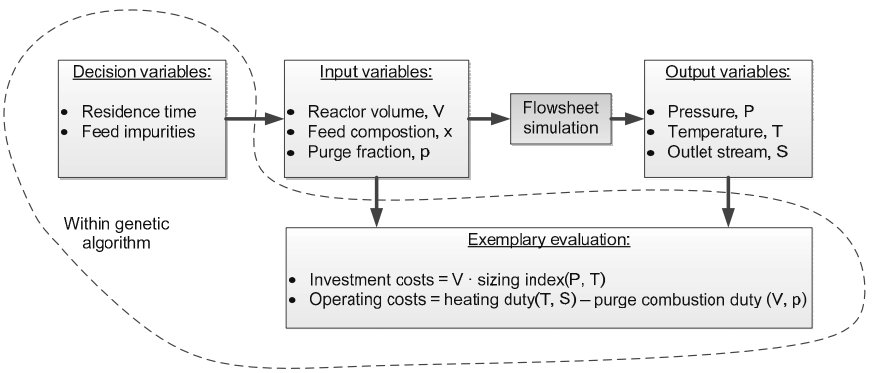

Figure 4: Relation between decision/input/output variables

4. Embedded targeting procedure

As far as the explanation from previous chapters go the investment costs as well as the operating costs are directly derived from the parameterisation of all process apparatuses. Taking direct heat recovery into account is a difficult task since the optimal heat exchanger network could be structurally different for each individual throughout the optimisation procedure. A possible solution would be the implementation of a heat exchanger superstructure to each flowsheet but the amount of decision variables would be rather large. This would result in a bad convergence behaviour.

In order to address this problem a pinch targeting step, novel in the case of multi-objective optimisation, is supposed. Heat exchangers for the purpose of direct heat integration between process streams or process units are completely removed from each individual flowsheet. Heating or cooling for process requirements is done solely by the use of utilities. The analysis of investment costs due to the acquirement of heat exchangers for direct heat integration as well as the analysis of operating costs due to the reduced utility consumption are uncoupled from the flowsheet and calculated separately. In terms of the notation introduced in Chapter 2 the mathematical background for the objective functions $f_1(\boldsymbol{x})$ and $f_2(\boldsymbol{x})$ is the following.

Investment costs:
$$f_1(\boldsymbol{x}) = \left(\sum_{i=1}^{I} f_{1,i}(\boldsymbol{x})\right) + t_1(\boldsymbol{x}) \tag{5}$$

Operating costs:
$$f_2(\boldsymbol{x}) = \left(\sum_{i=1}^{I} f_{2,i}(\boldsymbol{x})\right) + t_2(\boldsymbol{x}) \tag{6}$$

It can be seen that each objective function consists of a sum of the particular objective function values $f_{o,i}(\boldsymbol{x})$ for each apparatus i calculated with the help of the flowsheet simulation. In addition to this, an expression $t_1(\boldsymbol{x})$ for the investment costs and $t_2(\boldsymbol{x})$ for the operating costs calculated by the pinch targeting is added. An illustration is given by Figure 5. For the presented example the calculation of the pinch targeting for a set of composite curves provides the information about seven theoretical heat exchangers for the purpose of internal heat integration and as well as three units to satisfy the utility demand.

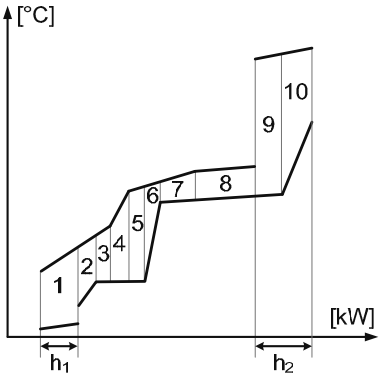

Figure 5: Pinch targeting at composite curves

$$t_1(\boldsymbol{x}) = \sum_{i=1}^{10} (a + b \cdot A_i^c) \tag{7}$$

$$t_2(\boldsymbol{x}) = d \cdot h_1 + e \cdot h_2 \tag{8}$$

With the help of the Equations 7 and 8 the addition to each objective function could be calculated. The investment costs are dependent on the area A_i of each theoretical heat exchanger modified by the costing parameters a, b and c. The operating costs are exclusively dependent on the required utility duty h_1 and h_2 modified by costing parameters d and e for hot or cold utility requirements. At this point it has to be said that the use of more complex economic models would also fit to the presented concept. The use of multiple utilities or other mathematical relations for different heat exchanger types may come to mind.

5. Technical implementation

In order to give a more complete description of the so far presented procedure a brief summary of the technical realisation will be given in this chapter. The genetic algorithm as well as the algorithm for composite curve calculation and targeting has been designed within the Matlab™ environment from MathWorks™. AspenPlus™ from AspenTech™ is used for the flowsheet simulation. The interface between those two is established by using an OLE (object linking and embedding) server. The server follows COM standard (component object model technology, Microsoft™) and is based on an DLL (dynamic link library) that is provided by AspenTech™. While the genetic algorithm could be designed using a different programming language, the full access on all simulation variables via a provided interface is crucial and not available for every commercial flowsheet simulator.

6. Conclusion

The fact that computational calculation speed doubles every two years is stated by the well-known Moore's law. This progress enables more and more advanced optimisation and design methodologies in the engineering sector. The design of a whole chemical process with overlaid multi-objective optimisation as it is presented within this document profits from this development due to the large calculation effort. Furthermore, the right choice of decision variables as well as the right setup of objective functions is crucial for comprehensive results. Apart from these drawbacks the presented concept can be easily extended by any kind of advanced targeting methodologies. Even for the presented targeting procedure it can be shown that a more detailed analysis of a process design is possible. The impact of applying this new procedure is presented by first analysis results in Figure 6 and Figure 7.

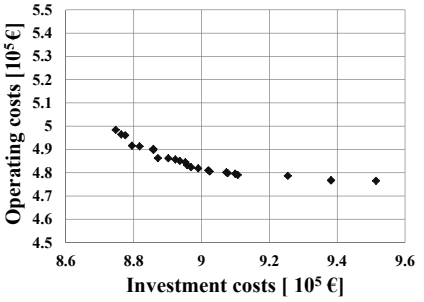

Figure 6: Results for novel approach

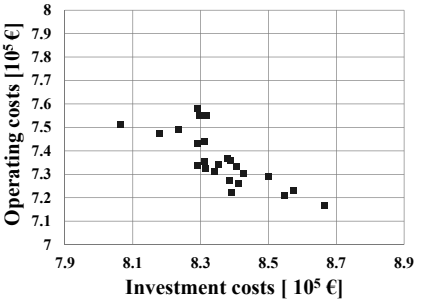

Figure 7: Corresponding results without targeting

The above presented results correspond to a process describing the dehydration of isopropanol to acetone (seven unit operations). Major decision variables have been the amount of separation stages, feed-stage and pressure of the distillation columns as well as the pressure, outlet temperature, length and amount of tubes for the tubular reactor. Figure 6 presents a front of Pareto optimal solutions for the last generation that has been calculated using the novel approach. Figure 7 presents the same individual solutions recalculated without the embedded targeting procedure of this work. It can be clearly identified that the new optimisation approach promotes solutions that otherwise would not participate in the final Pareto-front. It can be stated that the consideration of energy efficiency measures has an impact on the convergence behaviour of the genetic algorithm. Applying the new approach offers a more detailed insight while maintaining a wide variety of process alternatives to choose from.

Abstract

Fouling is a non-negligible problem to heat exchange operation, because it will cause sustained reduction to the overall heat transfer coefficient due to the growth of deposit over heat transfer surface of heat exchange equipments. Implementing regular (routine) cleaning is a recommendable means to remove fouling. As heat load distribution of parallel branches is related to split fractions, this paper presents an approach to arrange the cleaning schedule with having split fractions optimized concurrently. To avoid the numerous integer decision variables produced in time discretization method, the maximum allowable fouling resistance of a heat exchanger is taken as the optimization variable in this study. Then the proposed method is formulated into a Mixed Integer Nonlinear Programming (MINLP) model, to aim for the minimum operating cost of an existing HEN. At last of the study, an example from literature is studied, and the effectiveness of the method has been demonstrated by the proper results.

Keywords:heat exchanger network,optimization,fouling,cleaning schedule,split fraction

1. Introduction

The gradual accumulation of deposits over the surface of heat exchanger decreases heat transfer efficiency and generates fluctuation of the outlet temperatures of hot and cold streams. This phenomenon implies an increase in the extra utility consumption in the heat exchanger network(HEN). In the past two decades, scholars paid much attention on the fouling problem. Many measures were taken to mitigate the effect of fouling(Azad et al., 2011; Pan et al., 2013). Nevertheless, only periodic cleaning can effectively remove deposits and restore thermal performance of the equipment. Therefore determining the cleaning schedule of the heat exchanger network becomes a hot spot of researchers. Smaili et al.(1999) proposed the first formulation about cleaning management for an existing HEN aiming at the minimum steam consumption. Although improved algorithms(Smaili et al., 2002) were introduced subsequently, based on the

approach of time discretization , large amount of binary variables still formulated a mixed integer nonlinear programming (MINLP) model, resulting in the difficulty to solve the problem.

Until in the design of single heat exchanger, a maximum allowable fouling resistance was proposed in the optimization of the equipment design and cleaning policy(Caputo et al., 2011), which effectively reduced the number of decision variables. In HEN composed by multiple parallel branches, stream split fractions was demonstrated to affect the distribution of heat load in each branch. According to different fouling status of the existent heat exchangers, Oliveira Filho et al.(2009) investigated an alternative operating policy based on the optimization of stream splits aiming to the minimum operating cost. While the dynamic change of fouling wasn't considered. Taking the growth of fouling into account, this paper proposed an approach combined the optimization of split fractions with the optimal cleaning schedule aiming at the minimum operating cost in a existing HEN. In order to reduce complexity of the problem, the maximum allowable fouling resistance based on the literature was applied.

2. Problem description

Here the network configuration is fixed. A set of hot and cold streams with their heat capacity flow rates, inlet and outlet temperatures passing through the units are given and the initial split fractions of parallel branches are known. Assuming that all the heat exchangers are clean at the beginning, then an universal asymptotic fouling model was adopted to describe the deposits profile in the equipments.

The problem comprises two sets of decision variables. One is the maximum allowable fouling resistances, representing cleaning schedule, which will be expounded in the following part. The other is the split fractions, redistributing the flow rates of the hot and cold streams in each branch of the heat exchanger. They are both continuous variables, along with the state variables of the equipments, defining the optimization as a mixed integer nonlinear programming(MINLP) problem. The solution is found by using Genetic/Simulated Annealing(GA/SA) algorithm(Xiao et al., 2010).

3. NLP formulation for the optimization of split fractions and cleaning schedule

3.1. The maximum allowable fouling resistance

As most of the deposits involved in the petrochemical production grow asymptotically over time, an universal asymptotic fouling formation model is adopted to describe the growth of fouling represented with Eq. (1).

$$R(t) = R_f^{\infty}\left(1 - e^{-t^*/\tau}\right) \tag{1}$$

where R_f^{∞} and τ are empirical parameters obtained by experiments. t^* is the time elapsed since the exchanger was in the clean condition.

As shown in Figure. 1, heavy line represents no cleaning condition, thin lines represent periodic cleaning condition. By setting a maximum allowable fouling resistance, R_{all}, to define the threshold level, that is, when the fouling thermal resistance reach this value, the heat exchanger should be cleaned right now, below this value, the unit runs. As the fouling model is strictly monotonic function, each maximum allowable fouling resistance corresponds to a timing of the cleaning actions, T_{cy}.

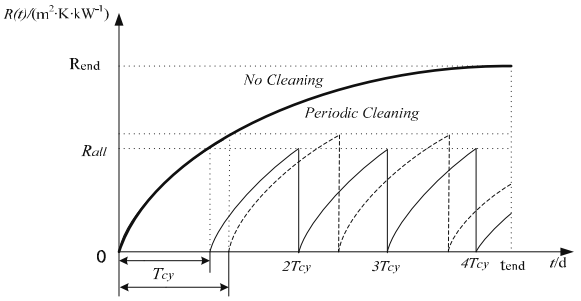

Figure 1. Scheme of a maximum allowable fouling resistance.

The following sets of indices are used to describe the network:
t is the number of days (1, . . . , T_{opr})
n is the unit number (1, . . . , NE)
where T_{opr} is the number of days that the HEN is operating and NE is the number of units. The total cleaning number of a unit, N_{cl}, can be calculated with Eq. (2).

$$N_{cl,n} = T_{opr} / T_{cy,n} \tag{2}$$

The selection of R_{all} is the key to solve the problem of cleaning schedule, referring to Figure. 1(thin and solid lines: smaller R_{all} ; thin and dashed line: larger one), the smaller is the R_{all}, the more cleaning actions should be taken, which will decrease the utility consumption yet produce more cleaning cost. There is a trade-off in the determination of R_{all} value.

3.2. Running state variables of heat exchangers

Each unit n over each day t is defined by a binary variable $Z_{t,n}$ where

$$Z_{t,n} = \begin{cases} 1 & \text{if unit n is on-line over day t} \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

It can be inferred that all the $Z_{t,n}$ equal to 1 except when the fouling thermal resistance reaches $R_{all,n}$, in other words, when the unit runs to $t = NT_{cy,n}$ (N=1,2,...,Ncl,n), it should be taken off-line or pass through other units if there are ones by a standby pass for cleaning. At that moment, $Z_{t,n}$ will change to 0.

3.3. Simulation of heat exchangers

The ε-NTU method is used to simulate heat exchangers suffering from different degrees of fouling. The method is based on three dimensionless parameters: CR, NTU, and ε.

Assuming the hot stream has lower heat capacity flow rate than the cold one, then the three parameters are defined as follows:

$$CR = \frac{FCp_h}{FCp_c} \tag{4}$$

$$NTU = U \cdot A / FCp_h \tag{5}$$

$$\varepsilon = \frac{1 - \exp\left[-NTU\left(1 - CR\right)\right]}{1 - CR\exp\left[-NTU\left(1 - CR\right)\right]} \tag{6}$$

In which, the overall heat transfer coefficient is related to that in the clean state by

$$U = 1/\left[1/U_{cl} + R(t)\right] \tag{7}$$

The outlet temperatures of hot and cold streams are expressed respectively as:

$$T_{h,out} = Z_{t,n} \cdot \varepsilon \cdot T_{c,in} + \left[1 - Z_{t,n} + Z_{t,n} \cdot \left(1 - \varepsilon\right)\right] \cdot T_{h,in} \tag{8}$$

$$T_{c,out} = Z_{t,n} \cdot CR \cdot \varepsilon \cdot T_{h,in} + \left[1 - Z_{t,n} + Z_{t,n} \cdot \left(1 - CR \cdot \varepsilon\right)\right] \cdot T_{c,in} \tag{9}$$

3.4. Modeling of parallel heat exchangers

As it is shown in Figure. 2, the hot and cold streams are separated into two branches, the heat capacity flow rate of each branch flowing through the No.1 heat exchanger is given by Eq. (10) and (11):

$$Fcp_{h,1} = x_h \cdot Fcp_h \tag{10}$$

$$Fcp_{c,1} = x_c \cdot Fcp_c \tag{11}$$

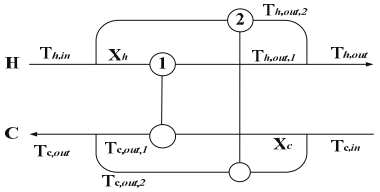

Figure 2. Schematic of parallel heat exchangers

in which x_h and x_c are the split fractions of hot and cold streams. The simulation of each heat exchanger is the same as above. It is worth mentioning that after flowing through the parallel units, each branch of hot or cold stream will be mixed,

$$T_{h,out} = x_h \cdot T_{h,out,1} + \left(1 - x_h\right) \cdot T_{h,out,2} \tag{12}$$

$$T_{c,out} = x_c \cdot T_{c,out,1} + \left(1 - x_c\right) \cdot T_{c,out,2} \tag{13}$$

But when one of parallel units is cleaned, it is advised to merge the stream which should be bypassed into the other one on-line instead. It is indicated that if $Z_{t,1}=0$, then $FCp_{c,2}=FCp_c$, $FCp_{h,2}=FCp_h$, $T_{c,out}=T_{c,out,2}$,$T_{h,out}=T_{h,out,2}$; similarly if $Z_{t,2}=0$.

3.5. Objective Function

The objective function to be minimized is the total operating cost over the time interval 0 to t_{end}, including extra energy required due to fouling, provided by heating and cooling utilities, C_E, and cleaning cost, C_{cl}.

$$obj = \min(C_E + C_{cl}) = \min[C_U \cdot \int_0^{t_{end}} (Q_{nofouling} - Q_{fouling\&cleaning}(t))dt + \sum_{n=1}^{NE} N_{cl,n} \cdot C_{cl,n}] \quad (14)$$

4. Case study

The optimization of split fractions and cleaning schedule using the above MINLP formulation will be demonstrated using an example from Oliveira Filho(2009). The optimal procedure was implemented in C++ Language.

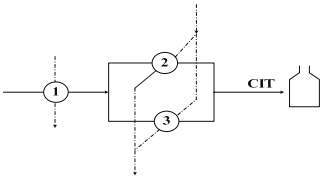

Figure 3. HEN for case study . solid line: cold streams; dotted lines: hot streams.

The parameters for case study is presented in Table 1. The HEN operates over 18 months starting from the clean state and the two splits of hot and cold stream passing through HEX 2 set to 0.5. The cost of furnace utility is taken as 0.01£/kWh. The each time cleaning cost $C_{cl,n}$ is 4000 £/unit.

Table 1. Parameters for Case Study

HEX	$T_{h,in}$/K	$T_{c,in}$/K	FCp_h /kW·K^{-1}	FCp_c /kW·K^{-1}	A/m^2	U_{cl} /kW·m^{-2}·K^{-1}	R_f^{∞} /(m^2·K·kW^{-1})	τ/d
1	523	373	49.84	100.08	800	0.2	4.68	120
2	623	439[a]	24.92	50.04	800	0.2	4.68	120
3	623	439[a]	24.92	50.04	800	0.2	9.35	120

[a]At the beginning/initial state

Table 2. Comparison of different optimization results

	Base Case	Case 1	Case 2
Operating Cost/£	192048	184858	172493
Utility Cost/£	192048	184858	164493
Cleaning Cost/£	—	—	8000
Split fraction	0.5 (H), 0.5 (C)	0.585 (H), 0.586 (C)	0.596 (H), 0.593 (C)
R_{all}/(m^2·K·kW^{-1})	Uncleaned	Uncleaned	4.00 (HEX 2)
Tcy/d			232 (HEX 2)

The results are displayed in Table 2. The extra energy consumption cost of the base case is 192048£ without cleaning. At first, only the split fraction is optimized(Case 1) while the fouling still grows, the optimal split fractions of hot and cold stream are 0.585 and 0.586, respectively. The extra utility caused by fouling is 184858£, which is 3.74% less compared with the base case. Then the split fractions and cleaning schedule are optimized simultaneously(Case 2), the optimal split fractions of hot and cold stream are

0.596 and 0.593, the total operating cost is 173944£. Besides the fuel consumption of furnace, the HEX 2 needs to be cleaned twice during the 18 months operation, which brings 6.69% less than the Case1.

5. Conclusions

This paper presents an approach that combined the optimization of split fractions with the optimal cleaning schedule. The maximum allowable fouling resistances were taken as the optimization instead of integer variables, effectively reducing the number of decision variables. The adjustment of split fractions made the allocation of heat load in the parallel units more reasonable, thus decreasing the total utility consumption of the heat exchanger networks to some extent. Cleaning actions could restore the heat transfer performance of equipments, further reducing the utility consumption.

Abstract

This paper discusses the design of water based heat collection system for recovery of industrial excess heat. The focus in on the problem of finding the optimal combinations of excess heat sources minimizing heat exchanger network capital costs for different amounts of total recovered heat. A cost targeting approach based on vertical heat transfer between hot process streams and the heat collection medium in Pinch Analysis diagrams is used. The set of process streams where heat shall be recovered is found by solving an optimization problem where heat recovery is maximized while minimizing the capital costs simultaneously. A genetic algorithm based optimization tool is used. The analysis is conducted for three plants belonging to a chemical cluster. The results are compared with results from previous investigations in which the process excess heat sources were chosen based on their incremental heat contribution. The new approach presented in this work allows identifying a much larger set of solutions as well as considerably lower capital costs for similar amount of recovered heat in cases when process streams largely differ in terms of temperature levels and heat transfer properties.

Keywords: heat exchanger network, excess heat, pinch analysis, optimization.

1. Introduction

Large amount of heat at medium and low temperatures is often dispersed from oil-refineries and petrochemical plants to the environment by means of water or air cooling. This heat can be to large extent recovered for different purposes such as for reducing on-site fuel demand by heat exchange with cold process streams (Hackl et al., 2011), for exporting heat to nearby urban areas by district heating networks (Morandin et al., 2014), or for producing electricity by means of organic Rankine cycles (Campana et al., 2013).

A practical way to reduce the complexity of new installations, to avoid extensive process retrofit, and to avoid potential hazard of process leaks, is to use heat collection systems based on water or oil loops. Water (or oil) is used to cool hot process streams and, once heated, to provide heat to cold process streams, to a district heating network, to a centralized power plant, etc.

Feasibility studies were recently conducted on heat recovery and excess heat export from a chemical cluster in the Swedish West Coast (Morandin et al., 2014). About 230 MW of heat can be potentially recovered from the chemical cluster which could be for instance delivered to a regional district heating network. However, this could represent a prohibitive investment in infrastructures both for the industries and for the municipal

utility companies. It is therefore interesting to consider a large range of possible heat recovery capacities, and not only the maximum amount of cluster excess heat. In addition, since revenues from excess heat utilization depend on the application, it is convenient to study the profitability of excess heat utilization by separating the capital costs estimation procedure from the actual profitability analysis.
In this work we tackle the problem of finding the optimal combinations of excess heat sources from three industrial plants of the aforementioned chemical cluster that minimize heat exchanger network capital costs for different amounts of total recovered heat. This implies to generate multiple heat exchanger network solutions to cover the large range of heat recovery capacity.
This study can be considered a particular case of heat exchanger network synthesis where only one cold stream (the cold side of the heat collection system) appears. Heat exchanger network synthesis is a rather old problem and a variety of methods were proposed in the past. While heuristic methods appears of easier implementation (Sun & Luo, 2011), more elegant problem formulations were proposed based on mathematical programming based on sequential (Anantharaman et al., 2010) or simultaneous (Laukkanen & Fogelholm, 2011) approaches.
Here we opted for a capital cost targeting method based on Pinch Analysis diagrams (Kemp, 2007) and avoided the rigorous syntheses of multiple heat exchanger networks. Still, we need to establish a priori the set of process streams where heat shall be recovered.
In a previous study where the district heating application was considered, a procedure was developed to organize the excess heat sources according to their maximum incremental contribution to district heating delivery capacity, based on the idea that the number of process streams should be minimized to minimize the complexity and therefore the total capital costs (Morandin et al., 2014). We are aware that these combinations of process heat sources might only represent suboptimal subset of solutions. Here, we take a step further in our methodology by introducing a two-objective discrete optimization problem where the excess heat sources are assigned binary variables and a genetic algorithm is used to sort out the front of optimal arrays of excess heat sources that maximize the amount of recovered heat by minimizing the investment simultaneously.
The analysis is conducted for three plants belonging to the chemical cluster with more than twenty excess heat sources each and where the maximum theoretical level of heat that can be recovered is of the same order of magnitude (between 50 and 70 MW).

2. Methodology

Pinch Analysis was used in this work for estimating the amount of heat that can be recovered from process excess heat sources by water based heat collection system. The heat contributions of the process streams that are today cooled by cold water or air are aggregated in a hot composite curve. The heat recovery target is estimated considering counter-current heat transfer with the cold side of the heat collection system. Note that the send and return temperatures of the heat collection system affect the heat recovery potential as well as the type and profitability of excess heat utilization and therefore should be regarded as design variables. However, we decided to leave this aspect to future investigations and these temperatures are here kept at constant values decided with the help of industrial partners (send:54 °C, return:84 °C). For a given array of process excess heat sources, the heat recovery potential is estimated by the condition in which the water thermal profile is at a minimum temperature difference (here 10 °C)

from hot composite curve (pinch point). In practice this was calculated by solving a linear programming problem where the heat transfer feasibility is formulated with a set of linear inequality constraints (Morandin, 2013).

Following the so-called area targeting method (Kemp, 2007), the heat exchanger network capital cost is estimated considering vertical heat transfer between the excess heat sources and the water thermal profile as it appears in the composite curve diagram. In particular, the diagram is divided in enthalpy intervals where the hot composite has constant slope. Since the cold side of the heat collection system is the only cold stream, in each enthalpy interval the number of required heat exchangers is equal to the number of excess heat sources involved.

The investment costs on the heat collection system I_{HCS} for a given array of process heat sources are estimated as in Eq. (1), according to costing methodology in common chemical engineering reference books (Turton et al., 2008). It consists in a sum of heat exchanger purchase cost calculated for each stream *h* belonging to each enthalpy interval *e* of the composite curve diagram where heat recovery occurs $(e \in HCS)$. Heat exchanger cost is a function of the heat transfer surface and ultimately of the stream heat capacity c_h, its mass flow rate $\dot{m}_h$, its inlet and outlet temperature in the enthalpy interval $T_{h,e}^{1}$ and $T_{h,e}^{2}$, the water inlet and outlet temperatures in the enthalpy interval $T_{HCS,e}^{1}$ and $T_{HCS,e}^{2}$, the stream specific global heat transfer coefficient U_h, as well as the type and material of heat exchangers. This sum is then multiplied with the *Lang* factor to account for other installation costs including piping and instrumentation. The reader is referred to a previous publication for the complete formulation of investment cost calculations (Morandin et al., 2014).

$$I_{HCS} = Lang \cdot \sum_{e \in HCS} \sum_{h} f(c_h, \dot{m}_h, T_{h,e}^{1}, T_{h,e}^{2}, T_{HCS,e}^{1}, T_{HCS,e}^{2}, U_h) \tag{1}$$

The above procedure for heat and cost targeting applies for a given array of process excess heat sources. The ultimate question we try to address here is which streams should be involved in the heat recovery. The number of combinations of excess process streams is 2^n with n the number of available process excess heat sources, so the comparison of the complete set is not feasible and not that interesting.

Based on the assumption that the cost of a heat exchanger network is highly determined by the number of streams involved, in a previous work (Morandin et al., 2014) it was decided to investigate a particular subset of excess heat sources that, in a suggested order, allow maximum heat recovery. The order in which the process excess heat sources should be picked up was established by a sorting algorithm where at the *h*-th step (n-*h*) composite curve diagrams are built by combining the already sorted (*h*-1) streams with each of the remaining streams and the resulting heat recovery targets are compared to find the *h*-th stream allowing the maximum increment. Note that this procedure converges after n(n-1)/2 steps and therefore significantly reduces the combinatorial complexity of the analysis.

However, since the process heat sinks have different temperature levels and heat transfer characteristics, a stream may introduce a large heat contribution at the expenses of a very large heat transfer area. In addition, since the *h*-th stream array includes the (*h*-1)-th array, early suboptimal solutions compromise subsequent solutions.

To study such issues and to possibly overcome them in the future while still retaining the Pinch Analysis cost targeting procedure, a two-objective discrete optimization

procedure is introduced in this work. Each stream is assigned a binary variable i_h and, when i_h is equal to 1, is included in a candidate stream array for which the investment costs are calculated. A genetic algorithm is used to find the Pareto front of stream arrays simultaneously maximizing the amount of recovered heat and minimizing the capital costs as symbolically shown in Eq.(2), where Q_{rec} is the heat recovery target estimated by means of composite curve diagrams as described in (Morandin et al., 2014), I is the total investment which consists of heat collection system capital costs I_{HCS}, calculated for the active streams ($i_h = 1$) and the extra investment in coolers for those candidate streams which heat cannot be fully recovered by the heat collection system ($e \notin HCS$) due to too low temperature levels.

$$\begin{aligned} &\max Q_{rec} = g(i_1, i_2, \ldots, i_h, \ldots, i_n) \\ &\min I = I_{\mathrm{HCS}} + \sum_{\substack{h, i_h = 1 \\ e \notin HCS}} I_h^{cooler} \end{aligned} \tag{2}$$

Note that it is necessary to include this second argument in order for the investment objective to be sensitive to the activation of those streams which do not contribute to the heat recovery (first objective) although this does not represent a real capital cost since coolers are already available at the process site. If this argument is omitted, streams arrays requiring extra cooling than what provided by the heat collection system (e.g. because one or more stream appear at too low temperature levels) are retained during the genetic algorithm based optimization thus leading to a Pareto front with a big share of uninteresting solutions.

The Matlab based GA optimization was carried out with generations of 1000 individuals, 80 % created by crossover, of which 350 are retained in the Pareto front. A stopping criterion of no more than 3 generation with a change in Pareto spread less than 10^{-6} tolerance was used.

3. Results

An optimization problem was solved for each of the three plants under investigation. Depending on the plat under investigation, the total number of stream arrays evaluated varied between 20,000 and 70,000 and the computing time varied between around 2 to 5 hours in a 2.7 GHz Intel Core PC. The results are shown in Figure 1 to 6.

The Pareto fronts showing the solutions maximizing the amount of heat recovery while minimizing the investment costs in the heat collection system are shown in Figure 1, 3, 5 for the three plants respectively. In the same figures the solutions obtained with previously developed approach where the excess heat sources are sorted in descending order according to their maximum incremental contribution to the heat recovery are also shown. 30 % error bars are also added to the latter solutions to discuss the actual improvement obtained with the discrete optimization method compared to this previously developed method. This appears the maximum accuracy of heat exchanger network cost estimation in reference books (Turton et al., 2008) and applies also to the solutions on the Pareto front although error bars are omitted for sake of clarity. It should also be added that the Pinch Analysis area and unit targeting approach may introduce an additional bias in our estimation compared to other more rigorous heat exchanger network design approaches.

Figures 2, 4, and 6 show the number of excess heat sources involved for different amount of recovered heat for the three plants respectively and provide further insights about how solutions involving fewer streams but with large heat transfer areas compete with those involving more streams but with smaller heat transfer areas.

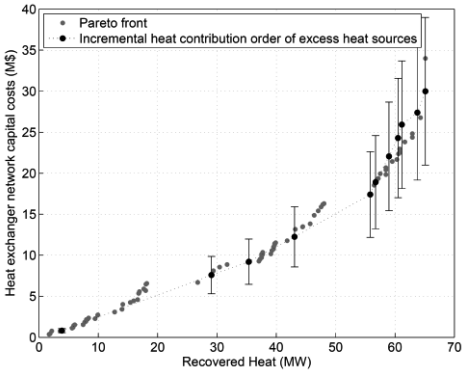

Figure 1: Capital costs, plant A.

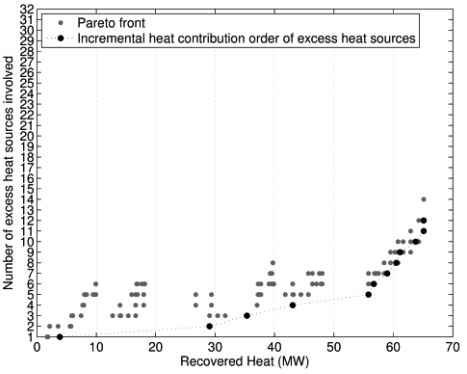

Figure 2: Excess heat sources involved, plant A.

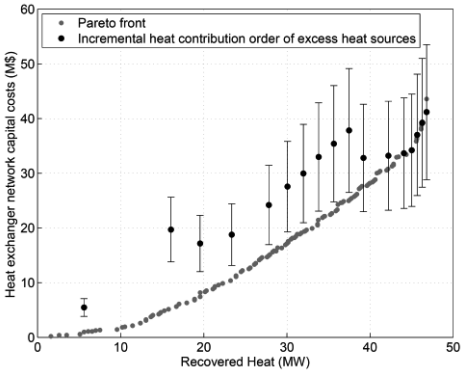

Figure 3: Capital costs, plant B.

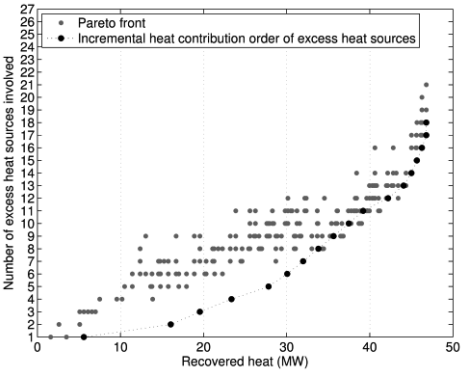

Figure 4: Excess heat sources involved, plant B.

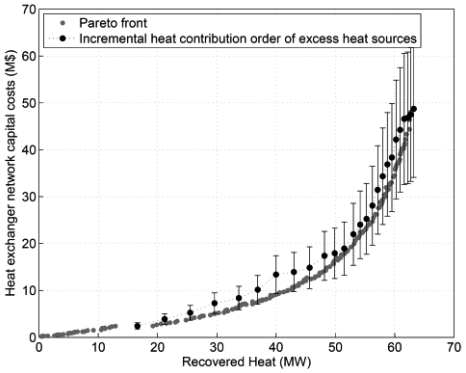

Figure 5: Capital costs, plant C.

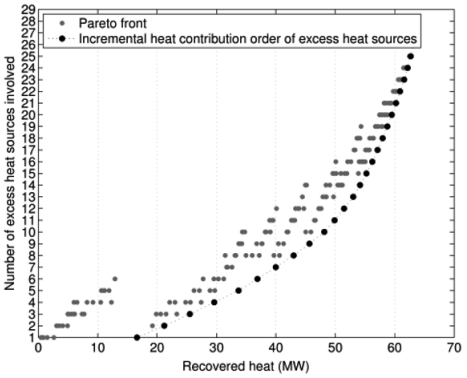

Figure 6: Excess heat sources involved, plant C.

The stream selection criterion based on the maximum incremental heat contribution order gives close to optimal solutions for plant A and plant C but substantially fails in the case of plant B. In this plant few process streams with very large heat contribution have poor heat transfer properties and are at low temperature levels and therefore compromise the selection of optimal arrays at even larger total amount of recovered heat if the old selection criterion is used. This is better shown in Figure 4 where the Pareto front solutions are based on considerably larger number of excess heat sources than the minimum baseline found with the previous approach.
With the discrete optimization based approach the whole optimal front of combinations of excess heat sources is mapped. This allows not only to pinpoint specific solutions which can be further refined in future investigations but also to highlight significant discontinuities in the optimal solution front such as in Figure 1 (plant A). These discontinuities can be in fact responsible for interesting leaps in profitability since much larger heat recovery can be obtained for very little increase in capital costs.

4. Conclusions

A discrete optimization procedure for selection of optimal arrays of process excess heat sources maximizing the amount of recovered heat while minimizing the capital costs of the heat collection system was developed and applied to the analysis of three plants belonging to a Swedish chemical cluster. The optimization results were compared with a previously developed short cut method for the selection of excess heat sources and showed that the understanding of the capital cost factors such as number of heat exchangers and total heat transfer surface can be significantly improved but is case dependent. In the best case, capital costs on heat collection system could be minimized by more than 30 % with respect to the solutions found with the previous method.

Abstract

The ability to determine enclosures for the image set of nonlinear functions is pivotal to many applications in engineering. This paper presents a method for the systematic construction of ellipsoidal extensions of factorable functions. It proceeds by lifting the ellipsoid to a higher dimensional space for every atom operation in the function's directed acyclic graph, thereby accounting for dependencies. We present theoretical results regarding the quadratic Hausdorff convergence of the computed enclosures. Moreover, we propose an efficient implementation, whereby the shape matrix of the lifted ellipsoid is stored in sparse format, and every atom operation corresponds to a sparse update in that matrix. We illustrate these developments with two numerical examples.

Keywords: Ellipsoids, Function Bounding, Interval Arithmetic

1. Introduction

The ability to compute tight enclosures of the image set of nonlinear functions is pivotal to many methods in global and robust optimization (Tawarmalani and Sahinidis, 2004; Stuber and Barton, 2011), reachability analysis (Althoff et al., 2008), uncertainty analysis (Rao and Berke, 1997), guaranteed parameter estimation (Jaulin and Walter, 1993), etc. For real-valued, factorable functions, interval arithmetic (Moore et al., 2009) provides a natural way of computing such enclosures, since the image set of any continuous function is itself an interval. In practice, an interval enclosure can be obtained by traversing a directed acyclic graph (DAG) of the function in order to bound its atom operations recursively and as tightly as possible (Schichl and Neumaier, 2005). Although simple, this approach suffers two main limitations, namely the dependency problem and the wrapping effect. The former happens when multiple occurrences of the same variable, e.g. in a complicated function expression, are treated as if they were independent from each other. The latter is due to the fact that the image of an interval vector under a vector-valued function, even a linear linear function, is generally not an interval vector itself, thus leading to overestimation in enclosing that image set with an interval vector (Lohner, 2001).

This paper presents a method for the systematic construction of ellipsoidal extensions of factorable functions. The algorithm starts with an ellipsoid containing the uncertainty host set and proceeds by adding an extra dimension (lifting) for every atom operation in the DAG. This is similar in essence to the construction of polyhedral relaxations using a decomposition-linearization approach (Tawarmalani and Sahinidis, 2004), with the added benefit of a well-developed ellipsoidal calculus (Kurzhanski and Vályi, 2004). We also analyze how fast the computed enclosures converge to the exact image as the uncertainty set is reduced, using the concept of Hausdorff convergence order (Bompadre and Mitsos, 2012), and we develop an efficient implementation as part of the software package MC++ (`https://projects.coin-or.org/MCpp`).

The remainder of the paper is organized as follows. After defining the problem in Sect. 2, we describe the construction of ellipsoidal extensions of factorable functions in Sect. 3. Theoretical

results regarding the Hausdorff convergence of the computed enclosures are presented in Sect. 4. Then, we discuss important implementation details in Sect. 5, and illustrate mitigation of both the dependency and wrapping effects with numerical examples. Finally, Sect. 6 concludes the paper.

Notation. Besides standard mathematical notation, the diameter of a compact set $Z \subseteq \mathbb{R}^n$ is defined by $\mathrm{diam}(Z) = \max_{z1,z2\in Z} \|z_1 - z_2\|$. The Minkowski sum of two compact sets Z, W is $W \oplus Z := \{w+z \,|\, w \in W, z \in Z\}$. If $W \subseteq Z$ the Hausdorff metric between these sets is given by $d_{\mathrm{H}}(W,Z) := \max_{z\in Z} \min_{w\in W} \|w-z\|$. An n-dimensional ellipsoid is defined as:

$$\mathscr{E}(q,Q) \;:=\; \left\{ q + Q^{\frac{1}{2}} v \;\middle|\; \forall v \in \mathbb{R}^n,\; v^{\mathsf{T}} v \leq 1 \right\} \;\in\; \mathbb{E}^n \,,$$

where $\mathbb{E}^n$ denotes the class of n-dimensional ellipsoids, the vector $q \in \mathbb{R}^n$ and the positive semidefinite matrix $Q \in \mathbb{S}^n_+$ are respectively the center and the shape matrix of the ellipsoid.

2. Problem Formulation

Consider a function $f : \mathbb{R}^{n_x} \to \mathbb{R}^{n_f}$, with its argument $x \in \mathbb{R}^{n_x}$ contained in the ellipsoid $\mathscr{E}(q_x, Q_x) \in \mathbb{E}^{n_x}$. The exact image of $\mathscr{E}(q_x, Q_x)$ under the function f is defined as

$$f(\mathscr{E}(q_x,Q_x)) \;:=\; \{f(x) \,|\, x \in \mathscr{E}(q_x,Q_x)\}\,. \tag{1}$$

The main focus of this paper is on computing an enclosure of the image set of f in the form of an ellipsoid $\mathscr{E}(q_f, Q_f)$; that is, $\mathscr{E}(q_f,Q_f) \supseteq f(\mathscr{E}(q_x,Q_x))$ with $(q_f,Q_f) \in \mathbb{R}^{n_f} \times \mathbb{S}^{n_f}_+$.

The main assumption we make to enable this construction is that the function f must be factorable, i.e. it can be decomposed into a finite number N of atom operations a_i from a finite library, such as binary addition, binary product, and outer composition with a univariate function. In particular, factorable functions can be evaluated by setting $u^0(x) = x$ and applying the recursive rule

$$\forall i \in \{1,\ldots,N\}, \quad u^i(x) \;=\; g_i(u^{i-1}(x)) \;:=\; \begin{pmatrix} u^{i-1}(x) \\ a_i(u^{i-1}(x)) \end{pmatrix}, \tag{2}$$

so that $f(x) = P u^N(x) = P[g_N \circ g_{N-1} \circ \ldots \circ g_1](x)$, where $P \in \mathbb{R}^{n_f \times (n_x+N)}$ is a projection matrix selecting the appropriate components. The j-th component of $u^i(x)$ is denoted as $u^i_j(x)$ subsequently.

The main problem addressed in this paper is the development of a constructive approach for an ellipsoidal extension $f^{\mathbb{E}} : \mathbb{E}^{n_x} \to \mathbb{E}^{n_f}$ of the factorable function f, whose image $f^{\mathbb{E}}(q_x,Q_x)$ yields the ellipsoidal enclosure, $\mathbb{E}(q_f,Q_f) := f^{\mathbb{E}}(q_x,Q_x) \supseteq f(\mathscr{E}(q_x,Q_x))$.

3. Ellipsoidal Arithmetic for Factorable Functions

The proposed algorithm proceeds by lifting the ellipsoid to a higher dimensional space for every atom operation in the function's DAG upon application of an ellipsoidal arithmetic. Starting with an ellipsoid $\mathscr{E}(q^0,Q^0) \in \mathbb{E}^{n_x}$ with $q^0 := q_x$ and $Q^0 := Q_x$, an ellipsoidal extension of each factor g_i, $i = 1,\ldots,N$ is obtained such that $g_i^{\mathbb{E}}(\mathscr{E}(q^{i-1},Q^{i-1})) = \mathscr{E}(q^i,Q^i)$, with

$$q^i := \begin{pmatrix} q^{i-1} \\ \lambda^i \end{pmatrix} \quad \text{and} \quad Q^i := \begin{pmatrix} I_{i-1} \\ \Lambda^i \end{pmatrix} Q^{i-1} \begin{pmatrix} I_{i-1} \\ \Lambda^i \end{pmatrix}^{\mathsf{T}}. \tag{3}$$

Here, $I_{i-1} \in \mathbb{R}^{(n_x+i-1)\times(n_x+i-1)}$ denotes the identity matrix; and the lifting parameters $\lambda^i \in \mathbb{R}$ and $\Lambda^i \in \mathbb{R}^{n_x+i-1}$ (row vector) depend on the functional form of the corresponding atom operation a_i. When the initial host set is not an ellipsoid but an interval box, the algorithm can be initialized by enclosing it within an ellipsoid. This adds the benefits of quadratic convergence and wrapping mitigation from ellipsoids at the cost of some initial overestimation.

At the end, the ellipsoidal extension $f^{\mathbb{E}}$ of f is retrieved by projecting the lifted ellipsoid $\mathscr{E}(q^N, Q^N) \in \mathbb{E}^{n_x+N}$ onto $\mathbb{R}^{n_f}$, giving

$$f^{\mathbb{E}}(q_x, Q_x) \;:=\; \mathscr{E}(q_f, Q_f) \;=\; P \times \mathscr{E}(q^N, Q^N)\,.$$

The following two subsections describe ways that such lifting parameters can be constructed for both linear and nonlinear atom operations.

3.1. Affine Atom Operations

Consider those operations $u^i(x) := g_i(u^{i-1}(x))$, where the atom operation a_i is an affine function of at most two factors $u_k^{i-1}(x)$, $u_m^{i-1}(x)$ with $k,m \leq i-1$. This corresponds to the case of addition, subtraction, scaling and shifting.

Addition and Subtraction Operations, $u_k^{i-1}(x) \pm u_m^{i-1}(x)$. The lifting parameters are given by:

$$\lambda^i := q_k^{i-1} \pm q_m^{i-1} \quad \text{and} \quad \Lambda_j^i := \begin{cases} 1 & \text{if } j = k, \\ \pm 1 & \text{if } j = m, \\ 0 & \text{otherwise.} \end{cases} \tag{4}$$

Scaling Operation, $\alpha u_k^{i-1}(x)$ for some $\alpha \in \mathbb{R}$. The lifting parameters are given by:

$$\lambda^i := q_k^{i-1} \quad \text{and} \quad \Lambda_j^i := \begin{cases} \alpha & \text{if } j = k, \\ 0 & \text{otherwise.} \end{cases} \tag{5}$$

Shifting Operation, $u_k^{i-1}(x) + \beta$ for some $\beta \in \mathbb{R}$. The lifting parameters are given by:

$$\lambda^i := q_k^{i-1} + \beta \quad \text{and} \quad \Lambda_j^i := \begin{cases} 1 & \text{if } j = k, \\ 0 & \text{otherwise.} \end{cases} \tag{6}$$

3.2. Nonlinear Atom Operations

Consider the operation $u^i(x) = g_i(u^{i-1}(x))$, where the atom operation a_i is a possible nonlinear function of the sole factor $u_k^{i-1}(x)$ with $k \leq i-1$ first. Note that the domain $D_i \subseteq \mathbb{R}$ of a_i is given by the projection of the ellipsoid $\mathscr{E}(q^{i-1}, Q^{i-1})$ onto its k-th component, given by $D_i := q_k^{i-1} + \sqrt{Q_{k,k}^{i-1}}\,[-1,1]$. In particular, we make the assumptions that: (i) D_i is included within the domain of definition of a_i throughout—this is relevant, for instance, for the univariate functions $z \mapsto \log(z)$, $z \mapsto 1/z$, $z \mapsto \sqrt{z}$, etc; and (ii) the function a_i is Lipschitz continuous.

One way of handling the nonlinear factor g_i involves constructing a linear estimator such that

$$\forall v \in \mathscr{E}(q^{i-1}, Q^{i-1}), \quad g_i(v) \;:=\; \begin{pmatrix} v \\ a_i(v) \end{pmatrix} \;\in\; \left\{ \begin{pmatrix} 0_{i-1} \\ \gamma_0^i \end{pmatrix} + \begin{pmatrix} I_{i-1} \\ \gamma_1^i e_k^\mathsf{T} \end{pmatrix} v \right\} \oplus \begin{pmatrix} \{0_{i-1}\} \\ [-\delta^i, \delta^i] \end{pmatrix}, \tag{7}$$

whereby the scalars γ_0^i, γ_1^i and δ^i can be derived, for instance, from a Taylor model or, better, a Chebyshev model of order $q \geq 1$ of the atom operation a_i on D_i (Neumaier, 2003; Rajyaguru et al., 2014); the latter is more advantageous in that it can be applied to nonsmooth atom operations, too. In (7), e_k stands for the kth basis vector and 0_{i-1} is a zero vector of size $i-1$.

The lifting operation proceeds in two steps. In the first step, the linear part of (7) is absorbed into the a lifted ellipsoid $\mathscr{E}(q^i, \tilde{Q}^i)$ in a procedure that is similar to the one used for shifting and scaling in (5)-(6), here with the lifting parameters

$$\lambda^i := \gamma_0^i \quad \text{and} \quad \Lambda_j^i := \begin{cases} \gamma_1^i / \operatorname{rad}(D_i) & \text{if } j = k, \\ 0 & \text{otherwise.} \end{cases} \tag{8}$$

In the second step the interval $[-\delta^i, \delta^i]$ enclosing the nonlinearity is added to the ith component of the lifted ellipsoid, in the Minkowski sense. Since the set of n-dimensional ellipsoids is not closed under Minkowski addition, we use an ellipsoidal extension of the Minkowski sum so that $\mathscr{E}(q^i, Q^i) := \mathscr{E}(q^i, \tilde{Q}^i) \oplus^{\mathbb{E}} \mathscr{E}(\Delta^i)$, with $\Delta^i := (\delta^i)^2 (e_i e_i^{\mathsf{T}}) \in \mathbb{S}^{n_x+i}$. We compute the shape matrix Q^i as:

$$Q^i := \frac{1}{\mu_0}\tilde{Q}^i + \frac{1}{\mu_1}\Delta^i \quad \text{with} \quad \mu_0 = 1 - \mu_1 = \frac{\sqrt{\mathrm{Tr}\left(\tilde{Q}^{i-1}\right) + \varepsilon}}{\sqrt{\mathrm{Tr}\left(\tilde{Q}^{i-1}\right) + \varepsilon} + \sqrt{\mathrm{Tr}\left(\Delta^i\right) + \varepsilon}}. \tag{9}$$

It is important to note that, since the Minkowski sum between two ellipsoids always introduces some overestimation, a nonlinear operation cannot be approximated exactly as with intervals.

Finally, in the case of binary product operations, the atom operation a_i is a bilinear term between two factors $u_k^{i-1}(x), u_m^{i-1}(x)$ with $k, m \leq i-1$. We use a simple DC-decomposition approach to yield an ellipsoidal enclosure of the bilinear terms. Rewriting them in the form

$$u_k^{i-1}(x) \times u_m^{i-1}(x) = \frac{1}{4}\left[(u_k^{i-1}(x) + u_m^{i-1}(x))^2 - (u_k^{i-1}(x) - u_m^{i-1}(x))^2\right], \tag{10}$$

we can apply recursively the rules of binary addition/subtraction and univariate composition for the square function $z \mapsto z^2$, as explained earlier. As an alternative, and potentially tighter, approach, one can envisage the use of semi-definite programming (SDP) to handle bilinear terms.

4. Convergence Analysis

We now turn our attention to analyzing the theoretical convergence properties of the ellipsoidal arithmetic presented in the previous section. An ellipsoidal extension $f^{\mathbb{E}}$ of f is said to have Hausdorff convergence order $q \geq 1$ on $\mathbb{E}^{n_x}$ if

$$d_{\mathrm{H}}\left(f^{\mathbb{E}}(\mathscr{E}(q_x, Q_x)), f(\mathscr{E}(q_x, Q_x)))\right) \leq \mathbf{O}(\mathrm{diam}(\mathscr{E}(q_x, Q_x))^q), \tag{11}$$

for every domain $\mathscr{E}(q_x, Q_x) \in \mathbb{E}^{n_x}$ with sufficiently small diameter where $f^{\mathbb{E}}$ is defined. The following result relates the convergence order of a factorable function to that of its atom operations.

Theorem 1. *If all the atom operations a_i in the DAG of a factorable function f are Lipschitz continuous and their ellipsoidal extensions have image Hausdorff convergence order q, then the ellipsoidal extension of f itself has image Hausdorff convergence q.*

Proof. The result follows by finite induction over the atom operations, using the triangle inequality for the Hausdorff metric d_{H} and the Lipschitz continuity of each atom operation a_i. □

We now present the main result of this section.

Theorem 2. *Let all the atom operations a_i in the DAG of a factorable function f be twice-continuously differentiable, and consider the ellipsoidal extension $f^{\mathbb{E}}$ of f as constructed from the lifting procedure in Sect. 3. Then, $f^{\mathbb{E}}$ has quadratic Hausdorff convergence on $\mathbb{E}^{n_x}$.*

Proof. We show that the ellipsoidal extension of each atom operation have quadratic Hausdorff convergence, so the result follows from Theorem 1 with $q = 2$. Since the class of ellipsoids is closed under affine transformations, all the extensions for affine atom operations in Sect. 3.1 are exact, and hence have infinite Hausdorff convergence order. Since binary product operations are handled by a combination of affine operations and univariate nonlinear operations, the Hausdorff convergence order of the extension $f^{\mathbb{E}}$ is completely determined by the Hausdorff convergence order of the latter. Consider the operation $g_i(u^{i-1}(x))$ where the atom operation a_i is a nonlinear

function of the sole factor $u_k^{i-1}(x)$ with $k \leq i-1$, and assume without loss of generality that $\mathscr{E}(q^{i-1}, Q^{i-1})$ is centered at zero (mainly for notation simplicity). By construction of $g_i^{\mathbb{E}}$ and invariance of ellipsoids under affine transformations, the ellipsoidal approximation $\mathscr{E}(\tilde{Q}^i)$ matches the exact image of the linear part in (7). The exact image of the corresponding residual term is

$$\Gamma := \left\{ g_i(v) - \begin{pmatrix} 0_{i-1} \\ \gamma_0^i \end{pmatrix} + \begin{pmatrix} I_{i-1} \\ \gamma_1^i e_k^\mathsf{T} \end{pmatrix} v \;\middle|\; v \in \mathbb{E}(Q^{i-1}) \right\}.$$

Then, we have:

$$\begin{aligned} d_\mathrm{H}\left(\mathscr{E}(Q^i), g_i(\mathscr{E}(Q^{i-1}))\right) &= d_\mathrm{H}\left(\mathscr{E}(\tilde{Q}^i) \oplus^{\mathbb{E}} \mathscr{E}(\Delta^i), \mathscr{E}(\tilde{Q}^i) \oplus \Gamma\right) \\ &\leq d_\mathrm{H}\left(\mathscr{E}(\tilde{Q}^i) \oplus^{\mathbb{E}} \mathscr{E}(\Delta^i), \mathscr{E}(\tilde{Q}^i)\right) + d_\mathrm{H}\left(\mathscr{E}(\tilde{Q}^i), \mathscr{E}(\tilde{Q}^i) \oplus \Gamma)\right) \\ &\leq d_\mathrm{H}\left(\mathscr{E}(\tilde{Q}^i) \oplus^{\mathbb{E}} \mathscr{E}(\Delta^i), \mathscr{E}(\tilde{Q}^i)\right) + \mathbf{O}\left(\operatorname{diam}(\Gamma)\right) \\ &\leq \mathbf{O}\left(\operatorname{diam}\left(\mathscr{E}(\Delta^i)\right)\right) + \mathbf{O}\left(\operatorname{diam}(\Gamma)\right), \end{aligned}$$

where the last inequality follows from the definition of the ellipsoidal extension of the Minkowski sum in (9). The result is obtained by noting that

$$\operatorname{diam}(\Gamma) \leq \mathbf{O}\left(\operatorname{diam}(\mathscr{E}(Q^{i-1}))^2\right) \quad \text{and} \quad \operatorname{diam}\left(\mathscr{E}(\Delta^i)\right) \leq \mathbf{O}\left(\operatorname{diam}(\mathscr{E}(Q^{i-1}))^2\right),$$

by the assumption that g_i is twice-continuously differentiable and by the Lipschitz-continuity of natural interval extensions, respectively. □

5. Numerical Implementation and Numerical Examples

Although simple, the algorithm describe in Sect. 3 is not the most effective way to implement the ellipsoidal arithmetic. Firstly, the number of atom operations N in the DAG of a factorable function is known a priori, which allows preallocation of the center vector and shape matrix. The second observation is that the lifting operation defined in (3) corresponds to an update in the ith row of the shape matrix; for instance, for an addition or subtraction operation $u_k^{i-1}(x) \pm u_m^{i-1}(x)$:

$$\forall j \in \{0, \ldots, i\}, \quad Q_{i,j}^i = \begin{cases} Q_{k,k}^i \pm 2Q_{k,m}^i + Q_{m,m}^i & \text{if } j = 1, \\ Q_{k,j}^i \pm Q_{m,j}^i & \text{otherwise.} \end{cases}$$

Therefore, an efficient implementation is possible, whereby the (symmetric) shape matrix of the lifted ellipsoid is stored in sparse format and every atom operation corresponds to a sparse update of the shape matrix. Such an implementation of the ellipsoidal arithmetic is available as part of the software package MC++ (`https://projects.coin-or.org/MCpp`).

We illustrate the benefits of ellipsoidal arithmetic compared with traditional interval arithmetic for two problems. The left plot in Fig. 1 considers the following factorable function with $n_x = n_f = 2$,

$$f_1(x_1, x_2) = \sqrt{x_1 + x_2} + x_1 x_2 \qquad f_2(x_1, x_2) = (x_1 - x_2)^2 + 3x_2.$$

The comparison between the actual image set and the corresponding interval and ellipsoidal extensions, here for a variable host set $\mathscr{E}(q_x, Q_x)$ with $q_x = \begin{pmatrix} 3 \\ 4 \end{pmatrix}$ and $Q_x = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$, illustrates the potential of ellipsoidal arithmetic to mitigate the dependency problem. The right plot of Fig. 1 shows the solution set of the parametric linear ODE (harmonic oscillator)

$$\dot{x}_1(t) = x_2(t) + p, \qquad \dot{x}_2(t) = -x_1(t) + p,$$

with joint ellipsoidal host set $\mathscr{E}(q_{x,p}, Q_{x,p})$ for the initial states $x_1(0), x_2(0)$ and the parameter p given by $q_{x,p} = (1 \;\; 0 \;\; 0)^\mathsf{T}$ and $Q_{x,p} = 0.01 I_3$. The unconditional stability of the reach tube illustrates the ability of ellipsoidal arithmetic to mitigate the wrapping effect, which is due to the property of invariance under affine transformations of ellipsoids.

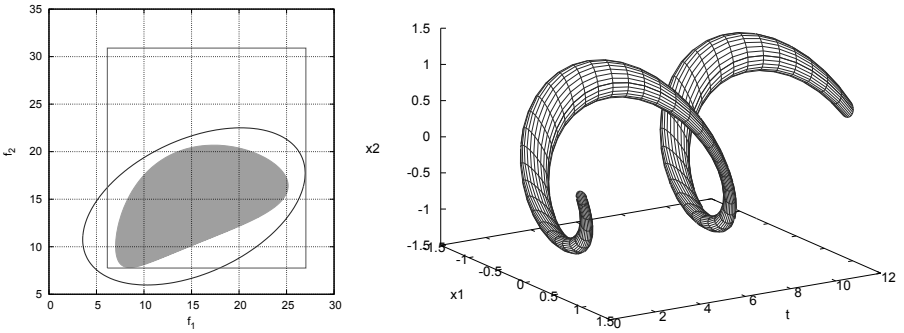

Figure 1: Left plot: Mitigation of the dependency problem using ellipsoidal arithmetic compared with interval arithmetic for a factorable function; Right plot: Mitigation of the wrapping effect by the property of invariance under affine transformation of ellipsoids for a parametric ODE.

6. Conclusion

This paper was concerned with the construction of ellipsoidal enclosures for the image set of factorable functions. Our approach provides such enclosures by traversing a DAG of the function, and it applies an ellipsoidal arithmetic that lifts the ellipsoid to a higher dimensional space for every atom operation. We have shown that this arithmetic yields quadratically convergent ellipsoidal extensions under mild assumptions, and that it can be implemented efficiently on account of sparsity. In practice, quadratic Hausdorff convergence is a very desirable property in branch-and-bound search for global optimization in order to reduce the cluster effect, as well as in the design of validated integrators for asymptotically stable systems. Further research is needed in order to extend existing interval-based algorithms to ellipsoidal techniques nonetheless.

Reduced model trust region methods for embedding complex simulations in optimization problems

John P. Eason and Lorenz T. Biegler

Department of Chemical Engineering; Carnegie Mellon University, Pittsburgh, USA
jeason@andrew.cmu.edu

Abstract

As advanced simulation technologies mature, it is desirable to utilize their predictive power in process design and optimization. However, these models present unique challenges for traditional optimization frameworks. Simulations can be very computationally expensive and derivative information may be unavailable. A common approach is to construct reduced order models (RMs) that approximate the behavior of the simulation with a simple algebraic form. By substituting a RM in place of the simulation, one may simultaneously optimize the entire flowsheet with traditional, derivative-based techniques. Using trust region concepts from nonlinear programming, we systematically construct a series of local RMs to help ensure convergence of the overall problem with the complex simulation. We compare two methods of handling the constraints: a penalty method capable of handling inequality constraints, and a novel approach using a filter method that is capable of handling both inequality and equality constraints. The advantage of the filter method is demonstrated and this method is applied to two flowsheet optimization examples: the Williams-Otto process and the ammonia synthesis process.

Keywords: reduced order models, nonlinear programming, simulation optimization

1. Introduction

Nonlinear programming can be a powerful tool for chemical process optimization. However, existing methods are not suitable for problems where some parts of the system are described by computationally expensive constraints (Biegler, 2010). Models in computational fluid dynamics, molecular modeling, and other complex simulations are emerging as important tools in engineering practice. However, these simulations are computationally expensive and do not provide derivatives. Therefore, to utilize these models in an optimization work process, a common approach is to represent the behavior of the complex simulation, or original detailed model (ODM), with a simpler algebraic form, or reduced order model (RM) (Biegler et al., 2014). The general form of the problem under consideration is given in Eq. (1), where the objective function $f : \mathbb{R}^n \to \mathbb{R}$, equality constraints $c : \mathbb{R}^n \to \mathbb{R}^m$, and inequality constraints $g : \mathbb{R}^n \to \mathbb{R}^p$ are all twice continuously differentiable. The ODM $d(x)$ embedded within the model is assumed to have continuous derivatives but the values may be unknown. The solution techniques that we consider will replace the ODM $d(x)$ by a RM $r(x)$ whose derivatives are known.

$$\min_x \quad f(x, d(x)) \tag{1a}$$

$$s.t. \quad c(x, d(x)) = 0 \tag{1b}$$

$$g(x, d(x)) \leq 0 \tag{1c}$$

In the chemical engineering literature, the most popular choice of data-driven RMs are artificial neural networks and Kriging interpolation. A sampling of works include Caballero and Grossmann (2008), Davis and Ierapetritou (2009), Eason and Cremaschi (2014), Henao and Maravelias (2011), and Biegler et al. (2014). A common approach for RM-based optimization is to sample the ODM, construct a RM, then solve problem (1) with $r(x)$ in place of $d(x)$. Experience has shown that this often terminates at a point of poor accuracy for the ODM, i.e. the optimizer exploits inaccuracy in the RM to artificially improve the objective. The RM can then be refined to increase accuracy in that region. However, such a method offers no guarantee of converging to the optimum of the original problem (1), as shown by Biegler et al. (1985). In that work, the authors even give an example where such an approach converges to a local maximum rather than minimum.

To overcome this difficulty, we note the connection between the RM-based optimization and derivative free optimization algorithms. There is a clear parallel between reduced order models and the so-called model function of certain derivative free optimization techniques. "Model based" derivative free optimization algorithms (for unconstrained problems) generate a sequence of steps based on a sequence of local model functions. The model functions are built in a region around the current iterate known as the trust region. Then, the step is also restricted to fall within this space so as not to extrapolate from the model. To guarantee convergence, the model function must satisfy the "fully linear property" (Conn et al., 2009). In essence, this property says that an upper bound on the error of the function value and gradient of the RM must be directly related to the size of the trust region, i.e. smaller trust regions yield more accurate models. The outline of the basic trust region algorithm is as follows: generate a simple model problem in the trust region, solve the model problem to generate a step, judge the quality of the proposed step according to some quality measure to either accept or reject the step, and adjust the trust region radius Δ_k according to that quality measure.

2. Penalty-based methods

Some attention must be given to the difference between an unconstrained derivative free problem and a constrained NLP with an embedded RM. The simplest way to incorporate constraints is through a penalty function. The penalty function combines objective function decrease and feasibility to a single quality measure to judge whether or not to accept a step. By adding a weighted term to the objective that penalizes constraint violation, it is possible to reach a local optimum (Conn et al., 2000). However, penalty methods have two main drawbacks. First, the correct value for the penalty parameter to ensure convergence to a feasible point is unknown. If the penalty parameter is too small, the optimization path will venture too far into infeasibility. If the penalty parameter is very high, the step size will be prohibitively small (Nocedal and Wright, 1999).

The first method that we present for solving flowsheet optimization problem via a trust region RM method uses penalty functions to recast the problem as an unconstrained problem as proposed by Biegler et al. (2014). The aforementioned issues with the penalty method become especially problematic for equality constraints because lack of derivatives from the ODM leads to a less accurate search direction. Therefore, equality constraints should be avoided. One may eliminate equality constraints by using system knowledge to identify the independent variables x^I with respect to the equality constraints. For a set value of these independent variables, $c(x) = 0$ can be solved uniquely for the remaining dependent variables x^D. Inequality constraints $g(x) \leq 0$ are handled with the penalty formulation. The optimization problem (1) is re-written as

$$\min_{x^I} \quad \psi(x^I) = f(x^I, x^D, d(x^I, x^D)) + \rho \|g_+(x^I, x^D, d(x^I, x^D))\| \tag{2a}$$

$$s.t. \quad c(x^I, x^D, d(x^I, x^D)) = 0 \tag{2b}$$

where $g_+(x^I, x^D, d(x^I, x^D))$ represents the violation of the inequality constraints and ρ is the penalty parameter. A step is generated in the independent variables x^I, then (2b) is used to solve for x^D.

Depending on the structure of the problem, this may require many evaluations of the ODM due to $d(x^I, x^D)$'s dependence on changing x^D. From a process engineering perspective, the process of solving for the dependent variables is equivalent to converging the flowsheet. If a process unit described by a complex simulation is included in a recycle loop, that simulation must be run several times to converge the recycle.

The full penalty algorithm is given as Algorithm II by Biegler et al. (2014). Under assumptions on smoothness and sufficient decrease of the trial step, Theorem 10.13 in Conn et al. (2009) leads to the following convergence result: $\lim_{k\to\infty} \|\nabla\psi(x_k^I)\| = 0$. This guarantees that the algorithm will find a stationary point of the penalized objective. However, two problems prohibit the tractability for penalty-based approaches. First, it is impossible to know an appropriate penalty parameter a priori. Second, and most importantly, the elimination of equality constraints can be very expensive. Therefore, a method to handle equality constraints and dependent variables directly in the optimization process is desired. For flowsheet optimization, this means that we seek a method that optimizes and converges the flowsheet simultaneously.

3. Filter methods

Filter methods emerged with Fletcher and Leyffer (2002) as an alternative to penalty functions. Instead of using a combined metric for objective improvement and feasibility, filter methods consider these criteria somewhat independently. A step is acceptable to the filter if it satisfies either an appropriate decrease in the objective function *or* a sufficient decrease in some infeasibility measure θ. The filter conditions are presented in equation (4) of section 3.1. We propose an adaptation of the trust region filter method for RM based optimization as presented by Agarwal and Biegler (2013). First, introduce variables y and constraint (3d) to match them to the ODM. For typical filter methods, θ is the norm of all constraint violation, from eqns. (3b), (3c), and (3d). However, with the introduction of variables y, we propose to enforce feasibility for (3b) and (3c) at all iterations, and only measure infeasibility as $\theta(z) = \|d(x) - y\|$ where we have introduced $z^T = [x^T, y^T]$.

$$\min_{x,y} \quad f(x,y) \tag{3a}$$

$$s.t. \quad c(x,y) = 0 \tag{3b}$$

$$g(x,y) \leq 0 \tag{3c}$$

$$y = d(x) \tag{3d}$$

The filter method handles constraints directly, so both the objective and feasibility have to be considered when generating a step. After constructing a RM $r(x)$ and substituting for $d(x)$ in (3d), the step generation is decomposed into two subproblems in the spirit of the method introduced by Omojokun (1990). First, the *normal subproblem* is taken to minimize $\theta^R(z) = \|r(x) - y\|$ subject to (3b), (3c) and within a fixed fraction of the current trust region radius, thus yielding θ^R_{min}. This provides some estimate of the achievable level of reduction in θ^R within the trust region. The *tangential subproblem* then minimizes the objective function subject to (3b), (3c), and $\theta^R(z) \leq \theta^R_{min}$, while keeping the total step within the trust region.

3.1. Trust region filter method for RM optimization

1. Initialization: Choose $0 < \gamma_c < 1 < \gamma_E$, γ_f, $\gamma_\theta \in (0,1)$, $\kappa_\theta \in (0,1)$, $\gamma_s > \frac{1}{2}$, an initial trust-region radius Δ_0, minimum radius Δ_{min}, termination tolerance ε_x, feasibility tolerance ε_θ, maximum infeasibility θ_{max}, and an initial iterate z_0. Initialize the filter $\mathscr{F} = \emptyset$. Evaluate $d(x_0)$. Construct a ROM $r(x)$ for the initial trust region. Set $k = 0$.
2. If $\theta(z_k) \leq \varepsilon_\theta$ and $\Delta_k \leq \Delta_{min}$, STOP.

3. If $\theta(z_k) \geq \theta_{max}$, or if $\Delta_k \leq \Delta_{min}$, add (θ_k, f_k) to the filter and go to the restoration phase and attempt to find a feasible point. If restoration succeeds, set z_k and Δ_k as indicated by the restoration procedure and go to Step 4.
4. Generate a ROM $r(x)$ approximating $d(x)$ within the trust region. Compute a step s_k from the normal and tangential subproblems with RMs (described above).
5. If $\|s_k\| \leq \varepsilon_x \Delta_k$, set $z_{k+1} = z_k$, $\Delta_{k+1} = \gamma_C \Delta_k$, and $k = k+1$. Go to Step 2.
6. Filter: Evaluate $\theta(z_k + s_k) = \|d(x_k + s_{x,k}) - (y_k + s_{y,k})\|$. If, for all $(\theta_j, f_j) \in \mathscr{F} \cup (\theta_k, f_k)$,

$$\theta(z_k + s_k) \leq (1 - \gamma_\theta)\theta_j \quad \text{or} \quad f(z_k + s_k) \leq f_j - \gamma_f \theta_j \tag{4}$$

   then the step is acceptable to the filter. If the step is acceptable to the filter, go to step 8. Else, continue to step 7.
7. *Trial step unacceptable to filter* - set $z_{k+1} = z_k$ and contract trust region $\Delta_{k+1} = \gamma_c \Delta_k$. Set $k = k+1$ and go to Step 3.
8. Evaluate the switching condition:

$$f_k(z_k) - f_k(z_k + s_k) \geq \kappa_\theta \theta(z_k)^{\gamma_s} \tag{5}$$

   If true, go to step 9. Else, go to step 10.
9. *f-type step* - Accept trial step $z_{k+1} = z_k + s_k$ and expand trust region $\Delta_{k+1} = \gamma_E \Delta_k$. Set $k = k+1$ and go to Step 2.
10. *θ-type step* - Add (θ_k, f_k) to the filter. Accept trial step $z_{k+1} = z_k + s_k$ and keep trust region radius $\Delta_{k+1} = \Delta_k$. Set $k = k+1$ and go to Step 2.

4. Williams-Otto process

The Williams-Otto problem is a simple flowsheet that provides a good example process for testing algorithms. A diagram of the process and the full optimization formulation is presented in Biegler (2010). The process consists of a reactor, heat exchanger, and two separation units described by component split ratios. To benchmark the trust region RM methods, the reactor is considered to be a complex simulation. In actuality, the reactor is described as a CSTR with three sequential second order reactions. When developing reduced order models, it is helpful to use the smallest possible sets of input and output variables to describe the complex behavior. In this case, extent of reaction is modeled as a function of temperature, volume, and inlet concentrations.

4.1. Results for Williams-Otto process with penalty function algorithm

The results of this optimization are shown in the first column of Table 1. A Kriging model was used as the RM. A good introduction to Kriging may be found in Sasena (2002) and the proof that Kriging functions can satisfy the fully linear property is shown in Wild (2009). The penalty-based optimization reaches the correct solution in 53 iterations. At each iteration the ODM is sampled to construct the RM. During these 53 iterations, 573 samples were obtained. A sample in this case is an evaluation of $\psi(z)$, including solving the system of equations (2b). Because solving the system of equations involves multiple evaluations of the ODM, the actual number of ODM calls is 11,622. For a realistic problem in which ODM evaluations may take minutes or even hours, this approach is clearly intractable.

4.2. Results for Williams-Otto process with filter algorithm

The results of the trust region filter method are shown in Table 1. Three variants of the method were tested, using three choices for RM. First, Kriging models were used to represent the extents

of reaction as a function of reactor conditions. Compared to the use of Kriging in the penalty formulation, more iterations were required to reach the optimum. However, the clear advantage of the filter method emerges when comparing the number of ODM evaluations. The filter method required only 1,621 evaluations, merely 14% of the 11,622 evaluations for the penalty approach.

	Penalty	Filter		
RM:	Kriging	Kriging	linear	linear
note:	x^I only	ODM inputs	interpolation	finite diff
Objective:	-1.2111	-1.2110	-1.2111	-1.2111
Iterations:	53	148	302	7
Sample points:	573	1621	2114	49
ODM calls	11622	1621	2114	49

Table 1: Results for Williams Otto problem for 4 algorithms

The next case that was studied examined the use of finite difference derivative estimates and fitting of a linear RM for reaction kinetics. The results are in the final column of Table 1. The algorithm terminated after only 7 iterations. Because each finite difference estimate required $n+1$ samples from the ODM where n is the number of inputs to $d(x)$, only 49 ODM evaluations were needed in total to reach the optimum. These samples are small perturbations from x_k.

To explain this remarkable performance, consider two reasons based on the properties of the RM. First, the finite difference approach focuses on accuracy at the center of the trust region, at the expense of accuracy elsewhere. Second, the linear RM is a much simpler functional form than the highly nonlinear Kriging models, which could result in artificial local minima in the subproblems. To test the validity of these reasons, a third RM was used. This third approach maintained the simple, linear functional form from the finite difference approach. But this time, the data to which the the linear surface was fit was generated with perturbation sizes equal to $\Delta_k/2$. Therefore, the derivative at the center of the trust region is only accurate for small trust region radii. As with Kriging, finite difference models satisfy the fully linear property described in Section 1.

The results in the third column of Table 1 show that this RM required more iterations and more ODM evaluations than Kriging. Therefore, it is doubtful that the simpler functional form of the RM has much effect on the overall convergence of the outer trust region filter method. Kriging models satisfy an interpolation condition at every data point used to construct them, and therefore in general will have more accurate function values throughout the trust region than the linear fit. However, these results suggest that the most important factor for fast convergence is a very good derivative estimate at the center of the trust region.

5. Ammonia synthesis process

The ammonia synthesis process provides a larger case study for the performance of the trust region filter method. A detailed reactor model consisting of a system of differential algebraic equations was proposed by Murase et al. (1970) and used as an ODM in the synthesis flowsheet. This model considers specific kinetic information for the ammonia synthesis reaction. The heat transfer equations and rate equation were discretized with Radau IIa collocation (Ascher and Petzold, 1998). The resulting system of equations was solved in IPOPT (Wächter and Biegler, 2006).

The rest of the ammonia synthesis process, consisting of three compressors, four heat exchangers, and two flash units, is modeled with cubic equation of state thermodynamics in the equation oriented process optimization framework presented in Dowling and Biegler (2015). The objective was to maximize revenue from product sales minus utility costs. The largest utility cost comes from refrigeration between the reactor exit and flash sequence. The detailed reactor model captures a complex trade-off between temperature, pressure, composition, and the conversion. These

relations are compounded with the task of achieving separation to specifications, either through the cheap flash separations or expensive refrigeration. There is clear potential for optimization to help balance these trade-offs.

A linear surface with finite difference derivatives is used as the RM based on the Williams-Otto results. The filter algorithm converged to a local optimum in 22 iterations. However, the initial point was obtained by optimizing the process with a fixed 30% conversion of nitrogen to ammonia. When these reactor conditions were tested with the ODM, the conversion was actually much lower. The first near-feasible iterate had an objective value of only \$1,744/hr. The trust region filter algorithm closes this gap during the optimization process. The objective at the optimal solution is \$2,868/hr, an increase in profit of \$8.9 million each year.

6. Conclusions

In this work we use trust regions to systematically use reduced order models in a way that can converge to the true optimum. A new filter-based method is introduced and compared to a previous penalty-based method. The filter method's ability to handle equality constraints directly allowed it to outperform the penalty approach. Additionally, it was shown that linear RMs based on finite difference derivative approximations outperform more nonlienar Kriging models. This suggests that using the best derivative estimate available in conjunction with the trust region filter algorithm can exploit the cheap derivatives in the known constraints to minimize the number of ODM evaluations required to reach the optimum.

Abstract

Natural gas is traditionally transported from gas fields to consumer sites with pipelines, but the total cost of pipeline transportation is unfeasible for long distances. The best way to introduce natural gas to new, scattered areas is by transporting it as liquefied natural gas (LNG). This paper presents a mathematical model to aid decision making in the LNG supply chain design, with the focus on inter-terminal transportation. The model, which considers distribution of LNG to consumers from multiple supply terminals through multiple satellite terminals by a heterogeneous fleet of ships, utilizes mixed integer linear programming for finding a supply chain structure that minimizes costs associated with fuel procurement. The model has been tested in a case study inspired by a potential real-life LNG supply chain in the Caribbean islands. The results show that the model works consistently and the computation time is relatively short. The proposed MILP model results in a flexible framework that can be easily implemented in other optimization-based applications.

Keywords: Optimization, MILP, Supply chain, Routing

1. Introduction

In the last decade, natural gas has seen a substantial increase in popularity among the fossil energy sources. The increasing world energy consumption, and the growing attention to environmental aspects connected to it, has put natural gas in a privileged position. Its low carbon-hydrogen ratio and its large remaining reserves make it a satisfactory alternative (among the other fossil fuels) to fulfil the energy demand.
The common way of transporting natural gas from the gas field to the consumers is through pipelines in gaseous state. When distances are very long or geographical restrictions make the pipeline solution unfeasible, it is more economical to transport it as liquefied natural gas (LNG). Natural gas is transformed into LNG by refrigeration processes which cool down the gas below −162°C and reduce its volume 600 times. Transportation can then take place by trucks or ships, with the latter being preferable for long distances and large amounts. Maritime transportation of LNG is performed through specially designed insulated vessels, which can keep the fuel in liquid state. From the liquefaction plants LNG is loaded into the ships which then depart towards the receiving ports, where LNG is unloaded in storages and usually vaporized and fed into the local pipeline. This LNG supply chain is often a large-scale one with vessels of average capacity of about 145,000 m^3. In this paper we study a small to medium-scale LNG supply chain where demands are smaller and sparsely distributed, as it could be the case for consumers located on islands. Maritime routing and optimization of supply chain have been studied long and there is a rich literature on these topics. Vehicle routing has

a long history, with the first papers being published in the seventies (Golden et al., 1977). Review papers on vehicle and maritime routing have also been published (Eksioglu et al., 2009). Christiansen et al. (2007) presented an ample overview on maritime transportation with a comprehensive survey on mathematical models for ship routing and scheduling. Song and Furman (2013) developed a general framework for maritime inventory routing problems. They also proposed an optimization based on heuristics. Large-scale LNG ship routing and scheduling have been studied by Halvorsen-Weare and Fagerholt (2013). They proposed a solution method by decomposition in subproblems, where routing and scheduling are treated separately. Agra et al. (2013) studied the short sea inventory routing problem for distribution of different oil products in the archipelago of Cape Verde, proposing both a discrete time and a continuous time arc-load-flow formulation. In a second paper (Agra et al., 2014) the authors also presented a heuristic-based method to treat realistic routing problems. In the present paper, we present a model as a general framework for ship routing within a given time horizon. The purpose of the model is to identify optimal routes, supply-receiving port connections, and ship sizes to solve the small-scale supply chain problem.

2. Problem Description

The problem studied can be classified as a strategic maritime transportation problem. We consider the regional supply of LNG from a set of potential supply ports to a set of receiving terminals. Demands at the receiving terminals are given and must be fulfilled within the given horizon. The ships delivering the fuel to the receiving ports can be selected from a heterogeneous fleet of vessels. Each type of vessel has a given capacity, cruising speed, and fuel consumption. Some vessels can be restricted from visiting certain receiving terminals due to their incompatibility with the port specifications (i.e., port depth). Limitations on the maximum amount of LNG available at the supply ports can be included. Different supply ports may have different price of the LNG. Every port can be visited more than once and some type of vessels can visit more than one port in the same voyage, i.e., allow for load splitting. Distances between all the ports are known. The aim of the model is to select the optimal fleet and routing scheme to fulfil the demand during the planned horizon at minimum cost.

3. MILP model

The problem formulation considers a set of receiving ports $(i,j) \in \mathcal{R}$ that need to be supplied with LNG from a set of supply ports $s \in \mathcal{S}$; with $\mathcal{R}$ and $\mathcal{S}$ being subsets of $(l,m) \in \mathcal{L}$, the set of all the locations. A set of different ship types $k \in \mathcal{K}$ is considered for the transportation. The routing of the ships and the transport costs are modelled using linear equations and constraints, creating a mixed-integer linear programming (MILP) problem to be solved.

3.1. Variables

The routing requires two sets of variables, a set of integer variables, $Y_{l,m,k}$, which represent the number of times a ship of type *k* traverses between the ports *m* and *l* and a set of continuous variables, $X_{l,i,k}$, which represent how much LNG is transported from port *l* to *i*. Additionally, the model includes a set of integer variables to determine the number of each type of ships needed, N_k.

3.2. The model

The objective of the task is to fulfil the demand at the receiving ports with minimum total combined costs. Parameters c_k^{fuel} and c_k^{rent} respectively represent propulsion and renting cost of ship type *k*. Capacity of the ship is given by C_k, and the vessel's speed by v_k. The ship's load limit factor f indicates the minimum load allowed for ships with splitting restriction, while S_i represents the size limit of the terminal. Distances between ports are given by $d_{l,m}$, demands at the receiving terminals by D_i, and docking times by t_l. The parameter a denotes the availability, in days, of the ship in the given time horizon. The LNG price and maximum amount of LNG available at the supply ports are given by P_s and S_s^{max}, respectively. The objective function and constraints are as follows:

$$\min c^{tot} = \sum_{l,m,k} c_k^{fuel} \cdot d_{l,m} \cdot Y_{l,m,k} + \sum_k c_k^{rent} \cdot N_k + \sum_{s,i,k} P_s \cdot C_k \cdot X_{s,i,k} \tag{1}$$

s.t.

$$\sum_{l,k} C_k \cdot X_{l,i,k} - \sum_{j,k} C_k \cdot X_{i,j,k} \geq D_i \quad \forall i \tag{2}$$

$$Y_{l,i,k} \geq X_{l,i,k} \quad \forall l, i, k \tag{3}$$

$$\sum_l X_{l,i,k} \geq \sum_l X_{i,l,k} \quad \forall i, k \tag{4}$$

$$\sum_m Y_{m,l,k} = \sum_m Y_{l,m,k} \quad \forall l, k \tag{5}$$

$$a \cdot N_k \geq \frac{1}{v_k} \cdot \sum_{l,m} d_{l,m} \cdot Y_{l,m,k} + \sum_l t_l \cdot \sum_m Y_{l,m,k} \quad \forall k \tag{6}$$

$$Y_{l,i,k} \cdot C_k \leq Y_{l,i,k} \cdot S_i \quad \forall l, i, k \tag{7}$$

$$\sum_{i,k} X_{s,i,k} \cdot C_k \leq S_s^{max} \quad \forall s \tag{8}$$

The objective function, Eq. (1), comprises three parts: shipping costs, rental costs and the cost of LNG. The first set of constraints, Eq. (2), determines the *X* variables so that the demands at the receiving ports are satisfied and the second set of constraints, Eq. (3), defines the integer *Y* variables based on the continuous *X* variables. Constraints (4) forbid intermediate loading at the receiving terminals. Equations (5) ensure route continuity and the fifth set of constraints, Eq. (6), define the number of ships based on time usage. Equations (7) and (8) ensure that terminal restrictions are complied with.

In the above form, the model allows for load splitting for all types of ships. In reality, there are some restrictions concerning load splitting in LNG transportation, especially with larger ships. Therefore, the following set of constraints may be used to apply a no-load-splitting condition on a specified subset of ship types, $\mathcal{K}^{spec}$:

$$\sum_{i,j} X_{i,j,k} = 0 \quad \forall k \in \mathcal{K}^{spec} \tag{9}$$

$$X_{s,i,k} \geq f \cdot Y_{s,i,k} \quad \forall s, i, k \in \mathcal{K}^{spec} \tag{10}$$

4. Case Study

In the case study the model was utilized to optimize the maritime routing of a small to medium-scale LNG supply chain in the area of the Caribbean islands. In this region there are a few LNG terminals in operation and more may be built in near future. The power production in the Caribbean islands is mainly oil and coal based. Lately, renewable sources (solar and wind) have been introduced and attention has been given to natural gas as well. With its economic, cleaner, reliable, and more environmental-friendly aspects, natural gas seems to be the natural bridge energy source between the oil sources and renewables. In the case study we assumed that power plants would be the main consumers of the natural gas imported at the receiving terminal, so LNG storages were taken to exist at the receiving terminals. Demands for the time horizon are taken to be smaller than the storage capacity. This is a reasonable assumption considering the comparatively small demands in the area. As set of possible supply ports we selected three ports geographically located to surround the receiving terminals. One of these is an existing LNG export terminal located in Trinidad and Tobago (Point Fortin), while the other two are at the stage of planning and proposal; they are located in Texas (Pass Sabine) and in Florida (Jacksonville). The receiving terminals are taken to be five and are located in different countries. Two are existing terminals, in Dominican Republic (AES Andres LNG Terminal) and in Puerto Rico (Punta Guayailla), while the other three have been selected according to some proposals found in news articles: they are in Haiti (Port-au-Prince), Jamaica (Port Esquivel), and The Bahamas (Ocean Cay). The demands used for the receiving terminals are approximations based on the overall energy demand of the country. Dominican Republic is the major consumer, followed by Puerto Rico with a demand which is one third less, and Haiti and Jamaica, the demands of which are similar and about one fifth of Puerto Rico's demand. Finally, The Bahamas has a demand half of that of Haiti or Jamaica. Ships of capacity 7,500 m^3, 15,000 m^3, 30,000 m^3, 60,000 m^3, and 120,000 m^3 were given as possible options. These sizes are based on data from the Norwegian small-scale LNG supply chain (TGE Marine Gas Engineering GmbH , 2009). The biggest vessel has a capacity falling between the two higher demands. Ship parameters (such as fuel consumption, cruising speed and renting cost) have also been taken from the above mentioned case. The time horizon was chosen to be 30 days. The distances among the locations vary in the range 150-2,000 nautical miles, which correspond to voyages of 0.5-4.5 days with the smallest ship.

The MILP model was implemented in AIMMS 4.1 using the IBM ILOG CPLEX Optimizer. The case study problem results in 285 integer and 206 continuous variables. The solution time was below 5 seconds on a computer with an Intel Core i7-2600K processor.

4.1. Results

The test case has been solved firstly allowing for load splitting for all types of ships (Case 1), i.e., without constraints expressed in equations (9) and (10). Later we solved the same case including the limitations on the load splitting (Case 2). In a later set of optimization runs, we modify the LNG price at the different supply ports, which was

previously set equal for the three ports, to investigate the threshold values related to this parameter (Case 3a-b). All the runs had the same parameters and limitations on availability of LNG at the supply ports and ship-port compatibility was not restricted.
The results from the optimization of Case 1 shows that only one ship of the biggest type is needed to fulfil the demand. The time the ship will be in use is 20.4 days and the routes are shown by arrows in Figure 1a. Note that the arrows only display the route from port-to-port and not the real maritime route, and that the figure does not show how many times the same route is travelled. In the specific case each route is covered only once and the ship performs sequential load splitting in Haiti, Jamaica, Dominican Republic, and The Bahamas before returning to the supply port in Florida. In Case 2 (Figure 1b), when load splitting is banned for ships with capacity $\geq$ 60,000 m^3, the optimal fleet suggested by the model includes one ship of 60,000 m^3 and one of 15,000 m^3. The ships are used for 23.6 and 26.1 days, respectively. The bigger ship delivers LNG to the bigger consumers while the smaller ship supplies the ports with minor demands. One voyage departing from Florida includes load splitting in Jamaica and Haiti. The total combined cost of the objective function increases by 0.4 % from Case 1 to Case 2.

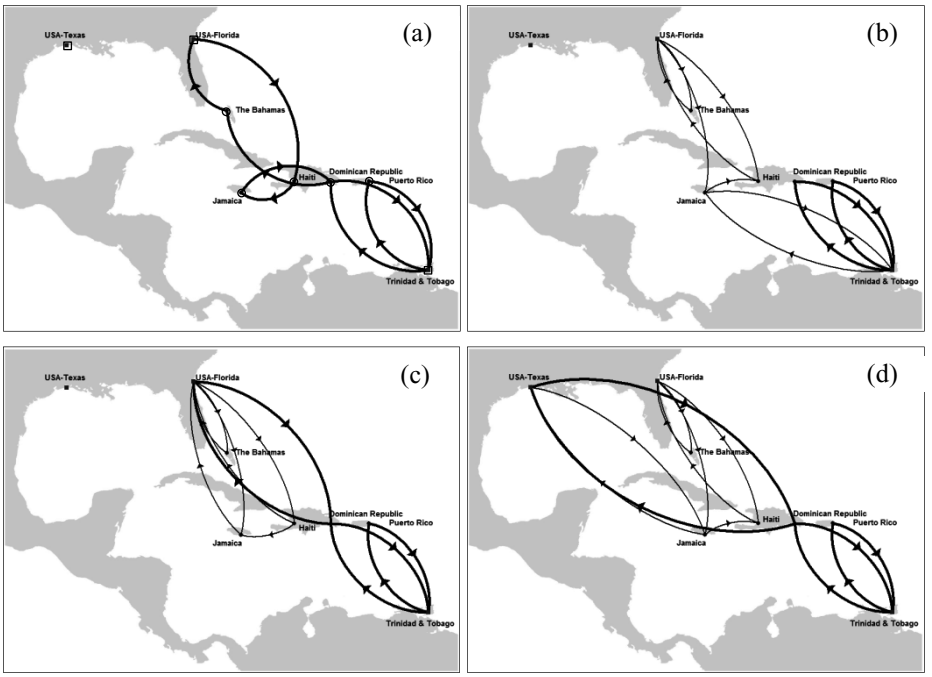

Figure 1. Optimal routes for Case 1 (a), Case 2 (b), and Case 3 (c-d). Squares in subfigure (a) denote supply port and circles demands ports. The thickness of the arrows is proportional to the capacity of the ship travelling the route.

When the LNG price at the supply ports was gradually changed (Case 3), the optimal routing was found to be sensitive to this parameter (Figure 1c-d). This is reasonable since the LNG price represents the major contribution to the total objective function. Increasing the price of LNG at Trinidad and Tobago by about 1 % makes Florida the only supply port used. In Figure 1c we show the solution for an intermediate state, where the LNG is 0.6 % more expensive in Trinidad and Tobago. The solution has changed slightly with respect to routes, but the optimal fleet configuration remains the

same as in Case 2. The main consumer (Dominican Republic) is now served by both supply ports, so we may conclude that the optimal solutions evolve in a logical way. The total cost increases by about 0.5 %. When the LNG price of the supply ports in Trinidad and Tobago and in Florida is increased by 1.8 % and 1.2 %, respectively, the terminal in Texas becomes the optimum supply port to fulfil the entire demand of the islands. Figure 1d displays an intermediate configuration where the LNG price in Trinidad and Tobago and in Florida is 1.2 % and 0.6 % more expensive. Some routes are seen to change while others remain the same as in Case 2 (Figure 1b). It is interesting to note that the same fleet can solve the problem optimally. However, more time is required due to the longer voyages, but the ship utilization is still a couple of days below the time horizon.

5. Conclusions

This paper has studied a small and medium-scale strategic maritime transportation problem. A MILP model that minimizes the costs related to fuel procurement has been presented. A case study illustrates that the model solves the problem efficiently and coherently when key parameters are perturbed. The proposed model is general enough to be easily implemented for tackling larger supply chain optimization problems. The idea is that this mathematically simple and computationally attractive model will serve as a "routing tool" within more complex applications. Future work will therefore be directed to optimization of larger energy chains and supply networks, with more realistic constraints. An analysis will also be performed to study the sensitivity of the results to uncertainty in the model parameters. This will be investigated by introducing stochastic perturbations of key parameters, such as LNG price and demands, solving the optimization problem on a large set of scenarios.

Abstract

We have considered the problem of designing a convenient piping layout in order to transport NGL (Natural-Gas Liquids) through a country subjected to an unstable economy. In this paper we provide a preliminary design of an optimization model by applying metaheuristic algorithms to a set of networks corresponding to a real-world case study. Experimental results for Simulated Annealing and Genetic Algorithms are presented and these techniques are compared.

Keywords: Metaheuristic, NLG, Pipeline Design, GARCH

1. Introduction

A current challenge in the oil industry is the optimization of transport from the extraction areas to the processing locations. The varying price of fuels and the associated increasing haulage costs boost research in the exploration of strategies that aim at exploiting and delivering dormant energy sources. For example, particularly in Argentina, which is the second place in the world in shale gas reserves, in the future it is expected to exploit gas fields that contain about 802 trillion cubic feet of natural gas (EIA, 2013).

Concomitantly, the extraction of natural gas implies the availability of natural gas liquids (NGL), which are convenient to process. Therefore, in view of this scenario, cost-effective solutions are required. Transport is a major consideration in predicting economic benefits. Pipelines are the primary mode of transportation for crude oil, petroleum products and natural gas in producer countries since it is safer and more reliable than roads or rails, apart from providing a substantial cost advantage. (Furchtgott-Roth, 2013). The distinctive features of the model formulation presented in this paper are the incorporation of both economic uncertainty over time and the geographical distribution of the production in order to achieve reliable optimizations.

We have also focused specially with search metaheuristics as general strategies for the design of heuristic procedures with high performance for the solution of optimisation problems related to pipelining. Several successful state-of-the-art metaheuristics have

lately been developed for varied purposes. Abd-El-Barr (2009) considered a variety of techniques for the problem of topological optimization of communication networks subjected to a number of computational design constraints. Osiadacz and Góreki (1995) made a reasonably comprehensive survey of the optimization of both water and gas distribution networks by means of heuristic methods, exact procedures that consider the availability of continuous diameters, and discrete optimization methods. In turn, Marcoulaki et al. (2012) presented an optimisation framework based on stochastic optimisation for the routing and equipment design of main pipelines to be employed for fluid transmission. In fact, stochastic optimization is the research field metaheuristics belong to. Sahinidis (2004) provided a short overview of stochastic optimization, discussing and contrasting various relevant modeling philosophies, like robust stochastic programming, probabilistic programming, and stochastic dynamic programming. Lately, André et al. (2013) solved the problem of the optimal design of a hydrogen transmission network by means of a local- search method and compared their procedure with a Tabu-search heuristics.

In this paper, the analysis was applied to the design of a real-world pipeline network. NGL coming from gas fields located in Santa Cruz province (Argentina) are sent to the processing plant, which is desired to be placed at Río Gallegos. Thanks to the employment of metaheuristics, an adequate pipeline network layout could be achieved.

2. Mathematical Formulation

The increasing cost of transporting fuels has stimulated our research in the problem statement. The formulation of the objective function should be posed to make the optimization results realistic. In this perspective, the Net Present Value (NPV) of a project (Eq.(1)) is obtained from revenue flows and all kinds of construction and operating costs. By comparing alternative pipeline layouts, the most valuable one is selected so as to maximize overall benefits.

$$\begin{aligned} NPV = & \sum_{t=1}^{o} \frac{P_t \, x \, Q_t}{(1+r)^{t+m+n}} - \sum_{t=1}^{n} \sum_{i=1}^{f+q} \sum_{j=1}^{q+p} \frac{CC_{ijt}}{(1+r)^{t-1}} FP_{IJ} - \sum_{t'=1}^{\frac{m+o}{l}} \sum_{i=1}^{f+q} \sum_{j=1}^{q+p} \frac{PC_{t'} \, x \, NP_{ij}}{(1+r')^{t'-1}(1+r)^{n}} FP_{IJ} \\ & - \sum_{t=1}^{m} \sum_{k=1}^{q} \frac{\beta_{kt}}{(1+r)^{t+n-1}} \; CN_k - \sum_{t=1}^{o} \sum_{i=1}^{f+q} \sum_{j=1}^{q+p} \frac{PW_{ijt}}{(1+r)^{t+m+n-1}} FP_{IJ} \\ & - \sum_{t=1}^{o} \sum_{i=1}^{f+q} \sum_{j=1}^{q+p} \frac{MC_{ijt}}{(1+r)^{t+m+n-1}} FP_{IJ} - \sum_{t=1}^{o} \frac{LC_t}{(1+r)^{t+m+n}} \end{aligned} \tag{1}$$

As pipeline layouts ensue diverse expenditures along the project lifetime, considering a discount rate proves to be essential in order to arrange alternative developments adequately. Moreover, a discount rate that contemplates uncertainty risks is a suitable way to estimate long-term cash flows that require this kind of investment in volatile economies.

In this sense, an interest rate series that reflects a similar level of risk for comparable projects was modelled by means of an Auto-Regressive Integrated Moving Average (ARIMA) regression analysis. As a variety of unknown events sooner or later arise, even more frequently in developing markets, the error term contained in the media

equation for an interest rate usually exhibits a non-constant variance. In other words, unsystematic shocks in the economy affect the estimation of model parameters and their efficiency. Those sudden variations can be taken into account with GARCH (Generalized Autoregressive Conditional Heteroskedasticity). By applying this econometric method, or its alternative specification "in Media" (GARCH-M), confidence intervals can be defined so that the decision-maker can adjust the discount rate according to different risk-aversion profiles (Enders, 2009).
As to the problem formulation, it was based on the following assumptions:

- A control system has been implemented in order to guarantee that a continuous NGL supply will be provided. The storage tanks, which are located at the "concentrating nodes", serve to balance the flowrate, acting as contingency reservoirs. By preventing unexpected variations over time in this way, the production transported through the pipelines is regarded as constant.

- The construction costs CC_{ijt} are based on both the pipe diameter and the covered distance. Land permissions, material and construction labour costs are included.

- The installation costs β_{kt} of the concentrating nodes are obtained by evaluating the corresponding equipment costs related to their dimensions.

- The number of pumps (NP_{ij}) and the required energy (PW_{ijt}) depend on the flow rate, the pipe diameter and the covered distance (Echarte, 2010).

- The maintenance cost MC_{ijt} varies by considering the entire structural value.

- The transport tariff P_t can be taken from the market in order to determine if the project is economically viable. Another approach consists in setting the price to zero so as to know the lowest profitable limit. The metaheuristic methods employed in this paper are flexible enough to allow both solutions.

3. Metaheuristics for Pipeline Design

The formulation described in the previous section constitutes an NP-complete combinatorial optimization problem (Cook, 1971). Hence, the difficulty to find an optimal solution increases exponentially with problem size. Therefore, instead of choosing exact methods, metaheuristic techniques become more attractive because they are able to find satisfactory solutions in reasonable times.
Our framework was conceived as a Decision Support System to accommodate more specific design criteria. With the decision-maker's intervention and his acceptance of the proposed network, our stochastic optimizer guides a subordinate heuristics by cleverly combining various concepts in order to explore and exploit adequately the search space. Metaheuristic techniques founded on trajectories, such as Simulated Annealing (SA) (Kirkpatrick et al., 1983) were considered together with population-based methods, like Genetic Algorithms (GA) (Whitley, 1994). We have tested the most important metaheuristics according to the classification that categorizes them into trajectory methods and population-based methods because this division allows a clearer distinction of the algorithmic strengths.
The search strategies of different metaheuristics are highly dependent on the philosophy of the metaheuristic itself. The trajectory methods evaluate several neighborhood

structures imposed on the search space. In contrast, population-based methods deal in every iteration of the algorithm with a set of solutions (called a population) rather than with a single solution. In this way, population-based algorithms supply a natural, intrinsic mechanism for the exploration of the search space (Alba, 2005). At each iteration some operators are applied to the individuals of the current population so as to generate the individuals of the population for the next generation (i.e., iteration).
Both algorithms were implemented in JAVA language an executed in an Intel Core i5-3330 PC with 8 GB RAM. The solutions were represented with sparse binary matrices, whose rows are the oil fields and their columns are either the concentrating nodes or a processing plant. Then, an element equal to 1 denotes a connection. Although the algorithms can determine the most convenient number of concentrating nodes by themselves, it is also possible for the decision-maker to pre-establish that amount. In the latter case, the search space is restricted and therefore, the best result is obtained fastly.
The following algorithmic parameters were chosen after several executions:

- For GA: population size = 50; number of generations = 250; crossover probability = 0.7; mutation probability = 0.1.

- For SA: number of iterations with different temperatures = 500; number of iterations with the same temperature = 3; initial temperature = 0.99

As to the behaviour of both algorithms in finding networks for the case mentioned in the last paragraph of the introduction, Fig. 1 shows the evolution of the fitness function (NPV) obtained for 30 independent executions, whose results are represented by various curves. Since algorithmic progress can be measured with different search-tracking indicators for each metaheuristics, the x axis for SA and GA correspond to the number of iterations and generations, respectively. In both cases, the fitness values decrease sharply during the first half of the evolution. Then, this representative behaviour exhibits the satisfactory robustness of SA and GA when solving this problem.
The average execution times of these algorithms have been compared. For GA the total CPU time required was 383 ms. In contrast, for SA the total CPU time required was only 138 ms, which represents 36 % of GA's algorithmic time.
The results shown in Table 1 reveal that after 30 independent executions, both algorithms performed satisfactorily and always yielded the best solution. In the third column, the efficacy reports the number of times the optimum is reached.

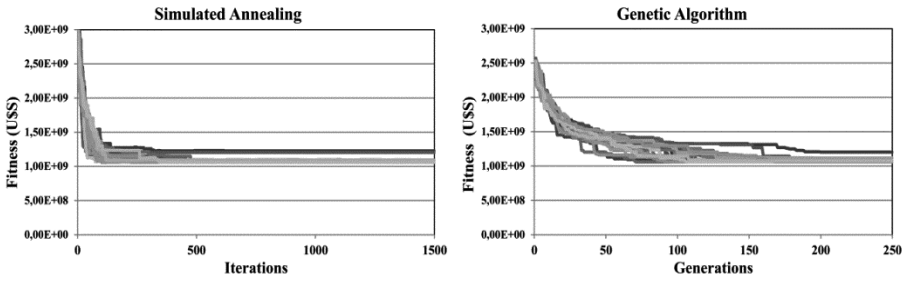

Figure 1: Contrasting the performance of SA and GA metaheuristics.

Table 1: Statistics for the final optimised networks

Algorithm	Best Solution (U$S)	Efficacy (%)	Computing Time (ms)	Number of Evaluations
GA	$1.057E^{+09}$	80	383	24038
SA	$1.057E^{+09}$	70	138	1500

GA proved to be more efficacious at the expense of CPU time, which is required because a great amount of evaluations is necessary for a population-based technique. It should be kept in mind that in our SA implementation preparing a neighbour solution takes more time than performing the crossover in our GA. For this reason, unlike SA, GA's time does not grow proportionally with the number of evaluations.

4. Conclusions

In this work a preliminary design of an optimization model is presented. In order to improve the design quality of the pipe network, a detailed economic optimization model for the fluid transportation pipe network throughout a country with an unstable economy was established, wherein the minimum investment was taken as the objective function.

The computational strategy consists in using metaheuristic algorithms in order to find the most convenient piping layout to transport NGL. The solution strategies of Genetic Algorithms and Simulated Annealing algorithms worked out in practice. Both SA and GA succeeded in finding the solution with excellent computing times. When comparing the results obtained using the GA and the SA algorithm, SA outperforms GA with better values and demanding less CPU time (36 %).

Based on this article and the expected industrial needs, we identify the following opportunities about further research for the continuation of this work:

I. As the hydrocarbon fields are getting older and oil prices are changing, economic models and transportation become more and more important. Therefore, more detail should be incorporated in the analysis.

II. Other application domains can be explored. For instance, substantial contributions can also be made by the rigorous simulation of offshore fields with enhanced objective functions.

III. It is vital to improve optimization results so that they can accommodate industrial concerns regarding techno-economical aspects, especially for unstable economies. This is often the reality where non- exploited fields are located. In those cases, uncertainties should also be contemplated.

IV. As to computational design, parallel computing with SA metaheuristics running in threads can be incorporated in order to generate more rigorous and efficient algorithms.

Nomenclature

CC_{ijt}: construction cost from the *i*-th to the *j*-th point, in the *t*-th period
CN_k: for the *k*-th concentrating node: CN_k=1 if active, otherwise CN_k=0
f: number of oil fields
FP_{ij}: feasible path from the *i*-th to the *j*-th point

l: pump's lifetime
LC_t: operating labor cost in the *t*-th period
m: total number of time periods related to the construction of pumps and concentrating nodes
MC_{ijt}: maintenance cost of the structure from the *i*-th to the *j*-th point, in the *t*-th period
n: total number of pipeline construction time periods
NP_{ij}: number of pumps from the *i*-th to the *j*-th point
o: project lifetime
p: number of plants
PC_t: pump installation cost in the *t*-th period
P_t: transport tariff in the *t*-th period
PW_{ijt}: pumping energy cost from the *i*-th to the *j*-th point, in the t-th period
q: number of concentrating nodes
Q_t: amount of NGL transported in the *t*-th period
r: discount rate
r': discount rate adjusted to the pump's lifetime
β_{kt}: installation cost of the *k*-th concentrating node in the *t*-th period

Deterministic Global Dynamic Optimisation using Interval Analysis

Carlos Perez-Galvan[a] and I. David L. Bogle[a]

[a]*Centre for Process Systems Engineering; Department of Chemical Engineering; University College London; London, United Kingdom*
d.bogle@ucl.ac.uk

Abstract

There is an interest in obtaining the global optimum for dynamic optimisation problems, i.e., the absolutely best solution since it often offers substantial improvement compared to locally optimal solutions. Furthermore, in safety critical applications it is important to ensure that the behaviour of the process is within (possibly prescribed) safe limits. Currently, the main bottleneck in the deterministic solution of global dynamic optimisation problems is the computation of tight bounds guaranteed to contain all the solutions of the ordinary differential equations (ODE) system.The methods available rely on sequential approaches in which a verified ODE solver and a spatial branch and bound framework are used. In this work, the dynamic set of constraints (ODEs) is solved using an interval Taylor series method with interval contractors (Perez-Galvan and Bogle, 2014) and a spatial branch and bound framework is used as the optimisation routine in a sequential approach. The results demonstrated that when the method described is used uncertainty ($\pm$1-2 %) can be introduced in the system parameters of the two-state case study besides using the Newton contractor took 50-60 % less CPU time than the Krawczyk contractor.

Keywords: Global Optimisation, Interval Analysis, Interval Contractors

1. Introduction

In chemical engineering a vast number of systems of interest can be modelled by ordinary differential equations (ODE) and for these systems it is often necessary to obtain the optimal performance. Among the dynamic optimisation applications that arise in this field are the determination of optimal operating profiles, the formulation of process control strategies, the parameter estimation for model development, etc.

Two main approaches are used to solve these kinds of problems; they are the simulaneous and the sequential approach. In the first, both the state variables and control variables are discretised and in the second one only the control variables are discretised. In this paper only the sequential approach is considered.

Finding the global optima is not an easy task since these problems are typically nonconvex and therefore exhibit multimple local minima. Several researchers have devoted their efforts to solve the deterministic global optimisation problem for dynamic systems and most of these research works implement an extensive search NLP such as a branch-and-bound framework and a verified ODE solver in a sequential approach. For example, a branch-and-bound framework was used with the αBB method (Adjiman et al. 1996) in a sequential approach and applied to four different optimal control problems and to parameter estimation problems (Esposito and Floudas, 2000). In

principle, this method provides a guaranteed global optimum, however, hard to obtain rigorous underestimators are needed for which only sampling approaches were proposed. Another sequential approach was used with a convex underestimating procedure (Papamichail and Adjiman, 2002). Some years later, a method was devised where McCormick relaxations and constant and affine bounds were applied (Papamichail and Adjiman, 2004). The approach used by Papamichail and Adjiman (2002, 2004) is computationally expensive in constructing tight affine underestimators and overestimators. A sequential approach was used for problems with an integral objective function (Singer and Barton, 2006) it implements McCormick relaxations to construct the convex relaxations . The dynamic optimisation problem has also been addressed with focus on the tightness of the ODEs state bounds by means of a Taylor models method with interval remainder term (Lin and Stadtherr, 2006). Later, they applied the same method but this time with a branch and reduce approach using a domain reduction technique (Lin and Stadtherr, 2007). Moreover, the latter method was extended to account for inequality path constraints in a rigorous way (Zhao and Stadtherr, 2011).

Nonetheless, tighter and more efficient bounds are required in dynamic optimisation applications. Because of this a number of ways to deal with this problem have been developed e.g. convex and concave relaxations (McCormick relaxations) have been incorporated along with interval bounds (Sahlodin and Chachuat 2011b). These relaxations have been used in the Taylor Model method in the remainder term in addition to the interval bounds (Sahlodin and Chachuat 2011a). Also for this purpose McCormick relaxations have been applied in a method to derive an auxiliary system of ODEs that uses interval bounds (Scott and Barton, 2013). A kind of Taylor model with ellipsoidal remainder term has also been devised with promising results (Villanueva et al., 2013).

The work presented here provides a new approach for the deterministic global optimisation that uses an algorithm based on an interval Taylor series method that makes use of interval contractors (Krawczyk and Newton contractors) for the reduction of the overestimation. The remainder of this paper is organised as follows: in section 2 the formulation of the problem to solve and the preliminaries are given, in section 3 the verified method for ODEs and the contraction techniques are described, in section 4 the application of the method to a case study in which uncertainty has been introduced is presented and in section 5 conclusions on the results obtained are provided.

2. Preliminaries

In this section the problem we are aiming to solve is formulated. We assume that the problem can be described by the ODE model $\dot{\mathbf{z}} = \mathbf{f}(\mathbf{z}, \boldsymbol{\theta})$, with $\mathbf{z}$, the vector of state variables and $\boldsymbol{\theta}$, the vector of system parameters. In this article the bold type notation is adopted to indicate vector-valued quantities and capital case to indicate interval-valued quantities unless otherwise specified. The formulaton of the dynamic optimisation problem can be stated as

$$\begin{aligned} &\min_{\boldsymbol{\theta}} \ \phi(\mathbf{z}(t_i, \boldsymbol{\theta}), \boldsymbol{\theta}; i = 1, \ldots, ns) \\ &s.t. \quad \dot{\mathbf{z}} = \mathbf{f}(\mathbf{z}, \boldsymbol{\theta}) \\ &\mathbf{z}(t_0, \boldsymbol{\theta}) = \mathbf{z}_0(\boldsymbol{\theta}) \\ &\qquad t \in [t_0, t_f] \\ &\qquad \boldsymbol{\theta} \in \boldsymbol{\Theta} \end{aligned} \tag{1}$$

where ϕ is the objective function, $\boldsymbol{\Theta}$ is an interval vector and $\mathbf{f}$ is assumed to be continuously differentiable with respect to $\mathbf{z}$ and $\boldsymbol{\theta}$. When a sequential approach is used a verified ODE method is applied to the dynamic part of the optimisation problem leaving a problem only constrained by the system parameters $\boldsymbol{\theta}$.

3. Verified ODE method, contraction techniques and branch-and-bound

The mathematical formulation of the systems of ODEs with parameter dependence is stated as before $\dot{\mathbf{z}} = \mathbf{f}(\mathbf{z}, \boldsymbol{\theta})$, $\mathbf{z}(t_0, \boldsymbol{\theta}) = \mathbf{z}_0(\boldsymbol{\theta})$, $t \in [t_0, t_f]$. An interval Taylor series method with High Order Enclosure (Nedialkov et al., 2001) has been used. This method consists of two main steps: validating existence and uniqueness, and computing a tighter enclosure. The first stage of this method satisfies

$$\tilde{\mathbf{Y}}_j = \mathbf{Y}_j + \sum_{i=1}^{k-1} [0, h_j]^i \mathbf{f}^{[i]}(\mathbf{Y}_j, \boldsymbol{\Theta}) + [0, h_j]^k \mathbf{f}^{[k]}(\tilde{\mathbf{Y}}_j^0, \boldsymbol{\Theta}) \subseteq \tilde{\mathbf{Y}}_j^0 \tag{2}$$

where k is the order of the Taylor series expansion, $\mathbf{Y}_j$ is the vector of tight enclosures of the solutions with ranges in $\tilde{\mathbf{Y}}_j^0$, $\boldsymbol{\Theta}$ is the vector of system parameters and $\mathbf{f}^{[i]}$ are the Taylor coefficients defined according to $\mathbf{f}^{[0]}(\mathbf{y}, \boldsymbol{\theta}) = \mathbf{y}_j$, $\mathbf{f}^{[i]}(\mathbf{y}, \boldsymbol{\theta}) = \frac{1}{i}\left(\partial \mathbf{f}^{[i-1]} / \partial_{\mathbf{y}} \mathbf{f}\right)(\mathbf{y}, \boldsymbol{\theta})$ for $i \geq 1$. These Taylor coefficients can be calculated using automatic differentiation.
The second stage involves the computation of a tight enclosure $\mathbf{Y}_{j+1} \supseteq \mathbf{y}(t_{j+1}; \boldsymbol{\Theta})$ given interval bounds $\mathbf{Y}_j$ at t_j. The second stage refines the a priori enclosure $\tilde{\mathbf{Y}}_j$ on $t \in [t_j, t_{j+1}]$ provided in the first stage. It satisfies the next equation (3)

$$\begin{aligned} \mathbf{Y}_{j+1} = & \overbrace{\hat{\mathbf{y}}_j + \sum_{i=1}^{k-1} h_j^i \mathbf{f}^{[i]}(\hat{\mathbf{y}}_j, \hat{\boldsymbol{\theta}})}^{u_{j+1}} + \overbrace{\left\{ I + \sum_{i=1}^{k-1} h_j^i \frac{\partial \mathbf{f}^{[i]}}{\partial \mathbf{y}}(\mathbf{Y}_j, \boldsymbol{\Theta}) \right\}}^{S_{j+1}^y} (\mathbf{Y}_j - \hat{\mathbf{y}}_j) \\ & + \underbrace{\left\{ \sum_{i=0}^{k-1} h_j^i \frac{\partial \mathbf{f}^{[i]}}{\partial \boldsymbol{\theta}}(\mathbf{Y}_j, \boldsymbol{\Theta}) \right\}}_{S_{j+1}^\theta} (\boldsymbol{\Theta} - \hat{\boldsymbol{\theta}}) + \underbrace{h_j^k \mathbf{f}^{[k]}(\tilde{\mathbf{Y}}_j, \Theta)}_{Z_{j+1}} \end{aligned} \tag{3}$$

For the sake of simplicity we rewrite equation (3) as

$$\mathbf{Y}_{j+1} = u_{j+1} + S_{j+1}^y (\mathbf{Y}_j - \tilde{\mathbf{y}}_j) + S_{j+1}^\theta (\boldsymbol{\Theta} - \tilde{\boldsymbol{\theta}}) + Z_{j+1} \tag{4}$$

In this method the interval matrix-vector product $S_{j+1}^y (\mathbf{Y}_j - \tilde{\mathbf{y}}_j)$ in equation (4) is known to be one of the main contributors of the wrapping effect (Jackson, 1975). Because of this, a number of methods have been developed to try to avoid direct evaluations of this matrix-vector product (Nedialkov et al., 1999). In this paper the QR factorization technique devised by Lohner (1992) is used in the interval Taylor series method.
The QR factorization technique consists on the substitution of the term $S_{j+1}^y (\mathbf{Y}_j - \tilde{\mathbf{y}}_j)$ by another term containing a matrix that induces an orthogonal coordinate system that often provides a better enclosure than in the original coordinate system.

$$\mathbf{Y}_{j+1} = u_{j+1} + (S_{j+1}^y) \Gamma_j + S_{j+1}^\theta (\boldsymbol{\Theta} - \tilde{\boldsymbol{\theta}}) + Z_{j+1} \tag{5}$$

where,

$$\Gamma_{j+1} = A_{j+1}^{-1} (Z_{j+1} - \hat{z}_{j+1}) + A_{j+1}^{-1} (S_{j+1}^y A_j) \Gamma_j + (A_{j+1}^{-1} S_{j+1}^\theta)(\boldsymbol{\Theta} - \tilde{\boldsymbol{\theta}}) \tag{6}$$

Here $\Gamma_0 = \mathbf{Y}_0 - \hat{\mathbf{y}}_0$, $A_0 = I$ and A_{j+1} is chosen as the midpoint of $S_{j+1}^y A_j$, the parallelepiped enclosure of Γ_{j+1}.

3.1. Interval contraction techniques

When a real valued function is evaluated using interval arithmetic usually some overestimation is present in the range of the function. Interval contractors offer the possibility to contract the

estimated range in an interval evaluated function. Some of these contractors are counterparts of the real arithmetic techniques and are able to contract nonlinear functions such as the Krawczyk contractor and the Newton contractor. Assume we have n_y variables linked by n_f relations of the form

$$f_q(y_1, y_2, ..., y_n) = 0,\ q \in 1, 2, ..., n \tag{7}$$

Each variable $\mathbf{y}_j$ belongs to a domain $\mathbf{Y}_j$, an interval. Equation (7) can be written in a vector form and a constraint satisfaction problem (CSP) can be formulated as in equation (8).

$$\mathbf{f}(\mathbf{y}) = 0,\ \mathbf{y} \in \mathbf{Y}_j \tag{8}$$

The solution set $\mathbf{B}$ of (8) is defined as

$$\mathbf{B} = \mathbf{y} \in \mathbf{Y}_j | \mathbf{f}(\mathbf{y}) = 0 \tag{9}$$

Contracting the CSP in (8) means replacing $\mathbf{Y}_j$ by a smaller domain $\mathbf{Y}'_j$ such that the solution set remains unchanged, i.e. $\mathbf{B} \subset \mathbf{Y}' \subset \mathbf{Y}$.

The contractors considered in this work are interval counterparts of classical point algorithms such as Gauss-Seidel and Newton algorithms. For more details see (Jaulin et al., 2001) and for application examples in deterministic global optimisation refer to (Balendra and Bogle, 2009). In this work two non-linear contractors have been used, namely the Krawczyk and Newton contractor.

Krawczyk contractor. The Krawczyk contractor considers a CSP as in (8) where the number of variables is the same as the number of relations and $\mathbf{f}$ is assumed to be differentiable. The function $\boldsymbol{\psi}(\mathbf{y}) = \mathbf{y} - M\mathbf{f}(\mathbf{y})$ is a fixed-point subsolver for (8) where M is any invertible matrix. And its centred inclusion function is

$$\boldsymbol{\Psi}(\mathbf{Y}_j) = \boldsymbol{\psi}(\hat{\mathbf{y}}_j) + J_\psi(\mathbf{Y}_j)(\mathbf{Y}_j - \hat{\mathbf{y}}_j) \tag{10}$$

where J_ψ is an inclusion function for the Jacobian matrix of $\boldsymbol{\psi}$ with $\hat{\mathbf{y}}_j$ as the midpoint of $\mathbf{Y}_j$. The intersection between the original domain and the one obtained with (10) results in the fixed-point contractor as in equation (11).

$$\mathbf{Y}_j \leftarrow \mathbf{Y}_j \cap \boldsymbol{\psi}(\hat{\mathbf{y}}_j) + \{I - MJ_f(\mathbf{Y}_j)\}(\mathbf{Y}_j - \hat{\mathbf{y}}_j) \tag{11}$$

Newton contractor. We consider again a CSP as in (8) and apply the mean value theorem to obtain

$$(\mathbf{f}(\hat{\mathbf{y}}_j) + J_f(\boldsymbol{\xi})(\mathbf{y}_j - \hat{\mathbf{y}}_j) = 0,\ \mathbf{y}_j \in \mathbf{Y}_j,\ \boldsymbol{\xi} \in \mathbf{Y}_j) \tag{12}$$

The CSP in (12) can be arranged as

$$(A\mathbf{p} + \mathbf{f}(\hat{\mathbf{y}}_j) = 0,\ \mathbf{p} = (\mathbf{y}_j - \hat{\mathbf{y}}_j),\ A = J_f(\boldsymbol{\xi}),\ \mathbf{b} = -\mathbf{f}(\hat{\mathbf{y}}_j),\ \mathbf{y}_j \in \mathbf{Y}_j,\ \boldsymbol{\xi} \in \mathbf{Y}_j) \tag{13}$$

In this way, a linear contractor can be used such as the Gauss-Seidel contractor. The Gauss-Seidel contractor is able to contract domains of linear systems of the form $A\mathbf{p} - \mathbf{b} = 0$. If A is square it can be decomposed as the sum of a diagonal matrix and a matrix with zeroes in its diagonal (extdiag):

$$diag(A)\mathbf{p} + extdiag(A)\mathbf{p} = \mathbf{b} \tag{14}$$

Also if A is invertible then (14) can be rewritten as

$$\mathbf{p} = (diag(A))^{-1}(\mathbf{b} - extdiag(A)\mathbf{p}) \tag{15}$$

Hence, the solution of the Gauss-Seidel contractor is defined as the intersection of the original domain $\mathbf{p}$ and the new $\mathbf{p}$ calculated with (15). This results in:

$$\mathbf{p} \leftarrow \mathbf{p} \cap (diag(A))^{-1}(\mathbf{b} - extdiag(A)\mathbf{p}) \tag{16}$$

Finally, the Gauss-Seidel contractor solution in (16) is used to update $\mathbf{Y}_j$ and the intersection $\mathbf{Y}_j \leftarrow \mathbf{Y}_j \cap (\mathbf{p} + \hat{\mathbf{y}}_j)$ is obtained to finish with the Newton procedure.

3.2. Implementation

In order to apply the interval contractors in the verified method with the aim of reducing the overestimation this work considers an implicit form of equation (4). Making this considaration it is possible to look at the new implicit equation as a CSP problem in the form of (8). The resulting implicit equation is

$$\mathbf{g}(\mathbf{y}) = u_{j+1} + (S^{y}_{j+1})\Gamma_j + S^{\theta}_{j+1}(\boldsymbol{\Theta} - \tilde{\boldsymbol{\theta}}) + Z_{j+1} - \mathbf{Y}_{j+1} = 0 \text{ or } \mathbf{g}(\mathbf{y}) = 0, \mathbf{y} \in \mathbf{Y}_j \tag{17}$$

In this way an interval contractor such as Krawczyk or Newton can be applied in equation (17) at each time step.

An implementation of a branch-and-bound procedure has been used in this article. In the branch-and-bound tree the node on which to branch was the one with the least lower bound. At each node, the variable with the greatest diameter (distance between its upper and lower bound) was selected for branching. The program was written in C++ and the libraries FADBAD++ (Stauning and Bendtsen, 2003) and Profil/Bias (Knuppel, 1994) were used for the computation of the Taylor coefficients and the interval arithmetic operations, respectively.

4. Case study

Oil Shale Pyrolysis model: The problem considers the calculation of the optimal temperature profile in a PFR. The reactions involved and the model of the problem are shown in (18). In the model only components A_1 and A_2 are included and the objective is to maximise the production of A_2. Here u is the adjustable parameter and is taken as a piecewise constant profile. Figure 1 shows one of the states of the dynamic part of the optimisation problem with two uncertain amounts: $x_1(0) = [0.99, 1.01]$ and $u = [0.22, 0.24]$. These were obtained with a verified method based on interval Taylor series that employs the Krawczyk or Newton interval contractor. The contractors used clearly reduce the overestimation in the dynamic simulation. After obtaining the information on the profiles, the gradient information can also be obtained (sensitivity equations). This in turn represents the input for the branch-and-bound algorithm.

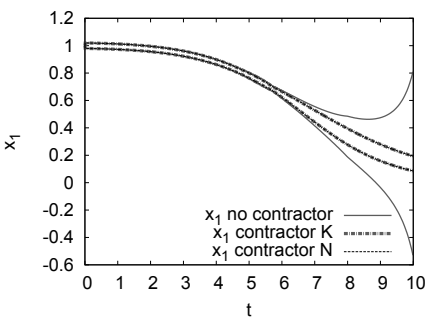

Figure 1: Simulation of x_1 with and without contraction techniques

$$\begin{aligned}
& & \min_u \ \phi &= -x_2(t_f) \\
A_1 \xrightarrow{k_1} A_2 & & s.t.\ \dot{x}_1 &= -k_1 x_1 - (k_3 + k_4 + 5) x_1 x_2 \\
A_2 \xrightarrow{k_2} A_3 & & \dot{x}_2 &= k_1 x_1 - k_2 x_2 + k_3 x_1 x_2 \\
A_1 + A_2 \xrightarrow{k_3} 2A_2 & & k_i &= a_i e^{\left(\frac{-b_i/R}{698.15+50u}\right)},\ i = 1,\ldots,5 \\
A_1 + A_2 \xrightarrow{k_4} A_3 + A_2 & & \mathbf{x}_0 &= ([0.99, 1.01], 0)^T \\
A_1 + A_2 \xrightarrow{k_5} A_4 + A_2 & & t &\in [t_0, t_f] = [0, 10] \\
& & u &\in [0, 1]
\end{aligned} \tag{18}$$

The dynamic optimisation problem has been solved to global optimality using an uncertain value of $x_1(0) = [0.99, 1.01]$ and $x_1(0) = [0.98, 1.02]$ in a second experiment. In the real application this means that the concentration of A_1 can be as uncertain as $\pm$1-2 %. The CPU time taken to obtain this solution using the Newton contractor was 606.8 seconds and 1475.6 seconds using the Krawczyk contractor and three iterations of the contractors were used in the integration stage. Since an uncertain value was used the problem was solved within an absolute tolerance of 20^{-2}. The CPU times are for an Intel^{TM} Core^{TM} i5 with 8Gb RAM, running Red Hat 6.6 and gcc 4.4.7.

5. Conclusions

The results proved that the method is able to address an small amount of uncertainty in one of the system parameters (1-2 %). Two interval contractors were used in the method presented and the Newton contractor demonstrated to take between 50 % and 60 % less CPU time compared to the Krawczyk contractor. The method behaves similarly when compared to experiments of case studies of up to six state variables (not reported here). Therefore, interval contractors are useful in the reduction of the overestimation in the solution of dynamic global optimisation problems.

Abstract

In this paper, the methodology of chance constraints programming with resource is proposed for the separation process optimization under uncertainty. In this approach, uncertain factors are classified into two types: the first type of uncertainties is compensated for by introducing a penalty term to the optimization objective, and the other uncertainties are expressed by chance constraints at certain confidence levels in the optimization model. The solution strategy is developed by a sequence transform hybrid algorithm involving both Monte Carlo integration and improved Benders decomposition strategies with sequential quadratic programming. 1-hexene separation process is optimized as a case study to illustrate the feasibility of the proposed strategy.

Keywords: Stochastic programming, uncertainty, chance constraint, recourse.

1. Introduction

Deterministic approaches have been widely used in separation process optimization. However, there are many uncertain variables in the process design and optimization, such as raw material prices, product demands, operation pressures and temperatures, etc. The estimation of these uncertainties with their expected values might lead to a conservative design with excessively high operating costs.

Researches considering optimization under uncertainty have attracted much interest in many fields (Sahinidis, 2004), and some uncertainty-based optimization methodologies and algorithms have been developed to account for different uncertain factors (Hukkerikar et al., 2012). Stochastic programming with recourse and chance constraint programming are two important stochastic programming strategies (Requiao et, al., 2012). However, there are limits associated of these two methods.

Stochastic programming with recourse (SPR) partitions the design problem into two stages: in the first stage the design decisions are made before the realization of any uncertainty in the variables. In the second stage the operational or recourse decisions are made following the first-stage plan and after the realization of the uncertainties. The aim of SPR is to choose the first-stage decision variables in a way that the sum of the first-stage objective and the expected value of the random second-stage objective are optimal. The presence of uncertainty is translated into a stochastic nature of the

recourse, and the penalize shortfall or corrective measures are compensated for by introducing a penalty term to the objective function accounting for any infeasibility.

SPR is a relatively strict and reliable method. But, sometimes, there can be difficulties setting up penalty terms accounting for the implementation of uncertain variables. For the SPR model solution, the calculation grows exponentially with the number of uncertain factors (Higle & Sen, 1991).

Chance constraint programming (CCP) is also known as a probabilistic programming (Li et, al., 2006). CCP allows the decision to be made to satisfy feasibility requirements while some constraints are violated with a certain probability no less than a confidence level (Rockafellar & Uryasev, 2000). The confidence level can quantify the reliability of the optimization objectives and constraints. The CCP is fairly simple and direct; however, the restriction reflexion might cause some risks.

2. Chance constraint programming with recourse

For the separation process design, the uncertain factors include the feed composition, the feed rate, steam/electricity/product prices, product demands, etc. They are divided into two types:

The fluctuation of the first type of uncertainties such as product demands, material and steam prices would cause the variations in the process costs. The compensation resulting from the implementation of these uncertainties are added to the economic objective based on the SPR.

For the second uncertain variables, the compensating measures require more complex calculations, but their impacts on the optimization objective and constraints are negligible up to a certain level, so the CCP would be optional to formulate the optimization model. In the distillation process optimization, the fluctuation of separation results due to the variations of the feed composition and the feed rate is acceptable in certain extent. Thus, the CCP is utilized to account for these uncertainties on the optimization model.

2.1. Stochastic optimization model

The separation process optimization aims to achieve the minimum process cost. The following strategy of chance constraint programming with recourse is proposed by combining the CCP with the SPR, formulating the optimization model as follows:

$$
\begin{aligned}
\text{Min}\quad & O = g(x,\theta) + E_{\theta_j \in \Omega}(Q(y,\theta_j)) \\
\text{s.t.}\quad & F(x,y,\theta) = 0 \\
& \mathrm{G}(x,\mathrm{y},\theta) \le 0 \\
& P\{h(x,y,\theta_i) \ge 0\} \ge \alpha \\
& \theta \in \{\theta_i, \theta_j\};\ i = 1,2\ldots,m;\ j = 1,2,\ldots n \\
& 0 < \alpha \le 1
\end{aligned}
\tag{1}
$$

With

$$Q(y,\theta_j) = \min \quad f(\theta_j)^T y, \quad j = 1,2,...,n$$
$$\text{s.t} \quad \mathrm{D}(\theta_j) y \geq H(\theta_j) - T(\theta_j) x \tag{2}$$

Where, the optimization object O is the minimum of the process profit; g is the first-stage objective function, and Q is the penalty term. x is the state variable, and y is operation variable. θ_i and θ_j are the first and second type of uncertain variables respectively. Ω is the domain of θ_j. E is the expectation of penalty function Q; F represents equality constraints and G implies inequality constraints, including mass balance, energy balance, available raw material constraints, safety consideration, equipment size constraints, equipment operating performance, etc. $P\{h(x, y, \theta_i)\geq 0\}\geq\alpha$ implies the probability of the constraint realization $h(x,\theta_i)\geq 0$ must be no less than a confidence level α; $f(\theta_j)$ is the coefficient matrix of y; D; H and T are the constraint matrixes in the compensation term.

2.2. Sequence transform hybrid algorithm

There are uncertain variables existing in both the objective and the constraints. In this work, a sequence transform hybrid algorithm both involving Monte Carlo integration and improved Benders decomposition strategies with sequential quadratic programming (SQP) is proposed to solve a large sized sampling problem with constraints. The uncertain variables in the constraint $P\{h(x, y, \theta_i)\geq 0\}\geq\alpha$ are converted into deterministic constraints. This conversation normally requires multiple integrals. The uncertain variables in the penalty term $E_{\theta\in\Omega}(Q(y, \theta_j)$ are translated into deterministic expression. are used to solve The deterministic model with extensive constraints resulting from the uncertain variables is solved by improved Benders decomposition strategies.

3. Case study

1-hexene separation process is optimized utilizing the proposed methodology. 1-hexene is produced through ethylene oligomerication catalytic reaction. The concentration of the product 1-hesene is required to be no less than 99%. Also, the by-products are recovered containing 1-hexene less than 10%. Ethylene and cyclohexane are required to be recycled back to the system. Table1 presents the feed mixture data.

3.1. Flowsheet analysis

Since there are gaps between the boiling points of the components in the feed mixture, the feed mixture would be separated by flash distillation and rectification. By the analysis on the separation units, separation sequence, and process energy integration, three flow scenarios are generated.

Scenario 1 (S1) is shown in Figure 1. The feed mixture is initially flashed to recover ethylene. The liquid mixture after the 2-stage flash is then separated passing through three rectification columns. 1-hexene is extracted from the top of T-A. Cyclohexane is recovered from the top of T-B. The by-product is obtained from the top of T-C. Other heavy components from the bottom of T-C would be combusted for emission. There is heat integration between the top steam of T-B and the residue from T-A, not shown in Figure 1.

Table 1: The feed stream date

Concentration wt%									Rate kg·h^{-1}	T °C	P MPa
Ethylene	1-hexene	cyclohexane	C_{10}	n-hexene	1-Octanol	ethane	methane	Butane	1785.5	120	5.0
0.125	0.358	0.477	0.0297	2.90 E-3	2.78 E-3	2.43E-3	1.18E-3	8.91E-5			

Figure 2 presents the flow chart of scenario 2 (S2). Eethylene is separated completely from the mixture by rectification in T-D instead of the flashing operation used in S1.

Scenario 3 (S3) shown in Figure 3 has different rectification separation sequence compared with both S1 and S2. Ethylene is recovered from the top of T-A. A side stream drawn from T-A is purified in T-B to give separated 1-hexene and the solvent. The heavy components recovered from the bottom of T-A are then separated in T-C. This scenario allows the separation to be performed with one less flash vessel or one less rectification column compared with S1 and S2. There is no heat integration in this scenario.

3.2. Optimal results

The optimization for this separation process is to reach the minimum process costs, including the capital costs and operating costs. The capital cost is mainly the function of the numbers of trays and the diameters of rectification columns. In this work, the column diameters are fixed, and the tray numbers are considered as the main capital variables. The principle factors affecting the operating costs are the steam utilization by the reboilers. At the condition of the fixed product outputs, the steam demands are the function of distillation reflux ratio.

From the process analysis, it is known that the rectification column T-A in S1, column T-A in S2, and column T-B in S3 are key equipment for this process separation. The state decision variable considered in each scenario is the tray number $N_{T\text{-}A}$ in S1, $N_{T\text{-}A}$ in S2, and $N_{T\text{-}B}$ in S3. The other capital costs are assumed to be fixed in the optimization. The operation decision variables are the rectification reflux ratios $R_{T\text{-}A}$ and $R_{T\text{-}B}$ in all these three schedules.

The concentration of 1-hexene in the feed mixture x_F, LP steam price $C1$, and MP steam price $C2$ are uncertain variables with probabilities following the normal distribution. Table 2 presents uncertain variables in this case. Table 3 lists main deterministic capital costs.

Equality constraints in the optimal model are mainly MESH equations. Inequality constraints are applied to limit the range of reflux ratios, the numbers of column trays, the separation requirements, the steam demands by the reboilers.

The influence on operating costs caused by C_1 and C_2 would be compensated for through changing the reflux ratio or through additional steam heating in the reboilers. The SPR is selected in this model setting. The variation of x_F would cause a change in the purity of the product 1-hexene. It is feasible to model this variation based on CCP.

The process is optimized by the proposed strategy of chance constraint programming with recourse under three confidence levels: α=0.5, α=0.7, and α=0.8. The optimization

results are listed in Table 4. The results comparisons with those using conventional deterministic methods are presented in Table 4 as well.

As shown in Figure 4, S1 is better from the economic view point while ignoring the uncertain factors. The design would be different while considering the fluctuations of steam prices and feed compositions. At different confidence levels, S3 spent lower costs at confidence levels at α=0.7 and α=0.8. When the confidence level α is set to be 0.5, the configuration S1 is found to be the optimal case with the minimum process cost.

The confidence level indicates how well the constraints are satisfied and the how higher the confidence level is, the stricter constraints being kept, the more reliable the optimization result will be achieved. The confidence level set at a low value means the constraints are easier to be satisfied, however, the optimization result is less reliable.

In reality, the steam price varies unavoidable. The development of the catalyst, the variation of the up-stream feed and the operation would change the feed concentration. So the optimization under uncertainty is more reliable in reality and practical.

4. Conclusions

The methodology of chance constraints programming with resource is proposed to overcome the shortcomings in model formation and model solution by using chance constraint programming and stochastic programming with recourse separately. A case study involving optimization of the 1-hexene separation process demonstrates the potential of the proposed methodology. It is clear from the optimal results that consideration of uncertainty may generate more reliable and practical results.

Optimal operating policies for synthesizing tailor made gradient copolymers

Cecilia Fortunatti*, Bruno Mato, Adriana Brandolin, Claudia Sarmoria, Mariano Asteasuain.

PLAPIQUI, Camino La Carrindanga km 7, Bahía Blanca (8000), Argentina
cfortunatti@plapiqui.edu.ar

Abstract

In this work, a detailed mathematical model of the TEMPO mediated copolymerization of S and MMA is used to analyze the most common experimental strategies employed to produce gradient copolymers as applied to these monomers. The model is able to predict average molecular properties as well as the full bivariate molecular weight distribution (MWD) of the copolymer. Typical experimental policies reported in the literature are simulated in order to determine the exact composition profile that results from them. Optimal operating policies necessary to produce different specific gradient structures are also obtained by solving optimization problems. The results show that comprehensive mathematical modeling can aid in finding appropriate operating policies. In this way, the simulation can be regarded as a valuable tool in the design of novel materials with pre-specified characteristics.

Keywords: probability generating function, MWD, CRP, copolymerization, optimization.

1. Introduction

The discovery of the controlled polymerization of styrene in the presence of 2,2,6,6-tetramethyl-1-piperidynyl-N-oxy (TEMPO) ushered the research of the promising controlled radical syntheses. Since then, TEMPO has been extensively studied and applied due to its low cost, commercial availability and lack of environmental issues (Braunecker and Matyjaszewski, 2007). Even though the operating temperature needs to be relatively high (> 100ºC) and the control over molecular structure is not as precise as with other controlled polymerization techniques, the advantages of TEMPO mediated polymerization still make it an appealing method for obtaining high value materials in an simple, economic and environmentally friendly way.

Controlled polymerization may be used to produce copolymers, and in particular gradient copolymers, where the composition distribution varies continuously from one end of the copolymer chain to the other. Several different gradient profiles could be desirable, such as linear, hyperbolic, or blocky gradient, which may lead to different final properties (Beginn, 2008; Sun et al., 2008). However, the majority of the reported experimental policies for synthesizing gradient copolymers have been developed by trial and error (Vidts et al., 2006; Min et al., 2007). In this way, it is very difficult to achieve a precise gradient profile. The most widely used operating policy consists on feeding the total amount of one of the comonomers at the start, and adding the second comonomer at a constant rate, regardless of the comonomer pair being used (Jakubowski et al.,

2008; Karaky et al., 2007). However, this feeding policy may lead to copolymer chains with portions of nearly constant composition, particularly close to the chain ends. A piecewise constant feeding policy, on the other hand, may be designed to obtain a steadier (e.g. linear) composition change along the chain backbone (Min et al., 2007).

It is clear that minor changes in operating conditions may lead to gradient copolymers with diverse composition profile shapes. However, manufacturing a material for a pre-specified application requires a precise knowledge of the formed structure. In this context, comprehensive mathematical models are valuable tools to determine the produced molecular architecture and find optimal operating policies to obtain tailor-made materials. Taking this into consideration, Wang and Broadbelt (2011) developed a Monte Carlo based algorithm to determine feeding policies conducive to the synthesis of copolymers with a pre-designed gradient profile. On the other hand, both Sun et al. (2007) and Zhao et al. (2009) manufactured gradient copolymers with pre-specified composition profiles with the help of a computer-controlled metering pump. In these works, the comonomer feeding rate profiles were dictated by mathematical models based on the methods of moments.

Mathematical models able to calculate the characteristics of the copolymer being produced are extremely helpful. These tools not only allow minimizing expenditure of resources thanks to better experimental planning, but also facilitate finding useful relationships between operating conditions and end-use properties. For this purpose, it is necessary to predict not only average properties but the full MWD as well. In previous works we developed a mathematical model for the copolymerization of styrene (S) and methyl methacrylate (MMA) mediated by TEMPO that predicts average properties together with the full MWD in an accurate and efficient way, using probability generating functions (pgf) (Fortunatti et al., 2014). In the present work this model is used to analyze the copolymer structure resulting from usual techniques employed to prepare gradient copolymers, and to design optimal operating policies for synthesizing gradient copolymers with pre-specified composition molecular characteristics.

2. Methods

2.1. Copolymerization Process and Mathematical Modeling

The kinetic mechanism considers the copolymerization of S and MMA mediated by TEMPO using AIBN as initiator. The synthesis was considered to be isothermal at 130ºC, and to be carried out in bulk in a semibatch reactor.

Average properties such as molecular weights, composition and conversion, were modeled using the well-known method of double index moments. The bivariate MWD was obtained using the 2D probability generating functions (pgf) technique. Details on these techniques and their mathematical implementation may be found elsewhere (Asteasuain and Brandolin, 2010; Brandolin and Asteasuain, 2013; Fortunatti et al., 2014).

2.2. Simulation of Typical Operating Policies

The most widely used operating policy for obtaining gradient copolymers consists on an initial charge of one of the comonomers and a subsequent feeding of the second monomer at a constant rate. Here this methodology is simulated for the S-MMA

copolymerization and the molecular structure of the resulting polymer is analyzed in detail.

2.3. Optimization of Operating Policies

Linear gradient structures were sought with a pre-specified global copolymer composition. For this to be fulfilled, the average number fraction of S in the copolymer should reach a specified value at the end of the reaction time. Three different final compositions were specified: 50% S, 60% S, and 70% S.

The optimization aimed to find an operating policy that would allow obtaining a linear gradient copolymer with a pre-specified global composition, as detailed above, and a target chain length ($\overline{L_{n,\text{target}}}$) of 125 units. The initial charge of S was fixed at 624 g while the gradient profile was meant to be controlled by continuous addition of MMA. The operating variables included in the optimization runs were: initial charge of AIBN (I) and TEMPO (Te) ($m_{i,0}$, i = I, Te) and MMA feeding policy ($f_{\text{MMA}}(t)$). A piecewise linear profile was selected for $f_{\text{MMA}}(t)$ since it would be easily achievable with a programmed metering pump. The polydispersity (PDI) should be less than 1.3 to obtain a uniform material. At the same time, the fraction of dormant molecules should be greater than 0.9 to maintain the "living" feature of the reaction. As a productivity constraint, a minimum of 10% conversion was required while reaction time could not exceed 24 hours.

The optimization problem was posed as follows:

$$\min_{m_{i,0},\,a_j,b_j,t_j} FO = \int_0^{t_f} \left(Inst\_comp_S(t) - \left(1 - p\overline{L_n}(t)\right)\right)^2 dt \tag{8}$$

s.t.

Process model

$$t_f = \sum_{j=1}^{5} t_j \tag{8.1}$$

$$f_{\text{MMA}}(t) = a_j t + b_j \quad \text{when} \quad \sum_{k=1}^{j-1} t_j < t \le \sum_{k=1}^{j} t_j \tag{8.2}$$

$$Conv\left(t_f\right) \ge 10\% \tag{8.3}$$

$$\overline{L_{n,\text{target}}} - 3 \le \overline{L_n}\left(t_f\right) \le \overline{L_{n,\text{target}}} + 3 \tag{8.4}$$

$$y_{\text{Dormant}}\left(t_f\right) \ge 0.9 \tag{8.5}$$

$$\text{PDI}\left(t_f\right) \le 1.3 \tag{8.6}$$

$$30 \text{ min} \le t_f \le 1440 \text{ min} \tag{8.7}$$

$$1 \text{ min} \le t_j \le 200 \text{ min} \tag{8.8}$$

$$0 \le m_{\text{I},0} \le 50 \text{ g} \tag{8.9}$$

$$0 \le m_{\text{Te},0} \le 50 \text{ g} \tag{8.10}$$

$$0 \le f_{MMA}(t) \le 10 \text{ g} \cdot \text{min}^{-1} \tag{8.11}$$

The objective function shown in Eq. (8) aims at obtaining an average instantaneous composition of S in the copolymer ($Inst\_comp_{\text{S}}$ (t)) that varies linearly along the

polymer chains. The slope p of this line is related to the final average global composition of S in the copolymer ($Glob\_comp_S$ (t_f)) by

$$p = \frac{2\left(Glob\_comp_S(t_f) - 1\right)}{\overline{L_n}_{,\text{target}}} \tag{9}$$

The simulations and optimization problems were formulated and solved in gPROMS v3.5.3 (Process Systems Enterprise, Ltd.) in a standard PC.

3. Results and Discussion

Firstly, the typical constant rate feeding policy of the comonomer was simulated. Styrene must be present in the reaction medium in order for TEMPO to act as an effective mediator. Therefore, the initial charge of S was fixed at 624 g while an equimolar mass of 600 g of MMA was fed at constant rate. Three different feeding rates were considered: 1.5 g min^{-1}for 400 min, 3 g min^{-1} for 200 min, and 4.5 g min^{-1} for 133 min. The composition profiles along the copolymer chain for the three cases can be observed in Figure 1. It can be seen that the variation in the instantaneous composition along the chain is quite steady for the three cases. An approximately linear profile is obtained for the slowest feeding rate, while the other ones exhibit a concave shape. As expected, as the MMA feeding rate increases a steeper slope of the instantaneous composition is obtained, because the MMA concentration in the reaction mixture is higher. At the same time, conversion is lower due to the shorter reaction time, which results in a shorter average chain length. The final global composition is the same for the three cases. It should be noted that, without the aid of a modeling tool, a time-consuming trial an error procedure would be needed in order to find the precise operating conditions for achieving specific molecular properties, such as average chain length, global composition and composition profile along the chains. Besides, a tuned feeding scheme would be needed for tailoring the composition profile shape (e.g. a linear gradient copolymer).

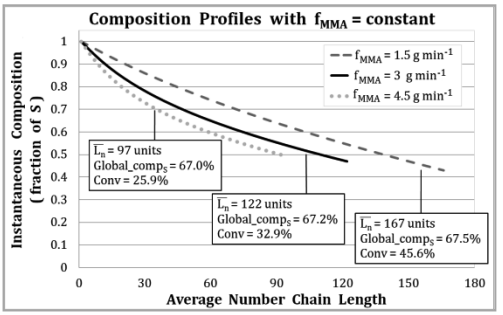

Figure 1. Composition profiles for constant feed rate policies ($m_{I,0}$ = 6.13 g, $m_{Te,0}$ = 4.9 g).

Secondly, the operating policy was optimized as described before. Figure 2 shows the optimum linear gradient profiles of the copolymers for the desired global average compositions. The optimization could take from 300 to 1400 seconds to be solved depending on how good the initial point was. To overcome the difficulties associated with the stiffness of the system of equations, the convergence tolerance of the DAE solver used in gPROMS was changed from the default value of 10^{-5} to 10^{-10} while for the re-initialization solver was set to 10^{-6}.

Perfectly linear gradients are obtained when it is required to obtain a copolymer with 60% and 70 % of S. Such perfect linear gradients are not possible when a 50% S content is sought. This is due to the reactivity ratios of S and MMA, which would require very low concentrations of S in the reaction mixture in order to achieve a 100 % composition of MMA close to the chain end. Even so, the discrepancies with respect to the linear gradient are within expected experimental errors. Figure 3 shows the optimal MMA feed rate profiles for each of the desired global average compositions.

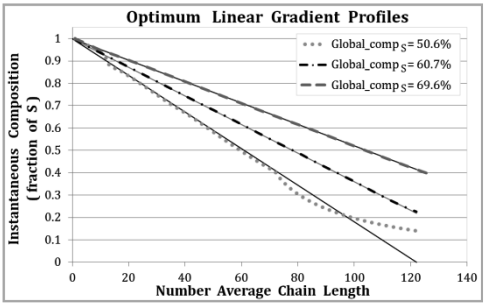

Figure 2. Optimum linear gradient composition profiles. Lines: desired composition profile – Symbols: actual composition profile.

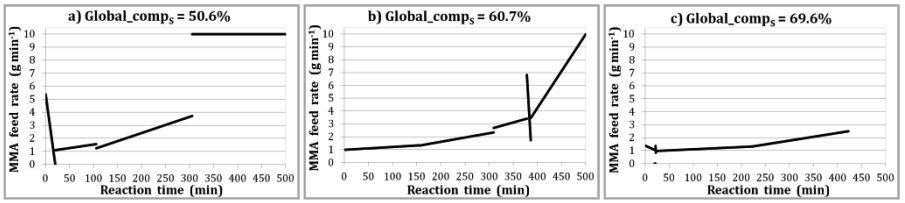

Figure 3. MMA feed rate policies for obtaining linear gradient copolymers with different average composition

Finally, in Figure 4 the MWD for the operating policy with a constant feed rate f_{MMA} = 3 g min^{-1} is presented next to the MWD for the linear gradient composition profile with a global composition of 69.6% S. It can be observed that even though similar composition profiles and average global composition are obtained, the molecular weight distributions differ, which could cause a variation in the material performance.

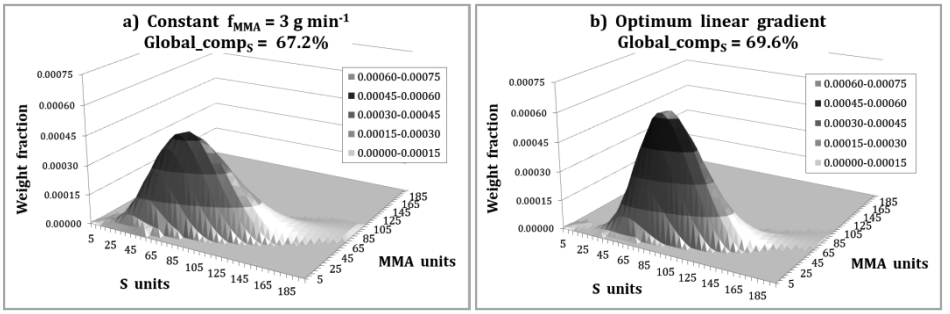

Figure 4. MWD for different composition profiles with similar global composition of S.

4. Conclusions

The effect of typical operating policies used to produce gradient copolymers was analyzed for the S-MMA copolymerization system. Besides, optimal operating policies for synthesizing polymers with pre-specified properties were computed. It was found that the composition profiles of S-MMA copolymers using constant feed rates can be different from linear profiles. Moreover, it was shown that the operating policy required for obtaining a pre-specified profile can be very difficult to find without the aid of modeling tools. Finally, the results showed that the full bivariate MWD can provide extra information about the copolymer molecular structure that could help to determine variations in the material performance.

Degeneracy Hunter: An Algorithm for Determining Irreducible Sets of Degenerate Constraints in Mathematical Programs

Alexander W. Dowling[a] and Lorenz T. Biegler[a]

[a]*Department of Chemical Engineering, Carnegie Mellon University, Pittsburgh, PA, United States*
biegler@cmu.edu

Abstract

Degenerate constraints, i.e. constraints that violate the Linearly Independent Constraint Qualification (LICQ), are prevalent in many process optimization problems. These result from poor model formulations (typically human error) and overspecifications, zero flowrates and disappearing units, and recycle loops. Because degenerate constraints lead to singular Karush-Kuhn-Tucker (KKT) systems and significant challenges for numeric solvers, these constraints complicate the solution procedure for nonlinear programs (NLPs, i.e. nonlinear optimization problems). Although most modern NLP solvers implement counter-measures to detect and eliminate degeneracies, increased computational effort and convergence failures may still result. Instead, the best approach is to reformulate the original NLP model. Unfortunately, this is difficult for complex models with thousands of equations. This work describes the *Degeneracy Hunter*, an algorithm that systematically analyzes any iteration from a continuous mathematical program solver and determines irreducible sets of degenerate constraints. This tool allows the expert modeler to focus on only a handful of equations, instead of the thousands that make up a typical process optimization problem. The algorithm has been prototyped in MATLAB and analyzes derivative information exported from GAMS. Calculation of irreducible sets of degenerate equations is formulated as a mixed integer linear program. The algorithm has been applied to a non-convex, highly nonlinear Air Separation Unit (ASU) design problem with 15,000+ variables and constraints, which identified three sources of degenerate equations. Straightforward revisions of the model to remove these degenerate constraints resulted in a 16% decrease in average CPU time and less frequent termination at infeasible points. Identification of these degeneracies would have been virtually impossible without a systematic approach.

Keywords: degenerate constraints, linearly dependent constraints, nonlinear programming

1. Introduction and Motivating Examples

We consider two classes of degenerate constraints: local and global. Local (or point) degeneracies occur only at specific values for variables in the mathematical program. For example, mass balance equations, shown in (1), become degenerate when flowrates go to zero ($F = L = V = 0$). The Jacobian of the equations is shown in (2), with F and z fixed. At the zero flowrate point, pivoting on the first two columns in (2b) shows that the Jacobian matrix is rank deficient.

In contrast, global degeneracies always lead to rank deficient Jacobians, regardless of the value of the variables. These most commonly are a consequence of overspecifications. For example, if $\sum_i y_i = 1$ and $y_i = K_i x_i \ \forall i$ are added to (1), the systems is always overspecified ($2 + 2n$ variables

and $3+2n$ equations when F, z and K are specified) and the Jacobian is rank deficient.

$$F = V + L \tag{1a}$$

$$Fz_i = x_i L + y_i V, \quad \forall i \in \{Comps\} \tag{1b}$$

$$\sum_{i \in \{Comps\}} (x_i - y_i) = 0 \tag{1c}$$

$$A = \begin{array}{c} \\ \text{Overall MB} \\ \text{MB } \ i=1 \\ \vdots \\ \text{MB } \ i=n \\ \sum \end{array} \begin{array}{c} \begin{array}{cccccccc} L & V & x_1 & \cdots & x_n & y_1 & \cdots & y_n \end{array} \\ \begin{pmatrix} -1 & -1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\ -x_1 & -y_1 & -L & \cdots & 0 & -V & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ -x_n & -y_n & 0 & \cdots & -L & 0 & \cdots & -V \\ 0 & 0 & 1 & \cdots & 1 & -1 & \cdots & -1 \end{pmatrix} \end{array} \tag{2a}$$

$$A(F = L = V = 0) = \begin{pmatrix} -1 & -1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\ -x_1 & -y_1 & 0 & \cdots & 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\ -x_n & -y_n & 0 & \cdots & 0 & 0 & \cdots & 0 \\ 0 & 0 & 1 & \cdots & 1 & -1 & \cdots & -1 \end{pmatrix} \tag{2b}$$

As another example, consider the system shown in Figure 1, comprising two vessels, a splitter and seven streams. Stream 1 is fed into the first vessel, which has two outlets: streams 2 and 3. Without loss of generality, let streams 2 and 3 represent two different phases in equilibrium. These streams are fed into the second vessel, producing effluent streams 4 and 5. Stream 5 is split into streams 6 and 7, and the latter is recycled into the first vessel. Pressure relationships for these streams are shown in (3). The equations are derived from a two simple rules: streams leaving a vessel are in pressure equilibrium, and pressure cannot increase across vessels and is constant across a splitter. This constraint system is overspecified (and degenerate), as there are seven constraints and seven variables, but there should be one degree of freedom (e.g. P_1 should be free).

$$P_2 = P_3 \tag{3a}$$

$$P_4 = P_5 \tag{3b}$$

$$P_6 = P_7 \tag{3c}$$

$$P_5 = P_7 \tag{3d}$$

$$P_1 \geq P_3 \tag{3e}$$

$$P_2 \geq P_5 \tag{3f}$$

$$P_7 \geq P_3 \tag{3g}$$

Many nonlinear programming (NLP) solvers implement safeguards to mitigate degenerate constraints. For example, CONOPT (Drud, 1994), a large-scale active-set generalized reduced gradient (GRG) optimization solver, removes degenerate constraints from the active set, effectively ignoring these constraints. However, determining the active set for inequality (and degenerate constraints) is an NP-hard task. On the other hand, interior point methods avoid the computational complexity of active set determination by penalizing inequality constraints with a barrier term. As a consequence, degenerate constraints cannot easily be removed from the active set. In IPOPT (Wächter and Biegler, 2006), a large-scale interior point method, degenerate constraints are instead dealt with using regularization techniques (Wang et al., 2013; Chiang and Zavala, 2014). However, neither of these strategies are fully effective, as shown in the case study (Section 3).

With global degeneracies, the best option is model reformulation. For example, consider the system in Figure 1. Either the recycle pressure constraint, (3g), should be removed and all of the inequality constraints converted to equality constraints, or a pump should be added to the recycle loop. Identifying the cause of degenerate constraints such as these, however, is difficult in large problems with thousands of constraints.

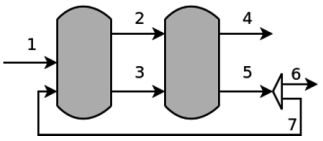

Figure 1: Pressure recycle degeneracy example

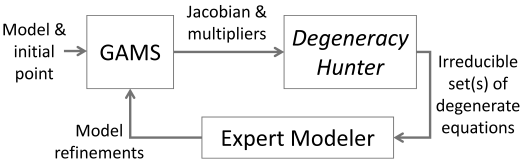

Figure 2: Recommend workflow with *Degeneracy Hunter*

Although factorization of the active Jacobian is sufficient for the identification of individual degenerate equations, it is still difficult to debug large models. Furthermore, blindly removing degenerate equation permanently from a model may be dangerous. For example, this could violate mass conservation when applied to (1). Instead *Degeneracy Hunter* aims to help expert modelers uncover the cause of degeneracies by finding the smallest sets of degenerate equations, i.e. **irreducible degenerate sets**. This allows the modeler to focus on a handful of equations instead of thousands (in large problems). Thus, the algorithms in *Degeneracy Hunter* are intended for post optimization analysis and not realtime use embedded in a NLP solver. The envisioned workflow with *Degeneracy Hunter* is shown in Figure 2.

2. The *Degeneracy Hunger* Algorithm

The *Degeneracy Hunter* algorithm is divided into four steps, and is summarized in Algorithm 1. First, in the **processing step**, the Jacobian and KKT (Karush-Kuhn-Tucker) multipliers are extracted from GAMS (or a similar environment), and the constraints are classified into four categories: equality, inactive inequality, strongly active inequality (non-zero multipliers) and weakly active inequality (zero multipliers). The *active Jacobian* (A_{dh}) is then assembled. It contains only the equality, strongly active inequality and optionally weakly active inequality constraints.

Next, in the **factorization step**, non-pivot rows of the active Jacobian are identified using either sparse or dense QR factorization. These rows are candidate degenerate equations. If the active Jacobian is not degenerate, there are no candidates and the algorithm terminates in this step.

In the **analysis step**, irreducible degenerate sets are calculated by solving a sequence of mixed integer linear programs (MILP), shown in (4), in order to minimize the number of non-zero elements in the adjoint vector λ. Integer variables y are used to count the number of non-zero elements. In order to avoid the trivial solution, $\|\lambda\| = 0$, the problem is resolved repeatedly with $\lambda_j = 1$ where $j = 1, \ldots n_{cand}$ are the indices of the n_{cand} candidate degenerate equations. Thus, this procedure may identify several irreducible degenerate sets instead of simply the smallest set. This is desirable, as there may be several independent sources of degeneracies in a large problem. Furthermore, because (4) is an MILP, its solution has the lowest possible cardinality. Through careful integration with mixed integer programming solvers, it would be possible to recover several irreducible degenerate sets containing candidate j with equal cardinality. Alternatively, it is also common for (4) to be infeasible. This indicates that candidate equation j does not significantly contribute to any degenerate set. Its original identification may have resulted from numerical noise in the factorization step. In the current implementation, the MILP is solved in GAMS with CPLEX or a

similar solver. For the test problems, including the case study with 15,000+ variables, the MILPs solve in (typically far) less than 1 CPU minute each. This is due both to the efficiency of commercial MILP solvers and the sparsity of the Jacobian for many chemical engineering problems.

$$\min \quad \sum_{i=1}^{n_{rows}} y_i \tag{4a}$$

$$\text{s.t.} \quad A_{dh}^T \lambda = 0 \tag{4b}$$

$$-My_i \leq \lambda_i \leq My_i \,, \quad \forall i = 1,...,n_{rows} \tag{4c}$$

$$\lambda_j = 1 \tag{4d}$$

Finally, in the **display step**, each irreducible degenerate set is reported (with the equation names from GAMS) along with the adjoint vector elements, λ, for these equations. This information allows the modeler to understand how a small number of equations interact to form degeneracies.

Data: Jacobian A, KKT multipliers m, constraint values c
Step 1: Assemble active Jacobian A_{dh} using A, m, c and user specified options ;
Step 2: Factorize A_{dh} and identify set of candidate degenerate equations $\{S\}$;
foreach $j \in \{S\}$ **do**
  Step 3: Solve (4) ;
  if *(4) is feasible* **then**
    Step 4: Display non-zero elements of λ (i.e. $y_i = 1$) and associated equation names ;
  else
    Step 4: Display equation j's name and "is not part of a degenerate set"
  end
end

3. Case Study: Air Separation Unit Design and Optimization

The authors previously developed an equation-based framework for flowsheet optimization in GAMS, and applied it to design air separation units for oxy-fired advanced power systems (Dowling and Biegler, 2015). The framework includes four key features: [1] embedded cubic equation of state thermodynamic calculations with vanishing and reappearing phases; [2] a novel equilibrium based distillation model with tray bypasses instead of integer variables; [3] simultaneous heat integration and process optimization; and [4] a trust region optimization algorithm to incorporate complex reactor models (e.g. computational fluid dynamics) without exact derivatives. Complementarity constraints are used throughout the framework to model switches, such as (dis)appearing phases and equipment being (in)active. The framework also includes a sophisticated initialization and multi-start procedure. In summary, a sequence of NLPs is solved in the framework. First the flowsheet is optimized with ideal thermodynamics and shortcut distillation models. These results are used to initialize more complex models, including cubic equation of state thermodynamics and the MESH with bypass distillation model. Applied to the ASU design problems, this ultimately yields a nonlinear program 15,000+ variables and constraints and ≈500 degrees of freedom.

Degeneracy Hunter has been applied to this model, and identified three sources of degenerate equations, which are a consequence of modeler (human) error.

3.1. Overspecifications

In the final stage of the optimization workflow for the equation-based framework, each half side of a heat exchange unit (condensers, reboilers, heat exchangers) is decomposed into a specified number of subunits. This is done to refine the constant heat capacity assumption used in the heat

integration model; with subunits, the heat capacity is now represented by a piecewise linear function. The subunits are spaced with equal temperature changes. For example, if a heat exchanger changes the temperature of a stream by 25 K, and it is decomposed into 5 subunits in series, each subunit would have a temperature difference of 5 K.

Unfortunately in this subunit model, there were two instances of overspecification. For the temperature differences, the following equations were originally used:

$$T_u^{in} - T_u^{out} = \Delta T, \quad \forall u \in \{\text{Heat Exchange Units}\} \tag{5a}$$

$$T_s^{in} - T_s^{out} = \Delta T/n, \quad \forall s(u) \in \{\text{Heat Exchange Subunits}\}(u) \tag{5b}$$

where n is the number of subunits (specified constant). Clearly, (5a) can be identified as degenerate and removed. (5b) is sufficient on its own to enforce the equal temperature spacing.

The second source of degenerate equations (overspecifications) comes from inequality constraints. Each subunit is defined by either heating or cooling, and the sign of the heat duty for each unit is restricted accordingly, as shown in (6a) & (6b). Furthermore, to assist with optimization inlet and outlet temperatures are also constrained (e.g. temperature may not decrease in a heating unit), as shown in (6c) & (6d). These additional equations are also redundant. When $Q > 0$, the extra equations are inactive, and when $Q = 0$, the equations create a local degeneracy.

$$Q^i n_h \geq 0, \; Q_h^{out} = 0, \quad \forall h \in \{\text{Heating Subunits}\} \tag{6a}$$

$$Q^i n_c = 0, \; Q_c^{out} \geq 0, \quad \forall c \in \{\text{Cooling Subunits}\} \tag{6b}$$

$$T_h^{in} \leq T_h^{out}, \; \forall h \in \{\text{Heating Subunits}\} \tag{6c}$$

$$T_c^{in} \geq T_c^{out}, \; \forall c \in \{\text{Cooling Subunits}\} \tag{6d}$$

Finally, there is also a third source of degenerate equations with a pressure recycle between the distillation cascades and reboiler, similar to Figure 1.

All three of these sources of degeneracy were identified using *Degeneracy Hunter*. Although these modeling mistakes seem trivial, they easily go undetected within an equation-based framework that has several modules spread over more than ten thousand of lines of GAMS code. Without a systematical debugging tool, it is difficult to diagnose poor optimizer performances as either inadequate initialization or the presence of degenerate equations.

3.2. Computational Results

The ASU design optimization problem from our previous study was solved for the same 288 initial points, with several different configurations for the degenerate equations (Dowling and Biegler, 2015). For all of these computational studies, a desktop computer, running Ubuntu Linux and GAMS 24.3.1 with a quad-core 2.8 GHz Intel i7 processor, was used. In order to quantify variations in timings due to background jobs, GAMS overhead, disk access, etc., several of the trials were repeated. The timings are consistent within a few seconds. The average CPU time for all 288 instances of the optimization problem are reported in Table 1 for each trial. These CPU times include the entire initialization procedure described by Dowling and Biegler (2015).

The best performance was obtained with all three sources of degeneracy removed (753.9 s) and the worst performance occurred with all three sources of degeneracies remaining in the optimization formulation (896.4 s). Thus with this case study, removing the degenerate equations decreased CPU time by 16%. Furthermore, the presence of degenerate constraints also impacted the termination status with CONOPT. The last two columns of Table 1 show the number optimal and only feasible solution points, as classified by CONOPT, for each trial. “High quality” solutions

Table 1: Comparison of CPU times for the ASU design optimization problem with various degenerate constraints removed.

Trial	Pressure recycle removed?	(5a) removed?	(6c) & (6d) removed?	Average CPU time	"High Quality" Optimal	"High Quality" Only Feasible
1	No	No	No	896.4 s	210	14
2	No	Yes	Yes	863.6 s	204	17
3a	Yes	No	No	791.2 s	215	20
3b	Yes	No	No	788.7 s	215	20
4a	Yes	Yes	No	817.5 s	205	13
4b	Yes	Yes	No	818.4 s	205	13
5a	Yes	No	Yes	858.0 s	204	23
5b	Yes	No	Yes	859.8 s	204	23
6a	Yes	Yes	Yes	753.3 s	214	18
6b	Yes	Yes	Yes	754.1 s	214	18
6c	Yes	Yes	Yes	754.4 s	214	18

are defined as completely heat integrated with no complementarity violations. CONOPT terminated at locally optimal points 214 times in trial six (all degeneracies removed). In contrast, with some degeneracies present in trial five, CONOPT terminated at locally optimal only 204 times. This performance difference is expected, as the KKT multipliers are not unique in the presence of degeneracies. For the feasible only points, the active-set strategy may have not removed all of the degenerate constraints. Furthermore, in trial four (218), CONOPT terminated at 17 more infeasible and/or not high quality points than trial three (235). This speaks to the complexity of NLP solution techniques and the initialization procedure used in the framework. It is likely the presence of degeneracies (especially the pressure recycle loop) causes the NLP solver, CONOPT, to take different convergence paths early in the initialization procedure. This can result in very different solutions for each initial point considered.

4. Conclusions

In summary, we develop and describe the *Degeneracy Hunter*, an algorithm for determining irreducible degenerate sets of equations. Calculation of these sets is formulated as a mixed integer linear program. This contribution is especially important for debugging complex nonlinear programs with thousands of constraints. As demonstrated in a process design case study, the presence of a few degenerate equations may have a dramatic impact on solution time with active set methods, such as CONOPT. With interior point methods, such as IPOPT, degenerate equations can be even more serious, and could cause the solver to terminate at infeasible points. *Degeneracy Hunter* is a model debugging tool that helps expert modelers to identify degenerate constraints, reformulate their problems, and improve the performance of the large-scale optimization strategy. We recommend using *Degeneracy Hunter* to diagnose poor performance in NLP solvers, especially due to cycling and termination at non-optimal feasible points as a result of small step sizes.

Abstract

This contribution presents a novel offline dynamic multi-objective optimization framework for high-pressure liquid chromatographic (HPLC) processes in batch elution mode. The framework allows for optimization of general elution trajectories parametrized with piecewise constant control signals. It is based on a simultaneous method where both the control and state variables are fully discretized in the temporal domain, using orthogonal collocations on finite elements, and the state variables are discretized in the spatial domain, using a finite volume weighted essentially non-oscillatory (WENO) scheme. The resulting finite dimensional nonlinear program (NLP) is solved using a primal-dual interior point method and automatic differentiation techniques. The advantages of this open-loop optimal control methodology are highlighted through the solution of a challenging ternary complex mixture separation problem for a hydrophobic interaction chromatography (HIC) system. For a bi-objective optimization of the target component productivity and yield, subject to a purity constraint, the set of Pareto solutions generated with general elution trajectories showed considerable improvement in the productivity objective when compared to the Pareto set obtained using conventional linear elution trajectories.

Keywords: Batch chromatography, Dynamic multi-objective optimization, Collocation

1. Introduction

Isolation of a high purity target component from a multicomponent mixture is of significant importance in the pharmaceutical and biochemical industries. Reproducible selectivity in chromatographic separation of closely related product impurities requires optimized elution mode and fractionation or cut-times (Sreedhar et al., 2013). The current state-of-the-art methodology for optimization of HPLC separation has been limited to linear, concave/convex and step elution trajectories (Damtew et al., 2009). The main purpose of the present study is to demonstrate a novel methodology for simultaneous optimization of general elution trajectories, target component pooling decisions, column loading, and batch cycle time. The realistic multi-component system dynamics required for analysis were generated by numerical solution of the *reaction–dispersive model* (Schmidt-Traub et al., 2012). This model is governed by a set of mass-balance partial differential equations (PDEs), with a modified Langmuir isotherm and experimentally validated kinetics. Hence, the proposed methodology implies formulating and solving a large-scale dynamic optimization problem (DOP) constrained by PDEs (Biegler, 2010). However, in chromatographic separation processes, there are several incommensurable objectives which require a trade-off to ensure a satisfactory design. For the purpose of this study, a set of Pareto solutions were generated for bi-objective scenarios, with target component productivity and yield, by means of a weighted sum (WS) scalarization method.

2. Modeling of HPLC Processes

The governing one-dimensional equations in the *reaction–dispersive model* (Schmidt-Traub et al., 2012) of the mobile and stationary phase, derived under the assumptions of infinitely fast diffusion into the particles and rate-limiting adsorption kinetics, defined in the spatial, $z \in [z_0, z_f]$, and temporal, $t \in [t_0, t_f]$, domains are:

$$\frac{\partial c_\alpha}{\partial t} = -\frac{\partial}{\partial z}\left(c_\alpha v_{\text{int}} - \mathscr{D}_{\text{app},\alpha}\frac{\partial c_\alpha}{\partial z}\right) - \frac{(1-\varepsilon_c)}{\varepsilon_c + (1-\varepsilon_c)\varepsilon_p}\frac{\partial q_\alpha}{\partial t}, \tag{1}$$

$$\frac{\partial q_\alpha}{\partial t} = k_{\text{kin},\alpha}\left(H_{0,\alpha}c_\alpha e^{c_S\gamma_\alpha}\left[1 + 2K_{\text{eq},\alpha}c_\alpha e^{c_S\gamma_\alpha}\right]\left[1 - \sum_{\beta\in\{A,B,C\}}\frac{q_\beta}{q_{\max,\beta}}\right]^{\nu_\alpha} - q_\alpha\right), \tag{2}$$

where c_α and q_α are the mobile and stationary phase concentration of component $\alpha \in \{A,B,C,S\}$, v_{int} denotes the interstitial velocity of the fluid, $\mathscr{D}_{\text{app},\alpha}$ the apparent dispersion coefficient, and ε_c and ε_p the column and particle void fractions. The hydrophobic interaction isotherm described in Eq. (2) is based on the Langmuir mobile phase modulator (Melander et al., 1989). Here, c_S denotes the concentration of the non-absorbing modifier (i.e. $\partial q_S/\partial t := 0$), $k_{\text{kin},\alpha}$ the kinetic rate constant, $H_{0,\alpha}$ the Henry's constant, γ_α the solvophobicity parameter, ν_α the binding charge ratio, $q_{\max,\alpha}$ the maximum concentration of adsorbed components, and $K_{\text{eq},\alpha}$ the equilibrium constant. Eq. (1) is complemented with Danckwerts boundary conditions:

$$c_\alpha(t,z_0)v_{\text{int}} - \mathscr{D}_{\text{app},\alpha}\frac{\partial c_\alpha}{\partial z}(t,z_0) = \begin{cases} c_{\text{load},\alpha}v_{\text{int}}\Pi(t,t_0,\Delta t_{\text{load}}) & \text{if } \alpha \in \{A,B,C\}, \\ c_{\text{mix},S}v_{\text{int}} & \text{if } \alpha = S, \end{cases} \tag{3}$$

$$\frac{\partial c_\alpha}{\partial z}(t,z_f) = 0, \tag{4}$$

where $c_{\text{load},\alpha}$ is the injected load concentration and $\Pi(t,t_0,\Delta t_{\text{load}}) \in [0,1]$ a smooth rectangular function in the temporal horizon $[t_0, \Delta t_{\text{load}}]$. The dynamics of the modifier concentration in the upstream mixing tank, $c_{\text{mix},S}$, is governed by:

$$\frac{\mathrm{d}c_{\text{mix},S}}{\mathrm{d}t} = \frac{1}{\tau_{\text{mix}}}\left(u(t) - c_{\text{mix},S}\right), \tag{5}$$

where u is the elution trajectory and τ_{mix} the residence time. Finally, the PDE system was approximated using the method-of-lines and an adaptive, high-order finite volume WENO scheme (Shu, 1998) on a uniform mesh where $z_j = j\Delta z$ is the discretized spatial coordinate and $j \in [1..N_j]$.

3. Dynamic Multi-Objective Optimization

The elution trajectories at the column outlet, $c_\alpha(t,z_f)$ and $\alpha \in \{A,B,C\}$, form the basis for evaluating the incommensurable objective functions of yield, Y_α, and productivity, P_α, with the intermediately eluting component B as target. The objective functions of the αth component collected in the pooling horizon $[t_c, t_f]$ are defined as:

$$\delta_{\text{load},\alpha}\frac{\mathrm{d}Y_\alpha}{\mathrm{d}t} = c_\alpha(t,z_f)v_{\text{int}}A_c\Pi(t,t_c,t_f), \tag{6}$$

$$\frac{\mathrm{d}P_\alpha}{\mathrm{d}t} = \frac{1}{V_c}\frac{1}{(t_f+t_r)}\delta_{\text{load},\alpha}\frac{\mathrm{d}Y_\alpha}{\mathrm{d}t}, \tag{7}$$

where $\delta_{\text{load},\alpha} = c_{\text{load},\alpha}v_{\text{int}}A_c\Delta t_{\text{load}}$ is the total injected sample amount, A_c and V_c the column cross-sectional area and volume, and $t_r = 2z_f v_{\text{int}}^{-1}$ the assigned regeneration and re-equilibration time (Schmidt-Traub et al., 2012) in column volumes (CV). Hence, the aim is to derive an optimal

elution trajectory, u, load duration, Δt_{load}, and pooling horizon, $[t_c, t_f]$ that maximize $Y_\alpha(t_f)$ and $P_\alpha(t_f)$ while fulfilling the constraint imposed on purity of the target component fractionization:

$$X_\alpha(t_f) = \delta_{\text{load},\alpha} Y_\alpha(t_f) \left(\sum_{\beta \in \{A,B,C\}} \delta_{\text{load},\beta} Y_\beta(t_f) \right)^{-1}, \tag{8}$$

where the numerator of the right hand side represents the captured amount of the target component in $[t_c, t_f]$ and the denominator represents the total amount captured. Hence, $X_\alpha(t_f)$ is incorporated in the DOP as a terminal inequality constraint, $X_{L,\alpha} - X_\alpha(t_f) \leq 0$, with an assigned lower purity requirement $X_{L,\alpha}$.

3.1. Dynamic Multi-Objective Optimization Problem Formulation

The WS scalarization method was used to combine the objectives in Eqs. (6 and 7) into a single performance index with a weight $\omega \in [0,1]$ and the resulting optimization problem can be cast in the frame for *min–min optimal control*:

$$\text{min.} \quad -\left(\omega \int_{t_0}^{t_f} \frac{\mathrm{d}P_B}{\mathrm{d}t} \mathrm{d}t + (1-\omega) \int_{t_0}^{t_f} \frac{\mathrm{d}Y_B}{\mathrm{d}t} \mathrm{d}t \right) + \mathcal{U} \sum_{i=2}^{N_u} \Delta u_i^2, \tag{9a}$$

$$\text{w.r.t.} \quad \left(\Delta t_{\text{load}}, t_f\right) \in \mathbb{R}^2,$$

$$\text{s.t.} \quad \Delta t_{\text{load},L} \leq \Delta t_{\text{load}} \leq \Delta t_{\text{load},U}, \quad t_{f,L} \leq t_f \leq t_{f,U}, \tag{9b}$$

$$(\boldsymbol{x}, u, t_c) = \arg\,\text{min.} \quad -\left(\omega \int_{t_0}^{t_f} \frac{\mathrm{d}P_B}{\mathrm{d}t} \mathrm{d}t + (1-\omega) \int_{t_0}^{t_f} \frac{\mathrm{d}Y_B}{\mathrm{d}t} \mathrm{d}t \right) + \mathcal{U} \sum_{i=2}^{N_u} \Delta u_i^2, \tag{9c}$$

$$\text{w.r.t.} \quad \boldsymbol{x} : [t_0, t_f] \to \mathbb{R}^{n_x},$$

$$t_c \in \mathbb{R}, \qquad u \in \mathbb{R}^{N_u},$$

$$\text{s.t.} \quad \boldsymbol{F}\left(t, \dot{\boldsymbol{x}}(t), \boldsymbol{x}(t), u(t), \Delta t_{\text{load}}, t_f, t_c\right) = \boldsymbol{0}, \quad \boldsymbol{x}(t_0) = \boldsymbol{x}_0, \tag{9d}$$

$$X_{B,L} - X_B(t_f) \leq 0, \tag{9e}$$

$$\boldsymbol{x}_L \leq \boldsymbol{x}(t), \qquad t_{c,L} \leq t_c \leq t_{c,U}, \tag{9f}$$

$$u_L \leq u \leq u_U, \qquad |\Delta u| \leq \Delta u_U, \tag{9g}$$

$$\forall t \in [t_0, t_f], \forall i \in [1..N_i], \qquad \forall z \in [z_0, z_f], \forall j \in [1..N_j].$$

Eqs. (9a and 9c) have a typical optimal control Lagrange term together with a quadratic penalty on the differences of the piecewise constant controls, Δu, in the temporal domain, which is discretized with N_i finite elements. This will influence the smoothness of u, and $\mathcal{U}$ is a weight. The optimization variables are the free operating parameters—the discrete control signal u and free time-invariant parameters $(\Delta t_{\text{load}}, t_f, t_c)$—and the state variables $\boldsymbol{x}(t) = (c_\alpha(t, z_j), c_S(t, z_j), c_{\text{mix},S}(t), q_\alpha(t, z_j), P_B(t), Y_\alpha(t), X_B(t))$ where $\alpha \in \{A, B, C\}$. The trajectories $\boldsymbol{x}$ are determined by the free operating parameters via the implicit differential algebraic equations (DAE) system of index one in Eq. (9d). Time-invariant bounds on variables are introduced in Eq. (9f) and bounds on u and Δu are introduced in Eq. (9g).

In this study, a decomposition strategy is adopted to transform the DOP into two levels: (i) the upper-level static optimization problem (Eqs. (9a–9b)) with respect to $(\Delta t_{\text{load}}, t_f)$ which is solved using a Nelder–Mead Simplex algorithm, and (ii) the lower-level DOP (Eqs. (9c–9g) constrained by the DAE system dynamics is transcribed into a NLP using direct collocation, as described in Section 4, and solved using IPOPT (Wächter and Biegler, 2006). By these means, the lower-level DOP is solved for a fixed temporal horizon $[t_0, t_f]$ which considerably reduces the NLP complexity and hence leads to an efficient computation.

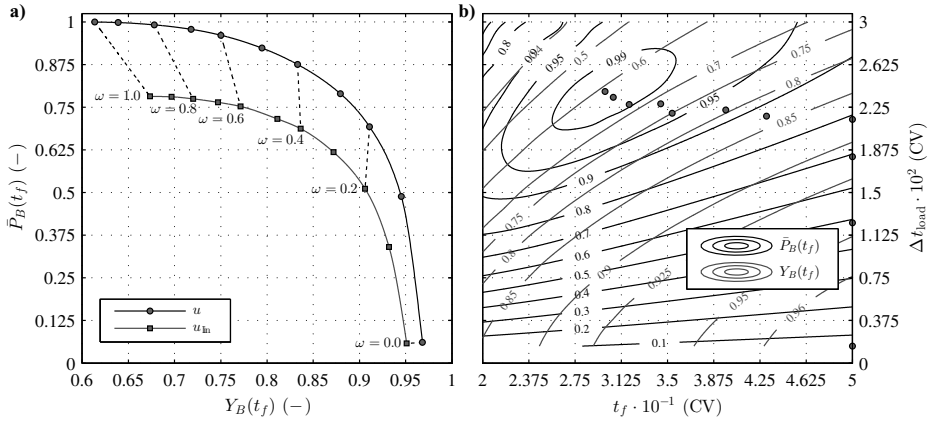

Figure 1: a) Pareto optimal solutions for $\omega \in [0.0, 1.0]$ and $X_{L,B}(t_f) = 9.9 \cdot 10^{-1}$. b) Interpolated sampled contours of $Y_B(t_f)$ and normalized $\bar{P}_B(t_f)$ generated for u as a function of $\Delta t_{\text{load}} \in [0.15, 3.0] \cdot 10^{-2}$ (CV) and $t_f \in [2.0, 5.0] \cdot 10^1$ (CV). Markers indicate the Pareto optimal time-invariant optimization variables of the upper-level static optimization problem (Eq. (9a–9b)).

4. Modeling and Optimization Environment

Modelica (The Modelica Association, 2012) was used as the description language for the HPLC process model presented in Section 2. The open-source platform JModelica.org (Åkesson et al., 2010) was used for simulation and optimization of the Modelica model. In the context of simulation, JModelica.org was used to compile the Modelica model into a functional mock-up unit (FMU) (Blochwitz et al., 2011), thus transforming it from a DAE form into an ordinary differential equation (ODE) form. JModelica.org's interface to SUNDIALS (Hindmarsh et al., 2005) was subsequently used to simulate the model.

The formulation of the DOP (Eq. (9c–9g) was made using the Modelica extension Optimica (Åkesson et al., 2010). The algorithm used in the work described in this paper to solve the DOP uses a direct and local collocation method (Biegler, 2010) on finite elements, using Radau points and Lagrange interpolation polynomials (Magnusson and Åkesson, 2012). The algorithm has been implemented in Python in the JModelica.org framework, using the computer algebra system with automatic differentiation (CasADi) optimization package (Andersson et al., 2012). By using CasADi's symbolic syntax, the DOP was transcribed into a finite dimensional NLP. The NLP was subsequently solved using the primal-dual interior point method IPOPT v.3.11.8 (Wächter and Biegler, 2006) and the linear solver MA57 from HSL (HSL, 2013).

5. Results and Discussion

The temporal horizon was discretized with $N_i = 1 \cdot 10^2$ finite elements with two Radau collocations points in each element and a piecewise constant control discretization with $N_u = 5 \cdot 10^1$ pieces was adopted. The spatial domain was discretized with $N_j = 2 \cdot 10^1$ finite volume elements with a 4th order WENO scheme and the resulting NLP has approximately $1 \cdot 10^5$ variables. In order to assess the performance of the general elution trajectories, these were benchmarked with conventional linear trajectories governed by:

$$u_{\text{lin}}(t) = u_{\text{lin}}(t_{\text{lin},0}) + \left[u_{\text{lin}}(t_f) - u_{\text{lin}}(t_{\text{lin},0})\right] \left(\frac{t - t_{\text{lin},0}}{t_f}\right), \tag{10}$$

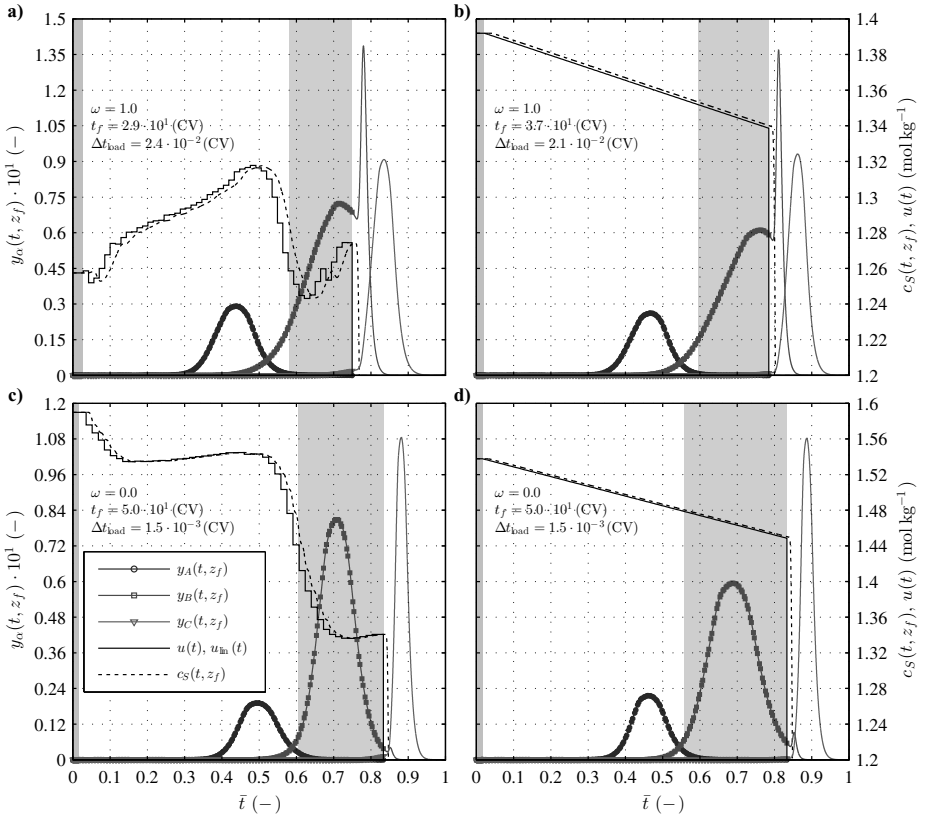

Figure 2: Optimal elution trajectories, where $y_\alpha(t,z_f) = c_\alpha(t,z_f)v_{\text{int}}(A_c^{-1}\sum_{\beta\in\{A,B,C\}}\delta_{\text{load},\beta})^{-1}$ is the normalized flux at $z = z_f$, as a function of normalized time $\bar{t} = t(t_f + t_r)^{-1}$. Markers indicate the solution at the Radau collocation points and solid and dashed lines the simulated response. The shaded areas indicate the pooling interval endpoints, $[t_c, t_f]$, and those of the initial load and wash, $[t_0, t_0 + \Delta t_{\text{load}} + \Delta t_{\text{wash}}]$.

where $t_{\text{lin},0} = t_0 + \Delta t_{\text{load}} + \Delta t_{\text{wash}}$ defines the onset of the elution mode and $(u_{\text{lin}}(t_{\text{lin},0}), u_{\text{lin}}(t_f))$ are the optimization variables. It is evident from analyzing the Pareto optimal fronts for $X_{L,B}(t_f) = 9.9 \cdot 10^{-1}$ depicted in Fig. 1a that the general elution trajectories, u, outperform the linear trajectories, u_{lin}, in terms of both objectives. Especially, for $\omega = 1.0$ the maximum productivity obtained with u is approximately 28% higher than that for u_{lin}. In addition, the dependency of $P_B(t_f)$ and $Y_B(t_f)$ on the time-invariant optimization variables $(\Delta t_{\text{load}}, t_f)$ associated with u depicted in Fig. 1b shows that $Y_B(t_f)$ is strictly decreasing as $\Delta t_{\text{load}} \to \Delta t_{\text{load},U}$ and $t_f \to t_{f,L}$ whereas $P_B(t_f)$ exhibits a convex behavior. The contours in Fig. 1b were generated by interpolating the solution to the lower-level DOP (Eq. (9c–9g) on a dense rectangular grid of $(\Delta t_{\text{load}}, t_f)$.

The associated elution profiles for $\omega = (0.0, 1.0)$ illustrated in Fig. 2 show a clear distinction in the system response generated with u and u_{lin}, respectively. As governed by Eq. (10), u_{lin} and hence the optimal modifier concentration is strictly decreasing in $[t_{\text{lin},0}, t_f]$ in order to increase hydrophobicity and to elute the components $\alpha \in \{A, B, C\}$. Contrarily, the modifier concentration

is freely controlled with the parametrized elution trajectories which ultimately promotes $P_B(t_f)$ through increasing Δt_{load} and reducing t_f while fulfilling the purity constraint (Figs. 2a and 2b). However, maximizing $Y_B(t_f)$ (which is time-invariant) implies injecting a minimal column load, and hence, $(\Delta t_{\text{load}}, t_f)$ are constrained by their lower and upper boundaries, and the gain in $Y_B(t_f)$ for u is therefore only moderate (Figs. 2c and 2d). Finally, it is noteworthy that the DOP (Eq. (9c–9g)) is solved for the temporal horizon $[t_0, t_f]$, and the control signal is prescribed a constant value of $5.0 \cdot 10^{-1}$ $(\text{mol}\,\text{kg}^{-1})$ for $t > t_f$, i.e. the column regeneration and re-equilibration.

6. Concluding Remarks

A novel methodology for rendering large-scale offline dynamic multi-objective optimization problems for HPLC processes in batch elution mode was developed in this paper. The assessment of the set of Pareto solutions generated with general elution trajectories, parametrized with a piecewise constant control signal, showed considerable improvement in the productivity objective when benchmarked with the Pareto set obtained using conventional linear elution trajectories.

Abstract

The dynamic optimization problems appear frequently in chemical industry, and these problems are quite challenging because they often involve multiple and conflicting objectives. In this paper, a new adaptive multi-objective differential evolution algorithm named EPSMODE is proposed, which can be used to solve the multi-objective dynamic optimization problems. To solve a specific multi-objective problem, the performance of differential evolution depends on the choice of the control parameters and mutation strategies. Therefore, aiming to improve the robustness of multi-objective differential evolution, the EPSMODE approach employs an ensemble of parameter values and mutation strategies, and these parameter values and mutation strategies compete to produce offspring based on Pareto domination mechanisms. The performance of EPSMODE is first compared with powerful multi-objective algorithms on benchmark multi-objective problems; then, by combining with the control vector parameterization approach, EPSMODE is applied to solve a multi-objective dynamic optimization problem with constraints. The computational results reveal the effectiveness and efficiency of the proposed approach.

Keywords: multi-objective optimization, dynamic optimization, differential evolution, ensemble strategy.

1. Introduction

Dynamic optimization problems (i.e., optimal control problems) are encountered in a large number of chemical engineering applications. In practical chemical dynamic optimization problems, multiple and conflicting objectives are often present. The multi-objective optimization problems (MOPs) give rise to a set of Pareto optimal solutions instead of one single solution. The designer will then select one solution from this Pareto optimal set.

Solution methods for generating the Pareto front can be divided into in two categories: scalarization and vectorization methods. The scalarization methods transform the multi-objective problems into a series of single objective optimization problems by classic convex weighted sum, or novel methods as normal boundary intersection, normalized normal constraint (Logist et al. 2008). The vectorization methods involve population-based multi-objective evolutionary algorithms (MOEAs), such as elitist nondominated sorting genetic algorithm (NSGA-II) (Deb et al. 2002), multi-objective particle swarm optimization (MOPSO) (Coello et al. 2004). Compared with the scalarization methods,

MOEAs have the following advantages: (i) they can find the entire Pareto optimal front in one single run; (ii) they can be useful when the gradient information is unavailable; (iii) they can avoid falling into the local Pareto optimal front. Because of these advantages, the use of MOEAs to solve MDOPs has drawn continuing attention from researchers (Sarkar and Modak 2005, Jia et al. 2012, Chen et al.2014).

Multi-objective Differential evolution (MODE) is a new population-based evolutionary algorithm. The computational results reported in published articles show that MODE has a better convergence speed than NSGA-II and a better diversity maintenance than MOPSO (Wang and Tang, 2014). However, to solve a specific multi-objective problem, the performance of differential evolution depends on the choice of the control parameters and mutation strategies. Therefore, to improve the robustness of MODE, we develop a new multi-parameters and multi-strategies adaptive MODE algorithm, called multi-objective differential evolution with ensemble of parameters and mutation strategies (EPSMODE). In the proposed approach, a pool of mutation strategies along with a pool of values for each control parameter coexists throughout the evolution process, and competes to produce offspring based on Pareto domination mechanisms. The computational results on benchmark multi-objective problems and a multi-objective dynamic optimization problem (MDOP) reveal the effectiveness and efficiency of the proposed approach.

2. Proposed approach

The DE algorithm is a stochastic, population-based algorithm designed for optimization problems in continuous search space (Storn and Price,1997), working through three operations: mutation, crossover, and selection. However, the effectiveness of DE in solving an optimization problem depends on the selected mutation strategy and its associated parameter values. Mallipeddi et al. (2011) introduced an ensemble strategy with adaptation of all parameters and mutation strategies to DE, and proposed a DE variant called EPSDE for single optimization problem. Motivated by the promising results obtained by EPSDE, we extend the idea of ensemble strategy to multi-objective optimization, and an adaptive MODE algorithm called EPSMODE is presented in this paper. In EPSMODE, a pool of mutation strategies along with a pool of values corresponding to each associated parameter competes to produce successful offspring based on Pareto domination mechanisms. In the following, EPSMODE is described in detail.

2.1. Selection of pools of strategies and control parameters

EPSMODE firstly initializes a population of NP individuals X_i, i=1,….,NP and evaluates these individuals. After initialization, a pool of mutation strategies and a pool of values for two crucial parameters, the scale factor F and crossover probability CR, are generated. The pool of mutation strategies contains DE/rand/1, DE/rand/2, and DE/current-to-rand/1. The pool of F values is taken in the range 0.4–0.9 in steps of 0.1, i.e. the set {0.4, 0.5, 0.6, 0.7, 0.8, 0.9}, and the pool of CR values is taken in the range 0.1–0.9 in steps of 0.1, i.e. the set {0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9}. In EPSMODE, each individual X_i is randomly assigned with one of the mutation strategy MS_i and the associated parameter values (F_i and CR_i) from the pools. The ensemble strategy in EPSMODE is illustrated in Figure 1(a).

2.2. Generate offspring with DE operators

EPSMODE performs mutation and crossover using the mutation strategy MS_i and the associated parameter (F_i and CR_i) corresponding to each individuals X_i. After the crossover operator, NP offspring U_i, i=1,…,NP are produced. EPSMODE combines the parents and offspring, and the total size of the population after combination becomes 2NP. Then, it sorts the population based on fast nondominated sorting and crowding distance. The NP better solutions are selected to enter into the next generation. The details implementations of nondominated sorting and crowding distance calculation can refer to NSGA-II.(Deb et al. 2002).

2.3. Update the mutation strategies and control parameter values

After selection operator, EPSMODE updates the mutation strategies and control parameters for each individual X_i using the following criteria:

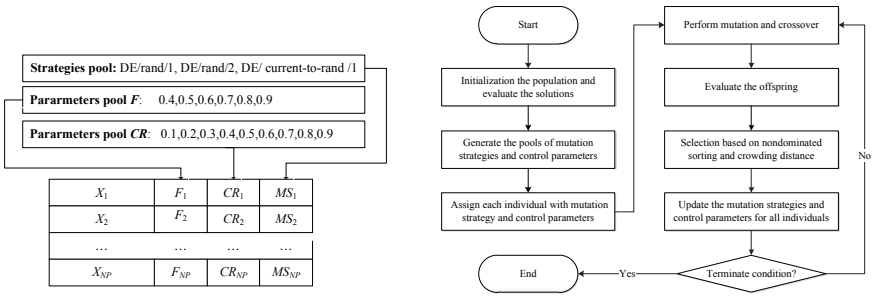
(i) If the offspring U_i survives into the next generation, the corresponding mutation strategy MS_i and parameter values (F_i and CR_i) are retained in the next generation; meanwhile, the mutation strategies and parameter values are added to a successful list.

(ii) If the offspring U_i fails surviving into the next generation, randomly select a new mutation strategy and parameter values from the pools or the store successful list with equal probability.

The two criteria lead to an increased probability of production of offspring by the better combination of mutation strategy and the associated control parameters in the future generations.

2.4. Constraint-handling method

Usually, most of practical engineering optimization problems have multiple constraints. So it is essential to handle the constraints to solve these problems. To handle these constraints, we use Deb's constrained-domination principle in EPSMODE (Deb et al. 2002). For two solutions X_1 and X_2, X_1 is said to constrained-dominate X_2 if any of the following three conditions is met: (i) both solutions are feasible, and X_1 dominates X_2; (ii) solution X_1 is feasible, but solution X_2 is infeasible; and (iii) both solutions are infeasible, and the constraint violation of X_1 is smaller than that of X_2. Based on subsection 2.1–2.4, the flowchart of the EPSMODE approach is given in Figure 1(b).



(a) (b)

Figure 1: EPSMODE (a) ensemble strategy of parameters and mutation strategies. (b) flowchart of EPSMODE.

3. Case Study

3.1. Case Study I: Benchmark Multi-objective Optimization Problems

To test the performance of the proposed EPSMODE, it is used to solve eleven constrained benchmark MOPs (Deb, 2001), and compared with two MOEAs: NSGA-II (Deb et al. 2002) and GDE3 (Kukkonen and Lampinen, 2005). The performance metric inverted generational distance (IGD) (Li and Zhang, 2009) which measures both convergence and diversity is used to evaluate the attained approximation Pareto front of an algorithm. All algorithms are conducted with population size *NP*=100, and maximum number of generations *Maxgen*=250. The results based on 30 runs are presented in Table 1.

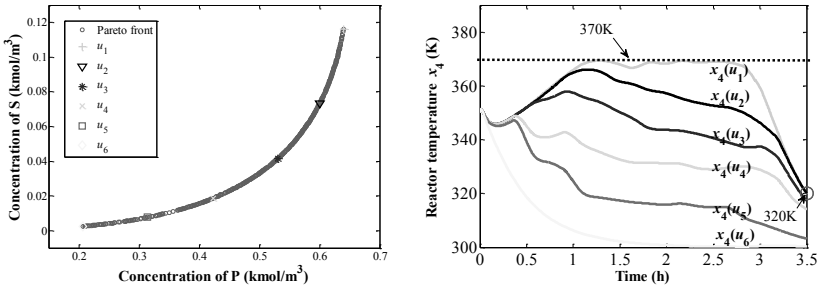
(a) (b) (c)

Figure 2: Adaptiveness of EPSMODE on problem TNK (a) Probability of an offspring production by a mutation strategy versus generations. (b) Probability of an offspring production by a particular *F* value versus generations. (c) Probability of an offspring production by a particular *CR* value versus Generation

From Table 1, it appears that our EPSMODE obtains the best IGD values on ten of eleven MOPs among the three algorithms. It means the EPSMODE achieves approximation Pareto fronts with best convergence and diversity on these problems. EPSMODE and NSGA-II get similar results on CTP6. GDE3 performs better than EPSMODE only on one problem SRN. Based on the above results, we can say that the proposed EPSMODE is a high competitive algorithm. To investigate the adaptiveness of EPSMODE, figure 2 show the probability of an offspring being produced by a particular mutation strategy or a particular parameter value versus generation on problem TNK. From the figure, all mutation strategies and parameter values in respective pools have equal probability to produce an offspring. However, as the evolution progresses, the inefficient mutation strategies and parameters are replaced with new mutation strategies and parameters, leading to an increase in the probability of producing an offspring by a suited mutation strategy and parameters.

3.2. Case Study II: Multi-objective Dynamic Optimization Problems.

By combining the control vector parameterization (CVP) approach (Balsa Canto et al. 2002), the EPSMODE is used to solve a MDOP: optimal operation for a batch reactor with cooling jacket. The problem formulates a first-order consecutive exothermic reaction, $A \rightarrow P \rightarrow S$, occurring in a batch reactor with a cooling jacket. The system dynamic equations are given in the literature (Sun et al, 2008). There are six state variables x_1 -x_6, where x_1, x_2, and x_3 denote the concentration of A, P, and S; x_4, x_5, and x_6 represent the temperatures (in Kelvin) of the contents in the reactor, the reactor wall, and the coolant, respectively. The control variable u is the coolant flow rate (expressed in units of m^3/h), which is bounded by $0 \le u(t) \le 9$ .The aim is to maximize the concentration of product P $x_2(t_f)$ and minimize the concentration of by-product S $x_3(t_f)$ at $t_f = 3.5h$. In addition, there are two constraints posed on the reactor temperature: one path constraint $x_4(t) \le 370K$ and one terminal constraint $x_4(t_f) \le 320K$.



(a) (b)

Figure 3: Computational results (a) Pareto optimal front obtained by EPSMODE. (b) Pareto optimal reactor temperature corresponding to u_1-u_6.

When using EPSMODE to solve this problem, the time interval is divided in to N=20 stages in CVP approach, and the parameters settings for EPSMODE are: population size NP=400, maximal number of generation $Maxgen$=1000. The Pareto front obtained by EPSMODE is shown in Figure 3(a). Clearly, there is a tradeoff between maximizing the concentration of product P and minimizing the concentration of by-product S. We mark six Pareto optimal solutions u_1-u_6 in the Pareto front, including two extreme solutions and four intermediate solutions. The concentration of product P ranges between 0.20570 and 0.63987 kmol/m^3, and the concentration of by-product S varies 0.00247 and 0.11619and kmol/m^3. Sun et al. (2008) considered the single objective problem to maximize the concentration of product P, their best value is 0.64469. Our result in extreme solution u_1 is 0.63987, which is within 0.1% of the reported best value. When we only consider minimizing the concentration of by-product S, our result in extreme solution u_6 is 0.00247. Other four intermediate solutions u_2-u_5 are presented with equal distribution. Which solution is selected in practice is decided by the preference of the decision maker and other factor such as the cost of the separation of the product and by-product.

Pareto optimal reactor temperatures $x_4(t)$ corresponding to u_1-u_6 are shown in Figure 3(b). Obviously, the path constraint $x_4(t) \le 370K$ and terminal constraint $x_4(t_f) \le 320K$ in all six solutions are satisfied. For u_1, the path constraint is active in

the middle of the time interval (about 1h to 3h) and the terminal constraint is active. For u_2, only the terminal constraint is active. For other solutions u_3-u_6, both the path constraint and the terminal constraint are non-active.

4. Conclusions

This paper has described a new adaptive MODE algorithm EPSMODE, which can be used to solve MDOPs in chemical processes. EPSMODE employs an ensemble strategy with adaptation of all parameters and mutation strategies to improve the robustness of MODE. The computational results on benchmark MOPs and a MDOP demonstrate the effectiveness and efficiency of the proposed approach.

Abstract

In the present study, the problem of optimization of thermal cracker (pyrolysis) operation is discussed. The main objective in thermal cracker optimization is the estimation of the optimal flow rates of different feeds (such as, Gas-oil, Propane, Ethane and Debutanized natural gasoline) to the cracking furnace under the restriction on ethylene and propylene production. Thousands of combinations of feeds are possible. Hence the optimization needs an efficient strategy in searching for the global minimum. The optimization problem consists of maximizing the economic profit subject to a number of equality and inequality constraints. Modelling, simulation and optimal operation via optimization of the thermal cracking reactor has been carried out by gPROMS (**g**eneral **PRO**cess **M**odelling **S**ystem) software. The optimization problem is posed as a Non-Linear Programming problem and using a Successive Quadratic Programming (SQP) method for solving constrained nonlinear optimization problem with high accuracy within gPROMS software. New results have been obtained for the control variables and optimal cost of the cracker in comparison with previous studies.
Keywords: Thermal Cracking, Mathematical Modeling, Olefins Pyrolysis, SQP.

1. Introduction

Hydrocarbon thermal cracking is the most significant operation in the production of olefins. Recently, the worldwide olefins production (mainly ethylene) increases rapidly (around 180 billion lb/yr), and is regarded one of the most important issues for chemical industries where improving its production operation can bring several benefits. Thus, the market demand for olefins production has accelerated the improvement of a more rigorous and reliable thermal cracking model of such process. Its annual industrial production depends on the thermal cracking (pyrolysis) of oil hydrocarbons, where the heart of the process with a massive economic effect is the reactor of the cracking process. Cracking of heavier fuel oils is done to produce mainly high quality (octane number) petrol, olefins (feed for petrochemical industry), coke (by coking) and to reduce the viscosity of fuel oil by visbreaking (Masoumi et al., 2006a, Babu and Angira, 2001). The main parameter of the optimal design of such reactor is the accurate prediction of yield and reactor performance. Each reactant is known to produce a certain distribution of products. When multiple reactants are employed, it is desirable to optimize the amounts of each reactant so that the products satisfy flow and demand constraints. Control systems are designed for achieving several goals, involving product quality, safety, and minimum cost (Masoumi et al., 2006b, Edgar and Himmelblau, 2001). The feed of a thermal cracking furnace can be a variety of components (such as ethane, propane, butane, isobutane, naphtha, and gas oil) and the main factor influencing the product is the feed composition (Lee and Aitani, 1990). The optimal design and operation strategy and purchase decisions for raw materials have become

main issues in the olefin industries (Joo and Park, 2001). It is extremely difficult to obtain the detailed operation factors in the reactor from direct measurements owing to the limitation of current techniques. Thus, mathematical simulation, as an alternative, has become a powerful tool for predicting control variable distributions and olefin yields. The thermal cracking reactor is the key parameters affecting the economics of the process and the olefin yields (Lan et al., 2007). The main focus in this study is to find the optimal design of pyrolysis reactor (thermal cracker) and objective function of the process (which is the estimation of optimal flow rates of different feeds to the cracking furnace) subject to a number of equality and inequality constraints using an alternative approach to describe the reactor operating conditions as accurately as possible. The optimization problem is posed as a Non-Linear Programming problem and is solved by employing a Successive Quadratic Programming (SQP) method (which is considered to be one of the most promising approaches for solving constrained nonlinear optimization problem in addition to its successful application to many engineering optimization problems) with high accuracy within gPROMS (**g**eneral **PRO**cess **M**odelling **S**ystem) software.

2. Problem Description

The problem presented by Edgar and Himmelblau, (2001) is to obtain the maximum profit of the process, while operating within the reactor and down stream process equipment constraints. Figure 1 shows various feeds and corresponding product distribution for a thermal cracker that produces olefins. The variables to be optimized are the amounts of the four feeds (mainly, Gas-oil, Propane, Ethane and Debutanized natural gasoline (DNG)). This problem will be solved utilizing SQP method within gPROMS package.

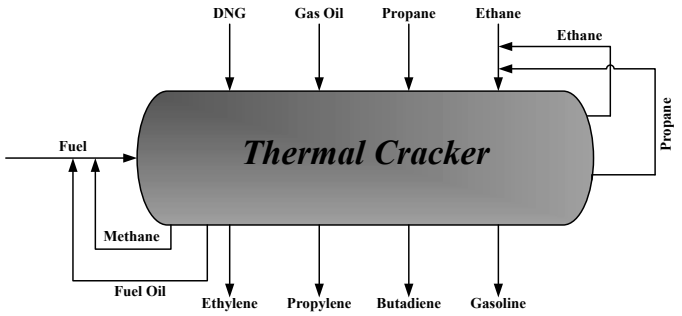

Figure 1: Pyrolysis Reactor

3. Mathematical Model of the Pyrolysis Reactor

Table 1 shows various feeds and the corresponding product distribution for a Pyrolysis reactor that produces olefins (Edgar and Himmelblau, 2001). The possible feeds include ethane, propane, debutanized natural gasoline (DNG), and gas oil, some of which may be fed simultaneously. Based on plant data, eight products are produced in varying proportions according to the following matrix. The capacity to run gas feeds through the cracker is 200,000 Ib/stream hour (total flow based on an average mixture). Ethane uses the equivalent of 1.1 Ib of capacity per pound of ethane; propane 0.9 Ib; gas oil 0.9 Ib/Ib; and DNG 1.0. Downstream processing limits exist of 50,000 Ib/stream hour on the ethylene and 20,000 Ib/ stream hour on the propylene. The fuel requirements to run the cracking system for each feedstock type are listed in Table 2. Methane and fuel oil

produced by the cracker are recycled as fuel. All the ethane and propane produced is recycled as feed. Heating values are shown in Table 3 (Geddes and Kubera, 2000).

Table 1: Yield Structure (wt. fraction)

	Feed			
Product	**Ethane**	**Propane**	**Gas oil**	**DNG**
Methane	0.07	0.25	0.10	0.15
Ethane	0.40	0.06	0.04	0.05
Ethylene	0.50	0.35	0.20	0.25
Propane	-	0.10	0.01	0.01
Propylene	0.01	0.15	0.15	0.18
Butadiene	0.01	0.02	0.04	0.05
Gasoline	0.01	0.07	0.25	0.30
Fuel oil	-	-	0.21	0.01

Table 2: Fuel Requirement

Feedstock type	**Fuel requirement (Btu/Ib)**
Ethane	8364
Propane	5016
Gas oil	3900
DNG	4553

Table 3: Heating Values

Recycled feed	**Heat produced (Btu/Ib)**
Natural gas	21,520
Methane	21,520
Fuel oil	18,000

Because of heat losses and the energy requirements for pyrolysis, the fixed fuel requirement is 20.0×10^6 Btu/stream hour and the energy (fuel) cost of $\$2.50/10^6$ Btu. The price structure on the feeds and products and fuel costs is presented in Table 4 (Edgar and Himmelblau, 2001).

Table 4: Feeds and Products Prices

Feeds	**Price($/Ib)**	**Products**	**Price($/Ib)**
Ethane	0.0655	**Methane**	0.0538 (fuel value)
Propane	0.0973	**Ethane**	0.1775
Gas oil	0.1205	**Propylene**	0.1379
DNG	0.1014	**Butadiene**	0.2664
		Gasoline	0.0993
		Fuel oil	0.0450 (fuel value)

The following variables for the flow rates (input and output) of the reactor (in Ib/h) can be defined as: C_1 = fresh ethane feed, C_2 = fresh propane feed, C_3 = gas oil feed, C_4 = DNG feed, C_5 = ethane recycle, C_6 = propane recycle, C_7 = fuel added.

Objective function (profit). The objective function is the economic profit depending upon the difference between the value of the product and the value of feed and energy cost and all costs are calculated in cents/h. In other words, the profit f is written as:

f = Product value – Feed cost – Energy cost

Product value:

Ethylene: $17.75(0.5C_1 + 0.5C_5 + 0.35C_2 + 0.35C_6 + 0.20C_3 + 0.25C_4)$ (1)

Propylene: $13.79(0.01C_1 + 0.01C_5 + 0.15C_2 + 0.15C_6 + 0.15C_3 + 0.18C_4)$ (2)

Butadiene: $26.64(0.01C_1 + 0.01C_5 + 0.02C_2 + 0.02C_6 + 0.04C_3 + 0.05C_4)$ (3)

Gasoline: $9.93(0.01C_1 + 0.01C_5 + 0.07C_2 + 0.07C_6 + 0.25C_3 + 0.30C_4)$ (4)

Total product sales $= 9.39C_1 + 9.51C_2 + 9.17C_3 + 11.23C_4 + 9.39C_5 + 9.51C_6$ (5)

Feed cost:

Feed cost (cents/h) $= 6.55C_1 + 9.73C_2 + 12.50C_3 + 10.14C_4$ (6)

Energy cost: The fixed heat loss of 20×10^6 Btu/h can be expressed in terms of methane cost using a heating value of 21,520 Btu/Ib for methane. The fixed heat loss represents a constant cost that is independent of the variables C_i, hence in optimization this factor can be ignored, but in evaluating the final costs this term must be taken into account.

The value for C_7 depends on the amount of fuel oil and methane produced in the cracker (C_7 provides for any deficit in products recycled as fuel). Equation (5) and (6) is combined to get the objective function, which is

$$f = 2.84C_1 - 0.22C_2 - 3.33C_3 + 1.09C_4 + 9.39C_5 + 9.51C_6 \quad (7)$$

Process limitations:

1- Cracker capacity of 200,000 Ib/h

$$Crc = 1.1C_1 + 0.9C_2 + 0.9C_3 + 1.0C_4 + 1.1C_5 + 0.9C_6 \leq 200{,}000 \quad (8)$$

2- Ethylene processing limitation of 50,000 Ib/h

$$Eth = 0.5C_1 + 0.35C_2 + 0.25C_3 + 0.25C_4 + 0.5C_5 + 0.35C_6 \leq 50{,}000 \quad (9)$$

3- Propylene processing limitation of 20,000 Ib/h

$$Pro = 0.01C_1 + 0.15C_2 + 0.15C_3 + 0.18C_4 + 0.01C_5 + 0.15C_6 \leq 20{,}000 \quad (10)$$

4- Ethane recycle

$$Ethr = C_5 = 0.4C_1 + 0.4C_5 + 0.06C_2 + 0.06C_6 + 0.04C_3 + 0.05C_4 \quad (11)$$

By rearranging equation (11), we get

$$Ethr = 0.4C_1 + 0.06C_2 + 0.04C_3 + 0.05C_4 - 0.6C_5 + 0.06C_6 = 0 \quad (12)$$

5- Propane recycle

$$Pror = 0.1C_2 + 0.01C_3 + 0.01C_4 - 0.9C_6 = 0 \quad (13)$$

6- Heat constraint. The total fuel heating value (THV) in (Btu/h) is given by

$$THV = \underset{\text{fuel}}{21{,}520C_7} + \underset{\text{methane from cracker}}{21{,}520(0.07C_1 + 0.25C_2 + 0.10C_3 + 0.15C_4 - 0.07C_5 + 0.25C_6)} + \underset{\text{fuel oil from cracker}}{18{,}000(0.21C_3 + 0.01C_4)} = 1506.4C_1 + 5380C_2 + 5932C_3 + 3408C_4 + 1506.4C_5 + 5380C_6 + 21{,}520C_7 \quad (14)$$

The required fuel for cracking (Btu/h) is

$$\underset{\text{ethane}}{8364(C_1 + C_5)} + \underset{\text{propane}}{5016(C_2 + C_6)} + \underset{\text{gas oil}}{3900C_3} + \underset{\text{DNG}}{4553C_4} = 8364C_1 + 5016C_2 + 3900C_3 + 4553C_4 + 8364C_5 + 5016C_6 \quad (15)$$

Thus the sum of eq. (15) + 20,000,000 Btu/h is equal to the THV from eq. (14), which gives the constraint

$$HC = -6857.6C_1 + 364C_2 + 2032C_3 - 1145C_4 - 6857.6C_5 + 364C_6 + 21{,}520C_7 = 20{,}000{,}000 \quad (16)$$

3.1. Optimization Problem Formulation

The optimal design problem is to obtain the optimal flow rate of different feeds giving maximum economic profits from the reactor operation corresponding to different constraints. Mathematically, the optimization problem can be stated as:

$$\begin{aligned} &Max && f \\ &C_i\,(i=1-7) \\ &s.t && y(x, u, q) = 0, && \text{(model, equality constraints)} \\ & && Ci^L \leq Ci \leq Ci^U, Crc \leq Crc^*, Eth \leq Eth^* && \text{(inequality constraints)} \\ & && Pro \leq Pro^*, Ethr = Ethr^*, Pror = Pror^*, Hc = Hc^* && \text{(inequality constraints)} \end{aligned}$$

The model equations can be written in compact form as: $y(x, u, q) = 0$, where x gives the set of all algebraic variables, u is the control variables, and q represents the design variables and the function y is assumed to be continuously differentiable with respect to all its arguments (Jarullah et al., 2011, Jarullah et al., 2012). L and U are the lower and upper bounds, respectively. The optimization solution method utilized by gPROMS is a two-steps method known as feasible path approach. The first step performs the simulation to converge all the equality constraints and to satisfy the inequality constraints. The second step performs the optimization (updates the values of the optimization parameters).

4. Results and Discussion

The purpose of this study is to obtain the optimal design of thermal cracking reactor via optimal flow rates of different hydrocarbons feeds (namely, Gas-oil, Propane, Ethane and Debutanized natural gasoline) to get maximum profit. The modelling, simulation and optimization process has been carried out by using gPROMS software and the

optimization problem based on a Non-Linear Programming (NLP) problem, which is solved using Successive Quadratic Programming (SQP) method. The optimal parameters obtained for two cases: case1 at maximum ethylene production of 50000 lb/hr and 100000 lb/hr for case2, are shown in Table 5. As noticed from the results presented in this Table that the maximum possible amount of ethylene is produced for both cases. Where, the optimal feed flow rate in lb/hr of ethane, ethane recycle and the fuel that should be added is 60000, 40000 and 32795.5 for case 1 and 109091, 72727.3 and 58867.9 for case 2, respectively with no feed of propane, gas oil, DNG and propane recycle for both cases. This means that the process depends mainly on the ethane (fresh feed as well as ethane recycle) in addition to the fuel. The maximum objective function (economic profit) is 5460 $/h for case 1 and 9927.28 $/h for case2 with satisfying all the inequality constraints. It has also been observed as the ethylene production constraint is relaxed, the objective function value increases. Once the constraint is raised above 90909.15 lb/hr, the objective function remains constant for whole process.

Table 5: Optimization Results for Pyrolysis Reactor

Control Variables	**Optimized value (lb/hr)**		**Process Constraints**	**Values (lb/hr)**	
	Case 1	**Case 2**		**Case 1**	**Case 2**
C_1 (Fresh Ethane Feed)	60000	109091	*Crc*	110000	200000
C_2 (Fresh Propane Feed)	0.0	0.0	*Eth*	50000	90909.15
C_3 (Gas Oil Feed)	0.0	0.0	*Pro*	1000	1818.183
C_4 (DNG Feed)	0.0	0.0	*Ethr*	0.0	0.0
C_5 (Ethane Recycle)	40000	72727.3	*Pror*	0.0	0.0
C_6 (Propane Recycle)	0.0	0.0	*Hc*	2×10^7	2×10^7
C_7 (Fuel Added)	32795.5	58867.9			
Objective function($/h)	*5460.0*	*9927.28*			

In order to describe the performance of the pyrolysis reactor, the simulation of such reactor is necessary. The simulation results for the products obtained by thermal cracking reactor for both cases are presented in Table 6. It is noted from this table that the highest favourable product (the main target), which is ethylene is achieved at 50000 lb/h for case 1 and 90909.15 lb/h for case 2 (whole process) among all products.

Table 6: Simulation Results for Stream Pyrolysis Reactor

Simulation Results		
Product (lb/hr)	**Case 1**	**Case 2**
Ethylene	50000	90909.15
Propylene	1000	1818.183
Butadiene	1000	1818.183
Gasoline	1000	1818.183
Methane	7000	12727.28
Fuel Oil	0.0	0.0

Table 7 shows the comparison results obtained from this study and those obtained by last studies. It is clearly observed from this Table that the new approach (SQP) used in this work to maximize the process profit related to thermal cracking reactor is better than the methods used with all previous works (that used different solution methods for maximizing the objective function to get the optimal design of pyrolysis reactor in this field). Where, the economic profit of the process is increased by 47% for both cases and the CPU-time was reduced by 86% for case 1 compared with last studies. This new result obtained can be attributed to the SQP approach employed in the present work (has high accuracy in evaluating the control variables of the process) within gPROMS package. Furthermore, this approach is a highly trusted method for solution of such mathematical models.

Table 7: Comparison results between this work and last studies

Authors	Solution method	CPU-time (sec) – Case1	Objective function ($/h)	
			Case 1	Case 2
Edgar &Himmelblau (2001)	LP	-----	3695.6	-----
Babu & Angira (2007)	LP Simplex	-----	3695.6	6760.18
Babu & Angira (2007)	DE with GA	0.113	3695.6	6760.18
This work (2015)	SQP	0.015625	5460.0	9927.28

5. Conclusions

In this paper, an optimal design of thermal cracking (pyrolysis) reactor is studied. The optimization framework has been presented to tackle the optimal design and operation problem of pyrolysis reactor. The optimization problem formulation has been presented to give maximum economic index of such process. It has been carried out using a new alternative approach (the optimization problem was posed as a Non-linear programming (NLP) problem and was solved using a SQP method within gPROMS software). Based on the results obtained from this study using two cases (based upon ethylene production), it can be concluded that the operation depends mainly on the ethane and the fuel under process restriction to get maximum profit and maximum yield. As well as, the accurate process model of such reactor is namely depends on the solution methods in evaluating the control variables of the process so that the model can be effectively used for simulation, optimization and control. SQP is the most efficient in terms of function evaluations in dealing with process constraint problems. Finally, SQP method has been demonstrated to be able to give accurate results of feed flow rates with corresponding economic profit of 9927.28 $/h for whole process and gave highest profit (increased by 47%) and lowest CPU-time (reduced by 86%) in comparison with those obtained by previous studies.

Representation of the Convex Envelope of Bilinear Terms in a Reformulation Framework for Global Optimization

Andreas Lundell[a] and Tapio Westerlund[a]

[a]*Optimization and Systems Engineering; Åbo Akademi University; Turku, Finland*
andreas.lundell@abo.fi

Abstract

Branch-and-bound in combination with convex underestimators constitute the basis for many algorithms in global nonconvex mixed-integer nonlinear programming (MINLP). Another option is to rely on reformulation-based techniques such as the α signomial global optimization (αSGO) algorithm, where power and exponential transformations for signomial or polynomial function and the α reformulation (αR) technique for general nonconvex twice-differentiable functions are used to reformulate the nonconvex problem. The transformations are approximated using piecewise linear functions (PLFs), resulting in a convex relaxation of the original nonconvex problem in an extended variable space. The solution to this reformulated problem provides a lower bound to the global minimum (of a minimization problem), and by iteratively refining the PLFs, the ε-global solution can be obtained. A drawback with many reformulation-based techniques is that known convex envelopes cannot directly be utilized. However, in this paper, a formulation for expressing the convex envelope of bilinear terms in the αSGO framework is described, and it is shown that this improves the tightness of the lower bound.

Keywords: Nonconvex global optimization, MINLP, reformulation framework, bilinear terms, signomial functions, convex envelope, αSGO algorithm, αR technique

1. Introduction

The αSGO algorithm as described in Lundell et al. (2013) can solve MINLP problems containing nonconvex constraints of signomial or general twice-differential type to ε-global optimality. The general formulation of applicable problem type is

$$\begin{aligned} &\text{minimize} && f(\mathbf{x}), \\ &\text{subject to} && \forall k \in K: \quad q_k(\mathbf{x}) + s_k(\mathbf{x}) + g_k(\mathbf{x}) \leq 0, \qquad s_k(\mathbf{x}) = \sum_{j \in J_k} c_j \prod_{i \in I} x_i^{p_{ji}}, \\ &&& \forall i \in I: \quad \underline{x}_i \leq x_i \leq \bar{x}_i, \end{aligned} \tag{1}$$

where the functions f and q are convex functions, s are nonconvex signomial functions and g are nonconvex twice-differentiable functions. A signomial function is a sum of positive or negative signomial terms, each made up by a product of power functions, *i.e.,* the c's and p's are real coefficients and powers respectively. This class of functions include also bilinear terms and in this paper these will be handled separately as described in Section 2. The variables $\mathbf{x} = [x_1, \ldots, x_I]$ can be integers or reals, so in the general form problem (1) is a MINLP problem. The variables in the signomial terms are assumed to be strictly positive, otherwise translations or other reformulations

are necessary, *cf.* Pörn et al. (1999). By using a simple reformulation, a problem with a nonlinear objective function f can also be rewritten in the form of problem (1) by including the constraint $f(\mathbf{x}) - \mu \leq 0$, with the variable μ being the new objective function of the reformulated problem. Nonlinear equality constraints $q_k(\mathbf{x}) + s_k(\mathbf{x}) + h_k(\mathbf{x}) = 0$ can be replaced by two inequality constraints with different signs.

In the αSGO algorithm, single-variable power and exponential transformations are used to obtain convex underestimators for nonconvex signomial functions and the transformations (represented as nonlinear equalities) are approximated by PLFs. The transformations are applied term-wise, so convex terms do not need to be convexified. For nonconvex twice-differentiable functions, quadratic convex spline functions overpowering all nonconvexities are added and linearizations through PLFs are subtracted. The result is a reformulated convex problem in an extended variable-space consisting of the original variables, transformation variables, and variables needed for the PLFs. The new problem is solved using a convex MINLP method such as Lundell et al. (2014), with the solution obtained being a lower bound to the nonconvex problem. By iteratively tightening the PLFs and resolving, the lower bound increases until all nonconvex constraints are fulfilled (to an ε-tolerance) and the global solution is found. No upper bound is needed in the algorithm.

1.1. Convex underestimation of signomial functions

Rules for the convexity of signomial terms have been presented in *e.g.,* Lundell (2009). For a positive signomial term, there are two separate cases: *(i)* all powers in the signomial term are negative, or *(ii)* all powers in the signomial term are negative except for one and the sum of the powers is greater than or equal to one. For a negative signomial term to be convex, all powers should be positive and their sum less than or equal to one. Based on these rules, it is possible to deduce the positive power transformation (PPT) and the mixed power and exponential transformation (MPET) for positive terms and the power transformation (PT) for negative terms. For more details see, *e.g.,* Lundell and Westerlund (2012).

1.2. Convexifying twice-differentiable constraints

In Lundell et al. (2013) the αR technique was described. In this method, the spline αBB convex underestimator from Meyer and Floudas (2005) is included in the SGO algorithm from Lundell and Westerlund (2012) for handling nonconvex twice-differentiable functions. A convex underestimator for a nonconvex function $g(\mathbf{x})$ is obtained by first adding a sum of convex quadratic spline functions S_i for each variable x_i and then subtracting a linearization W_i by the means of a PLF from the convexified function. Thus, the resulting reformulated constraint will be

$$g(\mathbf{x}) + \sum_{i \in I} S_i(x_i) - \widehat{S} \leq 0, \qquad \text{where} \qquad \widehat{S} = \sum_{i \in I} \text{PLF}\, S_i(x_i).$$

For fulfilling the convexity requirement, the coefficients of the quadratic terms in the splines must be positive and large enough so that the Hessian is positive semidefinite.

2. Including the McCormick underestimator in the reformulation framework

Instead of utilizing the signomial transformation strategies or the αR for reformulating bilinear terms, it is in this section described how the convex envelope for bilinear terms McCormick (1976) can be used in the αSGO framework. There are also other possible formulations available, see Wicaksono and Karimi (2008) for some variants, however the presented formulation utilizes the linearizations already available in the αSGO framework.

The convex envelope for a bilinear term $x_m x_n$ is given by the linear constraints

$$\begin{cases} w_{mn} \geq \underline{x}_m x_n + \underline{x}_n x_m - \underline{x}_m \underline{x}_n & (2) \\ w_{mn} \geq \overline{x}_m x_n + \overline{x}_n x_m - \overline{x}_m \overline{x}_n & (3) \end{cases} \qquad \begin{cases} w_{mn} \leq \overline{x}_m x_n + \underline{x}_n x_m - \overline{x}_m \underline{x}_n & (4) \\ w_{mn} \leq \underline{x}_m x_n + \overline{x}_n x_m - \underline{x}_m \overline{x}_n & (5) \end{cases}$$

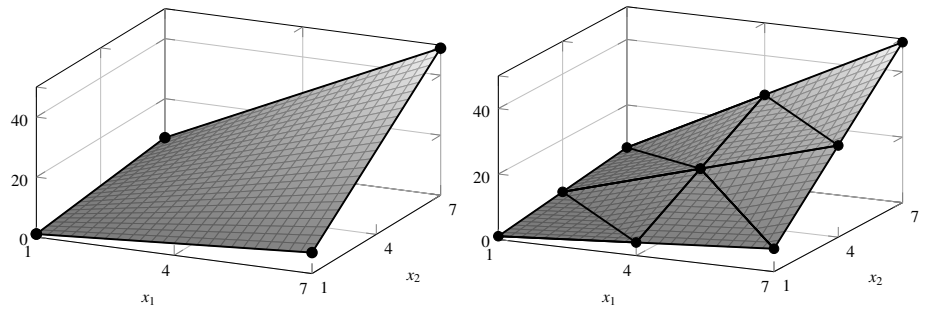

Figure 1: An illustration of the nonconvex term x_1x_2 on the interval $[1,7]\times[1,7]$ (*left*) and the piecewise convex envelope (underestimator) on the four regions $[1,4]\times[1,4]$, $[4,7]\times[1,4]$, $[1,4]\times[4,7]$ and $[4,7]\times[4,7]$ (*right*). The envelope in each region consists of the maximum of two planes.

on the box domain $[\underline{x}_m,\overline{x}_m]\times[\underline{x}_n,\overline{x}_n]$. For a positive term, the expressions (2) and (3) provide the lower bound and expressions (4) and (5) the upper bound, while the opposite is true for a negative bilinear term. Since all variables in bilinear terms are assumed to be positive in problem (1) no change of signs for the terms occur. An illustration of the underestimator is given in Figure 1.

To illustrate the difference in tightness of the convex underestimators mentioned earlier when applied to the bilinear term x_1x_2, the underestimation error of the MPET with exponential transformations only, the PPT (with transformation powers $Q_1=2$, $Q_2=-1$), the αR and the McCormick (MC) underestimator are shown in Figure 2 for two refinement levels of the PLFs. It is clear that including the McCormick underestimator for bilinear terms would render a tighter convex underestimator in the considered domain, and therefore we want to utilize this type of underestimator in the αSGO framework. In the framework, only the convex underestimator is required, so equations (2) and (3) or (4) and (5) are needed in the case of a positive or negative bilinear term respectively.

To partition the domain, some additional variables and expressions are required. The variables x_i and x_j are assumed to be partitioned in the intervals $[\omega_{m,1},\omega_{m,2}],[\omega_{m,2},\omega_{m,3}],\ldots,[\omega_{m,K_m-1},\omega_{m,K_m}]$, where $\omega_{m,1}=\underline{x}_m$, $\omega_{m,K_m}=\overline{x}_m$, and $[\omega_{n,1},\omega_{n,2}],[\omega_{n,2},\omega_{n,3}],\ldots,[\omega_{n,K_n-1},\omega_{n,K_n}]$, where $\omega_{n,1}=\underline{x}_n$, and $\omega_{n,K_n}=\overline{x}_n$, respectively. In other words, the variable x_m has the set of breakpoints $\{\omega_{m,1},\omega_{m,2},\ldots,\omega_{m,K_m}\}$ and x_n the set of breakpoints $\{\omega_{n,1},\omega_{n,2},\ldots,\omega_{n,K_n}\}$. With each of the breakpoint intervals a binary variable $b_{m,k}$ or $b_{n,k}$ and a real variable $s_{m,k}$ or $s_{n,k}$ are associated; these variables are zero if we are not in the corresponding interval. For the variable x_m (and equivalently for x_n) this can be expressed as

$$x_m=\sum_{k=1}^{K_m-1}\omega_{m,k}+\left(\omega_{m,k+1}-\omega_{m,k}\right)s_{m,k},\qquad \sum_{k=1}^{K_m-1}b_{m,k}=1, \tag{6}$$

$$\forall k=1,\ldots,K_m:\ 0\le s_{m,k}\le b_{m,k}. \tag{7}$$

These expressions can be reused for all bilinear terms containing x_m or other signomial transformations or αRs in the reformulated problem, *i.e.,* only one set of binaries $\{b_{m,k}\}_{k=1}^{K_m}$ and continuous variables $\{s_{m,k}\}_{k=1}^{K_m}$ are needed for each variable x_m involved in transformations in the problem.

For a positive term $w_{mn}=x_mx_n$, the piecewise McCormick underestimator should be defined by equation (2) in the unshaded regions in the left part of Figure 3, and by equation (3) in the shaded regions. For a negative bilinear term $w_{mn}=-x_mx_n$ equation (4) in the unshaded regions of the right part of Figure 3 and equation (5) in the shaded regions should be used instead. This requires the addition of a binary variable γ_{mn} for each unordered combination (m,n) in a bilinear term indicating if we are in the shaded domains or not. The expression (8) sets the values of γ_{mn} for a

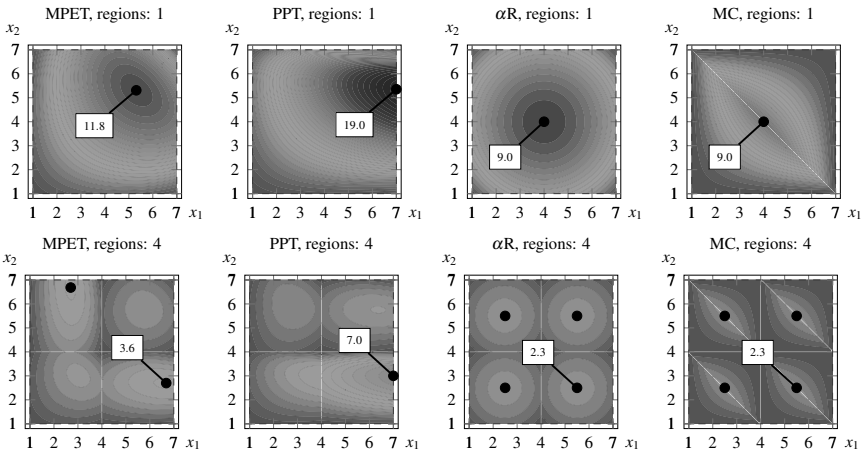

Figure 2: The underestimation error when underestimating the bilinear term x_1x_2 on the region $[1,7]\times[1,7]$ without extra partitioning (above) and with an extra breakpoint in the midpoint, *i.e.,* considering the regions $[1,4]\times[1,4]$, $[4,7]\times[1,4]$, $[1,4]\times[4,7]$ and $[4,7]\times[4,7]$ (below).

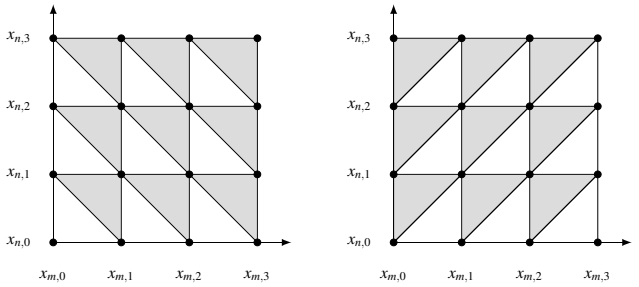

Figure 3: The shaded area indicates where the binary variable $\gamma_{mn}=1$ for a positive *(left)* or negative bilinear term *(right)*.

positive term $w_{mn}=x_mx_n$ and the expression (9) for a negative bilinear term $w_{mn}=-x_mx_n$:

$$s_{m,k_m}+s_{n,k_n}+b_{m,k_m}+b_{n,k_n}-3\leq\gamma_{mn}\leq s_{m,k_m}+s_{n,k_n}-b_{m,k_m}-b_{n,k_n}+2, \tag{8}$$
$$-s_{m,k_m}+s_{n,k_n}+b_{m,k_m}+b_{n,k_n}-2\leq\gamma_{mn}\leq+s_{m,k_m}+s_{n,k_n}-b_{m,k_m}-b_{n,k_n}+3. \tag{9}$$

Then, the underestimator for a positive term can be written $\forall k_m=1,\ldots,K_n-1\wedge k_n=1,\ldots,K_n-1$:

$$W_{mn}\geq\omega_{m,k_m}x_j+\omega_{n,k_n}x_i-\omega_{m,k_m}\omega_{n,k_n}+M_1\left(b_{m,k_m}+b_{n,k_n}-2\right)-M_1\gamma_{mn} \tag{10}$$
$$W_{mn}\leq\omega_{m,k_m}x_j+\omega_{n,k_n}x_i-\omega_{m,k_m}\omega_{n,k_n}-M_1\left(b_{m,k_m}+b_{n,k_n}-2\right)+M_1\gamma_{mn} \tag{11}$$
$$W_{mn}\geq\omega_{m,k_m+1}x_j+\omega_{n,k_n+1}x_i-\omega_{m,k_m+1}\omega_{n,k_n+1}+M_1\left(b_{m,k_m}+b_{n,k_n}-2\right)-M_1\left(1-\gamma_{mn}\right) \tag{12}$$
$$W_{mn}\leq\omega_{m,k_m+1}x_j+\omega_{n,k_n+1}x_i-\omega_{m,k_m+1}\omega_{n,k_n+1}-M_1\left(b_{m,k_m}+b_{n,k_n}-2\right)+M_1\left(1-\gamma_{mn}\right) \tag{13}$$
$$W_{mn}\leq M_2b_{m,k_m} \tag{14}$$

$$W_{mn} \leq M_2 b_{n,k_n} \tag{15}$$
$$0 \leq W_{mn} \leq M_2 \tag{16}$$
$$M_1 = \max\left\{\omega_{m,k_m}\omega_{n,k_n+1} + \omega_{n,k_n}\omega_{m,k_m+1} - \omega_{m,k_m}\omega_{n,k_n}, \omega_{m,k_m+1}\omega_{n,k_n+1}\right\} \tag{17}$$
$$M_2 = \omega_{m,k_m+1}\omega_{n,k_n+1}. \tag{18}$$

Here M_1 and M_2 are calculated parameters. The expressions (10) and (11) give the correct value for the underestimator if $\gamma_{mn} = 0$, *i.e.,* if we are in the lower left part of the box $[\omega_{m,k_m}, \omega_{m,k_{m+1}}] \times [\omega_{n,k_n}, \omega_{n,k_{n+1}}]$. If $\gamma_{mn} = 1$, *i.e.,* if we are in the upper right part of the same box expressions (12) and (13) are active. Expressions (14) and (15) make sure that the variable W_{mn} is zero if we are in another region, *i.e.,* if not both b_{m,k_m} and b_{n,k_n} are equal to one.

The corresponding expressions for a negative term are $\forall k_m = 1,\ldots,K_m - 1 \wedge k_n = 1,\ldots,K_n - 1$:

$$W_{mn} \geq \omega_{m,k_m+1}x_j + \omega_{n,k_n}x_i - \omega_{m,k_m+1}\omega_{n,k_n} + M_1\left(b_{m,k_m} + b_{n,k_n} - 2\right) - M_2\gamma_{mn} \tag{19}$$
$$W_{mn} \leq \omega_{m,k_m+1}x_j + \omega_{n,k_n}x_i - \omega_{m,k_m+1}\omega_{n,k_n} - M_1\left(b_{m,k_m} + b_{n,k_n} - 2\right) + M_2\gamma_{mn} \tag{20}$$
$$W_{mn} \geq \omega_{m,k_m}x_j + \omega_{n,k_n+1}x_i - \omega_{m,k_m}\omega_{n,k_n+1} + M_1\left(b_{m,k_m} + b_{n,k_n} - 2\right) - M_2\left(1 - \gamma_{mn}\right) \tag{21}$$
$$W_{mn} \leq \omega_{m,k_m}x_j + \omega_{n,k_n+1}x_i - \omega_{m,k_m}\omega_{n,k_n+1} - M_1\left(b_{m,k_m} + b_{n,k_n} - 2\right) + M_2\left(1 - \gamma_{mn}\right) \tag{22}$$
$$W_{mn} \leq M_2 b_{m,k_m} \tag{23}$$
$$W_{mn} \leq M_2 b_{n,k_n} \tag{24}$$
$$0 \leq w_{mn} \leq M_2. \tag{25}$$

The parameters M_1 and M_2 are the same as in the positive case. Expressions (19) and (20) gives the correct value for the underestimator if $\gamma_{mn} = 0$, *i.e.,* if we are in the lower right part of the box $[\omega_{m,k_m}, \omega_{m,k_{m+1}}] \times [\omega_{n,k_n}, \omega_{n,k_{n+1}}]$. If $\gamma_{mn} = 1$, *i.e.,* if we are in the upper left part of the same box, expressions (21) and (22) are active. Expressions (23) and (24) make sure that the variable W_{mn} is zero if we are in another region, *i.e.,* if not both b_{m,k_m} and b_{n,k_n} are equal to one.

Replacing a bilinear term $c \cdot x_m x_n$ ($c \in \mathbb{R}$) in the nonconvex function with $c \cdot W_{mn}$ and including expressions (8) and (10–16) if the term is positive or the expressions (9) and (19–25) if the term is negative as well as expressions (6) and (7) will render a reformulated convex problem whose solution is a lower bound to the global solution. The same expressions can be reused if the bilinear variable occurs in several constraints. The same is true for expressions (6) and (7) if the variables in the bilinear term are transformed using either signomial transformation strategies or αRs.

3. Computational comparisons

In Table 3, a comparison on the lower bounds of some reformulated and convexified problems from Floudas and Pardalos (1999) containing signomial and bilinear terms is given. When the formulation for bilinear terms in Section 2 is not used for the bilinear terms, the MPET with exponential transformations only is used to convexify all positive signomial terms including the bilinear ones. The PT transformation is used for negative signomial terms. The results are also compared to using the αR for reformulating all terms (including the signomial and bilinear terms) and αR for signomials only with the MC formulation for bilinear terms. Also the global solution is presented to illustrate the tightness of the convex underestimators. The reformulated problems were solved using the convex MINLP solver αECP available in GAMS. Obviously, the MC formulation gives a tighter or equally tight convex underestimation as the other underestimation methods. However, since bilinear terms are not present solely in the objective function of the test problems, the impact of the tightness of the convex underestimation may vary from problem to problem. The results also indicate (especially in the last two problems) that the αR may give a very bad underestimator compared to the signomial transformation strategies when applied to signomials.

Table 1: The obtained initial lower bounds of some problems from Floudas and Pardalos (1999) containing signomial and bilinear terms. The bold values indicate the tightest underestimator of the compared ones.

Problem	MPET + PT	MPET + PT + MC	αR	αR + MC	Global solution
7.2.1	1057.4	**1094.4**	1070.3	1090.7	1227.2
7.2.2	-0.9093	**-0.7028**	-1.0000	**-0.7028**	-0.3888
7.2.4	0.6376	**1.1774**	-9.7655	-9.7655	3.9511
7.2.5	9546.8	**9687.7**	9578.7	9669.3	10122

7.2.7	-8.2734	**-7.5827**	-80.649	-80.649	-5.7398
7.2.8	-9.8008	**-9.4017**	-8741.3	-8741.3	-6.0482

4. Conclusions

In this paper it was shown how a convex envelope for bilinear terms can be included in the αSGO reformulation framework for signomial problems. This further extends the available set of transformations that can be utilized for reformulating nonconvex problems in the αSGO algorithm. Being tighter than the signomial transformations, the McCormick underestimators will give a higher, and thus better, lower bound, as was illustrated by solving some test problems. It is also possible to include convex envelopes and special convex underestimators for other types of functions, *e.g.,* trilinear terms, but this needs to be investigated further.

Abstract

The manufacturing industry is faced with the challenge to constantly improve its processes under more and more stringent conditions, e.g., due to more strict environmental policies, lower profit margins and increased societal awareness. These three aspects are considered as the pillars of *sustainable development* and typically give rise to multiple and conflicting objectives. Hence, any decision taken will require trade-offs to be evaluated and compromises to be made. To support decision making, in this work an interactive multi-objective software framework is presented to systematically optimize nonlinear dynamic systems based on mathematical models. In particular, a numerically efficient strategy to account for parametric uncertainty, based on the Sigma Point method, is introduced allowing directly minimizing the operational risk. Consequently, the proposed software can provide sound decision-support for dynamic process optimization under uncertainty. The framework is tested on a three-objective case study of a fed-batch reactor.

Keywords: dynamic nonlinear optimization, uncertainty quantification, interactive multi-objective optimization

1. Introduction

The increased awareness towards societal (e.g., increase safety, maintain occupational level) and environmental aspects (e.g., reduce energy consumption and emissions) of public institutions has put great pressure on the manufacturing industry. Mathematical process models and model based optimization methods have over the years improved the economic sustainability (e.g., maximize profit or production). However, dedicated instruments: (i) to systematically include the societal and environmental impact in optimization studies, (ii) to quantify the *trade-offs* between conflicting objectives, (iii) to propose several alternatives for improvement and (iv) to make sound decisions for operating industrial processes under uncertainty, are scarce. However, model based methods are always afflicted by model related and also by external uncertainties (e.g., Sahinidis (2004)). When dealing with inherent uncertainty in dynamic processes and models, mainly two different strategies are used: (i) a *probabilistic approach* with the formulation of expected values and chance constraints (e.g., Wendt et al. (2002); Recker et al. (2012); Li et al. (2008)) or, (ii) a *worst case scenario approach* with the formulation of min-max optimization problems (e.g., Nagy and Braatz (2004); Houska and Diehl (2009); Houska et al. (2012)).

By directly accounting for uncertainty in optimization problems, an increased level of robustness is achieved. Unfortunately, this increased robustness is usually accompanied by a loss of performance (Datskov et al. (2006)). Hence, a trade-off between robustness and performance is introduced. This aspect can be studied via multi-objective optimization (Miettinen (1999)) as suggested

in Logist et al. (2011). However, robustness was not directly considered as one of the objective functions. Moreover, apart from the uncertainty and the multi-objective aspect, it has to be noted that optimizing the dynamic process operation already leads to dynamic optimization problems, which after discretization result in large-scale Nonlinear Programmming Problems (NLPs).

In this paper, a novel interactive adaptation of scalarization based multi-objective optimization algorithms (Marler and Arora (2004); Das and Dennis (1998); Sanchis et al. (2008)) is proposed along with a Graphical User Interface (GUI) for the systematic evaluation of the trade-offs arising between multiple and conflicting objectives in nonlinear dynamic optimization problems under uncertainty. The uncertainty is tackled in a computationally tractable way via the *Sigma Point* method (Julier and Uhlmann (1996)). Several contributions are combined in the novel tool *Pareto Browser*: (i) development of an interactive algorithm for high dimensional multi-objective optimization problems, (ii) development of a tailored GUI for the interactive solution and visualization of dynamic optimization problems under uncertainty, (iii) formulation of dynamic optimization problems under uncertainty to consider robustness as an objective function and (iv) efficient solution of the resulting large-scale optimization problems. The article is structured as follows: Section 2 introduces a generic problem formulation, gives a brief introduction to the Sigma Point method and defines the proposed reformulation. Then, Section 3 introduces the framework *Pareto Browser* and the GUI via the solution of a three-objective dynamic optimization problem under uncertainty.

2. Mathematical formulation

Generally, a multi-objective dynamic optimization problem with uncertainty can be formulated as:

$$\min_{\mathbf{x}(\xi),\mathbf{u}(\xi),\xi_\mathrm{f}} \{J_1, J_2, \ldots J_\mathrm{m}\}, \tag{1}$$

$$\text{subject to: } \frac{d\mathbf{x}}{d\xi} = \mathbf{f}(\mathbf{x}(\xi),\mathbf{u}(\xi),\xi,\mathbf{p},\lambda), \tag{2}$$

$$\mathbf{0} = \mathbf{b}_\mathrm{c}(\mathbf{x}(0),\mathbf{p},\lambda), \tag{3}$$

$$\mathbf{0} \geq \mathbf{c}_\mathrm{p}(\mathbf{x}(\xi),\mathbf{u}(\xi),\xi,\mathbf{p},\lambda), \tag{4}$$

$$\mathbf{0} \geq \mathbf{c}_\mathrm{t}(\mathbf{x}(\xi_\mathrm{f}),\xi_\mathrm{f},\mathbf{p},\lambda). \tag{5}$$

Here, $\mathbf{x}$ are the state variables, while $\mathbf{u}$ and $\mathbf{p}$ denote the time-varying and time-constant control variables. Moreover, λ represents the vector of uncertain parameters. The vector $\mathbf{f}$ represents the dynamic system equations (on the interval $\xi \in [0,\xi_\mathrm{f}]$) with initial conditions given by the vector $\mathbf{b}_\mathrm{c}$. In particular $\mathbf{f}$ comprises Ordinary Differential Equations (ODE) but extensions to Differential Algebraic Equations (DAE) and Partial Differential Equations (PDE) are possible. The vectors $\mathbf{c}_\mathrm{p}$ and $\mathbf{c}_\mathrm{t}$ indicate path and terminal inequality constraints on the states and controls.

This work introduces a low computational methodology and gives the possibility to directly consider robustness as an objective function. The uncertainty is quantified via the Sigma Point method (Julier and Uhlmann (1996)). The Sigma Point method allows to efficiently approximate probability distributions through any nonlinear transformation. The method is centred on the intuitive notion of approximating the resulting distribution via the propagation of a fixed number of selected samples from the parameter distribution, i.e., the *sigma points* π_i, rather than approximate an arbitrary nonlinear function. In this case, the sigma points are the nominal parameter values for the uncertain parameters (i.e., $\lambda = \pi_0$) and $2n_\lambda$ deviations (i.e., $\lambda = \pi_i$ for $i = 1,\ldots,2n_\lambda$ where n_λ is the number of uncertain parameters) which are calculated as in Julier and Uhlmann (1996). These Sigma Points are propagated through the nonlinear dynamic system and give rise to an equivalent number of outputs. The outputs are then used to compute the *expected value* and *variance-covariance* matrix of the state variables, constraints and objective functions.

The introduction of the *expected value* for the considered objective functions $\bar{J}_\mathrm{i}$ and the more critical constraints $\bar{\mathbf{c}}_{\mathrm{p,j}}$ and $\bar{\mathbf{c}}_{\mathrm{t,j}}$ allows to reformulate the multi-objective dynamic optimization problem under uncertainty as follows:

$$\min_{\mathbf{x}_\mathrm{i}(\xi),\mathbf{u}(\xi),\xi_\mathrm{f}} \left\{\bar{J}_1,\bar{J}_2,\ldots\bar{J}_\mathrm{m},-\alpha_{\mathrm{c_p}},-\alpha_{\mathrm{c_t}}\right\}, \tag{6}$$

$$\text{subject to: } \frac{d\mathbf{x}_\mathrm{i}}{d\xi} = \mathbf{f}(\mathbf{x}_\mathrm{i}(\xi),\mathbf{u}(\xi),\xi,\mathbf{p},\pi_\mathrm{i})\ \xi\in[0,\xi_\mathrm{f}], \tag{7}$$

$$\mathbf{0} = \mathbf{b}_\mathrm{c}(\mathbf{x}_\mathrm{i}(0),\mathbf{p},\pi_\mathrm{i}),\ \text{with i} = 0,\ldots,2\mathrm{n}_\lambda, \tag{8}$$

$$\mathbf{0} \geq \bar{\mathbf{c}}_{\mathrm{p,j}} + \alpha_{\mathrm{c_p}}\sqrt{\mathbf{P}_{\mathrm{c_p,jj}}},\quad \text{for j} = 1,\ldots,\mathrm{n}_{\mathrm{c_p}}, \tag{9}$$

$$\mathbf{0} \geq \bar{\mathbf{c}}_{\mathrm{t,j}} + \alpha_{\mathrm{c_t}}\sqrt{\mathbf{P}_{\mathrm{c_t,jj}}},\quad \text{for j} = 1,\ldots,\mathrm{n}_{\mathrm{c_t}}. \tag{10}$$

where $\mathbf{P}_{\mathrm{c_p,jj}}$ and $\mathbf{P}_{\mathrm{c_t,jj}}$ represent the diagonal element of the *variance-covariance* matrix of the constraints $\bar{\mathbf{c}}_{\mathrm{p,j}}$ and $\bar{\mathbf{c}}_{\mathrm{t,j}}$. Moreover, Eqs. (9)-(10) are formulated as *single chance* constraints. These constraints are approximately described by the Probability Density Function (PDF):

$$\Pr\left(\bar{\mathbf{c}}_{\mathrm{p,j}} + \alpha_{\mathrm{c_p}}\sqrt{\mathbf{P}_{\mathrm{c_p,jj}}} \geq \mathbf{0}\right) \leq A, \tag{11}$$

which defines the probability associated with the non-violation of the *single chance* constraints in Eqs. (9)-(10). $\alpha_{\mathrm{c_p}}$ and $\alpha_{\mathrm{c_t}}$ are *back-off* parameters and define the level of robustness of the *single chance* constraint by modifying the confidence level A. Moreover, if the PDF of the constraints is assumed to be normal then the parameters $\alpha_{\mathrm{c_p}}$ and $\alpha_{\mathrm{c_t}}$ can be interpreted as the quantiles of the Gaussian distribution. Hence, if, e.g., $\alpha_{\mathrm{c_p}} = 1.96$ then $A = 95\%$ in Eq. (11). The assumption of normality on the PDF of the constraints can be checked, e.g., via Monte Carlo simulations. In this work the parameters $\alpha_{\mathrm{c_p}}$ and $\alpha_{\mathrm{c_t}}$ will be taken as objective functions. This allows directly quantifying the trade-offs between increasing robustness of the solution and the other objectives.

3. Interactive multi-objective dynamic optimization under uncertainties

Scalarization methods reformulate the existing multi-objective optimization problem into a parametric single-objective optimization problem. By consistently varying the scalarization parameters (often called *weights* $\mathbf{w}$) an approximation of the Pareto set is obtained. However, the computation of the entire set could become expensive especially for nonlinear large-scale systems as typically occur in the (bio)chemical industry. Moreover, as the decision-maker is often only interested in a specific part of the Pareto front, an interactive algorithm for the progressive exploration of the Pareto set is introduced along with a dedicated Graphical User Interface (GUI).

3.1. Developed framework: The Pareto Browser

The proposed framework is developed within the programming language Python. Fig. 1 reports the framework schematically. As multi-objective optimization methods, the weighted sum (WS), normal boundary intersection (NBI) and enhanced normalized normal constraint (ENNC) methods are adopted. The scalarization parameter values or weights are initially generated automatically to enable a first coarse exploration of the criterion space, while afterwards they are adapted interactively. The exact features and GUI will be illustrated in the next

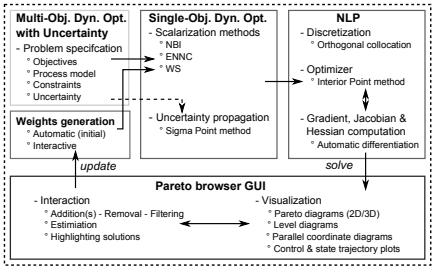

Figure 1: *Pareto Browser*'s schematic overview.

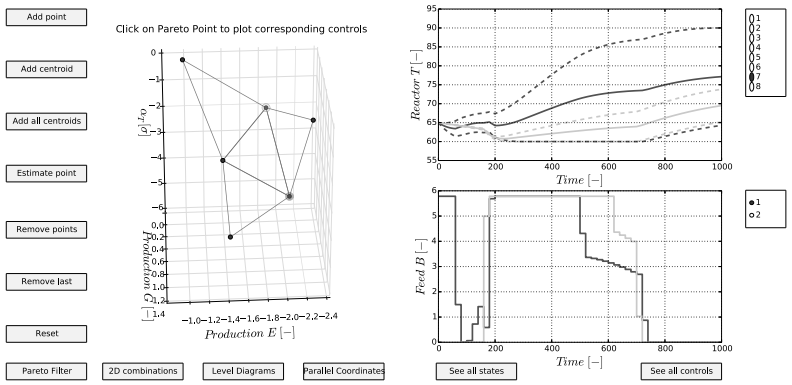

Figure 2: *Pareto Browser* applied to a three-objective case. Two points on the Pareto front (left) are highlighted and corresponding state (top right) and control (bottom right) profiles are plotted.

section based on a case study. To enable a computationally tractable uncertainty propagation through the optimization problem the Sigma Point method is exploited. To tackle the dynamic optimization problem an orthogonal collocation approach is employed delivering a large-scale NLP that is solved using the interior point optimizer IPOPT (Wächter and Biegler (2006)). Exact derivative information (i.e., gradients, Jacobians and Hessians) is provided through efficient automatic differentiation techniques (Andersson et al. (2012)). It has to be stressed that any model based optimization problem with multiple objectives can be tackled with the proposed framework, as long as it can be described as an NLP.

3.2. Case study: a fed-batch reactor with uncertain parameters

The Williams-Otto fed-batch reactor is considered. The following reaction scheme takes place in the reactor: $A+B \rightarrow C$, $C+B \rightarrow P+E$ and $P+C \rightarrow G$. A is initially present in the reactor and B is fed. The compounds P and E are useful products, whereas G is an undesired by-product. The jacket temperature can be manipulated. For the sake of brevity, the reader is referred to Logist et al. (2012) for the detailed model. The problem is formulated with the introduction of a *single chance* constraint (Eq. (12)) on the reactor temperature to account for the uncertainty on two parameters (with standard deviation of 10% from their nominal value) the feed temperature T_{F} and the heat transfer coefficient l_1 between the reactor and the cooling jacket. The *single chance* constraint is formulated via the Sigma Point method:

$$60\ ^{\circ}\mathrm{C} \leqslant \bar{T} - \alpha_{\mathrm{T}}\sqrt{\mathbf{P}_{\mathrm{T}}}, \quad \bar{T} + \alpha_{\mathrm{T}}\sqrt{\mathbf{P}_{\mathrm{T}}} \leqslant 90\ ^{\circ}\mathrm{C}. \tag{12}$$

Three objectives are defined in Eq. (13): (i) the maximization of product E, (ii) the minimization of waste product G, and (iii) the minimization of operational risks, i.e., the maximization of α_{T}.

$$J_1 = -x_E(t_{\mathrm{f}})V(t_{\mathrm{f}}), \qquad J_2 = x_G(t_{\mathrm{f}})V(t_{\mathrm{f}}), \qquad J_3 = -\alpha_{\mathrm{T}}. \tag{13}$$

The presented multi-objective dynamic optimization problem under uncertainty constitutes of 50 ODEs. The problem is subsequently reformulated into an NLP via orthogonal collocation with 50 piecewise constant intervals for the controls. The resulting NLP presents 8100 decision variables, 8000 equality and 300 inequality constraints. The solution of one NLP corresponds to a Pareto point and it is achieved in less than 10 s enabling real-time decision-making. Fig. 2 depicts the screenshot that appears when a multi-objective dynamic optimization problem under uncertainty is solved with the *Pareto Browser*. The decision-maker can click on interesting points in the left part.

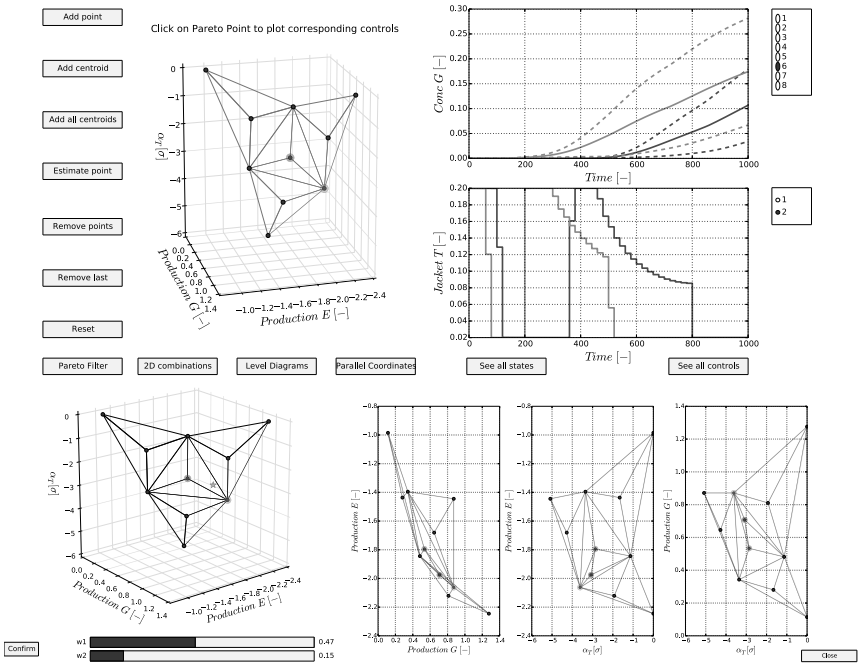

Figure 3: The centroids of all displayed simplices are added (top). Decision-support window for adding a point (bottom left). 2D plots with the three possible non-ordered combinations of two objective functions (bottom right).

These points will then be highlighted in the Pareto front while the corresponding state and control profiles will be depicted with matching colors in the right part (see Fig. 2). The confidence region associated with the value of the *back-off* parameter α_T is plotted with a dashed line for each of the state profiles as can be seen in the right part of Fig. 2. The different robustness levels adopted for the two points induce a difference in the reactor temperature profile T. In fact, the confidence region related to the solution highlighted in dark gray is much larger than the one corresponding to the Pareto point identified with a light gray color. Hence, a lower operational risk is achieved when the batch reactor is run according to the Pareto point highlighted in dark gray. The *radio buttons* on the right allow visualizing different states and controls. The amount of *radio buttons* is given by structure of the investigated case study, i.e., for this case eight states and two controls. Additionally, the Pareto set is divided into simplices. The collection of simplices is updated when a new solution is added or removed. This is achieved by clicking on one of the buttons on the left side of the left graph in Fig. 2. The simplicial discretization allows for a better understanding of the relation between different solutions and to add points in a systematic way, e.g., by adding the centroids of all displayed simplices (see top graph in Fig. 3). Dedicated decision-support windows are deployed to decide the desired location of the point to be added (see bottom left plot in Fig. 3). By moving the sliders, the position of the new point (orange star), changes. When the position is satisfactory to the decision-maker an optimization problem is solved by clicking on the *Confirm* button. Several visualization strategies are available (see bottom right plot in Fig. 3) and can be exploited to gain further insight in the achieved solution. Finally, it is possible to simultaneously visualize all states and controls in one single plot to verify that all the preferences of the decision-maker are correctly satisfied.

4. Conclusion

This work introduces the *Pareto Browser*, a novel interactive decision-support system for multi-objective optimization of nonlinear (dynamic) processes with uncertainty. The tool features: (i) an interactive algorithm for multi-objective optimization problems, (ii) a tailored GUI that allows to seamlessly exploit the algorithm's features, (iii) the use of interactive visualization strategies to enhance the understanding of the solutions, and (iv) a computationally efficient formulation for multi-objective (dynamic) optimization problems under uncertainty. The proposed formulation exploits the Sigma Point method to systematically account for parametric model uncertainty in the optimization problem. Hence, it increases the robustness of the solution by reducing the operational risk. The operational risk can be considered as an additional objective function enabling a direct *trade-off* evaluation between reducing operational risk and, e.g., productivity and/or energy consumption. Finally, the *Pareto Browser* is tested on a fed-batch dynamic optimization problem with two uncertain parameters and three objective functions. The *trade-offs* between the considered objective functions were correctly quantified while no additional computational time was spent in uninteresting parts of the Pareto set.

Abstract

The water-energy nexus considers the relationship between water and energy resources. The increase in environmental regulations and social pressures has made it necessary to develop processes that are conservative with respect to both these resources. This work outlines the development of an optimisation model of a water network comprised of water sources, water sinks and an electrodialysis unit for the partial purification of contaminated water. The optimisation model is based on a superstructure framework, where the objective is to minimise freshwater consumption, wastewater production, energy consumption and the operating and capital costs involved in the process integration. A comparison was done between the developed model and the more common black box model, which simplifies regeneration units to linear expressions. The results show that the black box approach can lead to inaccuracies of up to 85% in the costing of regeneration units. Furthermore, it is shown that there are significant environmental and financial benefits in the simultaneous minimisation of water and energy in water networks.

Keywords: Water-energy nexus, water minimisation, mathematical modelling

1. Introduction

In the realm of process integration, water minimisation involves the interaction of process units in a system with the goal of reducing the amount of freshwater consumed and/or the amount of wastewater produced by the individual units and the entire system. This can be achieved by either reusing or recycling effluent produced, in conjunction with partial treatment or regeneration of contaminated water. Partial purification can be achieved by membrane processes, such as electrodialysis, reverse osmosis, and ultrafiltration, as well as non-membrane processes, such as stream stripping or using ion exchange resins. The choice of which minimisation approach to adopt must be informed by the nature of the processes involved and the cost of regeneration.

Water purification is an energy intensive process. As such, it is necessary to minimise the amount of energy required to treat effluent in a water network. The treatment process considered in this work is electrodialysis (ED). The process of ED, depicted in Figure 1, involves electromigration of ionic species across selectively permeable and alternately charged membranes. This results in the formation of a highly concentrated concentrate stream, and a diluate stream with a low contaminant concentration.

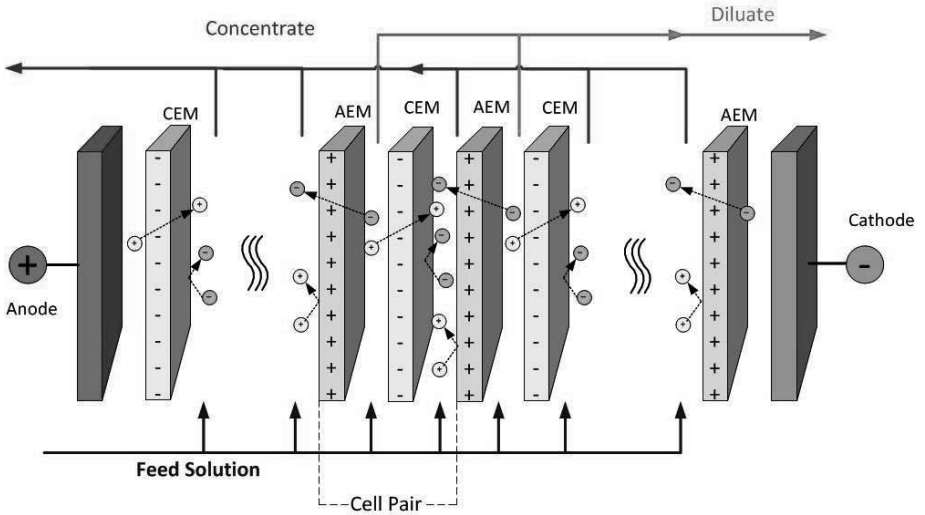

Figure 1: Schematic diagram of a single stage electrodialysis unit comprised of multiple cell pairs

Different approaches to ED modelling exist, including the convective-diffusion model, and the fixed flowrate design model. The latter was adopted in this work, owing to its simplicity and ease of integration. An ED design model was developed by Lee et al (2002) for single contaminant systems, to determine the area, current and voltage involved in desalination. This model was applied by Tsiakis and Papageorgiou (2005), to optimise the capital cost and energy consumption. It was also validated against experimental work by Brauns et al., (2009). In this work, a reformulation that allows the optimisation of multi-contaminant systemsis proposed. This involves the introduction of expressions for equivalent concentration and equivalent conductivity, taking into account the complex nature of ionic mixtures.

There are two major approaches adopted in water minimisation, namely, graphical and mathematical optimisation techniques. In this case, the mathematical optimisation approach was adopted, using the superstructure method. This approach allows the processing of complex systems containing multiple contaminants, as well as the capability to conveniently integrate the water network model with a regenerator model.(Khor et al., 2011).

In many of the water network superstructure models to date, regeneration units are represented by a simplified linear expression of the unit performance. The disadvantage of this approach is that it does not provide an accurate representation of the cost of the water network. In most instances, the cost of purification is not considered, or a generic linear cost function is applied. This results in an offset between the actual costs of regeneration and the costs factored into the regeneration model. This work aims to highlight the adverse impact if this simplification on achieving an optimum performance index.

2. Problem statement

A fixed flowrate approach was taken in the model development, i.e. a stream is described by the total flowrate of fluid and the concentration of each of the

contaminants in the stream. According to this assumption,a water source is a unit that produces water or effluent while a water sink is a unit that consumes water.

In short, the problem statement can be stated as follows. Given :

- A set of water sources, J, with known flowrates, F_j, and known contaminant concentrations, $C_{j,o}$
- A set of water sinks, I, with known flowrates, F_i ,and known maximum allowable concentrations, $C_{i,o}^{U}$
- A set of regenerators ,R, i.e. electrodialyisis unit, with some design parameters
- A freshwater source, with a variable flowrate, and known contaminant concentrations
- A wastewater sink, with a variable flowrate and known maximum allowable contaminant concentrations

It is required to synthesise the water network that minimises the amount of freshwater consumed, wastewater produced, the energy consumed in the regeneration unit and the overall cost of the water network. In addition, it is necessary to determine the optimum operating and design conditions of the electrodialysis unit (e.g. area, number of cell pairs, current and voltage).

3. Mathematical model

Material balances are established on the source-regenerator-sink basis.For the units involving mixing of streams, i.e. the regenerator and the sinks, a contaminant balance was conducted for each contaminant. The performance of the regeneration unit was described by the contaminant-specific removal ratio, *RR*, Eq. (1). This expression is often used in isolation when developing a black box model. It expresses the contaminant load in the concentrate stream, as a fraction of the contaminant load in the feed to the regenerator.

$$RR_{r,o} = \frac{C_{r,o}^{con} \sum_{i} F_{r,i}^{con}}{\sum_{j} C_{j,o} F_{j,r}} \qquad \forall\, r \in R,\ \forall\, o \in O \tag{1}$$

A comprehensive electrodialysis energy minimisation model is developed and included in the water network.The driving force for electrodialysis is the electric current, I, flowing across the unit. The current is determined using a modified expression of Faraday's law, given by Eq.(2), where z_o and $v_o$represent the valence and stoichiometric coefficient of either the cation or the anion of any contaminant, o. $Q^d$is the flowrate of the diluate stream, N, is the number of cell pairs in the ED unit, F, is the Faraday constant and ζ is the current efficiency.

$$I = \frac{F Q^d C^{\Delta}}{\xi N} \sum_{o} |z_o| v_o \tag{2}$$

In order to account for the multi-contaminant nature of the ED feed, C^{Δ},the concentration flux over the unit, is given in terms of the equivalent concentration of the

solution. For any given solution of salts with concentrations C_o, the solution equivalent concentration, C_{eq} is defined according to Eq. (3).

$$C_{eq} = \sum_{o} |z_o| v_o C_o \tag{3}$$

Based on the driving force, it is then possible to determine physical characteristics of the required unit, such as the membrane area, the length and the throughput. In addition, one is able to determine the amount of energy required for desalination and for pumping purposes, and subsequently, the capital and operating costs associated with regeneration.

The combination of the water network and ED model culminates in an objective function that takes into account freshwater consumption, wastewater production, and accurate capital and operating costs of ED units and necessary piping interconnections.

4. Illustrative Example

The above model is applied to a pulp mill and bleached paper plant adapted from Chew et al., (2008).In the original scenario, shown in Figure 2, four separate freshwater feeds are used, with a total consumption of 8 500 tonnes per day, and 4 separate effluent streams are produced, totalling 10 500 tonnes per day.

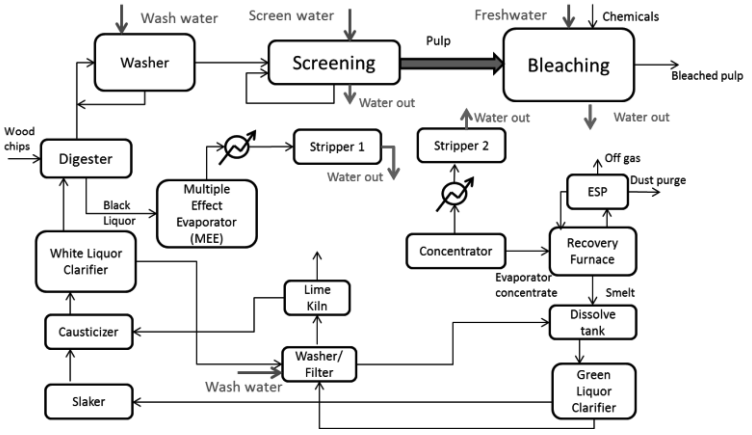

Figure 2: Simplified PDF of Pulp mill and bleached paper plant

Two alternate process integration scenarios were compared. Firstly, the case in which a black box model is used and the costing of the actual required ED unit is performed separately; i.e. water minimisation only.The second case involves simultaneous minimisation of water and energy, using the developed model. Two contaminants were identified,namely,NaCl and $MgCl_2$. The flowrates and contaminant concentrations of the sources and sinks are detailed in Table 1.

Table 1: Given data for water network

Sources				Sinks			
		Contaminant Concentration (Kmol/cm^3)				Maximum contaminant Concentration (Kmol/cm^3)	
Source	Flowrate (cm^3/s)	NaCl	$MgCl_2$	Sink	Flowrate (cm^3/s)	NaCl	$MgCl_2$
Stripper 1	2.07	0	0	Washer	3.26	0.0046	0.0004
Screening	0.34	0.046	0.035	Screening	0.34	0.0125	0.0007
Stripper 2	0.24	0	0	Washer/filter	1.34	0	0
Bleaching	7.22	0.026	0.0002	Bleaching	7.22	0.0002	0.00003
Freshwater	Variable	-	-	Wastewater	Variable	0.01	0.01

The results obtained from the optimisation are given in Table 2. In the first scenario,application of process integration results in a 36% saving in freshwater and 60% reduction of wastewater produced, in comparison with the original plant.The water minimisation black box model employs a linear cost function to determine the cost of regeneration. Such a function, however, is inaccurate as it does not account for the energy penalty associated with regenerating highly concentrated effluent. The deviation of the cost function from the actual cost of regeneration is 85%. The required ED unit has a total area of 438 m^2 and requires 353 cell pairs.

In the second scenario, the simultaneous minimisation of both energy and water within the water network results in a further reduction in freshwater consumption, wastewater production and cost of regeneration, as indicated in Table 2. By applying a penalty to the energy consumption, a more modest ED unit, with only 230 cell pairs and 144 m^{2}area, is required. Subsequently there is a 53% reduction in the total cost of the water network. The modified flowsheet after energy and water minimisation is given in Figure 3.

Table 2: Summary of costs in the 2 cases considered, values are given in $1000/annum

		Scenario 1		**Scenario 2**
	Original	Water minimisation - estimated ED cost	Water minimisation - true ED cost	Water and energy minimisation
Freshwater	2 814.86	1 776.00	1 776.00	1 736.70
Wastewater	3 468.12	1 122.80	1 122.80	1 083.50
Energy*	-	3.90	26.08	5.25
Piping	-	92.40	92.40	86.62
Total	6 282.98	2 995.10	3 017.28	2 912.07

*Energy associated with regeneration

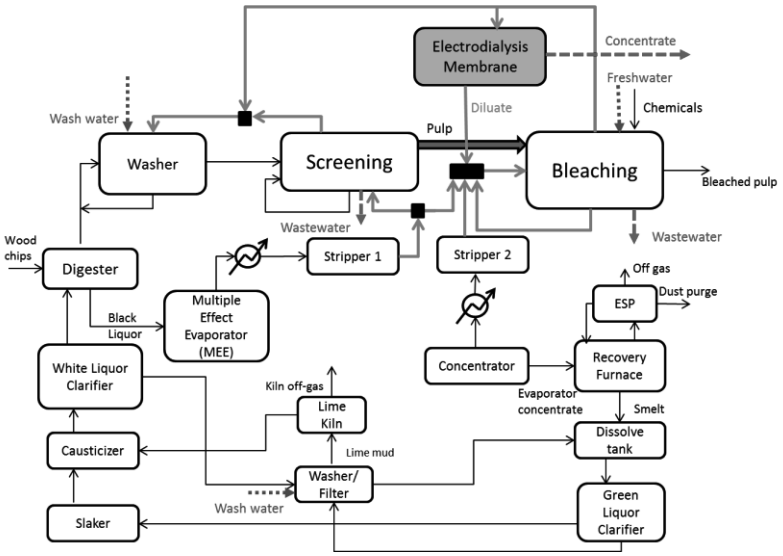

Figure 3: Process flowsheet after integration with the electrodialysis unit

5. Conclusion

This work explores the shortcomings of the black box model in water network optimisation by adopting an accurate representation of regeneration units. It is shown that by simultaneous minimisation of water and energy in the network, there is a significant reduction in freshwater consumption and wastewater production as well as an overall reduction in the cost of the water network. This approach also results in an 80% reduction in energy consumption in the regeneration units. Furthermore, the simultaneous approach results in more favourable design parameters for the regeneration units.

Deterministic Global Optimization and Transition States

Dimitrios Nerantzis and Claire S. Adjiman

Department of Chemical Engineering; Centre for Process Systems Engineering; Imperial College London; London SW7 2AZ; United Kingdom
dimitrios.nerantzis10@imperial.ac.uk; c.adjiman@imperial.ac.uk

Abstract

Transition states (index-1 saddle points) play a crucial role in determining the rates of chemical transformations but their reliable identification remains challenging in many applications. In the current literature deterministic global optimization methods have been employed for the location of transition states (TSs) by initially finding all stationary points and then identifying the TSs among the set of solutions. Aiming to focus the computational effort on the location of TSs of general nonlinear, three times continuously differentiable functions, we introduce regional tests for the identification of hyper-rectangular areas that do not contain any TS or that may contain a unique TS. These tests can be used within the framework of global optimization methods with the potential of reducing the computational time for TS location. We present the theory behind the tests and results on a simple benchmark function.

Keywords: global optimization, transition states, interval matrix, eigenvalue bounding

1. Introduction

We consider the following problem: Given a function $f : B \subseteq \mathbb{R}^n \to \mathbb{R}$, $f \in C^3$ we want to find all the critical points, $x^* \in B : \nabla f(x^*) = 0$, of f for which the Hessian matrix $\nabla^2 f(x^*)$ has eigenvalues $\lambda_n < 0 < \lambda_{n-1} \leq ... \leq \lambda_1$. Such points are called **Transition States** (TSs) or **index-1** saddle points. TSs play a crucial role in determining the rates of chemical transformations (Wales, 2003) and are also of interest in robotics and economics (Ellabaan et al., 2009). A number of local methods have been proposed in the literature for the identification of transition states. For example, in the Rational Function Optimization (RFO) method (Banerjee et al., 1985) a local search for a single TS is performed while in the Nudged Elastic Band method (Henkelman and Jónsson, 2000) an approximation of the minimum energy path between two minima is built. The point with the maximum energy on the path is a TS. Stochastic methods such as simulated annealing (Chaudhury and Bhattacharyya, 1998) and genetic algorithms (Ellabaan et al., 2009) have also been employed for locating TSs. While more computationally expensive, such methods do not require any starting points to locate a TS and may find multiple TSs.

Our focus in this paper is on deterministic global methods, that can guarantee the identification of all TSs within a specified domain. In the existing literature, the use of such methods for TS location includes the work of Westerberg and Floudas (1999) using the αBB algorithm (Androulakis et al., 1995; Adjiman et al., 1998) and the work of Lin and Stadtherr (2004) using the interval Newton method (Hansen and Walster, 2003). In (Westerberg and Floudas, 1999) and (Lin and Stadtherr, 2004) the authors locate all critical points of a potential energy function and then identify each type of solution based on the eigenvalues of the corresponding Hessian matrix. The drawback of this approach is that computational time is spent for the location of critical points with index > 1 (i.e., with a number of negative eigenvalues > 1).

Because of the computational cost associated with deterministic global optimization, it may be beneficial to focus the search on regions that contain TSs only. In this paper, we propose several regional tests that allow the elimination of certain regions and we apply this approach to a test function. We explore the trade-off between the cost of the tests and the number of iterations and CPU time required to identify all TSs.

The paper is organized as follows: In section 2, we introduce the general approach briefly. In section 3, the regional tests are discussed. The algorithm is applied to an example in Section 4 and conclusions are drawn in Section 5.

2. Proposed approach

We use the αBB algorithm and the formulation proposed in (Westerberg and Floudas, 1999) in order to search for critical points. However, aiming to focus the computational effort on the location of TSs, we introduce a number of tests which can be used to bound the number of negative and positive eigenvalues of an interval matrix. Since αBB is a branch & bound optimization algorithm, at any given iteration, it proceeds by calculating valid lower and upper bounds over hyper-rectangular subsets R of the initial domain B and then dividing each subset area to obtain better lower and upper bounds. Whenever the lower bound of a given area is found to be greater than the best upper bound so far, the area is fathomed. We modify the approach by applying, prior to each bounding step, a test on the interval Hessian matrix, $[\nabla^2 f(R)]$, calculated over R by the natural interval extension (Hansen and Walster, 2003) of the second derivatives $\partial^2 f/\partial x_i \partial x_j$. The interval Hessian can be seen as a superset of $\{\nabla^2 f(x) : x \in R\}$. If the test reveals that every matrix in $[\nabla^2 f(R)]$ has index > 1 then we fathom the area R. If the test reveals that every matrix in $[\nabla^2 f(R)]$ is index-1 then we perform a local search, since it can be shown that this implies that there can be at most one TS in R and: if we find a TS we fathom the area. Otherwise the test is inconclusive and so we proceed with the next step of the modified αBB algorithm.

3. Regional tests

In this section, we introduce three tests to assess whether a given region may contain a TS.

3.1. Recursive inertia test

Based on Haynsworth's theorem (Carlson et al., 1974) we can construct algorithms for obtaining bounds on the number of negative and positive eigenvalues of interval matrices. First we give the following definition:

Definition 3.1 (Inertia of a symmetric scalar matrix) *Given a symmetric matrix A, the inertia of A, In(A), is the triplet $(\pi(A), \nu(A), \delta(A))$ of the numbers of positive, negative and zero eigenvalues of A respectively.*

Theorem 3.2 (Haynsworth) *Given a symmetric matrix M partitioned in the form*

$$M = \begin{bmatrix} A & B \\ B^T & C \end{bmatrix} \text{ and assuming } A \text{ is non-singular, then } In(M) = In(A) + In(C - B^T A^{-1} B).$$

We can make use of Haynsworth's theorem recursively, as shown in Cottle (1974). Cottle considers scalar matrices and chooses A to be a single non-zero entry in the diagonal. By interchanging corresponding rows and columns simultaneously, thus not affecting the eigenvalues, we bring the selected entry A to the top right position of the matrix. We note the sign of A, we then calculate

$C - B^T A^{-1} B$ (this is the Schur complement of A in M) and we repeat. If all the elements in the diagonal are zero we are either left with a zero matrix or we can choose A to be of the form $\begin{bmatrix} 0 & a \\ a & 0 \end{bmatrix}$. This way we can always calculate the complete inertia of a scalar matrix.

A straightforward adaptation of this recursive scheme for interval matrices and for our purposes is simply to scan the diagonal for intervals that do not contain zero, calculate the interval Schur complement $[C] - [B]^T [A]^{-1} [B]$ and repeat. We should give priority to negative intervals. If at any point all the diagonal interval elements contain zero then we cannot proceed further with the analysis and stop. Note that in the interval case, each time we find a negative (resp. positive) interval in the diagonal of a subsequent Schur complement, this means that all the scalar matrices contained in the initial interval matrix have a further negative (resp. positive) eigenvalue. In a similar manner Meyer and Swartz (1998) used Schur's formula, $det(M) = det(A) det(C - B^T A^{-1} B)$, for a convexity test applied to interval matrices (such a test was mentioned in Cottle (1974) for scalar matrices) along with a branch-and-bound method. In algorithm 1 we give a pseudocode for the proposed recursive inertia algorithm, RecIn.

Algorithm 1 Pseudocode for RecIn algorithm: $O(n^3)$

Set $n = \dim([M])$. Initialize neg=0, pos=0 (number of negative and positive (interval) eigenvalues).
Search for a diagonal interval $[m_{aa}]$ with $0 \notin [m_{aa}]$. Give priority to negative intervals
if none found **then**
  Stop, test is inconclusive.
else
  $pos = pos + 1$, if $[m_{aa}] > 0$ or $neg = neg + 1$, if $[m_{aa}] < 0$
  if $neg > 1$ or $pos == n$ **then**
    Fathom area.
  else if $neg == 1$ and $pos == n - 1$. **then**
    Optional: Local search.
  else if $\dim([M]) > 1$ **then**
    Calculate the interval Schur complement of $A = [m_{aa}]$ in $[M]$, set $[M]$ to the Schur complement and repeat from step 2.
  else
    Test is inconclusive.
  end if
end if

3.2. 2×2 *Inertia test*

Another possible way to make use of theorem 3.2 for our purpose is to choose $[A]$, in $[M] = \begin{bmatrix} [A] & [B] \\ [B]^T & [C] \end{bmatrix}$, to be any of the 2×2 diagonal sub-matrices of $[M]$, $[A_{ij}] = \begin{bmatrix} [m_{ii}] & [m_{ij}] \\ [m_{ji}] & [m_{jj}] \end{bmatrix}$. The maximum eigenvalue, $\overline{\lambda_{ij}} = \max_{A_{ij} \in [A_{ij}]} \lambda_1(A_{ij})$, of each of these matrices is

$$\overline{\lambda_{ij}} = \frac{\overline{m_{ii}} + \overline{m_{jj}} + \sqrt{(\overline{m_{ii}} - \overline{m_{jj}})^2 + 4 \max\{\underline{m_{ij}}^2, \overline{m_{ij}}^2\}}}{2}, \tag{1}$$

where $\underline{m_{ij}}$ and $\overline{m_{ij}}$ are the lower and upper bounds of the interval entry $[m_{ij}]$ of $[M]$. If $\overline{\lambda_{ij}} < 0$ for any of the sub-matrices then by theorem 3.2 we know that every $M \in [M]$ has at least two negative eigenvalues and thus we can fathom the corresponding area. In algorithm 2 we give a pseudocode of this test to which we will refer as the 2×2 inertia test.

Algorithm 2 Pseudocode for the 2×2 inertia test: $O(n^2)$

```
Set n = dim([M]).
for i=1:n do
    for j>i:n do
        λ̄ = ((m̄_ii + m̄_jj + sqrt((m̄_ii − m̄_jj)^2 + 4 max{m_ij^2, m̄_ij^2})) / 2
        if λ̄ < 0 then
            Fathom area. Exit test.
        end if
    end for
end for
```

Note that the 2×2 inertia test does not remove minima and TSs and that it might be inconclusive even for a scalar matrix. However it is computationally cheap and easy to implement, and is thus worth investigating.

3.3. Rohn test

A third test is based on Rohn's method (Hladk et al., 2010) which is derived from the interval extension of Weyl's inequality (Golub and Van Loan, 1996).

Theorem 3.3 (Weyl) *Given symmetric (scalar) matrices C and E then*

$$\lambda_k(C) + \lambda_n(E) \;\leq\; \lambda_k(C+E) \;\leq\; \lambda_k(C) + \lambda_1(E).$$

Any given interval matrix $[M]$ can be written as $C+[E]$ where $c_{ij} = (\overline{m_{ij}} + \underline{m_{ij}})/2$ and $[e_{ij}] = [c_{ij} - \underline{m_{ij}}, \overline{m_{ij}} - c_{ij}]$. By calculating lower and upper bounds, $\underline{\lambda_n}$ and $\overline{\lambda_1}$, for $\lambda_n([E]) = \{\lambda_n(E) : E \in [E]\}$ and $\lambda_1([E]) = \{\lambda_1(E) : E \in [E]\}$ respectively then we would have,

Theorem 3.4 (Rohn) *Given a symmetric interval matrix* $[M] = C + [E]$ *then*

$$\lambda_k(C) + \underline{\lambda_n} \;\leq\; \lambda_k(C+[E]) \;\leq\; \lambda_k(C) + \overline{\lambda_1}.$$

Note that $\underline{\lambda_n} = -\overline{\lambda_1}$ and also that the widths of the intervals $\lambda_k([M])$ are all the same. We can calculate $\underline{\lambda_n}$ (and $\overline{\lambda_1}$) using a number of methods (Adjiman et al., 1998), the simplest being the interval extension of Gerschgorin's theorem ($O(n^2)$) and the most expensive being the Hertz-Rohn method ($O(2^{n-1})$). The Rohn test is summarized in algorithm 3.

Algorithm 3 Pseudocode for Rohn's test: $O(n^2)$ - $O(2^{n-1})$

```
Set n = dim([M]).
Calculate [λ_n] and [λ_{n−1}] for [M] using Theorem 3.4 and an eigenvalue bounding method.
if λ_n ≥ 0 then
    Fathom area (convex area).
else if λ̄_n < 0 and λ_{n−1} > 0 then
    Optional: Local search.
else if λ̄_{n−1} ≤ 0 then
    Fathom area.
else
    Test is inconclusive.
end if
```

4. Application to a benchmark problem.

The proposed tests have been implemented in the αBB algorithm (Adjiman et al., 1998). We investigate the performance the proposed tests on a small example, Ackley's function in three dimensions. The form and domain are given below.

$$f(x) = -20\exp(-0.2\sqrt{\tfrac{1}{n}\textstyle\sum_{i=1}^{n} x_i^2}) - \exp\left(\tfrac{1}{n}\textstyle\sum_{i=1}^{n}\cos(2\pi x_i)\right) + 20 + e,\ x \in [0.5,3]^3,\ n = 3. \quad (2)$$

We perform six runs, one run without any regional tests, one run with the 2×2 inertia test, two runs with the Rohn test (with and without the local search step) and two runs with the RecIn test. For bounding the eigenvalues in Rohn's test we use the interval extension of Gerschgorin's theorem (Adjiman et al., 1998). The CPU time and number of solutions of each type (minima, TSs, higher-index critical points) found are reported in table 1. The number of unfathomed nodes at each iteration for each run is shown in figure 1. The computations were performed on a 3060 MHz computer using an absolute convergence tolerance of 10^{-6} and a minimum box size of 10^{-6}. All 81 TSs are identified in all cases, and significant decreases in the CPU time can be observed, with all tests performing well. The local search is found to reduce the number of iterations and to lead to a further decrease in CPU time. This is likely to be critical when dealing with larger problems.

Table 1: CPU times without local search / with local search and number of solutions of each type found for each run for the Ackley function.

Test	**CPU Time**	**#Mins**	**#TSs**	**#index $>$ 1**
No test	65 sec	27	81	84
2x2 Inertia	33 sec	27	81	0
Rohn	30/21 sec	0	81	0
RecIn	28/19 sec	0	81	0

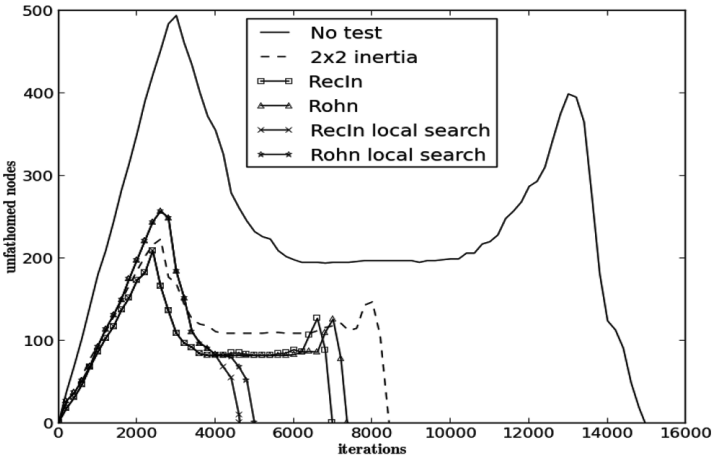

Figure 1: Number of unfathomed nodes at each iteration for each run.

5. Conclusions

In this paper we considered the problem of locating all transition states (TSs) of general nonlinear functions, in C^3, using global deterministic methods. In particular we used the αBB optimization method and we introduced a number of tests which we applied prior to the bounding step of the αBB algorithm. These tests help to identify areas of the search space which do not contain any TSs or may contain at most one. In the first case we fathom/remove the area while in the second we perform a local search and if a solution is found we fathom the area. Without the tests the algorithm simply locates all critical points while with the tests we aim to focus the computational effort on the location of TSs. We have presented the successful application of the proposed tests to a benchmark function. The results indicate that the addition of the tests can reduce the computational time significantly. Finally we note that the proposed tests can be used within any branch and bound algorithm or within the interval Newton method and that they can be altered in order to locate any index-k critical point, with the exception of the 2×2 inertia test.

Abstract

Supply Chain Design problems often result into multiperiod stochastic mixed integer problems that are hard to solve. In this paper we propose a metaheuristic algorithm as a specialization for two-stage problems of the so-named Fix-and-Relax Algorithm presented previously for solving large-scale multiperiod stochastic mixed 0-1 optimization problems under a time stochastic dominance risk averse strategy, so-named TSD. Some computational experience is presented.

Keywords: Two-stage stochastic mixed 0-1 optimization, metaheuristic, Fix and Relax, time stochastic dominance

1. Introduction

Given the large dimensions of the real-life problems under uncertainty and of supply chains systems in particular, algorithms seeking for the optimal solution are today unaffordable. By contrary, inexact decomposition algorithms are more appropriate assuming that a methodology for goodness assessment of the solution is provided. In this work a metaheuristic decomposition algorithm is proposed as a specialization for two-stage problems of the so-named Fix-and-Relax Algorithm (FRA) for solving large-scale multiperiod stochastic mixed 0-1 optimization problems that is presented in Escudero et al. (2014). The time stochastic dominance strategy, so-named TSD Escudero et al. (2014), is used for risk reduction of the negative impact in the objective function of non-wanted scenarios (i.e., the so-named swan scenarios).

In order to assess the solution procedure applicability, computational tests were performed on multi-period and multi-commodity closed loop supply chains randomly generated from a deterministic reference case previously addressed in Salema et al. (2010), that being a large scale case, its stochastic counterpart is a very large one Baptista et al. (2014).

2. Two-stage stochastic mixed 0-1 problems under strategy TSD

Without loss of generality, let the following compact representation of the two-stage stochastic mixed 0-1 model for maximizing the expected objective function value (say, profit) over the set of

scenarios along a time horizon by only considering the risk neutral (RN) strategy,

$$
\begin{array}{lll}
z_{RN} = & \max\{a_1 x_1 + b_1 y_1 + \sum\limits_{\omega\in\Omega} w^{\omega} \sum\limits_{t\in\mathscr{T}^-} (a_t^{\omega} x_t^{\omega} + b_t^{\omega} y_t^{\omega})\} & \\
\text{s.t.} & A_1 x_1 + B_1 y_1 = h_1 & \\
& A_1^{t\omega} x_1 + B_1^{t\omega} y_1 + \sum\limits_{t'\in\mathscr{T}^-:t'\le t} (A_{t'}^{t\omega} x_{t'}^{\omega} + B_{t'}^{t\omega} y_{t'}^{\omega}) = h_t^{\omega} & \forall t \in \mathscr{T}^-, \omega \in \Omega \\
& x_1 \in \{0,1\}^{nx(1)}, y_1 \in I\!R^{ny(1)} & \\
& x_t^{\omega} \in \{0,1\}^{nx(t)}, y_t^{\omega} \in I\!R^{ny(t)} & \forall t \in \mathscr{T}^-, \omega \in \Omega,
\end{array} \tag{1}
$$

where w^{ω} is the modeler-driven weight or likelihood of scenario ω for, the first stage 0-1 and continuous variables, respectively; a_1 and b_1 are the objective function coefficient vectors for the variables in the first stage vectors x_1 and y_1, respectively; A_1 and B_1 are the first stage constraint matrices for the variables in the vectors x_1 and y_1, respectively; x_t^{ω} and y_t^{ω} are the vectors of the second stage 0-1 and continuous variables, respectively, at time period t for scenario ω, for $t \in \mathscr{T}^-$, where $\mathscr{T}^- \equiv \mathscr{T}\backslash\{1\}$ and $\omega \in \Omega$, where Ω is the set of scenarios under consideration; a_t^{ω} and b_t^{ω} are the vectors of the objective function coefficients for the variables in the second stage vectors x_t^{ω} and y_t^{ω}, respectively; $A_1^{t\omega}$ and $B_1^{t\omega}$ are the second stage constraint matrices for the variables in the vectors x_1 and y_1; $A_{t'}^{t\omega}$ and $B_{t'}^{t\omega}$ are the second stage constraint matrices for the variables in the vectors $x_{t'}^{\omega}$ and $y_{t'}^{\omega}$, respectively; h_t^{ω} is the rhs; $nx(1)$ and $ny(1)$ are the number of the first stage 0-1 and continuous variables, respectively; and $nx(t)$ and $ny(t)$ are the number of the second stage 0-1 and continuous variables, respectively. Notice that the Non-Anticipativity Constraints (NAC) are satisfied for the first stage.

The main criticism that can be made to strategy RN is that it ignores the variability of the objective function value over the scenarios and, in particular in our case, the "left" tail of the non-wanted scenarios. Alternatively, there are some other approaches that also deal with risk management by providing hedging solutions against the occurrence of some non-desired scenarios considering risk averse strategies, see a survey in Alonso-Ayuso et al. (2014). Some of these strategies consider semi-deviations, excess probabilities, conditional value-at-risk, expect shortfall on reaching given thresholds as risk measure-based functions to optimize as well as the two recent new risk averse measures, namely, the first- and second-order Stochastic Dominance Constraint strategies, say FSD (Gollmer et al. (2008)) and SDD (Gollmer et al. (2011)), respectively.

In this paper we consider the specialization of strategy TSD for solving multistage problems introduced in Escudero et al. (2014) to the two-stage environment. That strategy is a time-based mixture of strategies FSD and SSD, such that each modeler-driven so-named profile for each selected period along the time horizon is included by an objective function threshold and the targets on given bounds on the probability of failure of reaching the threshold and the related expected shortfall on reaching and the scenario shortfall itself. So, strategy TSD requires a set of profiles $\{p\}$, say $\mathscr{P}_t \, \forall t \in \tilde{\mathscr{T}}$, given by the tupla $(\phi^p, S^p, \bar{s}^p \, \bar{v}^p)$, where ϕ^p is the objective function threshold to be satisfied up to time period t, $\tilde{\mathscr{T}} \subseteq \mathscr{T} - 1$ is the period set where the TSD policy is considered, S^p is the maximum *target* for the shortfall that is allowed on reaching the threshold up to time period t, $\bar{s}^p$ is the upper bound *target* of the expected shortfall on reaching the threshold over the scenarios with shortfall, and $\bar{v}^p$ is the shortfall probability bound *target*.

Let $s^{\omega p}$ denote the shortfall (continuous) variable that, obviously, is equal to the difference (if it is positive) between threshold ϕ^p and the profit up to time period t for $p \in \mathscr{P}_t, t \in \tilde{\mathscr{T}}$ for scenario $\omega \in \Omega$. And let $v^{\omega p}$ denote a 0-1 variable such that its value is 1 if the profit up to time period t is smaller than threshold ϕ^p and otherwise, 0. In order to model the expected shortfall over the scenarios with shortfall, say set $\{\omega \in \Omega : v^{\omega p} = 1\}$, besides the constraint $s^{\omega p} \le S^p v^{\omega p}$ that force the 0-1 variable $v^{\omega p} = 1$ for $s^{\omega p} > 0$, the constraint $v^{\omega p} \le s^{\omega p}$ is required. Although we exclude fractional 0-1 values for the latter (continuous) variable, this fact has very minor influence on the value of the expected shortfall given the usual magnitude of the objective function

value for profile p. Finally, the weight w^ω should be replaced with the weight, say $w^\omega_{v^{\omega p}}$, of the scenario ω in the subset of scenarios with shortfall for profile p; it can be represented as follows: $w^\omega_{v^{\omega p}} = \dfrac{w^\omega}{\sum_{\omega' \in \Omega: v^{\omega' p}=1} w^{\omega'}}$. The nonlinearity in the expression can be equivalently replaced with the expressions given in model (2).

$$z_{TSD} = \max\{a_1 x_1 + b_1 y_1 + \sum_{\omega\in\Omega} w^\omega \sum_{t\in\mathscr{T}^-} (a_t^\omega x_t^\omega + b_t^\omega y_t^\omega) - \sum_{t\in\tilde{\mathscr{T}}} \sum_{p\in\mathscr{P}_t} (M_S^p \varepsilon_S^p + M_{\bar{s}}^p \varepsilon_{\bar{s}}^p + M_{\bar{v}}^p \varepsilon_{\bar{v}}^p)\}$$

$$\begin{array}{lll}
\text{s.t.} & A_1 x_1 + B_1 y_1 = h_1 & \\
& A_1^{t\omega} x_1 + B_1^{t\omega} y_1 + \sum\limits_{t'\in\mathscr{T}^-: t'\le t} (A_{t'}^{t\omega} x_{t'}^\omega + B_{t'}^{t\omega} y_{t'}^\omega) = h_t^\omega & \forall t \in \mathscr{T}^-,\ \omega\in\Omega \\
& x_1 \in \{0,1\}^{nx(1)},\ y_1 \in I\!R^{ny(1)} & \\
& x_t^\omega \in \{0,1\}^{nx(t)},\ y_t^\omega \in I\!R^{ny(t)} & \forall t \in \mathscr{T}^-,\ \omega\in\Omega \\
& a_1 x_1 + b_1 y_1 + \sum\limits_{t'\in\mathscr{T}^-: t'\le t} (a_{t'}^\omega x_{t'}^\omega + b_{t'}^\omega y_{t'}^\omega) + s^{\omega p} \ge \phi^p & \forall p\in\mathscr{P}_t,\ t\in\tilde{\mathscr{T}},\ \omega\in\Omega \\
& 0 \le s^{\omega p} \le S^p v^{\omega p} + \varepsilon_S^p,\ v^{\omega p} \le s^{\omega p},\ v^{\omega p} \in \{0,1\} & \forall p\in\mathscr{P}_t,\ t\in\tilde{\mathscr{T}},\ \omega\in\Omega \\
& \sum\limits_{\omega\in\Omega} w^\omega s^{\omega p} \le \bar{s}^p (\sum\limits_{\omega\in\Omega} w^\omega v^{\omega p}) + \varepsilon_{\bar{s}}^p & \forall p\in\mathscr{P}_t,\ t\in\tilde{\mathscr{T}} \\
& \sum\limits_{\omega\in\Omega} w^\omega v^{\omega p} \le \bar{v}^p + \varepsilon_{\bar{v}}^p & \forall p\in\mathscr{P}_t,\ t\in\tilde{\mathscr{T}} \\
& \varepsilon_S^p \in I\!R^+,\ \varepsilon_{\bar{s}}^p \in I\!R^+,\ \varepsilon_{\bar{v}}^p \in I\!R^+ & \forall p\in\mathscr{P}_t,\ t\in\tilde{\mathscr{T}},
\end{array} \tag{2}$$

where ε_S^p, $\varepsilon_{\bar{s}}^p$ and $\varepsilon_{\bar{v}}^p$ are the non-negative slack variables that take the violations of the S^p-, $\bar{s}^p$- and $\bar{v}^p$-bounds, respectively, being M_S^p, $M_{\bar{s}}^p$ and $M_{\bar{v}}^p$ the related big enough M-parameters for the penalization of those slack variables in the objective function. Observe that the TSD model object consists of controlling the objective function value at modeler-driven periods, instead of only performing it at the end of the time horizon. It is very useful for applications with long horizons.

3. FRA2: a Fix and Relax Coordination algorithm for two-stage stochastic mixed 0-1 problems under TSD strategy

The main characteristic of the inexact approach that is proposed consists of considering levels along the time horizon defined by disjoint sets of consecutive periods. At each level a partial scenario mixed 0-1 model is solved by fixing the 0-1 variables of ancestor levels to the value obtained at the optimization of their related models and relaxing the integrality of the 0-1 variables related to successor levels as well as the cross scenario TSD system for those other levels, such that a backstep to the immediate ancestor level is performed in case of the infeasibility of the level's model.

Let $\mathscr{L}$ denote the set of levels, such that t_e^ℓ is the last period in level ℓ (and, then, $t_e^{\ell-1}+1$ is its first one) for $\ell\in\mathscr{L}$. For easying purposes, let $t_e^0 = 0$. At a given level ℓ, let M^ω denote the scenario model for $\omega\in\Omega$ from the original RN model (1) where the NAC have been relaxed, being z^ω its solution value, and M_{TSD}^ℓ denote the TSD model (2), being z_{TSD}^ℓ its solution value. The models $M^\omega\,\forall\omega\in\Omega$ and M_{TSD}^ℓ are to be alternatively solved for level $\ell\in\mathscr{L}$ at FRA2, such that $x_1 = \hat{x}_1$, $y_1 = \hat{y}_1$ and $x_t^\omega = \hat{x}_t^\omega$, $y_t^\omega = \hat{y}_t^\omega\ \forall\omega\in\Omega$ and period t for $t\in\mathscr{T} : t \le t \le t_e^{\ell-1}$. Notice that in order to satisfy the TSD system, the model M_{TSD}^ℓ will be used provided that $\exists t\in\tilde{\mathscr{T}} : t_e^{\ell-1}+1 \le t \le t_e^\ell$; else, the models $M^\omega\,\forall\omega\in\Omega$ are solved.

The main steps of FRA2 are as follows:

Step 0: (**Initialization**). Parameter *mback* (maximum number of allowed backsteps).

Step 1: (**Solution for first level**).
Solve model M^1_{TSD}. If it is infeasible then the original problem (2) is infeasible as well, STOP.
Set $nback := 0$ and level $\ell := 2$.

Step 2: (**Forward step**)
If $\nexists t \in \tilde{\mathscr{T}} : t_e^{\ell-1} + 1 \leq t \leq t_e^{\ell}$ then solve the scenario models $M^{\omega}\, \forall \omega \in \Omega$;
else solve model M^{ℓ}_{TSD}.

Step 3: (**Detecting infeasibility**)
If any model $M^{\omega}\, \omega \in \Omega$ or model M^{ℓ}_{TSD} is infeasible, whenever it has just been solved, then: If $nback = mback$ or $\ell = 1$ then STOP: "Original problem status: unknown"; else go to Step 4. If $\ell = |\mathscr{L}|$ then STOP: "A (hopefully, good) feasible solution has been obtained for the original problem".
Update $\ell := \ell + 1$.Go to Step 2.

Step 4: (**Backward step**)
Redefine the partition structure: $t_e^i := t_e^{i+1}\, \forall i = \ell - 1, ..., |\mathscr{L}| - 1$, $|\mathscr{L}| := |\mathscr{L}| - 1$.
Update $nback := nback + 1$ and $\ell := \ell - 1$. Go to Step 2.

4. Computational experience

In this section the results of a computational testing are reported for the multi-period and multi-commodity closed loop supply chains randomly generated from a deterministic reference case presented in Salema et al. (2010) and extended in Baptista et al. (2014) to its stochastic and risk averse version. Further this extension, now considers that returned products may be sold to a secondary market, sent back to the plant to be remanufactured or just disposed.

The Fix-and-Relax algorithm FRA2 considered in this work has been implemented in C++ code, being CPLEX v12.6 as the MIP optimization engine. The computational experiments were conducted on a laptop with a 2.4 GHz Core i5 processor and **4**GB of RAM.

As testbed, two networks (N1 and N2) were randomly generated considering $|\Omega| = 12$ scenarios, $T = 15$ periods and $|\mathscr{L}| = 4$ levels whose last periods are $t_e^1 = 1, t_e^2 = 6, t_e^3 = 11$ and $t_e^4 = 15$. For the last period of each level, there is a single profil, so $|\mathscr{P}_t| = 1$, $|\tilde{\mathscr{T}}| = 1$ being $t_e^{\ell} \in \tilde{\mathscr{T}}$. Notice that in all instances, the TSD bounds $S^1, \bar{s}^1, \overline{v}^1$ may be tight enough to require that the corresponding related slack variables $\varepsilon_S^1, \varepsilon_{\bar{s}}^1, \varepsilon_{\overline{v}}^1$ to be greater than zero for the 3 last levels.

The contents of the tesbed are as follows: Network N1 is defined by 3 plants, 3 warehouses, 18 customers and 3 disassembly centers; Network N2 is defined by 4, 9, 18 and 9 respective entities. Two random instances were created for N1 (N1V1 and N1V2) and a single instance (N2V1) was created for network N2. In each network 3 products are considered in the flow plants-warehouses, 6 for the flow warehouses-customers and 1 for the flow customers-disassembly. In disassembly centers, products are graded according to their quality (G1, G2 and G3) so that 2 different products graded G1 are the outflow to the market, 1 product flow graded G3 is the outflow to disposal and, finally, 2 flows' products graded G2 are the closing loop flows. 12 random scenarios were generated, defining each of the random parameters such as transportation costs, demand, sell prices in primary and secondary markets, products' return rate, product's quality rates G1 and G2, annual amortization costs and residual values and annual available budget. Finally, table 1 gives the models' dimensions. Its headings read as follows: *m*, *n*01, *nc*, *nel*, number of constraints, 0-1 variables, continuous variables and non-zero elements in constraint matrix; and *den*, constraint matrix density. Observe the large dimensions of the instances in the testbed. Note: Our better results in our limited experience been obtained by re-running the algorithm while imposing a reduction of one in the number of plants that have been selected in the solution of the other run.

Table 1: Models dimensions

	m	$n01$	nc	nel	den (%)
N1	200735	195	91215	784596	0.004
N2	627203	504	293496	2548833	0.014

4.1. Small CLSC network

The goal in this set of experiments consists of comparing the performance of CPLEX versus FRA2 in the solution value and elapsed time for solving TSD model (2). Therefore each instance of the network N1 was solved using the two different sets of scenario's probabilities (P1 and P2) given in Table 2. Notice that the scenarios are ranked according to their outcome so that Scenario 1 is the most optimistic and Scenario 12 is the most pessimistic of the 12 scenarios.

Table 2: Scenarios' probabilities

	Sc1	Sc2	Sc3	Sc4	Sc5	Sc6	Sc7	Sc8	Sc9	Sc10	Sc11	Sc12
P1	0.01	0.01	0.03	0.10	0.10	0.10	0.15	0.25	0.15	0.05	0.04	0.01
P2	0.01	0.01	0.01	0.02	0.05	0.10	0.05	0.15	0.10	0.18	0.12	0.20

Table 3 reports the results obtained in this experimentation. Its headings read as follows: z_{TSD}^{FRA2}, algorithm solution value; z_{TSD}^{CPLX}, best solution value obtained using plain use of CPLEX within the time limit of 8h (non optimal solutions are superscripted by *); GAP_z, respective gap, computed when the optimal solution is available ; y_{TSD}^{FRA2}, algorithm expected profit value; y_{TSD}^{CPLX}, optimal solution expected profit value obtained using plain use of CPLEX within the time limit of 8h; GAP_y, respective gap, computed when the optimal solution is available ; t^{FRA2} and t^{CPLX}, elapsed times (secs.) for obtaining z_{TSD}^{FRA2} and z_{TSD}^{CPLX}, respectively.

Table 3: Small network computational results

	z_{TSD}^{FRA2}	z_{TSD}^{CPLX}	$GAP_z(\%)$	y_{TSD}^{FRA2}	y_{TSD}^{CPLX}	$GAP_y(\%)$	t^{FRA2}	t^{CPLX}
N1V1P1	-65105.8	-115443.6^*	-43.59	20894.2	-	-	1890	43200
N1V1P2	-84891.5	-115183.6^*	-26.29	13108.4	-	-	1928	43200
N1V2P1	-281641	-281483.5	0.06	15359.3	15516.5	1.01	2979	30949
N1V2P2	-290181	-290103.7	0.03	6819.2	6896.0	1.10	3830	49488

Observe that the negative value of $GAP_z(\%)$ for the first two instances is very favorable for FRA2. Since CPLEX cannot prove the solution's optimality due to reaching the allowed time limit (8h.), we did not gather its related profit. However, CPLEX did prove the solution's optimality for the last two instances such that, since the values of $GAP_z(\%)$ are very small, it is worthy to point out that the CPLEX solution gives a slightly higher profit than FRA2. However, it pays a higher price in the violation of the TSD risk reduction bounds on the scenario shortfall, expected shortfall and fraction of scenarios with shortfall.

Regarding the results reported for these not so very large networks, two major facts should be additionally pointed out. First, the metaheuristic algorithm presents a remarkable computing time reduction with respect to plain use of CPLEX ranging from 93 up to 97%. Second, in all instances, the solution values obtained with the P2 probabilities present stronger penalty costs due to the heavier weight of worse scenarios.

4.2. Larger CLSC network

The goal in this set of experiments consists of comparing the performance of algorithm FRA2 for solving RN model (1) and TSD model (2), evaluating the deterioration of the expected profit in

the later model while considering the risk reduction for not reaching the modeler-driven profiles' thresholds of the profiles for the 4 levels in the RN solution. A single instance (N2V1) of network N2 was solved using the set of scenario's probabilities P2 given in Table 2.

This experiment with the RN model (1) shows an expected profit of 85515.48 but it has one scenario (probability 1%) out of 12 with a heavy loss at the end of the time horizon (i.e., end of level 4), in fact, the amount 82843.3. It proves the add-value of the risk averse strategy TSD in the context of very risky scenarios and very small feasible regions. It is assumed that the modeler-driven risk reduction (to be obtained by the TSD model (2)) allows one scenario with a loss but with a probability not higher than 1% and an amount not greater than 61738.6. The solution offered by the TSD model presents an expected profit over the 12 scenarios of an amount of 85665.04 (since it is an heuristic) and the loss of that scenario has been reduced to 63738.6, so, below the loss computed in the RN solutions.

5. Conclusions

In this work we studied the strategies Risk Neutral and risk averse Time Stochastic Dominance for general two-stage stochastic mixed 0-1 problems, where the uncertainty appears anywhere. A metaheuristic algorithm (FRA2) was proposed as a specialization for two-stage problems of the so named Fix-and-Relax Algorithm. Computational tests for multi-period and multi-commodity closed loop supply chains showed the algorithm applicability and the add-value of risk averse strategies as an alternative for plain use of even MIP state-of-the-art solvers.

Abstract

A dynamic optimization frame work is used to produce in a controlled way multilayered latex nanoparticles. The key feature of the method is to track a glass transition temperature profile, which is designed to produce polymer layers with the targeted properties. Several constraints are considered to achieve better control and produce nanoparticles with a specified particle diameter and layers' thicknesses.To enhance the control of the different layers,two separate monomer feeds are considered under starving conditions throughout the fed-batch stages. The emulsion copolymerization of styrene and butyl acrylate in the presence of n-C12 mercaptan, as chain transfer agent (CTA), is illustrated here as a case study. The optimal feed profiles of the pre-emulsioned monomers are obtained using a genetic algorithm.

Keywords:Multilayered nanoparticles, Dynamic optimization, Fed-batch emulsion copolymerization.

1. Introduction

One of the most important and difficult tasks for researchers and engineers in the field of nanotechnology is to produce nanoparticulate materials with perfectly tailored end-use properties at industrial scales. This requires an effective control of the physical, chemical, and morphological characteristics, such as particle size distribution (PSD), particles morphology, glass transition temperature (T_g), besides the molecular weight distribution (MWD) and polymer microstructure in the particular case of polymeric nanoparticles.Multilayered nanoparticles have drawn particular interest in the area of drug and gene delivery, biosensors and the development of miniaturized optical, electronic, optoelectronic, information-storage materials and devices (Ediriwickrema et al., 2014; Shevchuk et al., 2007). Different technics have been used to synthesize this class of nanoparticles, particularly self-assembly and layer-by-layer deposition.

It was shown recently that the optimization tools can be used to tailorthe end-use properties of latex particles at the nanoscale. First, a multiobjective dynamic optimization approach was used to determine the set of the best operating alternatives (i.e. Pareto set), among which, one operating alternative was selected using a multicriteria decision aiding approach (Benyahia et al., 2012). The best solution obtained was experimentally implemented with success. As an alternative to the

multiobjective optimization, a dynamic single objective optimization approach was adopted using a weighted sum of several objective functions (Paulen et al., 2014). In this paper, a single objective optimization approach is used to determine the optimal feeding profiles for the production of multilayered polymer nanoparticles. The objective function describes the tracking of a piece-wise constant gel transition temperature (T_g) profile. The emulsion copolymerization of styrene and butyl acrylate in the presence of n-C12 mercaptan, as chain transfer agent (CTA), is used here as a case study. The key feature of the method is to optimally control the polymerization reaction at the different stages of the process (i.e. different layers) using the feed profiles of two monomers, whose homopolymers have different T_g values. The approach presented here is the extension of the results obtained in the case of core-shell nanoparticles. Nevertheless, a significant modification is brought to improve the optimization procedure by using two separate feeds for the two monomers, while implementing a different set of constraints.

This paper is organized as follows: after the formulation of the optimization problem, the main simulation results are presented and discussed followed by the conclusions.

2. Formulation of the problem

The glass transition temperature (T_g) of a polymer has a major impact on the physical and mechanical properties of the final productat a given temperature (i.e. hard or rubber-like material). The T_g, in turn,depends strongly on the microstructure of the macromolecules, which if controlled will lead to controlled properties. Recently, the instantaneous glass transition temperature profile was proven to be an effective tool to tailor and produce core-shell nanoparticles with specific end-use properties(Benyahia et al., 2012; Paulen et al., 2014). Here, the idea is extended to the case of multilayered nanoparticles. The key feature of the method is to copolymerize two monomers, in a dynamically controlled way (i.e. tracking),in order to achieve a targeted glass transition temperature profile and therefore, specific end-use properties.

The process considered is an emulsion copolymerization of styrene and butyl acrylate in the presence of n-C12 mercaptan as a chain transfer agent (CTA). The homopolymers, poly(butyl acrylate) and polystyrene, have significantly different glass transition temperatures (-54 °C and 100 °C respectively). This key characteristic makes it possible to produce copolymers with T_g values between -50 and 100 °C. The process model was developed and validated elsewhere (Benyahia et al., 2010; Benyahia et al., 2012).The mathematical model is a hybrid differential algebraic system,which entails 18 ordinary differential equations and several algebraic equations.For more flexibility, two pre-emulsions feeds are considered (one for each monomer).

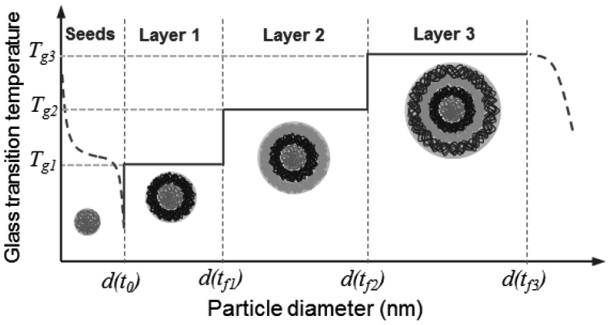

Figure 1: Instantaneous glass transition temperature (T_{gi}) profile of the multilayered particles.

The objective is to produce multilayered nanoparticles with specific final diameter, layer thicknesses and glass transition temperature profile,using optimal feed rate profiles of pre-emulsioned styrene and butyl acrylate.The resulting dynamic optimization problem is described by equations 1-13. The objective function describes the minimization of the error between the actual instantaneous glass transition temperature profile and the reference profile or trajectory (Fig. 1).

\end{cases}
$$

where T_g is the time dependent glass transition temperature T_{g1}, T_{g2}, $T_{g3}$the desired glass transition temperatures for the different layers (T_{g1}= 3 °C, T_{g2} = 10 °C, T_{g3} = 17 °C), t_{f1}, t_{f2},$t_{f3}$the time required to complete the different layers, X the overall conversion, $\boldsymbol{u}$ the control vector (feed rates and time periods). $\bar{M}_n$, $\bar{M}_w$the number and weight average molecular weights, $Q_{Mi,j}$the feed rate of the pre-emulsioned it hmonomer at the jth time period, and $M_{Mi,em}$ the total mass of the pre-emulsioned ith monomer.

At the first stage of the process, the primary particles are produced under batch conditions. This stage ends when the overall conversion reaches the value of 0.9 (Eq. 4). The reactor is then fed optimally and separately with the pre-emulsioned monomers to achieve a glass transition temperature of 3°C(T_{g1}). To improve the control of the three different layers,the polymerization is conducted as close as possible to the starving

conditions (no droplets are produced and the feed rates are equal to the polymerization rates). This is described by Eq. 3. The second stage (first layer) ends when the particle diameter is equal to 60 nm as described by the constraint in Eq. 5.The third and fourth stages (second and third layer) are conducted in a similar way under starving conditions. The objective is to achieve the targeted glass transition temperatures of 10 °C and 17 °C respectively. These stages end when the particle diameter is equal to 70 then 80 nm (Eq. 6-7). The final stage is operating under batch conditions. At this stage, the objective is to achieve a higher overall conversion to consume the residual monomers as described by Eq. 8. In addition, two constraints, inherent to the polymer properties, are imposed on the number and weight molecular weights (Eq. 9-10).

3. Result and discussion

The dynamic optimization problem described by Eq.1-13 is solved using an elitist genetic algorithm developed to solve both multiobjective and single objective optimization problems (Benyahia, 2009). The formulation used for the initial charge and pre-emulsioned monomers feeds are depicted in Table 1. The number of the control variables is 27 (i.e. 9 time periods and 9 feed rates for each monomer).

For the sake of brevity, only the key simulation results are presented in Fig. 2.Additional simulation results, such as residual mass fractions, number and weight average molecular weights,are not presented here.

First, the optimal feed rate profiles are depicted in Fig.2a. It is shown that more styrene than butyl acrylate is required at the beginning of the second stage (i.e. first layer). Indeed, the reactor contains more butyl acetate, at the end of the seeding stage, which presents a lower reactivity compared styrene. As a consequence, butyl acetate is consumed more slowly than styrene leading, at the end the batch stage, to a decreasing T_g profile (Fig.2b).A very good fit is achieved between the resulting and targeted piece-wise constant profiles. This result showed an enhanced control of the T_g profile over our previous optimization problem in which only the first layer is conducted under starting conditions (Benyahia et al., 2012; Paulen et al., 2014). However, due to the slow process induced by imposing this constraint throughout the production of the different layers, the overall time required (t_f) is much larger. The overall conversion profile, depicted in Fig. 2c, gives a good indication on the conversion trajectory, which fits in well with the specified constant profile (X=0.9) inherent to the specified starving condition. In addition, as specified by the constraints (Eq. 8), the process ends when the overall conversion reaches 0.99.

Table 1:Summary of the formulation used.

Species	Initial charge (g)	Feed charge 1 (g)	Feed charge 2 (g)
Butyl acrylate	12	48	0
Styrene	12	0	48
Initiator, $(NH_4)_2S_2O_8$	1.0	0	0
REWOPOL SBFA 50	3	6	6
Water	114	228	228
n-C12 mercaptan (CTA)	0.12	0.24	0.24
Temperature (◦C)	70	25	25

At last, fig.2d shows the dynamic profile of the particle diameter. First and foremost, the final diameter drifts less dramatically from the specified diameter, at the end of the last layer, compared to our previous optimization approaches (Benyahia et al., 2012; Paulen et al., 2014). This advantage is mainly due to the separated monomers feeds as well as to the extension of the starving condition to all polymer layers. In addition, it is proven that the diameter of the particles at the end of each stage, complies perfectly with the specified constraints.

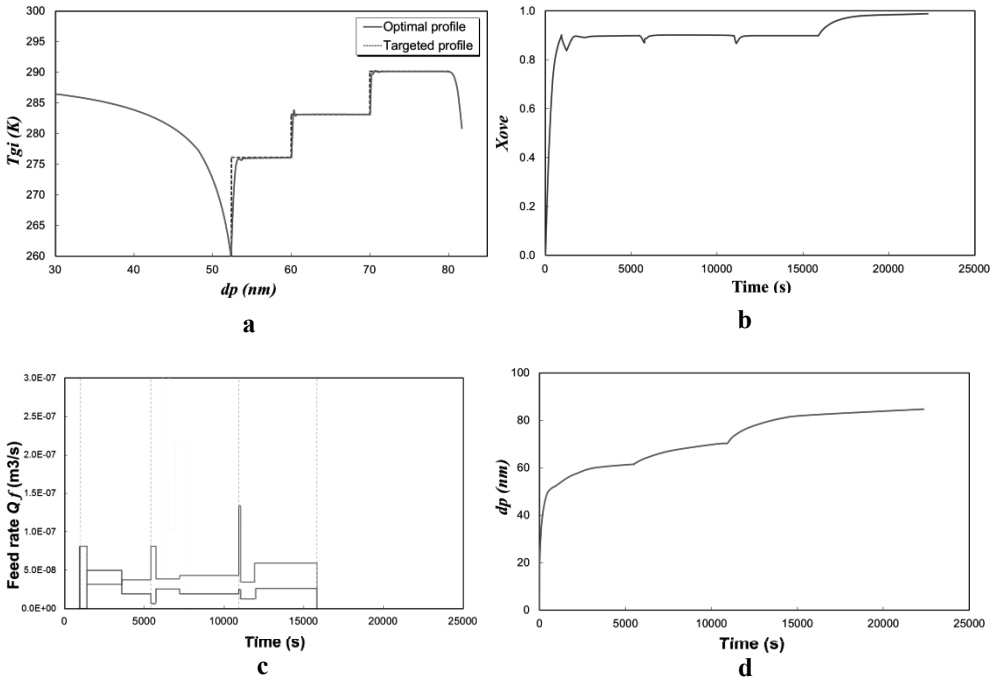

Figure 2: a-feed profile of the best solution, b- instantaneous glass transition temperature profile, c- overall conversion, d- average diameter.

4. Conclusions

A dynamic optimization framework is used to tailor the morphology of multilayer nanoparticles. A piece-wise constant T_g profile is used as a reference trajectory in the optimal tracking problem. To enhance the flexibilityof the optimization procedure, the pre-emulsioned monomers are fed separately. As a result, 27 control variables are used (9 time periods and 9 feed rates for each monomer). In addition, the starving condition is extended to all fed-batch stages. Although the process requires longer time, compared to the previous published approaches, a much better control of the T_g profile, and consequently to the resulting morphology, is achieved. In addition, a better control of the particle size is achieved as the final particle size doesn't drift away significantly. This key result is mainly due the constraint inherent to the starving condition thanks to whichthe final batch stage contains less residual monomers.

Abstract

The purpose of this study is to extend the approach that was introduced by Hillestad (2010) to handle chemical reactor design problem with multiple stages. Specifically, multi-objective optimization method will be used to generate Pareto optimal solutions that characterize the non-inferior solutions set for the problem. Following the identification of path-dependent design variables, several (possibly conflicting) design objectives will be selected and solutions of the corresponding problem will be generated from multi-objective optimization algorithm. This approach is investigated for two industrially important reactor systems: ethylene oxide and phthalic anhydride synthesis. By using reference-point based multi-objective evolutionary algorithm (R-NSGA-II), Pareto-optimal solutions are successfully generated within the region of user-specified reference points, thus facilitating in the selection of final optimal designs. Apart from the extensive selection of optimal candidate reactor designs, this approach also enables further insights to be obtained regarding the optimal arrangement of the path-dependent design variables along the reactor length.

Keywords: systematic staging; chemical reactor design; multi-objective optimization; R-NSGA-II; ethylene oxide; phthalic anhydride.

1. Introduction

Chemical reactors have always been considered as the heart of chemical processes. Improved reactor design and operation will usually translate into significant cost savings and revenue potentials for the chemical plants. Various analytical methods and design strategies have been introduced to handle the complexity nature of these problems. Among such methods are attainable region, phenomena vectors, and superstructure optimization. Recently, Hillestad, (2010) has proposed a chemical reactor design that is based on a systematic staging concept along the reactor path. In this concept, the reactor path is divided into stages where each stage is designed so as to optimize a single objective function. Additional path-dependent design functions can be introduced for this purpose, for example, fluid mixing profile, distribution of extra feed points, coolant temperature profile, catalyst dilution, and many more. In this approach, the design problem is converted into an optimal control problem where the optimal path designs become the additional degree-of-freedom for optimization. This approach has the potential to derive novel reactor design that can improve further the performance of the process.

There are many trade-offs that must be considered carefully when designing a chemical reactor. Among these trade-offs are balancing the reactor size with reactant conversion, balancing reactant conversion with selectivity, or balancing heat transfer area with hot spot temperature. Suitable reactor design parameters must be selected so that these trade-offs can be balanced in an appropriate way. The multi-objective nature of this problem can be handled systematically if multi-objective optimization algorithm is adopted. In this approach, these trade-offs will become the objective functions to be optimized simultaneously while the algorithm will be used to generate non-inferior solutions along the Pareto-optimal front of these objective functions. The application of this approach for reactor design problem has been investigated for several important industrial reactor systems in the past. Some of these examples are styrene reactor system (Yee et al., 2003), steam reformer (Rajesh et al., 2000), and ethylene reactor (Tarafder et al., 2005).

The purpose of this study is to apply multi-objective optimization approach to derive optimal reactor design that employs systematic staging along the reactor path. Two industrial reactor systems are adopted to illustrate this method, i.e. ethylene oxide and phthalic anhydride synthesis. The corresponding reactors resemble a multi-tubular fixed-bed reactor with constant coolant/wall temperature. It will be shown that systematic staging concept that is coupled with multi-objective optimization algorithm will enable derivation of novel reactor design that can improve further the performance of the process in various aspects.

2. Mathematical modelling and optimization formulation

2.1. Plug-flow model

All the reactors in this study are treated as a plug-flow system to simplify the mathematical representation for optimization purpose. As the optimization step that is adopted in this work is a time-consuming process, the choice of this simpler representation will be justified front the point of view of minimizing the complexity of mathematical model solution. If required, the results can be further validated by simulating the reactor system with more complicated mathematical model later. However, the effort is being made also to validate the approach by comparing the obtained solutions with industrial reactor design that is simulated by the same mathematical model that is used for optimization. The following mathematical models are adopted to represent the corresponding reactor systems in this study:

Ethylene oxide synthesis reactor (Peschel et al., 2011):

$$\frac{dn_i}{dz} = L_t A_c \alpha \rho_b \sum_{j=1}^{N_R} \nu_{i,j} r_j \tag{1}$$

$$\frac{dT}{dz} = L_t A_c \frac{-\alpha \rho_b \sum_{j=1}^{N_R} r_j (-\Delta H_j) - \frac{4}{d_i} U (T - T_{cool})}{\sum_{i=1}^{N_I} n_i C_{pi}} \tag{2}$$

$$\frac{dP}{dz} = -L_t \left[150 \frac{\mu u_0 (1-\varepsilon)^2}{d_p^2 \varepsilon^3} + 1.75 \frac{\rho_f u_0^2 (1-\varepsilon)}{d_p \varepsilon^3} \right] 10^{-5} \tag{3}$$

with initial conditions $z = 0 \rightarrow n_i = n_{i0}$, $T = T_0$, and $P = P_0$.

Phthalic anhydride synthesis reactor (Orozco et al., 2010):

$$u_s \frac{dP_a}{dz} + L_t \left(\frac{\rho_b M_m P_t}{\rho_g}\right) r_a = 0 \quad (4)$$

$$u_s \rho_g C_p \frac{dT}{dz} - L_t \left[(-\Delta H)\rho_b r_a + \frac{4U}{d_t}(T - T_w)\right] = 0 \quad (5)$$

with initial conditions $z = 0 \rightarrow P_a = P_{a0}$ and $T = T_0$.

The kinetics expressions for the corresponding reactions are taken from the respective literatures: ethylene oxide synthesis (Al-Saleh et al., 1988) and phthalic anhydride synthesis (Anastasov, 2003).

2.2. Path-dependent design variables

A path is a line along the reactor where the reactions take place (Hillestad, 2010). Along this path, additional design variables can be introduced that act as the forcing function to modify the characteristics of the reaction process taking place. The path-dependent design variables for the respective reactor systems are summarized in Table 1. The corresponding variables are parameterized by piecewise constant profiles. This method divides the reactor path into several stages, N_z where the length and design variable for each stage is optimized.

Table 1. Path-dependent design variables for the respective reactor systems

Reactor system	Path-dependent variables	Number of stages
Ethylene oxide synthesis	Catalyst dilution	2
Phthalic anhydride synthesis	Catalyst types – low productive catalyst (Catalyst I) versus high productive catalysts (Catalyst II and Catalyst III)	3

2.3. Objective functions

The multiple objective criteria that are selected for each reactor designs are summarized in Table 2. These criteria are selected based on the profitability, safety, and cost minimization aspect of the reactor design. It can be seen that these criteria are conflicting with each other, thus requiring necessary trade-off in the final reactor design.

Table 2. Design objectives for the respective reactor systems

Reactor system	Design objectives	Target
Ethylene oxide synthesis	Ethylene oxide productivity	Maximize
	Heat transfer area	Minimize
	Active catalyst mass	Minimize
Phthalic anhydride synthesis	Phthalic anhydride composition	Maximize
	Mass of high productive catalysts	Minimize
	Total reactor volume	Minimize

2.4. Multi-objective optimization formulation

The multi-objective optimization problem for the reactor designs can be represented generally by the following mathematical statement:

$$optimize\left(f_1(x), f_2(x), \ldots, f_n(x)\right) \quad \text{objective functions vector} \quad (6)$$

s.t.

$$g_i(x) \leq 0 \quad i = 1, 2, \ldots, n_i \quad \text{inequality constraints} \quad (7)$$

$$h_i(x) = 0 \quad i = 1, 2, \ldots, n_i \quad \text{equality constraints} \quad (8)$$

$$x_l \leq x \leq x_u \quad \text{decision variables bound} \quad (9)$$

where n is the number of objective functions to be optimized simultaneously, x is the vector of m decision variables (continuous and/or discontinuous) with lower (x_l) and upper (x_u) bounds, n_i and n_e are the number of inequality (g) and equality (h) constraints, respectively. The lists of decision variables and constraints for the respective reactor systems are presented in Table 3.

Apart from the path-dependent design variables, the following reactor design parameters (i.e. tube length, tube diameter, and number of tubes) are also included as additional decision variables for the optimization. Tube diameters and number of tubes are specified by discrete variables so as to follow precisely the allowable range of variation for the corresponding reactor design parameters. The inequality constraint for the minimum exit pressure is also specified to ensure that allowable pressure drop is maintained throughout the reactor length.

Table 3. Decision variables and constraints for the reactor design optimization

Reactor system	Decision variables	Constraints
Ethylene oxide synthesis	α_k, L_k	$0.5 \leq \alpha_k \leq 1$ $\sum_k^{N_z} L_k = L_t$ $T_{max} < 553.15$
Phthalic anhydride synthesis	γ_k, L_k	$\gamma_k \in \{Cat_I, Cat_{II}, Cat_{III}\}$ $\sum_k^{N_z} L_k = L_t$ $T_{max} < 703.15$

2.5. Solution by using R-NSGA-II

As opposed to single-objective optimization that only gives single optimal solution, solutions of multi-objective optimization problems give rise to Pareto-optimal solutions that characterize the non-inferior solutions set for these problems. These solutions have the property such that when one moves from one solution to another in the corresponding set, one objective function improves while the other worsens. In this work, reference- point based multi-objective evolutionary algorithm method (R-NSGA-II) (Deb et al., 2006), a modification of the well-known and popular multi-objective genetic algorithm method (i.e. NSGA-II) is adopted to solve the corresponding reactor design problems. The modification of the original NSGA-II algorithm allows the generation of Pareto-optimal solutions near the region of user-specified reference points, thus facilitating the selection of final optimal solutions. More information regarding the algorithm implementations can be found from their original literatures (Deb et al., 2002; Deb et al., 2006).

3. Results and discussion

Pareto-optimal solutions obtained from R-NSGA-II runs are shown in Fig. 1 for each reactor system considered. The corresponding Pareto solutions are obtained after 200 generations with population size 50, crossover probability 0.7, and mutation rate 0.3. The ε parameter that controls the spread of solutions near the chosen reference points for R-NSGA-II strategy is set at 0.01. The corresponding reference points and the representative industrial reactor designs are also shown in the same figures for comparison purpose. These Pareto solutions offer extensive selections of candidate reactor designs that can be found within the region of user-specified reference points. These solutions also offer insights into the optimal arrangement of the path-dependent

design variables along the reactor length. For ethylene oxide reactor design case, the analysis of the selected Pareto solution clearly indicates that the location of catalyst dilution zone should be near the reactor inlet (see Table 4). The benefits of this configuration are that total heat transfer area can be reduced without increasing the hot spot temperature beyond acceptable limit while at the same time the productivity of ethylene oxide can be further increased. For phthalic anhydride reactor design case, the examination of the selected Pareto solution clearly indicates that the optimum staging of catalyst types can improve further the phthalic anhydride (PA) exit composition if compared with the industrial reactor designs where only one type of catalyst is employed throughout the reactor (see Table 5).

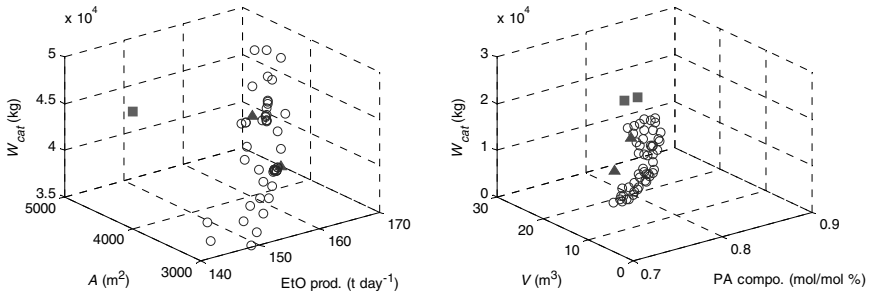

Fig. 1. Pareto optimal solutions for multi-objective optimization of ethylene oxide and phthalic anhydride reactor designs. Pareto solutions (circles), reference points (triangles), and industrial reactors (squares)

Table 4. Comparison of selected Pareto solution with industrial reactor (ethylene oxide reactor design case)

Reactor parameters	Industrial	2-stage configuration
Design parameters:		
Tube length (m)	8	6.19
Tube diameter (mm)	$d_o = 38.1$, $d_i = 31.3$	$d_o = 44.5$, $d_i = 42.7$
Number of tubes	5160	4068
Catalyst per reactor (kg)	42484	41823
Total heat transfer area (m^2)	4941	3519
Path-dependent design variables:		
α_k		$\alpha_1 = 0.5$, $\alpha_2 = 1$
L_k (m)		$L_1 = 1.64$, $L_2 = 4.55$
Operating parameters:		
Ethylene productivity (t d^{-1})	150.87	159.49
Hot spot temperature (K)	555.69	552.97

4. Conclusion

Systematic staging of chemical reactor design via multi-objective optimization approach has been investigated in this study. By demonstrating the application on two industrially important reactor systems (i.e. ethylene oxide and phthalic anhydride synthesis), it can be shown that optimal reactor designs can be obtained that utilized optimally the path-dependent design variables along the reactor length. These results show promising improvement to the reactor design and operation. Moreover, the analysis of the multi-objective optimization results also offers valuable insights into the optimal arrangement of the selected path-dependent design variables that can improve further the

performance of the reaction system. This multi-objective optimization approach is applicable to design other industrial fixed-bed reactors operated under non-isothermal condition.

Table 5. Comparison of selected Pareto solution with industrial reactor (phthalic anhydride reactor design case)

Reactor parameters	Industrial			3-stage configuration
Design parameters:				
Tube length (m)		2.8		2.84
Tube inner diameter (mm)		26		35.5
Number of tubes		10550		5579
Catalyst per reactor (kg)		23525		23486 (Cat. I = 45.2 %, Cat. II = 4.46 %, Cat. III = 50.34 %)
Total heat transfer area (m^2)		2654		1893
Total reactor volume (m^3)		15.68		15.66
Path-dependent design variables:				
γ_k				γ_1 = Cat. III, γ_2 = Cat. I, γ_3 = Cat. II
L_k (m)				$L_1 = 1.43$, $L_2 = 1.28$, $L_3 = 0.13$
Operating parameters:	Cat. I	Cat. II	Cat. III	
PA composition (mol mol^{-1} %)	0.733	0.785	0.771	0.81
Hot spot temperature (K)	727.10	703.19	688.09	701.43

Abstract

This work presents the development of a systematic framework for a simultaneous synthesis and design of process and water networks using the superstructure-based optimization approach. In this framework, a new superstructure combining both networks is developed by attempting to consider all possible options with respect to the topology of the process and water networks, leading to Mixed Integer Non Linear Programming (MINLP) problem. A solution strategy to solve the multi-network problem accounts explicitly the interactions between the networks by selecting suitable technologies in order to transform raw materials into products and produce clean water to be reused in the process at the early stage of design. Since the connection between the process network and the wastewater treatment network is not a straight forward connection, a new converter interval is introduced in order to convert the values of contaminants in the wastewater stream into wastewater characterizations. The systematic approach is used to manage the complexity of the problem by solving simultaneously process synthesis and water synthesis network problems with respect to environment, economics and sustainability. The applicability of the systematic approach is demonstrated using a conceptual case study to test the features of the solution approach under different scenarios depending on the design-synthesis problem.

Keywords: synthesis and design; simultaneous approach; process and water networks; superstructure; decision-making

1. Introduction

Currently, significant efforts are being made to reduce fresh water consumption and wastewater generation in process industries due to the escalation of fresh water and effluent treatment costs and stringent regulations. One of the more efficient ways to reduce fresh water consumption in the process is by reusing wastewater that is generated by the process after being treated in the wastewater treatment plant to acceptable limits. This can done by considering various treatment technologies and exploring numbers of alternatives. In addition, different process technologies and design alternatives are also being considered in the processing network to transform raw materials into products while reducing fresh water consumption and wastewater generation. One of the techniques used to represent the design space and identify best technology network is superstructure-based optimization techniques (Yeomans and Grossmann, 1999; Quaglia et al., 2012).

Process synthesis provides an attractive framework for tackling numerous design problems through a systemic approach either by using a sequential approach or a

simultaneous optimization approach. In a sequential approach, the subsystem, i.e., water network and heat exchanger network are solved or dealt after an optimal flowsheet is identified. As a contrast to the sequential approach, the simultaneous approach has advantages where all interactions and economical trade-offs are taken into account explicitly (Duran and Grossmann, 1986; Yee et al., 1990; Yang and Grossmann, 2013). However, it is important to note that the simultaneous optimization approach can become complex and difficult task since it involves many decision-making at the early stage of design where many alternatives are considered, involving the selection of raw materials, process and wastewater treatment technologies and product portfolio for the process network. Hence, in this contribution, we expand the framework developed by (Quaglia et al., 2012) by integrating the process and wastewater networks. A simultaneous optimization approach mathematically combines the problem of multi-network involving process and wastewater treatment networks into a single step (so called as *a network within a network*). The application of the solution approach is highlighted through a conceptual example.

2. Framework of Integrated Process and Wastewater Networks

The systematic framework for processing networks developed by Quaglia et al. is extended and the superstructure-based optimization approach is used to simultaneously synthesize and design a chemical process and its related water treatment network in order to find an optimal process flowsheet and the wastewater treatment processing path. The framework is supplemented by a software infrastructure based on EXCEL for gathering required input data and GAMS (GAMS Development Corporation, 2013) for the solution of the formulated optimization problem.

Step 1: Problem definition

The first step comprises the definition of the goal and problem scope, the selection of a suitable objective function and the description of optimization scenarios with respect to economics, resource consumption and sustainability. The selection of the objective function is based on the main goal of the synthesis and design problem.

Step 2: Superstructure representation and data collection

In this step, various alternatives for the process and wastewater treatment networks are specified with respect to raw materials, technologies and products which create the search space for the design problem. A combined superstructure is proposed for systematically addressing the simultaneous synthesis of the integrated process and water networks, and exploring the interactions between process network and water network. The superstructure is arranged as a sequence of process steps in order to transform raw materials into products/byproducts/wastewater by considering numerous technologies for each process and wastewater treatment step contained in the networks. The treated wastewater in the treatment tasks can be either discharged into the environment and/or it can be recycled for use in the same processes or in neighboring processes. A new feature of this superstructure is the connection between the process network and the wastewater treatment network through a converter interval. The purpose of this converter interval is to transform the values of contaminants in the wastewater stream into wastewater characterizations. In the superstructure, bypass intervals are considered in the process network and wastewater treatment network in order to allow the possibility of bypassing a certain type of process or treatment step. All data and information essential for the design problem formulation are collected. The data consist

of the parameters required to represent the activity of each process alternative and wastewater treatment alternative including mixing, reaction, waste splitting and product separation. If parameters used in the general process interval are not available, for instance, the complete stoichiometry of the reaction in converter interval, it can be estimated from available information about mass inlet and outlet streams of the interval using Eq. (1).

$$\gamma_{i,kk,rr} = \frac{-(mass_{(i,kk,rr)out} - mass_{(i,kk,rr)in})/MW_i}{(mass_{(react,kk,rr)out} - (mass_{(react,kk,rr)in})/MW_{react}} \quad (1)$$

Step 3: Model development

The next task is the development of generic models describing each of the elements of the superstructure as well as of models required for the calculation of the objective function and other performance indicators. All the necessary equations and constraints relevant to each process and wastewater treatment technology are also formulated in this step prior to be solved as MI(N)LP problems in optimization software i.e. GAMS.

Step 4: Formulate and solve MI(N)LP problem

The models represent the mass input-output model for each process interval in the superstructure, process constraints, structural constraints, effluent limit constraints, performance indicators and cost models together with the objective function are formulated as a MI(N)LP problem and solved in this step. The objective function is indicated based on the main goal of synthesis and design problem as defined previously in Step 1 (e.g. maximize product yield, maximize gross operating income, minimize total annual cost etc.).

2.1 Generic Interval Model

Each process interval in the superstructure is modeled in a generic way, which has been adapted from a previous study on a soybean processing network (Quaglia et al., 2012). The process interval incorporates generic models to represent alternatives in the process and wastewater treatment steps. A process interval combines different process tasks in one block. It can be described by a simple process flowsheet of different arrangements or represented as a series of unit operations depending on the identified process technology, which comprises of flow mixing (Eq. (2)), utility dosage (Eq. (3)), reaction (Eq. (4)), waste separation (Eq. (5)), product separation (Eq. (6)). It is noteworthy that the process task could be inhibited along with the relevant variables and equations if one or more of the process tasks are not available in the specific process interval. The generic interval model is given in Eq. (2-6).

$$ff_{i,kk} = fin_{i,kk} + \alpha_{i,kk} R_{i,kk} \quad (2)$$

$$R_{i,kk} = \sum_{ii} (\mu_{i,ii,kk} \cdot fin_{ii,kk}) \quad (3)$$

$$ffbar_{i,kk} = ff_{i,kk} + \sum_{rr,react} (\gamma_{i,kk,rr} \cdot \theta_{react,kk,rr} \cdot ff_{react,kk}) \quad (4)$$

$$ffdbar_{i,kk} = ffbar_{i,kk} \cdot (1 - SW_{i,kk}) \quad (5)$$

$$Fout1_{i,kk} = ffdbar_{i,kk} \cdot SPr_{i,kk} \quad (6)$$

3. Application Example: Conceptual Case Study

A conceptual case study is considered in order to show the application of the proposed framework. In the process, feed 1 contains of 95% of component A with 5% impurity E (unreactive component) while feed 2 contains of component B and it is desired to produce product C. The main chemical reaction in the process is given by:

$$A + B \rightarrow C + D$$

which is accompanied by the side reaction:

$$2C \rightarrow G + B$$

There are several alternatives to produce product C from reactant A and B. In this process, water is used as raw material and solvent. Threfore, wastewater produced from the process contains contaminants and need to be treated in a wastewater treatment facility. The objective of the conceptual case study is to synthesis and design the process and the wastewater treatment network that minimize the total annualized cost (TAC). In this scenario, effluent discharge and recycle water to be reused in the process as raw material is considered as the final products of the wastewater treatment. The aim of the problem is to determine the optimal processing route and water treatment configuration in order to satisfy product-process specification, environment limitation and water-using process requirement.

3.1 Superstructure representation and data collection

As can be seen in Figure 1, the combined process and water network superstructure are composed of 2 raw materials, 15 process intervals structured in 9 processing steps, 1 converter interval, 11 treatment intervals organized in 4 treatment steps, and 6 possible products and byproducts. Also, 16 components and 10 utilities are considered in this problem. The recycled water stream is included in the superstructure to further reduce fresh water intake. The selection of a wastewater treatment process depends on the characteristics of the wastewater. Since most of the compounds involved in the process plant are organic compounds, thus the wastewater can be characterized in terms of chemical oxygen demand (COD), biological oxygen demand (BOD) and total suspended solids (TSS). A correlation exists between the biodegradable part of the COD and the BOD but the relation between these two is usually determined experimentally and is highly dependent on the type of wastewater considered (Tchobanoglous et al., 2004). The COD values of the wastewater stream are determined by calculating the theoretical oxygen demand based on the oxygen equivalent,which is determined from the chemical formula of the organic matter. In order to simplify the calculations, BOD and TSS are assumed to be 0.6 and 0.1 of the total COD for a typical chemical industry (Smith, 2005). Since the stoichiometry reaction for the converter interval is not available, it can be estimated using Eq. (1)). A pseudo-reaction represents the conversion of the compounds in the wastewater stream generated by the process.

On the other hand, following the systematic data collection procedure, all the necessary data for the process interval models have been collected. An example is provided here

to illustrate a process model for the upflow anaerobic sludge blanket (UASB) treatment interval. The key reactant here is selected and removed with a conversion efficiency of ($\theta_{react,\ kk,\ RR}$) 90%. Although being removed from the system, it consumes nutrient (NH_3), and produces carbon dioxide (CO_2) and methane (CH_4) together with biomass. All the removal, consumption and production are defined related to the key reactant by the reaction stoichiometry given in $\gamma_{i,kk,rr}$ matrix. The required ammonia consumption is calculated to be 445.4 kg/day and this amount is added to the system via $R_{i,kk}$ and totally mixed ($\alpha_{i,kk}=1$) with the incoming flow $Fin_{i,k,kk}$. On the other hand, all of generated sludge and 30% removal efficiency of the rest solids are removed as waste. The gas produced (CO_2 and CH_4) during treatment process are 100% recovered in the secondary outlet stream.

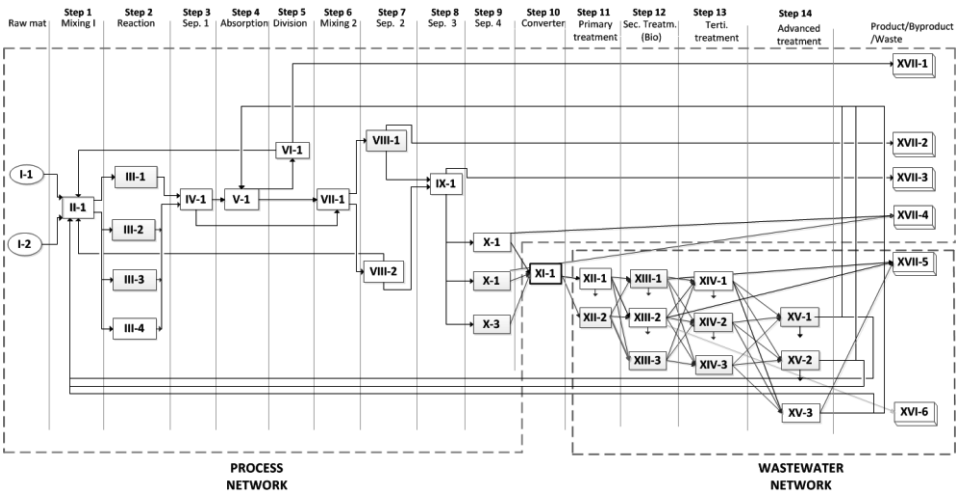

Figure 1: Process and wastewater network superstructure for conceptual case study.

3.2 Results and discussion

The problem is formulated as MINLP and solved using GAMS/BARON to identify the optimal process and water networks. The case study was performed using a standard computer, equipped with 3.60 GHz Intel (R) Xeon (R) E-51620. The superstructure of the combined process and water network features 148,120 continuous variables, 143,493 equations and 20 binary variables. In this scenario, one possible recycled water alternative is considered to reduce fresh water consumption in the process. It should be noted that the effluent discharge of partially treated wastewater to the environment is one of the options. The results in Table 1 present the comparison of optimal process and wastewater treatment path for the problem with and without considering recycled water. It is important to note that by considering recycled water opportunity to be used in the process as raw material resulted in savings of up to 51.1% fresh water consumption. On the other hand, the synthesis problem with recycled water option gives higher TAC since one of tertiary treatment has been selected in order to produce higher quality of treated wastewater to be recycled to the process as a raw material.

Table 1: Comparison of different objective functions for base case scenario. In bold the process intervals which are different from the ones selected for both scenarios

	Optimal Network				Obj. function (Min TAC)
	Raw material	Process steps	Water Treatment steps	Product/Byproducts/Effluent	
Without recycle option	I-1 I-2	II-1 III-4 IV-1 V-1 VI-1 VII-1 VIII-2 IX-1 X-1	XII-1 XIII-2 **XIV-3 (BP)** XV-3 (BP)	XVI-1 XVI-3 XVI-4 XVI-5 XVI-6	M$ 65.2 /y
With recycle option	I-1 I-2	II-1 III-4 IV-1 V-1 VI-1 VII-1 VIII-2 IX-1 X-1	XII-1 XIII-2 **XIV-1** XV-3 (BP)	XVI-1 XVI-3 XVI-4 XVI-5 XVI-6	M$ 73.2 /y

4. Conclusion and Future Work

A systematic approach is used to manage the complexity and solving simultaneously process synthesis and water synthesis network problem with respect to economics, resources consumption and sustainability. In order to achieve this task optimally and efficiently, a new superstructure is proposed and formulated for the simultaneous synthesis of the process and water network. The superstructure-based optimization methodology has been shown to be a useful decision support tool for early stage synthesis and design networks by screening a large number of design alternatives. In addition, the interaction between two networks is visualized via selection appropriate raw materials, technologies and alternatives for process and water treatment as well as products. Future work will focus on the application of the framework on different case studies involving various types of chemical processes and optimization scenarios in order to develop a flexible and versatile methodology.

Optimization of High-Density Polyethylene Process Based on Molecular Weight Distribution and Chemical Composition Distribution under Uncertainty

Jiayuan Kang[a], Xi Chen[a], Zhijiang Shao[a*]

[a] *State Key Laboratory of Industrial Control Technology, Department of Control Science and Engineering, Zhejiang University, Hangzhou, Zhejiang, 310027, *zjshao@iipc.zju.edu.cn*

Abstract

High-density polyethylene (HDPE) is widely used as the main material in the film, pipe, and container industries. Currently, introduction of copolymer into the HDPE polymerization process can significantly improve the performance of the product due to the balance of microstructures. Microstructures of copolymers such as molecular weight distribution (MWD) and chemical composition distribution (CCD) are thus of great importance for evaluating quality of HDPE products. However, due to technical restrictions, current measurement methods bring uncertainty in the determination of polymer microstructures. This paper addresses the optimization of HDPE product with expected MWD and CCD under these uncertainties. The formulation of the optimization problem includes uncertainty metric of target MWD and CCD and productivity optimization of the HDPE process. A decomposition strategy is adopted to evaluate the uncertainty at upper level and optimize the process rigorous model at lower level. Linear Taylor expansion of the target profiles at design point is used to characterize the "worst case" adopting deterministic approach. An industrial HDPE process is discussed and the results show the effectiveness of the approach.

Keywords: copolymerization**,** MWD, CCD, uncertainty formulation, process optimization

1. Introduction

HDPE is one of the most consumed commodity polymers due to the low production cost and versatility in mechanical and rheological properties. Currently, introduction of copolymer into the HDPE polymerization process can significantly improve the performance of the product. The end-use properties such as polydispersity indices (PDI), number average molecular weights (Mn), and comonomer average molar fraction $\overline{F_A}$ are determined by the MWD and CCD profiles. However, rheological based MWD and CCD measurement methods give rise to quite uncertainty to the true profiles. Symmetric deviation of the GPC/SEC trace leads to a broaden MWD, while TREF or CRYSTAF profiles can only provide apparent values of CCD (Soares et al, 2012). These uncertainties give rise to discrepancy of HDPE product determination. This kind of uncertainty can be modelled as a symmetric and bounded random uncertainty set (Ben-Tal and Nemirovski, 2000). The uncertainties in MWD and CCD profiles involve a large number of uncertain parameters that are not suitable to be chosen as design

parameters directly. The MWD and CCD deconvolution approaches determine the best fit of the profile parameters (Alghyamah and Soares, 2009).
In this paper, the MWD and CCD uncertainty metric is proposed. By using linear Taylor expansion at the nominal profile parameters, the maximum effect of target uncertainty is characterized. A sensitivity-based uncertainty decomposition approach is proposed to evaluate the uncertainty of the target profiles in the first step and optimize the operation conditions in the second step. In the present project, an equation-oriented (EO) model is developed for an industrial HDPE process. The problem formulation and solving approach that optimizes the productivity at given MWD and CCD under uncertainty are then presented.

2. Model Development

Figure 1 illustrates the flowsheet of an industrial HDPE slurry process with two CSTRs in series under study. A five-site Ziegler-Natta catalyst with $TiCl_4$ as the primary catalyst and $Al(C_2H_5)_3$ as the co-catalyst is used. 1-Butene is introduced as the comonomer of HDPE product. A complete EO model is established for the process. The modeling work consists of thermodynamics, copolymerization kinetics, MWD and CCD calculation. Thermodynamic properties are surrogated by Kriging method based on streams, which was described in our previous work (Zhang et al, 2013).

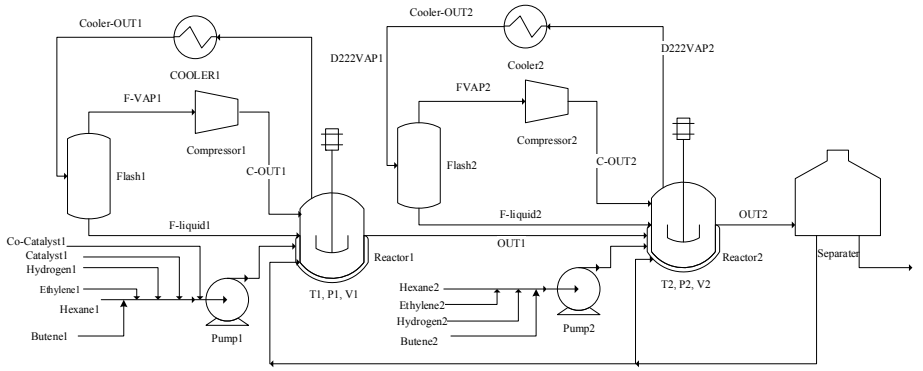

Figure 1. Flow chart of HDPE process

2.1 Copolymerization Kinetics and Moment Model

The copolymerization kinetics consist of catalyst activation, initiation, propagation, transfer to hydrogen, transfer to monomers, transfer to co-catalyst, transfer β-hydride, and deactivation. The terminal model (first-order Markov model) of binary copolymers, involving four propagation rate constants is used for the copolymerization mechanism. Population balances and the method of moments are adopted to describe the mass conservation of the polymer components. Zeroth and first order moment for both living and dead polymers are calculated for MWD and CCD models.

2.2 MWD and CCD Calculation

Instantaneous distribution method can be applied to steady state HDPE reactors (Zhang et al, 2013). The chain length distribution (CLD) made at site *j* is described by Flory distribution with a single parameter τ_j defined by pseudokinetic constants.

$$w_j(n) = n\,\tau_j^2/(1+\tau_j)^2 \tag{1}$$

The comonomer molar fraction distribution, called chemical composition distribution for binary copolymers is given by the Stockmayer bivariate distribution:

$$w_{\gamma j} = 3\tau_j^2\beta_j^2/(2\beta_j\tau_j+\gamma^2)^{5/2}, \quad \beta_j = \overline{F_{Aj}}(1-\overline{F_{Aj}})\sqrt{1-4\overline{F_{Aj}}(1-\overline{F_{Aj}})(1-r_{Aj}r_{Bj})} \tag{2}$$

where γ is the difference between the molar fraction of monomer A in a copolymer chain, F_{Aj}, and the average molar fraction of monomer A in the whole copolymer sample, $\overline{F_{Aj}}$; r_{Aj} and r_{Bj} are the reactivity ratios.

The entire distribution for a single reactor is represented as a weighted superposition of the Flory or Stockmayer distribution from each site type, respectively:

$$w(n)=\sum_{j=1}^{m} mf_j w_j(n) \quad , \quad w_\gamma=\sum_{j=1}^{m} mf_j w_{j\gamma} \tag{3}$$

where mf_j is the mass fraction of copolymer made on site type *j*.

Similarly, the CLD or CCD of the final product is also a weighted superposition of the two instantaneous distributions in each reactor, respectively:

$$w(n)=\frac{m_1 w1(n)+m_2 w2(n)}{m_1+m_2} \quad , \quad w_\gamma=\frac{m_1 w1_\gamma+m_2 w2_\gamma}{m_1+m_2} \tag{4}$$

where m_1 and m_2 are the copolymer masses made in the first and second reactors, respectively, which can be derived from the moment models.

3. Problem Formulation and Uncertainty Decomposition Approach

3.1 Problem Formulation and Uncertainty Metric of MWD and CCD

Generally, the HDPE productivity maximization problem can be formulated as a multi-object optimization problem, which maximizes the productivity and minimizes the quality deviation simultaneously. An alternative formulation is to add the quality tolerance constraint in the productivity maximization problem.

$$\begin{aligned} &\max_u F_{HDPE} \\ &s.t. \quad \left\|MWD_{cal}-MWD_{tar}\right\|\le\varepsilon_1 \quad , \quad \left\|CCD_{cal}-CCD_{tar}\right\|\le\varepsilon_2 \\ &f(z,u)\le 0 \, , \; g(MWD_{cal},z,u)=0 \, , \; h(CCD_{cal},z,u)=0 \end{aligned} \tag{5}$$

where F_{HDPE} is the flow rate of the final HDPE product, MWD_{cal} and CCD_{cal} are the calculated profile from the model, while MWD_{tar} and CCD_{tar} are the target profiles sampled from GPC and TREF data set, u and z are decision and state variables, respectively. The MWD and CCD deviation tolerance are set as ε_1 and ε_2, respectively. Considering the error of the GPC and TREF measurement may be as large as 20%, the tolerance cannot be too small, and is set all by experience.

In this paper, a symmetric and bounded random uncertainty set is used to characterize the potential behaviour of data uncertainty (Ben-Tal and Nemirovski, 2000). Associated with the uncertain target profile, denote a random variable θ, which obeys an unknown but symmetric probability distribution, and takes values in $[-\delta,\delta]$, where δ is the bound of the uncertainty set, i.e. the maximum error of GPC and TREF measurement. The uncertain data model is given by $y_{obs}=y_{nom}(1+\theta)$, where y_{obs} is the observed data set and y_{nom} is the unknown nominal profile. At given upper and lower bounds of the nominal profile y_{nom}, a relaxed deterministic description of the uncertainty set is

$$y_{obs}/(1+\delta)\le y_{nom}\le y_{obs}/(1-\delta) \tag{6}$$

To determine the source of uncertainty in distribution profile y_{nom} derived from y_{obs}, some prior knowledge is needed. The expression of Flory distribution and Stockmayer distribution consists of three parameters under determined as mf_j, τ_j, and β_j. Luckily, we have the prior estimate of mf_{prior}. Under the same catalyst system, the mass fractions

of copolymer made on different site are determined by the configured kinetic constants: $mf_{prior} = k_{pAA}(j) / \sum k_{pAA}(j)$ (Zhang et al, 2014). This estimate will not be affected by the uncertainty. Thus the nominal profile y_{nom} can be modelled as $y_{nom}(\tau_{nom} + \Delta_\tau)$, where τ_{nom} is the MWD or CCD parameter under determined, and Δ_τ is the perturbation caused by uncertainty θ. Hence the data uncertainty model (6) is modified by

$$y_{obs} / (1+\delta) \le y_{nom}(\tau_{nom} + \Delta_\tau) \le y_{obs} / (1-\delta) \tag{7}$$

Considering the inequality constraints, the effect of uncertainty Δ_τ on y_{nom} at the design point can be approximated by linear Taylor expansion as

$$y_{nom}(\tau_{nom} + \Delta_\tau) = y_{nom}(\tau_{nom}) + \sum_j \frac{\partial y_{nom}}{\partial \tau_{nom}} \Delta_{\tau j} + o(\Delta_\tau{}^2) \tag{8}$$

Neglecting high-order terms and substitute $y_{nom}(\tau_{nom} + \Delta_\tau)$ into (7), the nominal design point τ_{nom} will surely fulfill (7) if it fulfills the worst case (Beyer and Sendhoff, 2007):

$$y_{obs} / (1+\delta) \le y_{nom}(\tau_{nom}) - \sum_j \left| \frac{\partial y_{nom}}{\partial \tau_{nom}} \Delta_{\tau j} \right| \;,\; y_{nom}(\tau_{nom}) + \sum_j \left| \frac{\partial y_{nom}}{\partial \tau_{nom}} \Delta_{\tau j} \right| \le y_{obs} / (1-\delta) \tag{9}$$

The uncertainty metric of y_{nom} is given by $\max_{\tau_{nom}} \|\Delta_\tau\|$, which determines the maximum effect of uncertainty on the nominal design point τ_{nom}.

3.2 Sensitivity-based Uncertainty Decomposition Approach

The optimization problem (5) in Section 3.1 is hard to solve. The MWD and CCD constraints contribute to a large scale and ill-conditioned problem. Moreover, since the MWD and CCD calculation and the process model are not strongly coupled, it is reasonable to separate them into two parts. The first step is to estimate the profile parameters as mf_j, τ_j, and β_j, then the operation conditions are optimized. The most common approach is to minimize the scaled deviation of calculated distribution profiles to the target profiles:

$\min_{\tau_j, \beta_j, mf_j} \|(MWD_{cal} - MWD_{tar}) / MWD_{tar}\| + \|(CCD_{cal} - CCD_{tar}) / CCD_{tar}\|$ (Formulation I)

Formulation I provides the best fit of target MWD and CCD profiles. However, without modelling of uncertainty of the target profiles, these parameters are deterministic values, which contribute to tight bounds and solving difficulty for the process optimization in the second step.

The sensitivity based uncertainty decomposition approach evaluates the uncertainty of the target MWD and CCD profiles by solving a series of subproblems.

Step I: Evaluation of uncertainty metric

$\max_{\tau_{nom}} \|\Delta_\tau\|$ (Formulation II)

$$s.t. \quad MWD_{tar} / (1+\delta) \le MWD_{nom}(\tau_{nom}) - \sum_j \left| \frac{\partial MWD_{nom}}{\partial \tau_{nom}} \Delta_{\tau j} \right|$$

$$MWD_{nom}(\tau_{nom}) + \sum_j \left| \frac{\partial MWD_{nom}}{\partial \tau_{nom}} \Delta_{\tau j} \right| \le MWD_{cal} / (1-\delta) \;,\quad -\varepsilon \le mf_{nom} - mf_{prior} \le \varepsilon$$

Formulation II evaluates the uncertainty metric of MWD parameters, and contributes to robust intervals of MWD parameters, i.e. $[\tau_{nom} - |\Delta_\tau|, \tau_{nom} + |\Delta_\tau|]$, for the subsequent steps.

Next the same procedure is done for CCD to evaluate the uncertainty of β_j.

Step II: Process optimization

$\max_u F_{HDPE}$ (Formulation III)

$$s.t. \;\; \tau_{nom} - |\Delta_\tau| \le \tau_{cal} \le \tau_{nom} + |\Delta_\tau| \;,\; \beta_{nom} - |\Delta_\beta| \le \beta_{cal} \le \beta_{nom} + |\Delta_\beta| \;,\; -\varepsilon \le mf_{cal} - mf_{prior} \le \varepsilon$$

$f(z,u) \le 0$, $g_1(\tau_{cal}, z, u) = 0$, $g_2(\beta_{cal}, z, u) = 0$, $g_2(mf_{cal}, z, u) = 0$

Step II optimizes the operation conditions at the robust interval of nominal MWD and CCD parameters.

4. Results and Discussions

A simple case is analyzed to demonstrate the uncertainty metric evaluation procedure first. Considering single site MWD uncertainty metric evaluation, the real nominal parameters of the six experiments are shown in the first column of Table 1. The suffix (a) and (b) represent the uncertainty level of MWD_{tar}, i.e. δ in Formulation II, respectively. Here a=0.1, b=0.2, and corresponding Gaussian noises are imported to simulate the 100 MWD_{tar} values sampled from GPC with 10% and 20% error, respectively. Formulation I and II are adopted to estimate the MWD parameter τ. The estimated value of τ is shown in the second and third column. It should be pointed out that Formulation II provides the estimated nominal values and the uncertainty metric of τ. The sum of square deviations from the estimated MWD_{cal} or MWD_{nom} to the observed target MWD_{tar} is marked as D_{obs}, which is shown in the fourth and fifth column. D_{real} represents the sum of square deviations from the estimated MWD_{cal} or MWD_{nom} to the real MWD profile as shown in the sixth and seventh column.

Table 1. Comparison of Formulation I and II in uncertainty evaluation

Nominal	τ ($\times 10^{-6}$)		D_{obs} ($\times 10^{-6}$)		D_{real} ($\times 10^{-6}$)	
	I	II	I	II	I	II
0.001(a)	997.6	998.6 ± 4.7	6916	6922	37	13
0.002(a)	2003.2	1999.4 ± 8.5	5855	5877	16	0.6
0.003(a)	3004.1	2998.6 ± 14.8	4229	4251	12	1.5
0.001(b)	995.3	995.8 ± 9.2	27666	27668	147	117
0.002(b)	2006.5	1998.8 ± 14.8	23418	23509	66	2.3
0.003(b)	3008.2	2995.1 ± 28.3	16914	17039	48	18

From the fourth and fifth column in Table 1, we can see that D_{obs} calculated by Formulation I are always smaller than that of Formulation II. This can be explained that Formulation I minimizes the deviations from estimated nominal values to the observed values. Note that most of the deviations are contributed by the uncertainties. From the sixth and seventh column of Table 1, we can see that D_{real} calculated by Formulation II are always smaller than that of Formulation I, which means Formulation II can reduce the effect of MWD uncertainty, giving more accurate nominal estimate. Moreover, Formulation II provides the robust interval of the nominal estimate, as well as the MWD uncertainty metric, which is helpful for the subsequent process optimization steps.

The above case illustrates the effectiveness of Formulation II to uncertainty metric and reduction. An industrial HDPE case is analysed adopting the uncertainty decomposition approach proposed in Section 3.2. The uncertainty metric of target MWD and CCD are evaluated first according to Step I. The uncertainty level of MWD_{tar} and CCD_{tar} are set as $\delta_{MWD} = 0.2$ and $\delta_{CCD} = 0.3$ according to the prior information of GPC and TREF error level. Then the process optimization is performed adopting simultaneous approach, using interior point optimizer (IPOPT) as NLP solver. Comparisons of the final bimodal MWDs and CCDs are illustrated in Figure 2 and Figure 3. The unimodal MWDs in Figure 2 are the MWDs generated in each reactor. The MWD and CCD are consistent with the targets while the effect of uncertainty keeps a low level. The maximum scaled uncertainty metric of MWD is 0.0721, which is much larger than that of single site case. This means that multi-site of MWD or CCD under uncertainty contributes to more

uncertainty of design parameters. And the optimal operation conditions are presented in Table 2.

Table 2. Optimal operation conditions

	T(K)	P(atm)	Hydrogen(kmol/h)	Ethylene(kmol/h)	Butene(kmol/h)	Hexane(kmol/h)
Reactor1	358.15	7.93	4.05	125.89	0.30	14.43
Reactor2	345.20	4.18	0.22	128.26	1.87	12.30

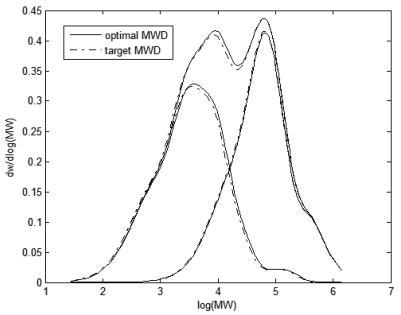

Figure 2 Comparison of MWD profiles

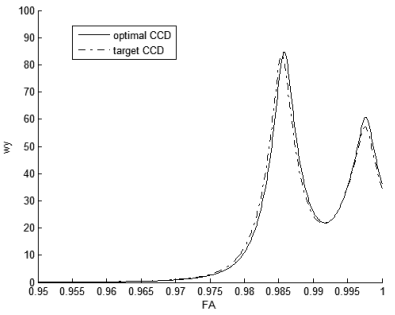

Figure 3 Comparison of CCD profiles

5. Conclusions

This study presents the optimization approach of HDPE process considering uncertainty in target MWD and CCD profiles. The uncertainty metric of MWD and CCD is proposed to evaluate the effect of uncertainty on design parameters. As has been shown, the uncertainty metric provides the nominal estimate and the robust interval of design parameters. On this basis, the proposed sensitivity-based uncertainty decomposition approach evaluates the uncertainty by solving a series of subproblems. The results show that this approach can reduce the uncertainty of MWD and CCD on the product, providing potential applications in product design.

Abstract

The increasing environmental pressures to minimize wastewater discharge from industrial plants to the environment have led to the emergence of policies and regulations that promote Zero-Liquid Discharge (ZLD) solutions. These systems are typically associated with high capital and operating cost and pose a significant economic burden to implementing industries. ZLD solutions are explored as End-of-Pipe treatment options to eliminate liquid discharges. Instead, ZLD options should be explored in the context of overall water integration of industrial facilities to achieve desired reductions in water footprints through efficient reuse together whilst achieving ZLD. In this work, we propose a systematic approach to screen sustainable and low cost strategies that will assist in targeting water integration for Zero Liquid Discharge (ZLD) in industrial parks. The optimization model represents a decision support tool that can help the designer in quickly evaluate potential reuse and recycle scenarios with ZLD. The default objective is to achieve ZLD at minimum total annual cost. A case study of an industrial park with three plants has been solved and analysed in a number of scenarios to illustrate the usefulness of the proposed model.

Keywords: Zero Liquid Discharge, Eco-industrial parks, Water recycle/reuse, Cost minimization.

1. Introduction

Significant quantities of desalinated and surface water are used by the industrial sector for their process operations, municipal needs and other uses. The water usage together with water production in processes results in substantial wastewater discharge requirements. The conventional wastewater disposal options include discharge to the sea, surface water, deep well injection, or evaporation ponds (Mickley, 2006). In view of water scarcity in many parts of the world, there is increasing pressure to reduce water footprints of industrial facilities. This can be achieved through water integration through reuse and recycle (El-Halwagi, 2012). Eliminating waste water altogether and thereby achieving Zero-liquid Discharge (ZLD) for such industrial parks requires the consideration of high recovery treatment, ZLD processing systems and other ZLD options. This work constitutes a first approach to address ZLD options in the course of water integration for industrial parks (Mickley, 2006).

2. Previous Work

Numerous process integration techniques have been proposed to optimize water usage in the process industries. The work on water integration started first for single plant where El-Halwagi and Manousiouthak (1989) have developed a pinch analysis tool for cost effective mass exchange networks with single and multicomponent targets. Wang and Smith (1994) have presented two graphical design methods to identify targets for wastewater minimization for single and multiple contaminant. On the contributions addressing water integration across plants, Olesen and Polley (1996) have applied the water minimization targeting technique given by Wang and Smith with considering geographical constraints. Lovelady and El-Halwagi (2009) proposed a cost optimization formulation for water integration in eco industrial parks. Rubio-Castro et al. (2011) developed a MINLP model that takes into account reuse and recycle across plants for multiple contaminants. Alnouri et al. (2014, 2015) developed a spatially representation that targets shortest connections between sources and sinks in industrial facilities. Bishnu et al. (2014) developed a multi-period planning model for inter plant water integration.

ZLD is described by maximization of the reuse and recycle of water to avoid the strict environment requirements that wastewater discharge might entail. Koppol et al. (2004) presented a model to study the feasibility of achieving ZLD for various industries through enabling water reuse and recycle to minimize liquid discharge. Deng et al. (2008) presented a graphical method to estimate the targets for ZLD for fixed mass loads with single pollutant. Faria and Bagajewicz (2011) presented a planning model that takes into consideration the variation of contaminants load and number of water using units over time with considering ZLD. So far, ZLD systems have not been explored in the context of inter-plant water network synthesis for industrial parks to achieve desired reductions in water footprints through efficient reuse together whilst achieving ZLD.

3. Problem statement

Given is an industrial complex that consists of a set of plants, in which each plant consists of a set of process sources and process sinks (Rubio-Castro et al., 2011). Further information is also given about fresh water source, candidate decentralized treatment options, decentralized ZLD systems and beneficial uses sinks in term of their flow rates, water quality, cost, treatment performances, treatment recovery percentages and constraints as well as distances between all possible options. The goal is to determine the cost optimal network in terms of connections and flowrates to achieve ZLD to sea and to explore ZLD scenarios.

4. Model Formulation

The approach expands an Eco-Industrial Park (EIP) representation for water integration (Rubio-Castro et al., 2011) to include different possible ZLD options. The model has been formulated as a Mixed-Integer Non-Linear Program (MINLP) based on the superstructure presented in Figure 1, to act as a decision making tool to obtain a cost effective water allocation for an industrial complex to achieve ZLD of process water to the environment. The model is formulated to allow streams to be reused internally and externally in each plant, recycled in a shared decentralized treatment and in ZLD

systems, and utilized for a number of options that can constitute ZLD including beneficial usage and/or ZLD processing.

The objective function in this work is to Minimize Total Annual Cost (TAC) which consist of fresh water annual cost, decentralized treatment annual cost, decentralized ZLD system annual cost and piping annual cost.

Source streams from each of the process units and treatment options can segregate and directed to different sinks based on their water flow and quality requirements. The freshwater source stream can split to feed a number of sinks as needed. An if-binary function (zero or 1) has been used to determine the existence of pipe connection between the sources and sinks.

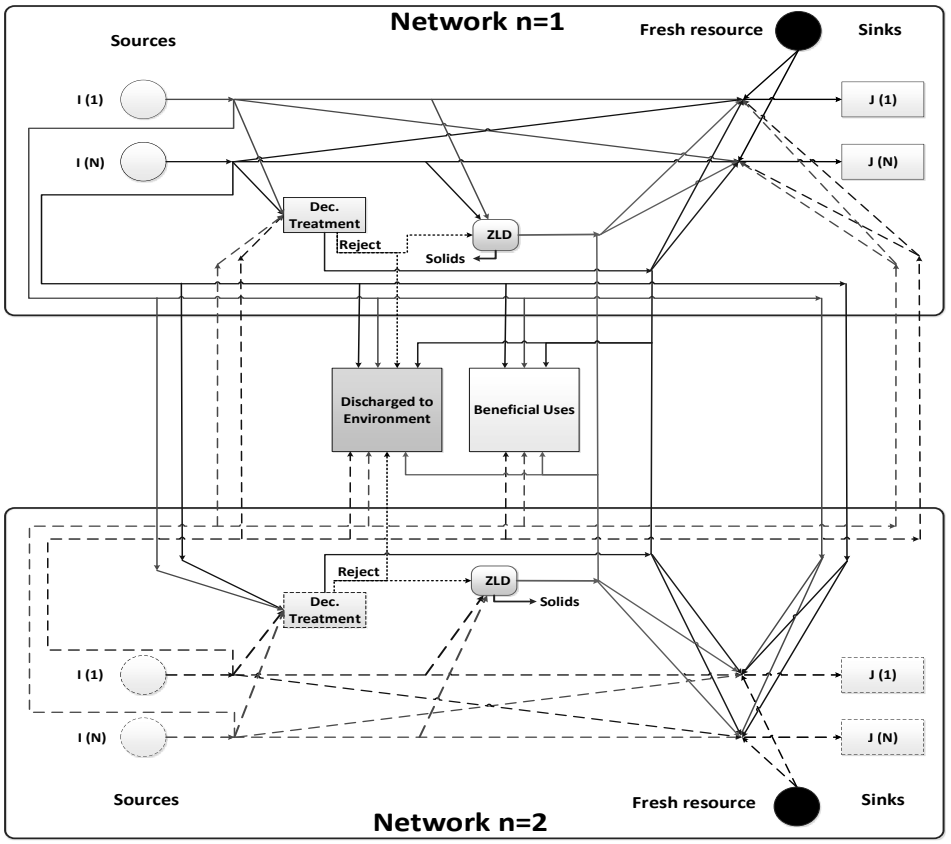

Figure 1: Proposed Superstructure for water integration to target ZLD

5. Case study

An artificial case study presented in Table 1 has been used to illustrate the effectiveness of the proposed model to target ZLD to environment and to explore various scenarios. The case study simulate an industrial complex with three plants, each plant has two process sources and two process sinks as shown in Table 1. Single contaminant has been considered in this work. Table 2 list the costing parameters, recovery percentage

and treatment performances for the decentralized treatment and ZLD systems. It has been assumed that the first decentralized treatment stage already exists in all of the plants and therefore no capital costs were considered. The operating costs have been set to be based on inlet flow size to treatment for the first treatment stage, and based on mass of contaminant removed for second treatment stage. Furthermore, the decentralized ZLD systems which are a combination of brine concentrator followed by crystallizer were considered in this work to treat highly contaminated process streams as well as to treat the treatment rejected concentrated streams. For simplicity, distance between all possible points within the same plant were assumed to be 100 meters and across the plants to be 500 meters. The fresh water cost is (0.13 US$/ton)(Rubio-Castro et al., 2011) and is available at 2 ppm contamination level. Water quality constrains for beneficial usage and wastewater discharge to environment are 100 ppm and 300 ppm respectively. In addition, no cost were considered for the utilization of the surplus quantities of treated water generated from the industrial complex and sent to beneficial usage sinks, as it has been assumed that it is the responsibility of the end user.

Table 1: Industrial complex case study data

	Sources				Sinks		
Plant	Number	Flowrate (ton/h)	Contaminants concentration (ppm)	Plant	Number	Flowrate (ton/h)	Contaminants concentration (ppm)
1	1	50	600	1	1	50	150
	2	70	300		2	70	200
2	3	80	500	2	3	80	40
	4	60	800		4	60	300
3	5	40	400	3	5	40	100
	6	55	1000		6	55	400

Table 2: Treatment and ZLD systems costing parameters

Treatment stages	Recovery (%)	Capital unit cost per flow size (US$/ton/h)	Operating unit cost per flow size (US$/ton)	Operating unit cost for mass of contaminant removed (US$/kg)	Inlet Con. Constraint (ppm)	Outlet Con. (ppm)
Stage 1 (Existing EOPT)	100	0	-	0.25	1000<C<300	200
Stage 2	95	20000	0.1	-	500<C<50	50
ZLD system	95	74500	1.1	-	40000<C<5	5

6. Results and discussion

The case study has been solved in two scenarios in addition to the original case, referenced by scenario zero, which does not involve any sort of water integration. The first scenario considers solving the case study with applying inter-plant water integration, while the second scenario considers applying Inter-plant Water Integration

with ZLD. The optimization model was solved using What'sBest!12.0.1.5 LINDO Global Solver for a 32-bit operating system.

It is clearly shown from the obtained results (Figure 2), that the total annual cost will reduce considerably after applying inter-plant water integration. This is because of the achieved reductions in water footprints through efficient water reuse and water recycle inside and across plants. However, by achieving ZLD to environment (scenario 2), the total annual cost will peak again. This is because of the higher utilization of the decentralized treatment and the involvement of the expensive ZLD systems to treat the wastewater to higher quality standers to be reused in process sinks and beneficial usage sinks rather than discharge to environment at lower water quality.

The consumed quantities of fresh water and the wastewater discharge to environment dropped from 355 (ton/h) to 97 (ton/h) after implementing inter plant water integration. In addition, after achieving ZLD (scenario 2), the 97 (ton/h) discharged to environment was recovered and utilized in process sinks and beneficial usage sinks.

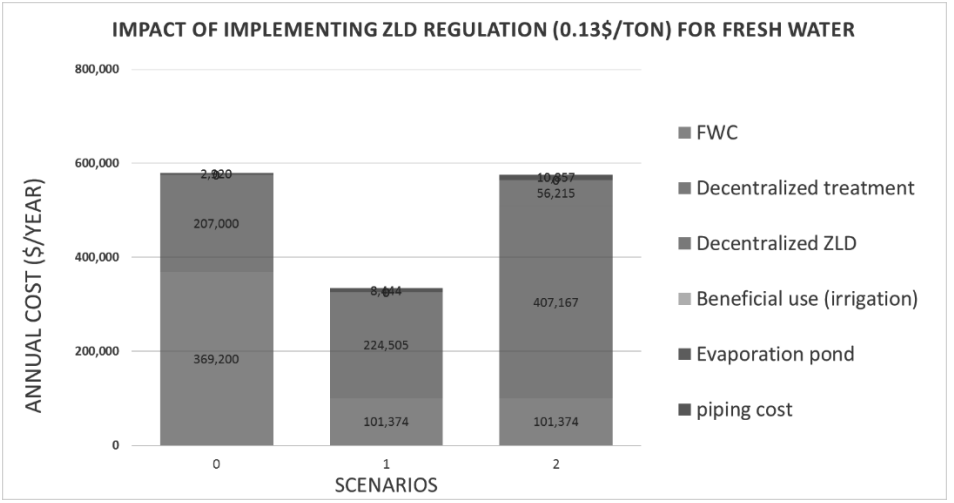

Figure 2:Impact of targeting water integration and ZLD

7. Conclusions

A method for inter-plant water integration to achieve zero liquid discharge has been developed. The developed model will support decision-making with respect to the selection of cost effective networks and flowrates. The main motivation has been to accentuate that ZLD options should be explored in the context of overall water integration to achieve desired reductions in water footprints together whilst achieving ZLD. This has been illustrated in the studied case through utilizing ZLD systems alongside with treatment.

Abstract

In this work an application of decomposition techniques on a propylene production unit from REPLAN refinery by Petrobras S.A. is presented. It is shown that the classic Lagrangian Relaxation (LR) technique and the alternative technique called "Pricing Interprocess Streams Using Slack Auctions" (PISUSA) do not converge for the case study presented. The issues involved in each decomposition approach are identified and discussed; then a modification of the Lagrangean Relaxation algorithm is proposed using a new constraint-updating rule. This modified algorithm is able to overcome the issues and solve the decomposed problem properly.

Keywords: real-time optimization, process optimization, decomposition techniques.

1. Introduction

Chemical process industry has a high demand for methods and tools to perform process optimization in order to enhance profitability. An alternative to increase the profitability of continuous processes is to implement the Real Time Optimization technique (RTO), which the main objective is to drive the plant at each instant of time, as close as possible to the optimal operating conditions (Sequeira et al., 2002). The classic RTO framework includes the following sequential steps: steady state detection, treatment of gross errors, data reconciliation, parameter estimation and economic optimization (White, 1997).

The problem of economic optimization encompasses the whole refinery. In 1995, Naysmith and Douglas presented two possibilities to implement the economical optimization in large refinery problem. The first method considers a centralized structure (a unique model for the whole plant), which is highly complex and then it can be more practical to solve simpler optimizations problems (models for each division) than to optimize the entire refinery considering only one model (Friedman, 1995; Rinaldo and Ungar, 2000). The second approach, distributed structure, decomposes the centralized problem into some less complex smaller optimization problems, which require the use of decomposition technique to specify, adequately, the prices for intermediate streams, allowing each division of the unit to be independently optimized.

For this purpose, two decomposition techniques (LR and PISUSA) are applied and tested in a real refinery problem. The results show that these techniques present a number of difficulties, which inspired the proposition of an alternative approach, allowing the effective decomposition of the case study.

2. Decomposition techniques for process optimization

The main concepts of the two literature decomposition techniques (LR and PISUSA) are given in this section. A detailed explanation of each method can be found in the original works.

2.1. Lagrangean Relaxation decomposition

LR decomposition is based on an iterative algorithm, which relaxes the complicating constraints (intermediary streams, e.g. eq.5 and 6) of the original optimization, generating sub-problems coordinated by a master problem. Lagrange multipliers (λ) are used in the relaxation and represent the shadow price of intermediate products; as a consequence, each division of the plant could be optimized individually, aiming to obtain the best profit for the entire unit (Conejo et al., 2006; Guignard, 2003).

2.2. Pricing Interprocess Stream Using Slack Auctions

In this technique, the complicating constraints are rewritten as resource constraints (inequality constraints) to be used as a criterion for the algorithm convergence. A negative term is added to the maximization economic objective function of each sub-problem, which is composed of a weight parameter (*p*) multiplied by the absolute value of the complicating constraints, enforcing their difference to decrease at each iteration. For economic purposes, *p* represents the price of the intermediate streams that is updated at each iteration (Rinaldo and Ungar, 2000).

3. Case study: propylene production unit

The flowsheet shown in Figure 1 illustrates the main features of the propylene production unit that is composed by three divisions: Depropanizer (D_1), De-ethanizer (D_2) and C3 splitter (D_3). The process is fed by a GLP stream, supposed in our model, to contain 10 components (mainly, propylene 37% and propane 13%). The most relevant conditions of the columns are presented in Table 1.

Table 1. Operating conditions of the propylene operating unit

Column	# of trays	Product Specification		Column Capacity	
		Bottom	Top	Max	Min
T-1	51	< 1% molar light comp.	< 0.1% molar heavy comp.	23,804	17,312
T-2	61	< 120 ppm of ethane	< 35% molar of propylene	10,865	4,939
T-3	197	< 5% molar of propylene	> 95% molar of propylene	10,061	4,573

The entire unit comprises: 3 distillation columns (T-i=1,..,3), 6 valves ($V_{i=1,...,6}$), 4 condensers ($HX_{i=1,...,4}$), 3 reboilers ($RB_{i=1,...,3}$),4 pumps ($B_{i=1,...,4}$), 8 splitters ($SB_{i=1,...3}$; SP_1; $SR_{i=1,...,3}$;SC_1), 2 mixers ($M_{i=1,2}$), 1 reflux tank (TA_1) and 1 compressor (C_1). The propylene production unit was modeled, simulated and optimized using the equation-oriented environment EMSO (Environment for Modeling, Simulation and Optimization, Soares and Secchi, 2003). The model was based on Mendoza et al. (2013), where the same assumptions were done. The optimization problem for this process has the following structure:

$$\max \quad P_1*F_9 + P_2*F_{10} - P*F_1 + P_3*F_{14} + P_4*F_{29} + P_5*F_{26} - OCD\_1 - OCD\_2 - OCD\_3 \quad (1)$$

$$\text{s.t.} \quad \text{Model and operational constraints D\_1} \quad (2)$$

$$\text{Model and operational constraints D\_2} \quad (3)$$

$$\text{Model and operational constraints D\_3} \quad (4)$$

$$5D\_1 = 5D\_2 \quad (5)$$

$$17D\_2 = 17D\_3 \quad (6)$$

where P, P_1, P_2, P_3, P_4 e P_5 are the product market prices of F_1, F_9, F_{10}, F_{14}, F_{29}, e F_{26}, respectively; OCD_1, OCD_2 and OCD_3 are operating costs of each division D_1, D_2 and D_3. Equation (5) and (6) are the so called complicating constraints.

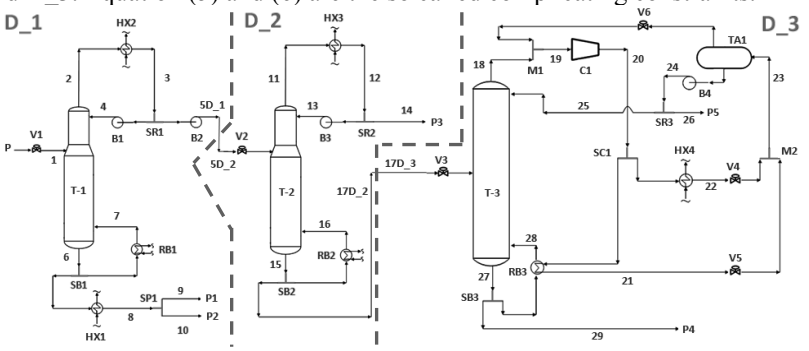

Figure 1. Simplified diagram of the propylene production unit

Solving the centralized structure, the gross operating profit (GOP) was increased by 4% from the operational condition. This new optimum operational point is the target for the decomposition techniques, applied in the next section.

4. Application of LR and PISUSA techniques

Based on Conejo et al. (2006), the resolution algorithm for LR is composed by the follows steps: at step 0, initial guesses for all the λ's are specified, this information is used at step 1, where all the optimization sub-problems are solved independently. At step 2, the λ's are updated using the classic subgradient approach; finally, at step 3 the convergence criterion is checked. Figure 2 shows the λ's obtained at each iteration. The results obtained in this case study demonstrate that there is no λ_1 and λ_2 (shadows prices of streams 5D_1; 5D_2 and 17D_2; 17D_3 respectively) able to converge the algorithm. This is due to two main causes identified by Rinaldo and Ungar (2000):

Issue 1, Indifferent divisions: In this case, there is no linear dependence between the gradients of the complicating constraints and the gradient of objective function, unless the complicating constrains variables are equal to zero (e.g. 5D_1=0 and 5D_2=0) or λ's are zero. For this reason, these results are useless for the decomposition approach, because those assumptions do not have physical or economical mean.

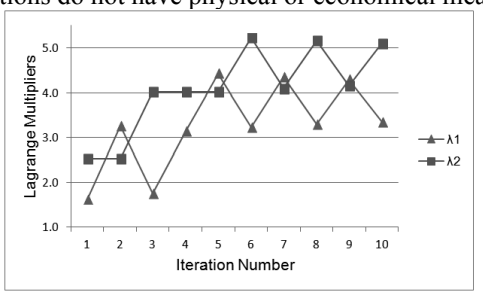

Figure 2. Convergence problem of the LR technique

Issue 2, Divisions with linear objectives: In this case, the divisions D_1, D_2 and D_3 always propose the maximum or the minimum value for the intermediate streams, depending on the value of λ_1 and λ_2. In short, for this algorithm there is no λ's values

that can guarantee the constraints 5D_1 = 5D_2 and 17D_2 = 17D_3 satisfaction (see Figure 3).

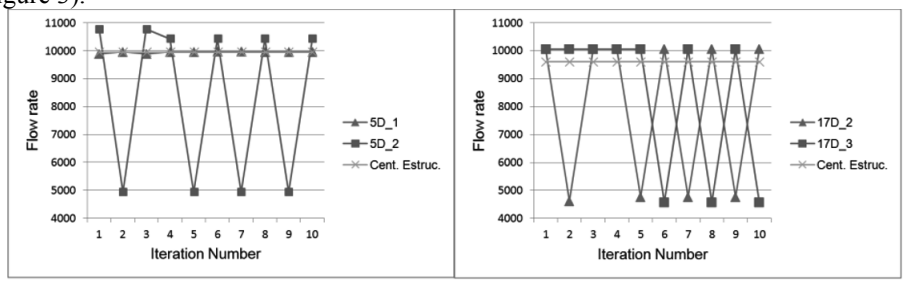

Figure 3. Flow rates of the intermediate streams obtained by centralized and LR approaches

Considering that the feed flow rate (D_1) is fixed at 21,456 kg/h, it can be observed that the intermediate product flow rate (5D_1, ▲ mark) does not swicht between the upper and lower bounds, due to the purity specification of the top product of T_1.

The second technique, based on Rinaldo and Ungar (2000), starts at step 0, in which the initial values of *p* and complicating constrains variables are set. At step 1, the sub-problems are solved independently. Then at step 2, the algorithm convergence is checked. If the convergence is not reached the algorithm continues. At step 3, the reference values for the complicating constraints variables and the price value (*p)* are adjusted in accordance to the previous results and go back to step 1.

The values obtained for the intermediate products (5D_2 and 17D_3) are p_1 = 7 \$/kg and p_2 = 9.7 \$/kg, respectively (an arbitrary scale is assumed for confidentiality reasons). Those prices for the intermediate streams are larger than the market prices of the final products in each division, which are 1.6; 2.4; 2.7; 6.27 and 1.6 \$/kg for the streams F_9, F_{10}, F_{14}, F_{26} and F_{27}, respectively. Also in this case, the algorithm is unable to converge, because the slack term included in the objective function of each sub-problem always tries to maximize the product that has a price defined by the market. Once the intermediate stream has a negative weight, price multiplied by a negative signal in the objective function, the only way this approach can converge is by setting high prices values (*p*). However, when this setting is implemented the price (*p*) loses all its economical meaning, seeing that the intermediate product price is higher than the market price of the final products. Finally, this method is not effective for the studied problem (joint production).

5. Modified Lagrangean Relaxation algorithm (proposed approach)

In this section the classic LR algorithm is modified to overcome the convergence problem observed in the previous section. For this reason, a new variable called availability of intermediate product (AIP) is now considered. The modifications of the classic LR algorithm (see Section 2.1) is introduced as follows: at step 0, initial guesses for all λ's are specified and the AIP variables are initialized as the maximum feed flow rate that can be processed in each division; at step 1, the resource constraints are added to the feed stream of each division, then all sub-problems are solved independently. For example, in our case study, the optimization problem is decomposed in three sub-problems, and the resource constraints are given by $5D\_2^{(v)} \leq AIP_1^{(v)}$ for division D_2 and $17D\_3^{(v)} \leq AIP_2^{(v)}$ for division D_3, where (v) is the iteration number. The resource constraint is not considered in D_1, because the feed stream F_1 is fixed.

D_1	Max $P_1*F_9 + P_2*F_{10} - P*F_1 + \lambda_1*5D\_1 - OCD\_1$	(7)
	s.t. Model and operational constraints D_1	(8)
D_2	Max $P_3*F_{14} - \lambda_1*5D\_2 + \lambda_2*17D\_2 - OCD\_2$	(9)
	s.t. Model and operational constraints D_2	(10)
	$5D\_2^{(v)} \leq AIP_1^{(v)}$	(11)
D_3	Max $P_4*F_{29} + P_5*F_{26} - \lambda_2*17D\_2 - OCD\_3$	(12)
	s.t. Model and operational constraints D_3	(13)
	$17D\_3^{(v)} \leq AIP_2^{(v)}$	(14)

At step 2, Lagrange multipliers are updated by the subgradient method, while the API's variables take the values of intermediary output flow rate from a previous division, resulting from the independent optimization problems. In our case study this is: $AIP_1^{(v+1)} \leftarrow 5D\_1^{(v)}$ and $AIP_2^{(v+1)} \leftarrow 17D\_2^{(v)}$. This ensures that in the next iteration the feed flow rate of each division is physically available. At step 3, the convergence criterion is checked, then, if the difference between the λ's of two consecutive iterations is less than an arbitrary tolerance (ε) the solution was found, otherwise return to step 1.

Figure 4 depicts the results obtained by the new approach. Note that after 9 iterations the algorithm converges, and the shadow prices for the intermediate streams are properly determined. In other words, the shadow prices are coherent to the market price of final products (1.85 $/kg for 5D_1 and 5D_2 streams; 2.8 $ for 17D_2 and 17D_3 streams).

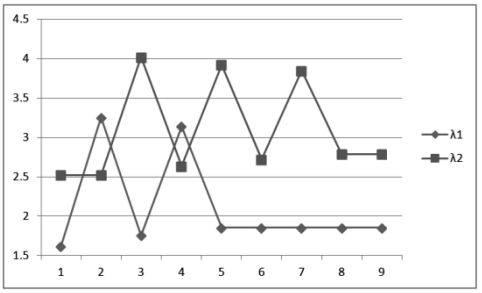

Figure 4. Convergence of the Lagrange multipliers for the proposed algorithm

Figure 5 shows a comparison of the new decomposition algorithm with the centralized approach. It can be observed that the flow rates of the intermediate streams are similar, which means that the proposed algorithm optimizes the whole plant to an operational point close to the centralized approach.

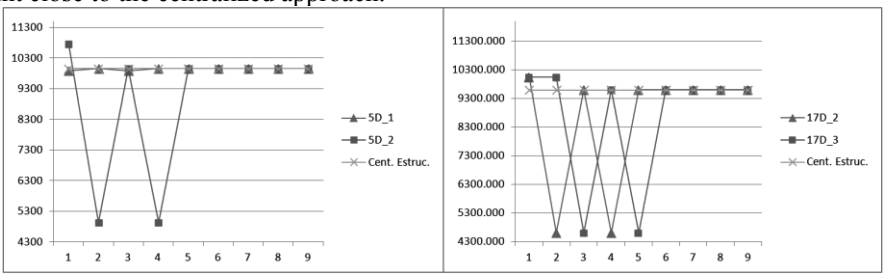

Figure 5. Flow rate values obtained by the proposed algorithm and the centralized approach

Table 2 presents some relevant information about the optimization problems of each approach disscused in the present paper. It can be observed that the distributed approaches reduces the problem complexity, since it decrease the number of variable of

each subproblem. Furthermore, each sub-problem generated by the decomposition thecniques can be optimzated in parallel, using different processors to reduce the total amount of time expended by the whole process optimization (Darby and White, 1988).

Table 2. Relevant information used in each approach

Optimization Structure	Centralized	LR			PISUSA			Proposed approach		
		D_1	D_2	D_3	D_1	D_2	D_3	D_1	D_2	D_3
# Variables	13,640	2,393	2,746	8,510	2,393	2,746	8,510	2,393	2,746	8,510
# Equations	13,634	2,391	2,743	8,507	2,391	2,743	8,507	2,391	2,743	8,507
# Inequalities	22	6	10	10	6	10	10	6	11	11
GOP ($/h)	71,622.92	---			---			71,754.71		

The distributed approch obtained a GOP 0.184% greater than the centrlized approach. This difference is due to non-linearity of the optimization problem studied, which results in different local optimum solutions.

6. Conclusions

In the present paper, the economic optimization problem of large process plants is addressed, with a case study of a propylene unit at REPLAN refinery (Petrobras S.A.). First of all, the whole unit was optimized as a centralized structure. Then, two selected literature decomposition techniques were applied. The results show that these techniques were not able to converge to feasible solutions, due to different issues. Those problems inspired the proposition of a modified LR algorithm, adding a new variable called AIP, the novel algorithm guarantees a feasible solution for the distributed structure of this case study, presenting slight better results than the local optimum obtained by the centralized problem. This proposed approach is promising to be studied and tested in other processes with similar characteristics to be generalized.

Abstract

Real Time Optimization (RTO) uses a model of the process to calculate the optimal operating conditions of the plant. In order to deal with plant-model mismatches, measurement-based adaptation strategies are used. The modifier-adaptation method performs corrections in the cost and constraint functions in the model of the optimization problem to match the necessary optimality conditions for the plant. By doing this, an operating point that satisfies the KKT optimality conditions of the actual process is obtained. This methodology ensures convergence to the (local) optimum of the plant. However, complex processes usually correspond to models with a large number of non-linearities and non-convexities, often leading to multiple local solutions. Typical algorithms that are used to solve these problems cannot guarantee the global optimum; hence, non-convex models are not properly exploited. This paper aims at dealing with this situation by incorporating a global optimization methodology within the modifier-adaption framework. In order to implement this composite structure we used GAMS to handle the global optimization problem and Matlab to handle the modifier-adaptation scheme. The advantage of this new technique is shown through an illustrative case study.

Keywords: Real-Time Optimization, Modifier Adaptation, Global Optimization.

1. Introduction

Process optimization aims at improving the performance of a given plant. Real-time optimization (RTO) is a subject of growing importance in industry and in the academic community (Darby et al., 2011). The main reason for this trend is that the implementation of an RTO system often generates significant returns on investment. In a high-capacity chemical plant, a small percentage improvement may mean significant annual earnings. One of the main challenges in RTO systems arises from the fact that the models are simplified representations of reality and therefore are subject to uncertainty, which is often present in the form of plant-model mismatches and unmeasured disturbances. A classical RTO scheme typically proceeds by a two-step approach, a parameter estimation step followed by an optimization step. With the availability of online data, it is possible to update the model in order to obtain a better prediction of process variables.

In contrast, in the modifier-adaptation approach, measurements are used to adapt the model via first-order correction terms, including correction modifiers for constraint values, as well as for constraints and cost gradients. This requires the use of some experimental data to estimate process gradients. A comparison of different methods for gradient estimation can be found in (Srinivasan et al., 2011). The optimal values of inputs that are obtained by the algorithm are applied directly to the plant. However, the modifier adaptation does not ensure feasibility of the steady state operation upon convergence. In order to handle such situations, the modifier adaptation approach is integrated with a model-based predictive control, where both layers use the same decision variables. Equality constraints and active inequalities are controlled by their optimal values, and the remaining degrees of freedom are controlled in their optimal values over the selected input direction, so new gradient modifiers are defined that correct the projected gradients in the tangent space of the equality constraints as proposed in (Marchetti et al., 2011).

2. Problem statement

A model-based RTO must be able to accurately predict the plant in its current operating point for the entire range of operating conditions. However, models are simplified representations of reality and therefore are subject to uncertainty. If the constraints are not well predicted by the model, the solution may be infeasible or sub-optimal. With the availability of operating data, the process model can be updated to provide a better prediction of the behavior of the plant. Often, a parameter estimation scheme is used to update the parameters of the models. However, it is known that in most of the chemical processes, physicochemical and thermodynamic relations that are part of these models are non-linear and this often leads to non-convex models (Ruiz and Grossmann, 2011). Given the non-linearities and non-convexities of the model, the implementation of a parameter estimation scheme within a RTO framework where this update is done frequently is often prohibitive. With this in mind, to avoid solving a complex optimization problem frequently the modifier-adaptation approach has been proposed.

The main idea behind this method is to use measurements with a simplified plant model and iteratively modify the model so, upon convergence, the necessary (local) optimality conditions of the modified optimization problem match those of the plant. This is possible with the use of modifiers that, at each iteration, adjust the simplified model based on the differences between predicted and measured values of the constraints, and the predicted and measured gradients of the cost function and constraints. In the k^{th} iteration, optimal inputs computed using the modified model is applied to the plant, and the resulting values of the constraints of the plant and the gradients of the cost function and constraints are compared with model predictions. Then the following optimization problem is solved to determine the next u_{k+1}:

$$\begin{aligned} \min_{u} \quad & J_m(u) = J(u) + (\lambda_k^J)^T u \\ s.t. \quad & H_m(u) = H(u) + \varepsilon_k^H + (\lambda_k^H)^T (u - u_k) = H_0 \\ & G_m(u) = G(u) + \varepsilon_k^G + (\lambda_k^G)^T (u - u_k) \le G_0 \\ & u_L \le u \le u_U \end{aligned} \tag{1}$$

where modifier values are calculated as:

$$\varepsilon_k^H = H_p(u_k) - H(u_k) \qquad (\lambda_k^H)^T = \frac{\partial H_p}{\partial u}(u_k) - \frac{\partial H}{\partial u}(u_k)$$
$$\varepsilon_k^G = G_p(u_k) - G(u_k) \qquad (\lambda_k^G)^T = \frac{\partial G_p}{\partial u}(u_k) - \frac{\partial G}{\partial u}(u_k) \qquad (2)$$
$$(\lambda_k^J)^T = \frac{\partial J_p}{\partial u}(u_k) - \frac{\partial J}{\partial u}(u_k)$$

The notation $()_m$ is related to modified model variables, $()_p$ to plant variables and no subscript to model variables; H are the equality constraints with H_0 values, G are the inequality constraints with G_0 upper values, ε are equality and inequality constraint value modifier and λ are equality and inequality constraint gradient modifiers.
It can be proved that the modifier-adaptation method guarantees that the point that is found upon convergence satisfies the KKT conditions (i.e. (local) optimum of the plant), even with structural plant-model mismatches (Chachuat et al., 2009).
However, in the presence of multiple local optima due to non-linearities and non-convexities of the process, the modifier adaptation approach may fail to find the global optimum since the data that is used to estimate plant gradients and plant constraint values belongs to the neighborhood of local solutions. Therefore, when the modified optimization problem is solved, the process will converge to a sub-optimal solution instead of the true optimum. A procedure that overcomes this issue is presented in this work.

3. Proposed technique

In order to avoid falling in local optimal solutions while still taking advantage of the benefits of the modifier-adaptation technique, we propose to add a global optimization layer that will handle the inherent non-convexities of the plant. Note that the proposed model is supposed to be detailed enough to represent most relevant non-convexities. This can be achieved by using a first-principle model.

The general procedure can be summarized as follows:

(1) The method starts by solving a first-principle model to global optimality by means of a non-linear global optimization solver. The solution obtained is defined as u_{MOD}.
(2) At the current steady state, u_{INI}, the process control set-points are set to u_{MOD}, so the process can get closer to the neighborhood were the true optimum lies.
(3) A convex approximation is performed to the detailed model around u_{MOD} to be used by the modifier-adaptation scheme.
(4) At this new process state, the modifier-adaptation approach is activated, so the modified optimization problem is iteratively solved until convergence to the optimal solution (u_{SOL}).

Under the assumption of having a detailed model, it is expected that u_{MOD} is at least in the domain of attraction of the global solution of the process, and therefore the method will converge to the true optimal solution. Considering that the step (1) in the method is computationally expensive, one major question that arises is whether we need to use it at each iteration. As long as no major changes are incurred in the plant, a significant change in the domain of attraction of the optimal solution is not expected. Hence, step (1-3) could be skipped. Having this in mind it is important to detect when the difference between the detailed model and the plant is large enough. We propose to do this by calculating the norm of the differences between predicted and measured outputs and comparing it with a preset threshold. Additionally, the distance between the solution

that was obtained with the modifier-adaptation (u_{SOL}) and model (u_{MOD}) as well as significant changes in bounds of major variables could be taken into consideration. Finding the right threshold in any of these strategies is not trivial and will be the subject of analysis in a future work.

4. Illustrative case study

4.1. Problem description

In this work, a modified version of the plant that is described in (Marchetti et al., 2012) is used as a case study. In this problem we aim at applying the proposed RTO framework to a continuous-time state-space non-linear system which consists of two state variables $x=[x_A\ x_B]^T$, three input variables $u=[u_1\ u_2\ u_3]^T$, and two measured output variables, h and y, where the output y measurement is only available at steady-state intervals. The dynamic non-linear plant equations are the following:

$$\begin{aligned} \dot{x}_A &= (-17x_A + u_3 - 1)/30 \\ \dot{x}_B &= (u_1 - 9)^2 + (u_2 - 11)^2 - x_A x_B \\ h &= (1.3 + x_A)^4 + (1/25)x_A x_B \\ y &= x_A x_B - 204x_A \end{aligned} \tag{3}$$

The steady-state plant equations are:

$$\begin{aligned} x_A &= (u_3 - 1)/17 \\ x_A x_B &= (u_1 - 9)^2 + (u_2 - 11)^2 \\ H_p(u) &= (1.3 + (u_3 - 1)/17)^4 + ((u_1 - 9)^2 + (u_2 - 11)^2)/25 \\ Y_p(u) &= (u_1 - 9)^2 + (u_2 - 11)^2 - 204(u_3 - 1)/17 \end{aligned} \tag{4}$$

The linear discrete state-space model that is used in the MPC problem is obtained by linearizing the system at the steady state operating point u_{LIN} (i.e. $H_p(u_{LIN})=10$). The MPC parameters such as discretization sample time, prediction horizon (p), control horizon is (m), and input bounds are given in Table 1.

The optimization problem for the plant is defined as:

$$\begin{aligned} \min_u \quad & J_p(u) \\ s.t. \quad & H_p(u) = 10 \\ & 1 \le u_1, u_2 \le 10, 1 \le u_3 \le 8 \end{aligned} \tag{5}$$

Where the original objective function Φ_p is modified as follows:

$$\begin{aligned} J_p(u) = \Phi_p(u) &+ 0.098u_1^4 - 1.95u_1^3 + 11.27u_1^2 - 8.42u_1 \\ &+ 5u_2 - 0.9u_3^2 + 11.4u_3 + \frac{u_1 u_2}{4} - \frac{u_2 u_3}{2} \\ \Phi_p(u) &= u_1 + 5u_2 + u_3^2 + Y_p(u) \end{aligned} \tag{6}$$

The plant-model mismatch is stated as the parametric uncertainty in the objective function J with parameters Θ_1 and Θ_2, in the equality constraint H with parameters Θ_3 and Θ_4 and in the lower bound of u_1 with parameter Θ_5. Such parameters are given in Table 2. The steady-state model equations are:

$$\begin{aligned} \min_{u} \quad & J(u) = \Phi_p(u) + +0.098u_1^4 - 1.95u_1^3 + 11.27u_1^2 - 8.42u_1 \\ & +(2\theta_3 - 17)u_2 - 0.9u_3^2 + (2\theta_4 - 17)u_3 + \frac{u_1 u_2}{4} - \frac{u_2 u_3}{2} \\ s.t. \quad & H(u) = \left(1.3 + \frac{(u_3 - \theta_1)}{17}\right)^4 + \frac{(u_1 - \theta_2)^2 + (u_2 - 11)^2}{25} = 10 \\ & \theta_5 \le u_1, u_2 \le 10, 1 \le u_3 \le 8 \end{aligned} \tag{7}$$

4.2. Results

In this illustrative example we aim at showing the benefits of the proposed method by comparing its behavior with a traditional modifier-adaptation approach. The modifier-adaptation step was implemented in the MATLAB environment, while the global optimization step was implemented in GAMS and then linked together by a MATLAB-GAMS interface. In Figure 1 (left) we show the case in which the system starts at a point P_{01}, which lies in the domain of attraction of the plant global optimum. As it is expected both algorithms converge to the plant global optimum P_{G1} from the initial point P_{01}. Note that the proposed technique achieves this after a first iteration to the global optimum of the detailed model M_{G1}. In Figure 1 (right) we show the case in which a modification on the lower bound of u_1 occurs (Θ_5 = 3) moving the domain of attraction of the plant global optimum. If we apply the traditional modifier-adaptation technique the algorithm will converge to the point P_{L2} from the initial point P_{02}, which is a local solution of the process. If, on the other hand, we apply the proposed technique, an iteration to the new global solution of the model M_{G2} is first performed. Then, within the convergence zone, the modifier-adaptation leads the process to a neighborhood of P_{G2}, which is the true global optimum. The initial points (P_{0k}), the model local and global solutions (M_{Lk}, M_{Gk}) and the plant local and global solutions (P_{Lk}, P_{Gk}), where k=1,2 as well as the cost function values are given in Table 3.

5. Conclusions

An RTO technique to deal with the presence of multiple local optima has been presented and applied in an illustrative case study. We showed that a modifier-adaptation technique may fail to find the global optimum if the initial point is not within its neighborhood. This is the case because the information that is used by the modifier-adaptation technique to build the optimization problem that is solved at each iteration is only local. With this in mind we proposed a framework that adds an upper layer to the traditional modifier-adaptation approach that brings the process near a neighborhood of the true optimum of the plant. We showed how this upper layer is very important to avoid local sub-optimal solutions. Hence, leading the process to the true global optimum.

Abstract

Model-based optimal design of experiments (M-bODE) is a crucial step in model parametrization since it encloses a framework that maximizes the amount of information extracted from a battery of lab experiments. We address the design of M-bODE for dynamic models considering a continuous representation of the design. We use Semidefinite Programming (SDP) to derive robust minmax formulations for nonlinear models, and extend the formulations to other criteria. The approaches are demonstrated for a CSTR where a two-step reaction occurs.

Keywords: Design of experiments, Model parametrization, Semidefinite Programming, Robust design

1. Introduction

M-bODE is a classic problem with substantial interest nowadays, particularly in pharmacokinetics, pharmacodynamics, drugs trials design, and on general model parametrization, a challenge shared by various disciplines such as Chem. Eng. (Goos and Jones, 2011). Kiefer (1959) proposed to relax the original combinatorial experiment design problem to obtain a tractable convex optimization representation. This alternative is designated as *the approximate optimal design problem*, and consists in determining a probability measure over the design space (rather than the exact number of trials for each point of the design space). Many authors have proposed algorithms to compute optimal designs in a systematic way, starting with the exchange-based method of Wynn (1972) for local designs (see also Chaloner and Larntz (1989) for Bayesian optimal designs). Within the same framework Duarte and Wong (2014b) proposed a systematic algorithm for finding minmax optimal designs employing a reformulation to convert the original problem into a semi-infinite program. The criterion to maximize is a concave operator of the Fisher Information Matrix (FIM), which in turn is linear with respect to the design measure. Convex analysis can thus be used to establish the optimality conditions of a design, also known as *equivalence theorems*, see Pukelsheim (1993). This theoretical framework enabled to derive convex programming formulations for the M-bODE problem, although the regressor domain needs to be discretized (see Atkinson et al. (2007, Chap. 12) for discretized designs). Exploiting this route, among others Vandenberghe and Boyd (1999) proposed SDP formulations for $D-$, $A-$, and $E-$optimal designs for linear models, Sagnol (2011) derived Second Order Conic Programming formulations, and recently Duarte and Wong (2014a) extended the SDP formulations to nonlinear models employing the Bayesian paradigm. Here we derive SDP formulations for robust minmax optimal designs for nonlinear models in the spirit of

Wong (1992) employing discretization techniques to convert the original semi-infinite program into a convex optimization problem.

2. Mathematical formulation

2.1. Preliminaries

We consider dynamic models represented by Differential-Algebraic Equations of the following form, the regressor being $t \in T \equiv [0, t^{\max}]$

$$\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = f(\mathbf{x}, \boldsymbol{\theta}), \quad \mathbf{x}(0) = \mathbf{x}_0 \tag{1a}$$

$$\mathbf{y} = g(\mathbf{x}), \tag{1b}$$

where f and g are continuously differentiable functions, the process states are $\mathbf{x}(t) \in \mathbb{X} \subset \mathbb{R}^{\mathrm{m}}$, measurements at time t are $\mathbf{y}(t) \in \mathbb{Y} \subset \mathbb{R}^{\mathrm{n}}$, and $\boldsymbol{\theta} \in \Theta \subset \mathbb{R}^{\mathrm{p}}$ is an unknown parameter. The domain Θ is a cartesian box $\times_{j=1}^{\mathrm{p}} [\theta_j^{\mathrm{LO}}, \theta_j^{\mathrm{UP}}]$. For the sake of simplicity we consider $\mathrm{n} = 1$, so measurements are scalar, but it is straightforward to extend our approach to larger values of n. The goal of the M-bODE problem is to find a *design* –i.e., a selection of measurements– that enables to estimate $\boldsymbol{\theta}$ with the best possible accuracy.

The time domain is discretized into s points, denoted by $\mathbb{T} = \{t_1, \ldots, t_s\}$, and $[s] = \{1, \cdots, s\}$. A design ξ with support points in $\mathbb{T}$ can be represented using the notation $\xi = \begin{pmatrix} t_1 & \cdots & t_s \\ w_1 & \cdots & w_s \end{pmatrix}$, where $\mathbf{w} \in [0,1]^s$ is a vector of weights satisfying $\sum_{i=1}^{s} w_i = 1$, and w_i represents the fraction of the total number of measurements N to perform at time t_i. The quantity Nw_i should be constrained to take integer values for all i, but this constraint is dropped for approximate designs, and in practical applications of M-bODE we may require to round the optimal approximate design. The set of all design measures supported by $\mathbb{T}$ is denoted by Ξ.

The FIM of a single "observational unit" t_i at $\boldsymbol{\theta} = \boldsymbol{\theta}_0$ is $M(t_i, \boldsymbol{\theta}_0) = \boldsymbol{\eta}(t_i, \boldsymbol{\theta}_0)\boldsymbol{\eta}(t_i, \boldsymbol{\theta}_0)^{\mathrm{T}}$, where $\boldsymbol{\eta}(t_i, \boldsymbol{\theta}_0) = \left.\frac{\partial g(\mathbf{x}(t_i, \boldsymbol{\theta}))}{\partial \boldsymbol{\theta}}\right|_{\boldsymbol{\theta}=\boldsymbol{\theta}_0}$ is the sensitivity of the measurement at t_i with respect to $\boldsymbol{\theta}$. The FIM of an approximate design ξ is obtained by summing the FIM over the individual design points

$$\mathscr{M}(\xi, \boldsymbol{\theta}_0) = \int_T M(t_i, \boldsymbol{\theta}_0)\, \mathrm{d}(\xi) = \sum_{i \in [s]} w_i M(t_i, \boldsymbol{\theta}_0) \succeq 0, \tag{2}$$

where $A \succeq 0$ means that A belongs to the space of symmetric positive semidefinite matrices $\mathbf{S}_+^{\mathrm{p}}$. Note that for $\boldsymbol{\theta}_0 \in \Theta$, $\mathscr{M}(\xi, \boldsymbol{\theta}_0)$ depends only on the weights w_i of the design, and so we also denote it by $\mathscr{M}(\boldsymbol{w}, \boldsymbol{\theta}_0)$. The quality of a design is measured by a criterion Φ, such as the $D-$optimality, $\Phi_D(M) = (\det\, M)^{1/p}$, $A-$optimality, $\Phi_A(M) = (\mathrm{trace}\ M^{-1})^{-1}$, or $E-$optimality, $\Phi_E(M) = \lambda_{\min}(M)$. We refer to Pukelsheim (1993) for more details on optimality criteria.

The representation of $\mathscr{M}(\xi, \boldsymbol{\theta})$ for nonlinear models depends on the unknown parameters that we wish to estimate, which is a challenging cyclic problem. In practice there are three approaches to handle it: *i.* sequential designs which rely on a sequence of local designs, computed at the current best estimate $\hat{\boldsymbol{\theta}}$ of $\boldsymbol{\theta}$; *ii.* Bayesian designs which are derived to optimize the expectation over Θ of an optimality criterion assuming that a prior distribution for parameters is available; *iii.* minimax designs which are derived so that we maximize the design efficiency for the worst combination of parameters in Θ. Such a framework is used in this paper, that is, we want to find a design ξ solving the following saddle point optimization problem:

$$\max_{\xi \in \Xi} \min_{\boldsymbol{\theta} \in \Theta} \Phi(\mathscr{M}(\xi, \boldsymbol{\theta})). \tag{3}$$

2.2. Construction of the FIM

The sensitivity of the measurements with respect to $\boldsymbol{\theta}$ at $\boldsymbol{\theta}_0$ is determined by solving the sensitivity equations (4) simultaneously with Model (1) employing a DAE solver. The sensitivity of state x_i with respect to parameter θ_j is denoted by $\sigma_{i,j}$, yielding:

$$\frac{\mathrm{d}\sigma_{i,j}}{\mathrm{d}t} = \sum_{k=1}^{\mathrm{m}} \frac{\partial f_i(\mathbf{x},\boldsymbol{\theta}_0)}{\partial x_k}\,\sigma_{k,j} + \frac{\partial f_i(\mathbf{x},\boldsymbol{\theta}_0)}{\partial \theta_j}, \qquad i\in[m],\ j\in[p], \tag{4a}$$

$$\boldsymbol{\eta}(t_i,\boldsymbol{\theta}_0) = \sum_{k=1}^{\mathrm{m}} \frac{\partial g(\mathbf{x})}{\partial x_k}\,\sigma_{k,j}(t,\boldsymbol{\theta}_0), \qquad j\in[p]. \tag{4b}$$

2.3. Robust minmax SDP formulation

We recall that a concave function $f:\mathbb{R}^{n_1}\to\mathbb{R}$ is called semidefinite representable (SDr) if and only if inequalities of the form $u\le f(\boldsymbol{x})$ are equivalent to a linear matrix inequality (LMI). More precisely, f is SDr if and only if there exists some symmetric matrices $M_0,\ldots,M_{n_1+n_2}$ such that

$$u\le f(\boldsymbol{x}) \Longleftrightarrow \exists \boldsymbol{y}\in\mathbb{R}^{n_2}:\ uM_0+\sum_{i=1}^{n_1} x_iM_i+\sum_{j=1}^{n_2} y_jM_{n_1+j}\succeq 0.$$

The criterions of $A-$, $E-$, and $D-$optimality are known to be SDr (Ben-Tal and Nemirovskiĭ, 2001, Chap. 2-3), which gave rise to SDP formulations for the computation of local optimal designs (Boyd and Vandenberghe, 2004, Sec. 7.3). We also point out that Kiefer's Φ_p-criterion is SDr for all rational values of $p\in(-\infty,1]$ (Sagnol, 2013). Due to space limitations, we give a semidefinite representation for the $D-$criterion only. The inequality $\tau\le(\det[\mathscr{M}(\xi,\boldsymbol{\theta})])^{1/\mathrm{p}}$ holds if and only if there exists a $p\times p-$lower triangular matrix $\mathscr{C}$ such that

$$\begin{bmatrix}\mathscr{M}(\xi,\theta) & \mathscr{C}^{\mathrm{T}}\\ \mathscr{C} & \mathrm{Diag}(\mathscr{C})\end{bmatrix}\succeq 0 \quad\text{and}\quad \tau\le\left(\prod_{j=1}^{\mathrm{p}}\mathscr{C}_{j,j}\right)^{1/\mathrm{p}},$$

where $\mathrm{Diag}(\mathscr{C})$ is the diagonal matrix with same diagonal entries as those of $\mathscr{C}$. The inequality involving the geometric mean of the $\mathscr{C}_{j,j}$ can, in turn, be expressed by a series of 2×2 LMIs, see Ben-Tal and Nemirovskiĭ (2001). It is also straightforward to show that when the concave functions $f_1,\ldots,f_q$ are SDr, then their pointwise minimum $f:\boldsymbol{x}\mapsto\min(f_1(\boldsymbol{x}),\ldots,f_q(\boldsymbol{x}))$ is also concave and SDr. There exists user-friendly interfaces, such as `cvx` (Grant et al., 2012) or PICOS (Sagnol, 2012), which automatically transforms constraints of the form $\tau\le\Phi[\mathscr{M}(\xi,\boldsymbol{\theta})]$ as a series of LMIs, and pass them to SDP solvers such as SeDuMi (Sturm, 1999) or Mosek (Andersen et al., 2009).

In this paper, we consider a sampling mechanism $\mathscr{S}(q)$ that extracts a finite number q of values in Θ, denoted by $\boldsymbol{\theta}_j\in\Theta,\ j\in[q]:=\{1,\ldots,q\}$ and we define $\mathbb{P}:=\{\boldsymbol{\theta}_1,\ldots,\boldsymbol{\theta}_q\}$. Then, we replace $\min_{\boldsymbol{\theta}\in\Theta}\ \Phi[\mathscr{M}(\xi,\boldsymbol{\theta})]$ by a minimum of finitely many terms, $\min_{j\in[q]}\ \Phi[\mathscr{M}(\xi,\boldsymbol{\theta}_j)]$. As a result, we obtain a SDP formulation that approximates the minmax optimal design problem (3):

$$\max_{\xi\in\Xi}\ \min_{\boldsymbol{\theta}\in\mathbb{P}}\ \Phi[\mathscr{M}(\xi,\boldsymbol{\theta})] = \max_{\tau\in\mathbb{R},\boldsymbol{w}\in\mathbb{R}^s}\ \tau \tag{5a}$$

$$s.t. \qquad \forall j\in[q],\quad \tau\le\Phi[\mathscr{M}(\boldsymbol{w},\boldsymbol{\theta}_j)] \tag{5b}$$

$$\forall i\in[s],\quad w_i\ge 0 \tag{5c}$$

$$\sum_{i=1}^{s} w_i = 1, \tag{5d}$$

where –as mentioned above– the constraints (5b) can be rewritten as LMIs if Φ is SDr; however we used this compact formulation for the sake of generality, and because constraints (5b) are accepted *as is* by high-level interfaces.

2.4. Algorithm

To prevent sub-optimal solutions for problem (3), which can be due to the insufficient variability of the sample of parameter combinations $\mathbb{P}$, we use an iterative procedure. Let $\tau^*, \boldsymbol{w}^*$ be a solution returned after solving Problem (5). Then, it is clear that the design associated with the weights $\boldsymbol{w}^*$ solves Problem (3) if and only if τ^* is equal to the optimal value of

$$\min_{\boldsymbol{\theta}\in\Theta} \Phi[\mathscr{M}(\boldsymbol{w}^*, \boldsymbol{\theta})]. \tag{6}$$

This justifies the following procedure: at each iteration, we seek a parameter combination $\boldsymbol{\theta}^*$ that solves Problem (6). The procedure stops if $\tau^* \leq \Phi[\mathscr{M}(\boldsymbol{w}^*, \boldsymbol{\theta}^*)] + \varepsilon_r$, where ε_r is a small tolerance parameter. Otherwise, $\boldsymbol{\theta}^*$ is added in the sample $\mathbb{P}$ and we go to the next iteration. After the convergence is achieved a pruning step deletes support points with $w_i < \varepsilon^p$. This procedure is summarized in Algorithm 1.

In practice, the nonlinear optimization problem (6) might be hard to solve. However, since Θ is usually a cathesian box of relatively small dimension, the optimum can be found by using local optimization procedures and multiple restarts. Of course, it is also possible to add several local optima of (6) in the sample $\mathbb{P}$. However, note that (approximate-)optimality of a design can only be assessed when the $\boldsymbol{\theta}^*$ used in the algorithm is a global optimum of (6), which would theoretically require the use of a global NLP solver.

Algorithm 1 Algorithm to find a robust minmax design with support on $\mathbb{T}$

procedure FINDDESIGN($\mathbb{T}, \Theta, \mathscr{S}, q, \varepsilon^r, \varepsilon^p$)
  Discretize T ▷ Find the grid $\mathbb{T}$
  Generate the initial sample $\mathbb{P} = \mathscr{S}(q)$ ▷ Sample Θ
  $\ell^* \leftarrow -\infty, \tau^* \leftarrow +\infty$
  while $\tau^* > \ell^* + \varepsilon_r$ **do**
    Compute $\boldsymbol{\eta}(t_i, \theta_{\mathbf{j}})$ and $M(t_i, \theta_{\mathbf{j}})$ for all $(i, j) \in [s] \times [q]$ ▷ Single point FIMs
    Get a solution $(\tau^*, \boldsymbol{w}^*)$ of the SDP (5) ▷ Get upper bound τ^*
    Get a solution $\boldsymbol{\theta}^*$ of Problem (6), $\ell^* \leftarrow \Phi[\mathscr{M}(\boldsymbol{w}^*, \boldsymbol{\theta}^*)]$ ▷ Get lower bound ℓ^*
    $\ell^* \leftarrow \Phi[\mathscr{M}(\boldsymbol{w}^*, \boldsymbol{\theta}^*)]$, $\mathbb{P} \leftarrow \mathbb{P} \cup \{\boldsymbol{\theta}^*\}$, $q \leftarrow q + 1$ ▷ Update the sample
  end while
  Prune ξ
end procedure

2.5. Extension to find the optimal support points over T

When the criterion Φ is differentiable, it is known that a design ξ is minmax optimal if and only if there exists a probability measure γ supported by $V_\Theta(\xi) := \arg\min_{\boldsymbol{\theta}\in\Theta} \Phi[\mathscr{M}(\xi, \boldsymbol{\theta})]$ such that

$$\forall t \in T, \quad h_\gamma(t) := \int_{\boldsymbol{\theta}\in V_\Theta(\xi)} \psi(\xi, \boldsymbol{\theta}, t)\, \gamma(\mathrm{d}\boldsymbol{\theta}) \leq 0, \tag{7}$$

with equality attained only at support points of ξ, where $\psi(\xi, \boldsymbol{\theta}, t)$ denotes the directional derivative of Φ at $\mathscr{M}(\xi, \boldsymbol{\theta})$ in the direction of $(M(t, \boldsymbol{\theta}) - \mathscr{M}(\xi, \boldsymbol{\theta}))$, see e.g. Fedorov and Leonov (2013, Theorem 2.5). Let ξ be a solution of Problem (5) and assume without loss of generality that $V_\mathbb{P}(\xi) = \{\boldsymbol{\theta}_1, \ldots, \boldsymbol{\theta}_k\}$. By construction, ξ is minmax optimal over the discretized sets $\mathbb{T}$ and $\mathbb{P}$, so there must exist a discrete probability measure $\boldsymbol{\gamma}$ such that Equation (7) holds if we replace T by $\mathbb{T}$ and Θ by $\mathbb{P}$. This measure can be found easily by solving the following linear program (LP):

$$\min_{\boldsymbol{\gamma}\in\mathbb{R}^k_+,\, U\geq 0} \; U \qquad \text{s.t.} \qquad \sum_{j=1}^{k} \gamma_j = 1, \qquad \forall i \in [s],\; h_{\boldsymbol{\gamma}}(t_i) := \sum_{j=1}^{k} \gamma_j\, \psi(\xi, \boldsymbol{\theta}_j, t_i) \leq U.$$

Table 1: Robust minmax designs obtained for $T=[0,20]$, $\mathbb{T}=\{0,0.2,\ldots,20\}$, and $\Theta\equiv[0.5,1.0]\times[0.1,0.5]\times[1.0,2.0]\times[1.0,2.0]$. Designs are given using the notation $\xi=\left(\begin{smallmatrix} t_1 & \cdots & t_s \\ w_1 & \cdots & w_s \end{smallmatrix}\right)$.

support	criterion	Optimal design	CPU (s)	iterations
fixed	Φ_D	$\left(\begin{smallmatrix} 0.4 & 1.6 & 1.8 & 4.4 & 4.6 & 10.8 & 11 \\ 0.2493 & 0.1517 & 0.0994 & 0.1436 & 0.1057 & 0.0330 & 0.2158 \end{smallmatrix}\right)$	11.0	1
support over $\mathbb{T}$	Φ_A	$\left(\begin{smallmatrix} 0.2 & 1.6 & 4.6 & 10.8 & 20 \\ 0.3881 & 0.2266 & 0.1595 & 0.1392 & 0.0862 \end{smallmatrix}\right)$	7.94	1
	Φ_E	$\left(\begin{smallmatrix} 0.2 & 1.6 & 4.6 & 10.8 & 20 \\ 0.3889 & 0.2278 & 0.1565 & 0.1341 & 0.0917 \end{smallmatrix}\right)$	11.93	1
optimal	Φ_D	$\left(\begin{smallmatrix} 0.44 & 1.66 & 1.7 & 4.0 & 4.49 & 10.77 & 10.8 \\ 0.2498 & 0.0846 & 0.1654 & 0.2448 & 0.0048 & 0.1151 & 0.1338 \end{smallmatrix}\right)$	39.19	5
support over T	Φ_A	$\left(\begin{smallmatrix} 0.27 & 1.61 & 4.61 & 4.63 & 10.50 & 19.0 \\ 0.3463 & 0.2527 & 0.0670 & 0.1061 & 0.1415 & 0.0851 \end{smallmatrix}\right)$	27.46	6

Then, natural candidate support points for the minmax optimal design arise as local maxima of the function $h_{\boldsymbol{\gamma}}(t)$ over T. More precisely, we propose to change the stopping condition of the main loop as "**while** ($\tau^* > \ell^* + \varepsilon_r$ and $\max_{t\in T} h_{\boldsymbol{\gamma}}(t) > \varepsilon_r$) **do**", and to add the following statements at the end of the **while** loop in Algorithm 1:

$$\text{Compute the dual weights } \boldsymbol{\gamma}\in\mathbb{R}^k, \quad \mathbb{T}\leftarrow\mathbb{T}\cup\arg\max_{t\in T} h_{\boldsymbol{\gamma}}(t), \quad s\leftarrow\text{card}(T).$$

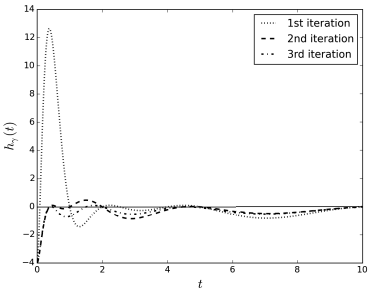
3. Application and results

To test the algorithm presented in Section 2 we use the example of Atkinson et al. (2007, pag. 270), referring to the model for two consecutive reactions $\mathrm{A}\xrightarrow{\pi_1}\mathrm{B}\xrightarrow{\pi_2}\mathrm{C}$ occurring in a constant volume CSTR, where the concentration C_B of product B is observed, cf. the model in Equations (8).

The measurements must be selected so as to estimate the vector of parameters $\boldsymbol{\theta}=(\pi_1,\pi_2,\lambda_1,\lambda_2)$ for $\Theta\equiv[0.5,1.0]\times[0.1,0.5]\times[1.0,2.0]\times[1.0,2.0]$. We considered $T=[0,20]$, discretized as $\mathbb{T}=\{0,0.2,0.4,\ldots,20\}$ (i.e., $s=101$). The sampling mechanism $\mathscr{S}$ selects the $2^4=16$ corners of Θ, plus 34 vectors drawn from a uniform distribution over Θ (i.e., $q=50$). We used $\varepsilon^p=\varepsilon^r=10^{-3}$, and solved the SDPs with Mosek interfaced by PICOS (Grant et al., 2012; Sagnol, 2012).

Table 1 compares the optimal designs, obtained for D-, A- and E-criteria, for both the case of fixed support points (Section 2.4) and optimal support points over T (Section 2.5). We observe that the D-optimal design is in good agreement with the local designs presented by Atkinson et al. (2007, pag. 270). The local designs were determined for a singleton Θ employing an exchange algorithm which does not require the discretization of the time domain, and are consistently based on 4 support points. Our designs are based on 7, and 6 support points, respectively, which is consistent with the trend observed by several authors, that minmax and Bayesian designs tend to have more support points than local designs (Chaloner and Larntz, 1989). The increase of the number of support points occurs to handle the larger uncertainty caused by broadening the parameters domain. The sampling instants are similar for all designs, and the $D-$optimality criterion produces a design without the point $t=t^{\max}$ which has low weight for $A-$ and $E-$optimal designs. For the case of fixed support points, the optimal design was found after a single iteration for all three criteria. The reason is that the function $\boldsymbol{\theta}\to\Phi[\mathscr{M}(\boldsymbol{w}^*,\boldsymbol{\theta})]$ seems to exhibit a concave behaviour, so that its minima are at the corners of the region Θ. For example, the *answering set* for minmax $D-$optimality over $\mathbb{T}$ is $V_\Theta(\xi^*)=\{(\frac{1}{2},\frac{1}{10},2,2),(\frac{1}{2},\frac{1}{2},2,1),(\frac{1}{2},\frac{1}{2},2,2)\}$.

Figure 1 displays the evolution of the function $h_{\boldsymbol{\gamma}}(t)$ with the iterations of the modified version of Algorithm 1. We see that as support points are added, the upper bound of h_γ is pushed toward 0. Our algorithm was also tested with the logistic model — a nonlinear algebraic model commonly used for benchmark testing — and the results were in agreement with those obtained with other algorithms.



$$\frac{\mathrm{d}C_A}{\mathrm{d}t} = -\pi_1\, C_A^{\lambda_1}, \qquad C_A(0) = 1.0 \quad (8a)$$

$$\frac{\mathrm{d}C_B}{\mathrm{d}t} = \pi_1\, C_A^{\lambda_1} - \pi_2\, C_B^{\lambda_2}, \qquad C_B(0) = 0.0 \quad (8b)$$

$$\frac{\mathrm{d}C_C}{\mathrm{d}t} = \pi_2\, C_B^{\lambda_2}, \qquad C_C(0) = 0.0 \quad (8c)$$

$$y(t) = C_B(t) \quad (8d)$$

Figure 1: Evolution of $h_{\boldsymbol{\gamma}}(t)$ for $D-$optimality.

4. Conclusions

We propose a robust minmax SDP formulation for finding the optimal design of experiments for dynamic models. Our approach relies on the discretization of time domain, and subsequent construction of generalized FIM for a sample of parameter combinations. The minmax optimal design problem is solved employing convex optimization techniques. To prevent suboptimal solutions due to the small size of the sample, we iterate to add the worst parameter combinations in the sample, until a convergence condition is satisfied. A small modification of the algorithm allows one to identify the optimal support points of the minmax design. The algorithm is tested for a dynamic model for two consecutive reactions, and the results compare well with earlier references.

Abstract

The core of this study is the design of Water Allocation Networks (WAN) defined by a superstructure integrating different processes, regeneration units and contaminants. In this work, different optimization frameworks are compared to identify the main elements and criteria to be considered as well as the more robust methodology to solve problems involving multiple contaminants and several regeneration units from a multi-objective perspective. A case study previously analysed by (Feng et al., 2008) and (Boix et al., 2011) and formulated as a Nonlinear Programming (NLP) and Mixed Integer Non-Linear Programming (MINLP) problem, respectively, is treated by minimizing objective functions such as fresh water consumption, the number of network connections and the regenerated water flow rate. The comparison of the obtained results show that the use of binary variables in the MINLP approach leads to a better WAN with less connections thus eliminating low flow rates among the processes although the computation time is longer.

Keywords: Water networks (WAN), multi-contaminant, multi-objective optimization, MINLP, ε-constraint.

1. Introduction

The declining supply and higher cost of raw water is forcing industry to implement recycling technologies in an increasingly competitive market and stringent regulations and standards. During the last decades, the scientific community has been largely involved in the topic of the design of optimal water networks while minimizing both economic and environmental objectives. The design of Water Allocation Networks (WANs) is a complex task, especially when multiple contaminants are treated in the same plant with particular emphasis on the decision about the use of many regeneration units. This problem has been identified in previous works (e.g. Boix et al., 2011; Feng et al., 2008; Gunaratnam et al., 2005) and formulated as a generic framework considering one or several objective functions. The analysis of the dedicated literature shows that a robust approach that can take into account large problems is far from being straightforward and that the definition of constraints or assumptions must be specified and adapted to a case study, thus hampering the development of a generic approach. Depending of the nature of these constraints, the model can be expressed with either a Non Linear Programming (NLP) or a Mixed Integer Non Linear Programming (MINLP) formulation. In this work, the first objective is to identify a robust methodology to deal with large problems for the WAN design through multi-objective optimization. The second goal consists in defining the main criteria to be taken into

account. For this purpose, the comparison of different solution strategies will be analysed. The remainder of this paper is organised as follows: section 2 is devoted to the WAN formulation. The mathematical model and criteria are presented in section 3. Section 4 is dedicated to the development of the solution strategy. The definition of the case study and the obtained results are presented in section 5. Finally, conclusions and perspectives are given.

2. Formulation of the Water Allocation Network (WAN)

A general superstructure for WAN modelling is presented in Figure 1. From a given number of regeneration units and processes, all the possible connections between them may exist, except regeneration recycling to the same regeneration unit or from a process to the same one. Each process admits fixed maximal input and output concentrations, and in the same way, regeneration units have a given processing capacity. For each water-flow rate using a process, the water input may be freshwater, used water coming from other processes and/or recycled water; the water output for such a process may be directly discharged, distributed to other processes and/or to regeneration units. Similarly, for a regeneration unit, the input water may come from processes or other regeneration units. Regenerated water may be reused in the processes or directed to other regeneration units. For each process, input or output contaminant mass fractions (ppm) are imposed by the user, and constitute bounds for the optimization problem. Each task performed by a given process contaminates its input water up to a given mass fraction. The amount of pollutant *i* generated by a process *j* is noted $M_{i,j}$ and is expressed in mass flow rate (g h^{-1}) in order to have consistent units with the water flow rate (t h^{-1}) and the contaminant mass fraction (ppm). The regeneration units are represented by the indices *l* and *m*.

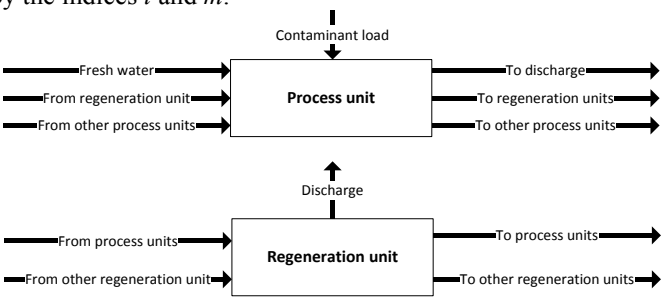

Figure1. Generic elements of the superstructure (Boix et al., 2011)

3. Mathematical model for the multi-contaminant problem

A multi-contaminant WAN can be generally stated in terms of concentrations and total mass flows involving water balances on processes and regeneration units, contaminant and mass balances on inlet processes and regeneration units and finally, the overall mass balances of contaminants on discharge considering the environmental limits for each contaminant. For reasons of brevity, not all the equations are presented here but they can be found in (Feng et al., 2008) with different constraint features (i.e. equality, inequality or bounded). Several criteria can be optimized. Let us recall that multi-objective optimization is relevant to antagonist objective functions. Several objective functions presented in the works of (Boix et al., 2011; Feng et al., 2008) can be used to solve a multi-contaminant problem with several regeneration units. The first criterion is the total flow rate of fresh water in the network (F1) (see Eq. (1)) where F1 represents the sum of freshwater flow rates at the entrance of each water-using process *j* (W_j^1):

$$F1 = \sum_j W_j^1 \quad (1)$$

The second function (F2) presented here was firstly proposed by (Feng et al. 2008). Eq. (2) minimizes the regenerated water flow considering a weighting coefficient for each of them. The water flow rate going from the process *j* (W^{PR}) and from the regeneration unit *m* to regeneration unit *l* (W^R, in t h^{-1}) is multiplied by the weighting coefficient for the treatment unit *l*(λ^{reg}: without considering directly the cost associated to the treatment units but a weight):

$$F2 = \sum_l \left[\left(\sum_j W_{\overrightarrow{j,l}}^{PR} + \sum_m W_{\overrightarrow{m,l}}^{R} \right) \times \lambda_l^{reg} \right] \quad (2)$$

A third criterion (F3) also proposed by (Feng et al. 2008) refers to the contaminant regeneration load and was also considered in this study. The water flow rates going from the regeneration unit *l* to the process *j* and the regeneration unit *m* (W^{RP} and W^R, in t h^{-1}) are multiplied by the difference inlet/outlet concentration of contaminant *i* for the regeneration unit *l* ($Cr^{In/out}$, in ppm) by the weighting coefficient for the three contaminants in the treatment unit *l* (λ^{cont}), this last value is assumed by the user.

$$F3 = \sum_l \left\{ \left(\sum_j W_{\overrightarrow{l,j}}^{RP} + \sum_m W_{\overrightarrow{l,m}}^{R} \right) \times \left[\left(\sum_i Cr_{i,l}^{In} - \sum_i Cr_{i,l}^{Out} \right) \times \lambda_l^{cont} \right] \right\} \quad (3)$$

Feng et al. (2008) used criteria [F1-F3] to solve the case study presented by (Gunaratnam et al. 2005) with the use of continuous variables in a nonlinear framework. This NLP model was solved using sequential optimization to find the optimal WAN. In a different approach, (Boix et al., 2011) minimized F1 and highlighted the complexity of the network by the use of interconnection between processes and regeneration units. The criterion of interconnections (F4) is presented in Eq. (4) where the number of connections is given by the sum of the binary variables *Y* among the processes *j*.

$$F4 = \sum_j Y_j \quad (4)$$

The inlet water flow-rate to the regeneration unit (F5) simply expressed as the sum of the water flow rates going from a process to a regeneration unit and from a regeneration unit to another is also minimized (Eq. 5). This criterion is directly related to an economic basis because if the amount of regenerated water increases, the cost will increase for the user, conversely**.**

$$F5 = \sum_l \left(\sum_m W_{\overrightarrow{m,l}}^{R} + \sum_j W_{\overrightarrow{j,l}}^{PR} \right) \quad (5)$$

The approach NLP presented by (Feng et al., 2008) does not consider the addition of binary variables to minimize the interconnections but apply sequential optimization to find the optimized WAN where the weighting coefficients for each contaminant and treatment unit (λ_l^{cont} *and* λ_l^{reg}) are difficult to set. To overcome this limitation, the approach MINLP presented by (Boix et al., 2011) [min F1, F4 and F5] is also assessed.

4. Optimization strategy

The multi-objective problem is solved by lexicographic and ε-constraint methods where all but one objective are converted into constraints by setting an upper or lower bound to each of them, and only one objective is to be optimised. By varying the numerical values of the upper bounds, a Pareto front can be obtained. Finally, a Multi-Criteria Aid Decision Making (MCDM) tool based on the so-called M-TOPSIS method (Ren et al., 2007) (Modified Technique for Order of Preference by Similarity to Ideal Solution) is selected to choose the best compromise solution. In this work, we first validate (Feng et

al., 2008) values by using GAMS instead LINGO. The second step involves the minimization of the fresh water flow rate for each contaminant to find the limiting pollutant. Then, the multi-objective optimization is applied. Finally, instead of evaluating the cost network, the so-called global equivalent cost (GEC) is used (Boix et al., 2011) expressed in equivalent of water flow rate which allows expressing the overall cost of the network in amount of fresh water. In GEC calculation, the fresh water flow rate and amounts of regenerated and discharged flow rates weighted by their contributions relative to the fresh water one (equal to 1) are considered. Consequently, three criteria are merged into only one according to the following relation:

$$GEC = F1 + \alpha \times F5 + \beta \times FD \quad (6)$$

F5 refers to the regenerated water and FD is waste flow rate to discharge. In Eq.(6), α and β are cost elements respectively related to the regenerated water cost and post-treatment cost for water sent to the discharge; α depends on the type of regeneration unit (see Table 1) and β is equal to 5.625 according to (Bagajewicz and Faria, 2009).

Table 1. Values of α according to types of regeneration units

Regeneration type	Treatment unit weight (Feng et al., 2008)	α (calculated based on (Bagajewicz and Faria, 2009)
I	49 %	3.13
II	37 %	2.34
III	14 %	0.89

5. Results for the case study

5.1. Case study

A case study for a simplified petroleum refinery (Gunaratnam et al. 2005) is treated and analysed from a multi-objective viewpoint. The problem consists of 5 water processes and 3 treatment units with three contaminants (i.e. hydrocarbon (HC), hydrogen sulfide (H_2S), and suspended solids (SS)). The regeneration units are defined by their given efficiency depending on the pollutant under treatment. The regeneration units treat wastewater up to a fixed post-regeneration concentration for each contaminant.

5.2. Solving the WAN problem through NLP

In the NLP model, freshwater consumption, regenerated water flow rate and contaminant regeneration load are minimized using sequential optimization to design an economic water network for this system. The results obtained under (Feng et al. 2008) conditions have also been found again by the use of IPOPT solver, thus validating the proposed approach (see Figure 2). It must be highlighted that the use IPOPT does not guarantee global optimality but a very good solution is found that satisfies all constraints. The quality of the solutions is good enough for industrial uses.

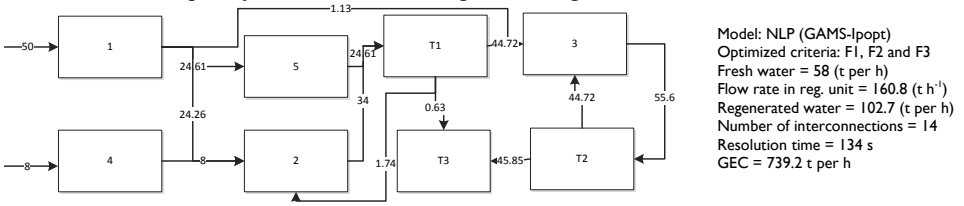

Figure 2. Solution network for the NLP formulation

The chosen point is a non-dominated solution obtained by lexicographic optimization. In this case, the number of interconnections is not minimized (a total of 14 is obtained). The GEC is also calculated to serve as a basis (739 t h^{-1}). The minimal fresh water flow rate is 58 t h^{-1} and the inlet flow rate in the regeneration unit is 160.8 t h^{-1}.

5.3. Mono-contaminant versus multi-contaminant impact

Once the NLP problem is validated, it is possible to identify the limiting contaminant. A study based on the key contaminant is valid in the aim of finding the minimum freshwater target but cannot be implemented for designing an optimal water network regarding several objectives. Figure 3 displays the results of bi-objective optimization (fixing the fresh water flow rate and minimizing the regenerated water) for the three mono-pollutant water networks compared to the multi-contaminant network. The first observation is that Pareto fronts are not straight lines for each network. The three mono-contaminant networks involve lower flow rates than the multi-contaminant one, which is relevant because the problem is more constrained with more components. It is highlighted that the addition of single points of the three contaminants given by freshwater flow rate is higher than the one obtained by the multi-contaminant problem. The key contaminant is related to the highest amount of regenerated water. In this example, the key contaminant is the second one because its curve is above the two others. The dotted line in Figure 3 shows the changing point to discontinuous pace of the mono and multi-contaminant curves. These preliminary results reinforce the interest of implementation of a multi-objective MINLP procedure because the key component method cannot be used for determining the regenerated water flow rate and also the interconnections.

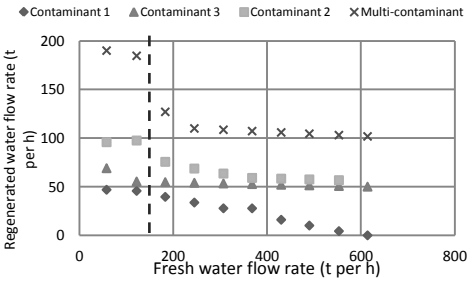

Figure 3. NLP results for the multi-contaminant water network

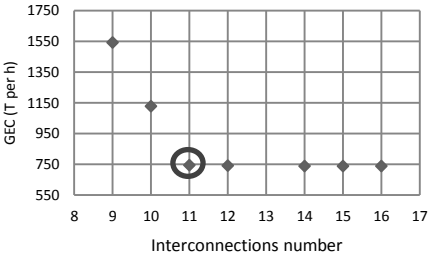

Figure 4. Minimum GEC for each value of connections

5.4. Multi-objective optimization for the MINLP formulation

The MINLP model involves 234 continuous variables, 77 discrete and 455 equations. The optimization runs were implemented with an Intel (R) Core (TM) 17-3540 CPU @3.00 GHz processor machine. The pay-off table of mono and multi-objective optimization is presented in Table 2. In the first section, results concerning mono-objective optimization are displayed where the lower and upper bounds are identified by bold characters.

Table 2. Pay-off table for mono- and multi-objective optimization approaches

Pay-off table obtained by:	*mono-objective optimization*			*lexicographic optimization*		
Resulted value/Minimize:	Fresh water (t per h)	Connect.	Reg. water (t per h)	Fresh water (t per h)	Connect	Reg. water (t per h)
Fresh water (t h^{-1})	58	597	610	**58**	613	600
Number of connections	44	9	11	10	**9**	10
Regenerated water flow-rate	1380.10	964	102.5	157.20	104	**102.50**
Resolution time (s)	6	1000	13	1000	1918	188

By using the abovementioned bounds, the 3 objective optimizations are run following the lexicographic method. This methodology allows finding non-dominated solutions for each criterion. For example, in a mono-objective optimization of fresh water, we identified the minimal value of 58 t h^{-1} with 44 connections and 1380 t h^{-1} of water flow rate in the regeneration unit (CPU time of 6 s): this is a dominated solution with respect

to the lexicographic optimization results: 58 t h^{-1}, 10 connections and 157 t h^{-1} of water flow-rate in the regeneration unit (CPU time of 1000 s).

5.5. Global equivalent cost minimization

Finally, a bi-objective optimization parameterized by the interconnection number is carried out in the range [9, 16]. Starting from the lowest bound for F4, all the possible values for GEC are tested. According to Figure 4, with an increasing interconnection number, the GEC decreases but above 14 interconnections, the GEC remains as 739 T h^{-1} because the number of connections does not have an impact on the cost. If both the GEC and interconnection numbers are considered, the most preferred network includes 11 connections by using 58 T h^{-1} and 164 T h^{-1} of freshwater and regenerated water, respectively according to the TOPSIS analysis. The GEC of this network solution is 744 T h^{-1} and is shown in Figure 5. It is highlighted that the main advantage of this network is the use of less interconnections where low flow rates are discarded.

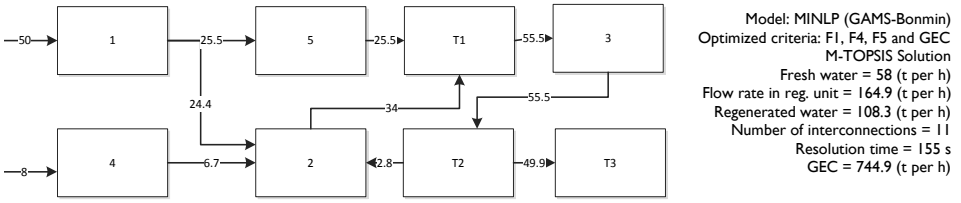

Figure 5. Solution network for the MINLP formulation

6. Conclusions

In this paper the WAN design for a multi-contaminant network considering several regeneration units has been evaluated from different perspectives. A robust methodology for WAN problems has been identified to deal with large problems through multi-objective optimization by the comparison of different solution strategies. First, an NLP model has been solved by sequential optimization following the methodology proposed by (Feng et al., 2008). In this strategy, a network with relatively good performances is obtained but suffers from the need to use arbitrary weight coefficient for each contaminant in the objective function involving the regenerated water flow. In a second time, the MINLP problem was solved using lexicographic and ε-constraints methods. The number of interconnections and the global equivalent cost (GEC) are minimized as well as flow rates. A network with less interconnections resulted from this approach with a low impact in the GEC. The calculation time is higher due to the introduction of binary variables. This second approach is based on the minimization of flow rates and of the number of interconnections. The formulation is generic enough so that new constraints could be added to the WAN problem to integrate the Heat Exchange Networks (HEN) so that a water/energy nexus could be tackled.

Abstract

One of the most important processes in the petrochemical industry is the cracking of light hydrocarbons to produce commercially more important products such as light olefins and aromatics, which are considered key components of the chemical industry. This process is carried out at high temperatures in a tubular reactor located in large gas–fired furnaces that supplies heat. The topic of this work is to apply process optimization to the operation of thermal cracking of ethane in order to maximize the production of ethylene. The cracking reactor was modeled as a one–dimensional tubular reactor, and the kinetic mechanism used here is a detailed free–radical scheme that was carefully selected from literature. This application is a challenging problem because of the presence of a free–radical mechanism that coupled with material, energy, and momentum balances of the reactant–product flow along the reactor leads to stiff differential equations that are difficult to solve. In this work, these differential–algebraic equations are discretized using orthogonal collocation on finite elements, and the collocation equations are used as equality constraints in the non–linear optimization problem. GAMS optimization–modeling platform is used to implement this optimization problem. A comparison between model results and experimental data shows that the used approach is a good alternative for dealing with this type of optimization problem.

Keywords: Reactor optimization; Thermal cracking; Ethylene

1. Introduction

Ethylene is utilized to produce a wide variety of more high value–added industrial products, e.g., polymers, co–polymers, ethylene oxide and ethylbenzene. For that reason, this is a valuable intermediate feedstock in petrochemical industry. Ethylene is commercially produced by thermal cracking of feedstocks derived from hydrocarbons such as ethane, propane, butane, naphtha, heavy gas–oil and kerosene. The thermal cracking for olefins production is carried out in long coils (tubular reactors) suspended in large gas–fired furnaces operating in very high temperatures (900–1,200 K). An typical coil is composed by several straight tubes connected by bends, and an industrial furnace may contain several such coils, heated by burners to provide the necessary heat for the endothermic cracking reactions (Froment et al., 2010). Steam is added as a diluent to the process in order to reduce the partial pressure of hydrocarbons and limit undesirable side reactions, typically a dilution rate between 0.2 to 1 kg steam/kg hydrocarbons is used (Sadrameli, 2015). Thermal cracking furnaces are divided into three sections; radiation section or firebox, convection section, and cooling section or transfer line exchangers. A simplified sketch of a steam cracking furnace is depicted in Figure 1. In the convection section the feedstock is mixed with steam and preheated to around 773–923 K. The cracking process occurs in the radiant section, this section is composed by burners and cracking tubular reactors (coils) where the pyrolysis reactions take place. Finally, the

highly reactive cracked gas leaves the radiant coils of the furnace at temperatures between 1,050–1,160 K, and must be quickly cooled down in order to prevent other side reactions and to provide the highest yield. This rapid cooling takes place in the transfer line exchangers (Sadrameli, 2015).

On the other hand, modelling, simulation and optimization are very important tools to get a better understanding of chemical processes and achieve higher performance. In this manner, many studies in this field have been reported in literature for the thermal cracking, endeavoring to investigate the influence of the operating parameters on the process in order to find an optimal operating strategy and to increase profitability. Additionally, while rigorous models that capture the behavior of the physical and chemical phenomena that occur in the reactor are preferred, thermal cracking is commonly modelled as a plug flow reactor where radial and axial dispersion are negligible, which leads to the simplification of the model. Currently, one dimensional models are accepted, and several studies indicate that these are enough to produce a reasonable level of accuracy and to have a correctly understanding of the thermal cracking (Froment et al., 2010). Reactor models consist generally of a set of mass, energy and momentum balance equations, which have to be coupled with the reaction network and some constitutive equations to predict the mixture properties. These models form a set of differential–algebraic equations (DAEs) that must be solved numerically. When the reaction network in the thermal cracking process is formulated by a free-radical mechanism, which is the most detailed and accurate way to represent this complex reaction network, the resulting model leads to a stiff non–linear DAE system due to the large differences in concentration gradient between molecular and radical species (Froment et al., 2010). In this way, the goal of the present paper is to find an optimal profile for the heat flux added along the coil length of an industrial ethane steam cracking reactor to maximize the production of ethylene. To overcome the stiffness problem in the system of equations the orthogonal collocation on finite elements method (OCFE) was incorporated in the optimization procedure.

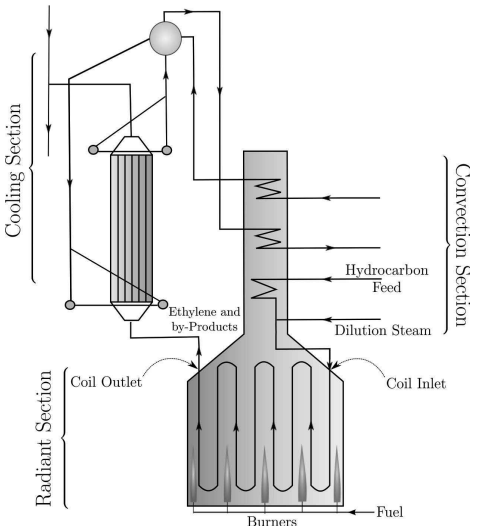

Figure 1: Sketch of a typical furnace for the steam cracking of hydrocarbons

2. Mathematical modeling

The well known one–dimensional plug flow model in steady state is considered in this study to represent the reactor. Thus, the set of differential equations consisting of mass balance for each specie is simultaneously solved with the energy and momentum balances and the kinetic model. The kinetic model used in this work describes ethane cracking with 49 reactions including 11 molecular components and 9 radical species. The rigorous reaction model has been reported in detail by Sundaram and Froment (1978). It's worth mentioning that more accurate results have been reported by using this free radical model than with other molecular kinetic models. The reactor equations are as follows:

• Mass balance for each component:

$$\frac{dF_i}{dz} = R_i \cdot A_t \tag{1}$$

with F_i the molar flow rate of component i; R_i the net production rate of component i and A_t the cross sectional surface area.

• Energy balance:

$$\sum_i F_i \cdot C_{p,i} \cdot \frac{dT}{dz} = Q(z) \cdot \pi \cdot d_t + A_t \cdot \sum_j (-\triangle H_j) \cdot r_j \tag{2}$$

with T the temperature of the reactor; $Q(z)$ the heat flux at length z of the reactor; $C_{p,i}$ the heat capacity of component i at temperature T; d_t the coil tube diameter; $\triangle H_j$ the enthalpy of reaction j and r_j the reaction rate of reaction j.

• Momentum balance:

$$-\frac{dP}{dz} = \alpha \cdot F_r + \rho \cdot u^2 + \alpha \cdot \rho \cdot u \cdot \frac{du}{dz} \tag{3}$$

with P the total pressure of the reactor; α a conversion factor for pressure; F_r the friction factor; ρ the density of the gas mixture and u the gas velocity. The momentum equation accounts the friction losses in the straight part of the coil according to the Fanning equation and an additional loss in the bends. A detailed description of the applied model can be found in Froment et al. (2010). In order to carry out a cracking reactor simulation, it is necessary to know the heat flux along the reactor $Q(z)$, so before solving the DAEs system referred above the heat flux or tube skin temperature profile should first be calculated, which is used as boundary condition in the model. Otherwise the system has a certain degree of freedom. This heat flux is commonly predicted by either independent or coupled simulations of the furnace and the coil, which are solved with iterative processes. Algorithms of such procedures are well described elsewhere in (Heynderickx and Froment, 1996). Recently, furnace CFD simulations are coupled with PFR simulations to predict accurately the heat flux (Hu et al., 2012). It is important to highlight that such prediction of heat flux was not necessary in this work because the problem was formulated as an optimization problem (Non–Linear Programming, NLP), and the heat flux was considered as decision variable.

3. Optimization Methodology

The goal of this optimization problem is to find an optimal profile for the heat flux that maximizes the production of ethylene. Hence, the most suitable objective function to be chosen from a practical standpoint of the reaction system is the ethylene yield, which can be written as the product of the ethane conversion ($X_{C_2H_6}$) and ethylene selectivity ($S_{C_2H_4}$). The equality constraints of this optimization problem are the non–linear differential–algebraic equations distributed in space presented in the previous section, which lead to an DAE–constrained optimization problem. An effective way of dealing with this kind of optimization problem is carrying out a full discretization of the DAE system and incorporating the discretized DAEs into an NLP formulation. A robust method of discretization is, therefore, necessary to deal with the stiffness caused by the kinetic model used. In this fashion, the orthogonal collocation on finite elements method is chosen in this work, along with Radau collocation points because of their compatibility with the NLP formulations and desirable stability properties (Biegler, 2010). Finally, the applied methodology leads to a large set of nonlinear algebraic equations (large scale NLP problems), and these usually require efficient solution strategies. For that reason, a robust and efficient NLP solver must be chosen for solving the optimization problem. In consequence, IPOPT solver, which is an solver based on interior–point methods, was implemented, and the problem was formulated within GAMS optimization–modeling platform. More details on the background of this methodology can be found in Biegler (2010). Inequality constraints were also included in the optimization. These

Table 1: Specifications of the simulated industrial reactor (Froment et al., 1976)

Parameter	Value
Length of the straights tubes [m]	8.85
Length of the bends [m]	0.55
Number of straights tubes	10
Number of bends	10
Total reactor length [m]	95
Tubes diameter [m]	0.108
Bend radius [m]	0.178
Inlet mass flux $\left[\frac{kg}{m^2 \cdot s}\right]$	68.68
Inlet temperature [K]	950
Inlet pressure [kPa]	303
Steam–to–ethane mass ratio	0.4

were formulated in accordance with the industrial practice (Tarafder et al., 2005; Van-Goethem et al., 2010). The only decision variable considered in this study was the heat flux along of the reactor length, however, other decision variables like inlet feed conditions (temperature, pressure, dilution factor and molar flows of reactants) and design conditions (number of tubes and tube diameter) can also be considered.

4. Results and Discussion

Before solving the optimization problem, some preliminary simulations of the reactor were required in order to provide an appropriate number of finite elements and collocation points in the discretization method used. Another reason of implementing such simulations was to provide suitable initial guesses for states in order to initialize the optimization problem in the full discretization approach and solve it more efficiently. Specifications of the industrial cracking reactor simulated here are presented in Table 1. These were taken from Froment et al. (1976). This industrial reactor has been used several times in the literature for validation purposes. Table 2 provides a comparison between simulation results in this study and experimental results reported by Froment et al. (1976), as well as a comparison with simulation data reported in Tarafder et al. (2005). It can be seen that the simulated results obtained in this work are in good agreement with the industrial data and previous simulations of the same reactor. The ethane conversion, coil outlet temperature and pressure as well as the yields of the main components of the reactions (methane, ethane, ethylene and hydrogen), which constitute more than 95 wt % of the final gas mixture, are predicted within 6 % of the experimental data. The reactor pressure, gas temperature and conversion profiles resulted from the simulation are illustrated in Figure 2. It is important to highlight that the quadratic expression used by Tarafder et al. (2005) for representing the heat flux profile was imposed in the simulation. This simulation was implemented in GAMS with a dummy objective function and without any degrees of freedom. Moreover, 15, 20 and 30 finite elements with 3 Radau collocation points were tested to carry out the simulation, but the obtained results showed no significant differences. Accordingly, the OCFE method can be successfully applied to simulate an industrial cracker by employing only 15 finite elements and 3 collocation points. Also, the stiffness of the system is handled satisfactorily with relatively few finite elements. The solution tooks 7 CPUs (4GB and 2.2GHz HP laptop) using IPOPT.

After the solution of the simulation was obtained, these results were then used as initial guesses

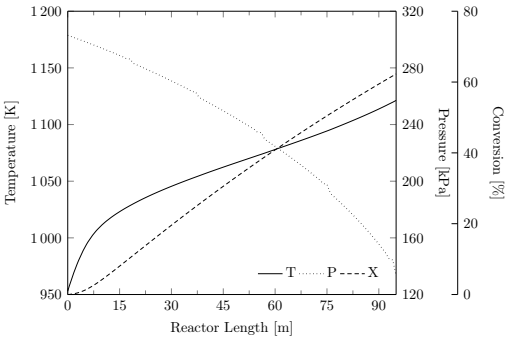

Figure 2: Temperature, pressure and conversion profiles for simulation case

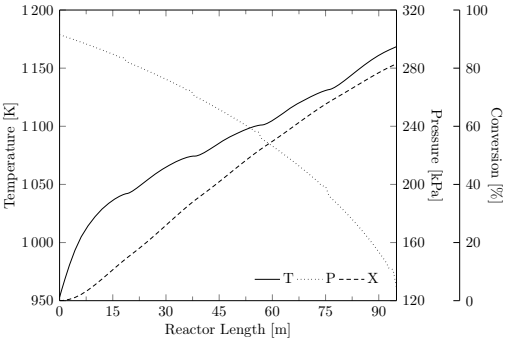

Figure 3: Optimal temperature, pressure and conversion profiles

of states and given to the optimization problem. In this way the optimization problem was solved applying the full discretization approach to the DAE model with 3 Radau collocation points and 15 finite elements, which leads to an NLP with 13,164 variables and 13,119 equality constraints, resulting in an optimization problem with 45 degrees of freedom. Using GAMS, the optimal solution was obtained in 85 CPUs (4GB and 2.2GHz HP laptop) with 17 iterations of IPOPT solver. As can be seen in Figure 3 the optimal profiles appear to follow the same trend as the simulation case, with a significant increase in the conversion and the temperature profiles. These increases are consequence of the optimal heat flux profile obtained along the reactor length. This heat flux profile is shown in Figure 4, and presents similar trend to the heat flux reported in other works using those iterative procedures referred in mathematical modeling section. The peaks in Figure 4 correspond to the bottom bends of the coils and the valleys to the top ones. The strong non–uniformity is explained as follows: At the top of the furnace the heat flux is much lower than at the bottom, where there are sharp peaks, since there are no burners in the top section of the furnace, and the heat flux decreases as the reactor length is higher because the temperature of the gas mixture increases and, therefore, the temperature gradient between the furnace and the coil becomes smaller (Sabbe et al., 2011; Hernández, 2012).

The optimal molar flow profiles for ethane and ethylene are shown in Figure 5. The maximum ethylene yield obtained was 60 wt % which corresponds to an ethane conversion of 81.5 % and an ethylene selectivity of 78.9 %. This maximum ethylene yield was obtained for a coil outlet temperature of 1,168.6 K, this is in agreement with the currently applied reaction conditions in industrial crackers that lead to a coil outlet temperature around 1,000–1,200 K (Sadrameli, 2015). However, typical conversions and maximum ethylene yields achieved in industrial ethane cracking reactors (70 % and 55 wt % respectively (Van-Goethem et al., 2010)) are lower than those obtained in this work. Similar results were reported by Van-Goethem et al. (2010) (maximum allowed temperature of 1,145 K, ethane conversion of 92 % and ethylene yield of 66.8 wt %), an ethylene yield higher than that achieved here. Nonetheless, in this work the only decision variable was the heat flux, and the ethylene yield could increase if more degrees of freedom are incorporated in the optimization study.

5. Conclusions

From the successful optimization of an industrial ethane cracking reactor carried out, it can be concluded that the methodology developed and applied in this work is able to provide reliable results when compared with industrial data, although with the kinetic scheme used it was not possible to predict accurately the yield of the minor species. In this way, other large kinetic schemes like the industrially proven kinetic scheme in SPYRO can be incorpored for a better

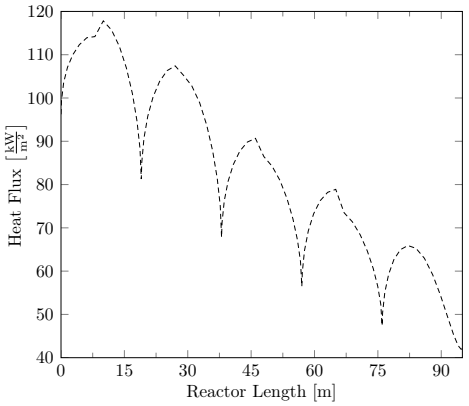

Figure 4: Optimal heat flux profile for thermal cracking of ethane

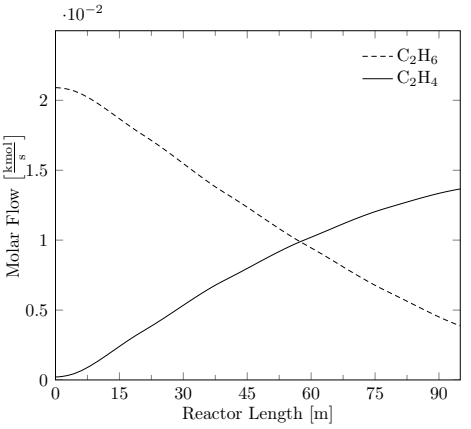

Figure 5: Optimal mass flow profiles of ethane and ethylene

prediction of these minor species. With the OCFE method implemented no stiffness problem was found either in simulations nor in the optimization. Therefore, this is a computationally efficient discretization method that can be successfully applied to theoretical studies about thermal cracking of hydrocarbons in order to improve existing industrial processes. In relation to the optimal values obtained, it can be suggested that the current ethane cracking technologies can be improved in terms of productivity. Consequently further optimization studies are required in this area and should be conducted in the future.

Abstract

The optimal design of distillation systems is a highly non-linear, multivariable and multimodal problem. The rigorous model of distillation columns is represented by mass, equilibrium, sum and heat equations called MESH equations and phase equilibrium calculations (Thermodynamic model). Furthermore, it has several local optimums and is subject to several kind constraints such as, design and topology scheme constraints, and achieves targets of purity and recovery for each split component. In this paper, we propose the employment of a novel stochastic algorithm called Boltzmann Univariate Marginal Distribution Algorithm (BUMDA, Valdez, S. I. et al., 2013) coupled with self-adaptive handling constraints technique to optimize a well-known distillation process scheme. The optimization problem consists in minimizing the total reboiler duty in a distillation train to split a mixture made of four components. The BUMDA's performance is compared with Differential Evolution (DE) due to the fact that this last algorithm is used frequently in the optimization of distillation columns. The results show that the BUMDA algorithm is better than the DE algorithm regarding effort computing, quality solution, and time used to find solution. The BUMDA algorithm is efficient, trusted, easy to use and of general applicability in any chemical engineering process.

Keywords: Optimization, BUMDA, Stochastic Algorithms, Distillation train, EDA's.

1. Introduction

The optimization of a distillation system is considered a computer problem of large proportion with a significant number of strongly nonlinear equations that cause serious numerical difficulties when solving the model. Nowadays, this optimization problem is tackled with deterministic and stochastic approaches. Deterministic strategies tackle the problem considering the sequence as superstructures which can be solved with mixed-

integer linear programming and non-linear programming approaches; other authors consider reduced models. On the other hand, the stochastic algorithms can deal with multi-modal and non-convex problems in an effective way and without the mentioned limitations. They are a suitable alternative to the design and optimization of complex separation schemes. In chemical engineering processes, distillation is a widely used separation process and a very large consumer of energy. A great amount of research has been carried out to improve the energy efficiency of distillation systems, in terms of either the design of optimal distillation schemes or improving internal column efficiency. Nowadays, the optimal design of multicomponent distillation systems remains one of the most challenging problems in processes engineering.

In this work, BUMDA algorithm performance is compared with Differential Evolution algorithm (DE) due to the fact that it is one of the most used evolutionary algorithms for solving global optimization problems in chemical engineering processes (R. Vakili et. al., 2011; Cabrera-Ruiz et. al., 2011). Both algorithms were coupled with self-adaptive handling constraints technique and were employed to optimize a distillation train that split a four components mixture.

2. Case study

In chemical engineering processes MESH equations and thermodynamic equilibrium equations have high levels of nonlinearities and nonconvexities and also present convergence difficulties. This leads to high computational times and the requirement of good initial guesses and bounds on the variables to achieve convergence.

Following case of study is described. The objective of a distillation train is to separate a multicomponent mixture using only single columns. Each column receives a feed-in and carries out the distillation of two adjacent components (adjacent volatility), and delivers two products: one at the top and the other at the bottom. In order to separate a mixture of *N* components, it is necessary to use *N-1* single columns. The order in which the components are separated is based on their relative volatility (Figure 1).

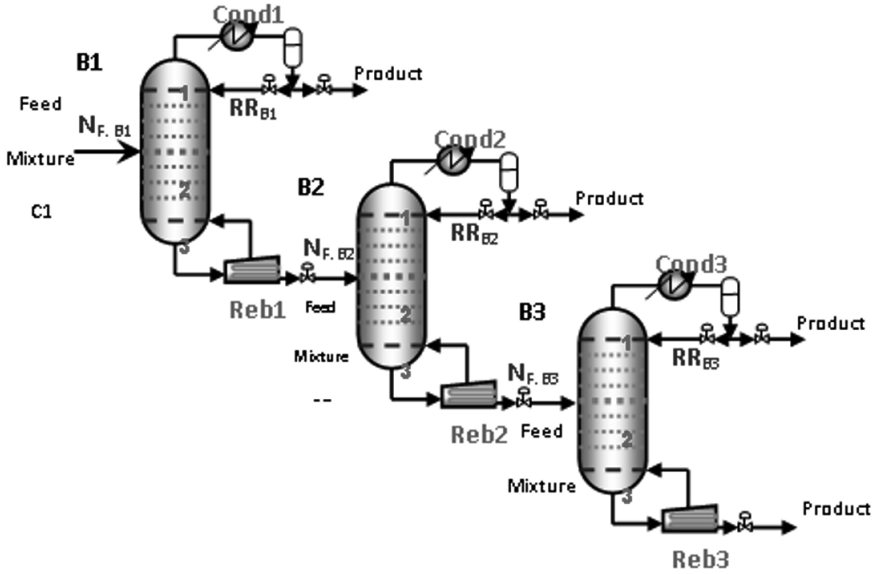

Figure 1. Flowsheet of distillation train to split a mixture of four components.

The basic design of each distillation column requires finding the best values of: the total number of stages *NT*, feed stage *NF* and reflux ratio *RR,* which is the relationship between the liquid flow *L* that returns to the column and the vapor flow *V* that rises in the column.This takes places on the upper part of the column. With this set of variables, the main goal of design is to obtain the minimum total heat duty possible to achieve the separation of the mixture. In mathematical terms, the problem statement optimization is described as following:

Find vector

$$Z = (NT_{B1}, NF_{B1}, NT_{B2}, NF_{B2}, NT_{B3}, NF_{B3}, RR_{B1}, RR_{B2}, RR_{B3})$$

To minimize fitness function

$$Q = f(Z)$$

Subject to constraint function

$$g_{1,j}(Z) = x^{\text{pur}}_{\text{target}} \qquad j = 1,...,M_{\text{constraints}}$$

$$g_{2,j}(Z) = x^{\text{rec}}_{\text{target}} \qquad j = 1,...,M_{\text{constraints}}$$

And subject to boundary constraints

$$z_i^{(L)} \le z_i \le z_i^U \qquad i = 1,...,D$$

$$2 < NF_{Bl} \le NT_{Bl} \qquad l = 1,...,B_{columns}$$

Where for each column *B*, *NT* is the total number of stages and *NF* is the number of feed stage. These dimensions are discrete variables and *RR* is the reflux ratio. These are continuous variables; in total we have nine dimensions, of which six are discrete and three are continuous. The fitness function is to minimize the total heat reboiler duty *Q* that is a function of vector *Z*. Regarding the design constraint, we have two types: one is referred to as purity, and other one as recovery; these exist for each component. Also it is important to consider the boundary constraints, because *NF* should always be less than *NT* and each dimension, *Zi* is between lower and upper boundaries.

3. Optimization strategy

In this research, we chose two stochastic algorithms: Differential Evolution (Viswanathan, J. and Grossmann, I. E., 1993). Which generates new points that are perturbations of existing points, and Boltzmann Univariate Marginal Distribution Algorithm BUMDA (Valdez, S. I. et al., 2013), that uses a normal distribution to approximate the Boltzmann Distribution, using the mean and variance of the population. These algorithms are coupled with self-adaptive handling constraints that allow use to find feasible solutions that achieve all design and specification constraints throughout distillation column optimization. Furthermore, it is important to mention that the optimization approach has been developed using an interface which links the optimizer algorithms with the modular simulator through databases. Following the characteristics of the algorithms, technique of handling constraints and optimization approach are briefly described.

3.1. Boltzmann Univariate Distribution Algorithm (BUMDA)

EDA's use a probability distribution, called the search distribution, to sample new candidate solutions. Hence, the search strategy in EDA's is to increment the probability of sampling the optimum from the search distribution. The advantage of the BUMDA algorithm is the preservation of the desired characteristics of the Boltzmann distribution,

while maintaining a low computational cost in the estimation and sampling steps. It also focuses on sampling as many promising solutions as possible, avoiding sampling promising and non-promising solutions and then rejecting some of them. The BUMDA algorithm starting with a population is initialized between the bounds of the search space and the fitness function calculated. 30% of the best individuals are stored in the selected set, and used to compute the mean and variance parameters of the Normal distribution. Then new individuals are simulated from a Normal distribution with such parameters to populate the next generation.

3.2. Differential Evolution (DE)

Differential evolution is proposed by Storn and Price (Storn, R. and Price, K., 1995). DE is a stochastic direct search method using population or multiple search points. DE has been successfully applied to the optimization problems including non-linear, non-differentiable, non-convex and multi-modal functions. It has been shown that DE is fast and robust when applied to these functions. In DE, initial individuals are randomly generated within the search space and form an initial population. Each individual i contains D genes as decision variables or a decision vector Zi. At each generation or iteration G, all individuals $Npob$ are selected as parents. Each parent is processed as follows: the mutation process begins by choosing three individuals from the parents except for the parent in the processing. The first individual is a base vector. Subsequent individuals are paired to create difference vectors. The difference vectors are scaled by the scaling factor F and added to the base vector. The resulting vector is then mated or recombined with the parent. The probability of recombination at an element is controlled by the crossover factor CR. This crossover process produces a trial vector. Finally, for survivor selection, the trial vector is accepted for the next generation if the trial vector is better than the parent.

3.3. Optimization Process

For the optimization approach implemented in this work, we have developed an interface which links the optimizer BUMDA or DE (Master, coded in MatLab) with the modular simulator Aspen Plus (Fitness Function Evaluator) through the Excel (Database). In this interface the stochastic algorithm needs one individual physically feasible of beginning the optimization process. Here, physically feasible implies that for a distillation column, the feed stage must be smaller than the total number of stages, and the reflux ratio is greater than zero. The stochastic algorithm generates individuals with the proper dimensionality, which is sent to Aspen Plus, one by one, in order to simulate the distillation scheme and get the values of the fitness function evaluated with constraints.

4. Discussion and Results

In this paper, a comparative analysis of performance ED and BUMDA stochastic algorithms is presented. Many authors have used ED algorithm to optimize chemical engineering problems while the BUMDA algorithm has been used only once. Both algorithms are tested to optimize two well-known problems in chemical engineering. The problem is to purify a four aliphatic hydrocarbons mixture in a distillation train. We carried out tuning of parameters in two algorithms. The total number of evaluation is the stop criterion and the fitness function is the total heat duty minimization. The simulations were carried out with a PC computer with an i5 processor core, clock frequency at 2.8 GHz, and 8 GB of RAM. In this case we study a mixture made of four lineal aliphatic hydrocarbons fed at a flow-rate of 100 kmol/h; which is introduced in the first column as saturated liquid. The characteristics and constraints of the mixture

are presented in Table 1. The proportion of each component is shown in mol fraction. Each component must be delivered with the specified purity and recovery. The design pressure for the separation was chosen to ensure that cooling water was used in the condensers. The phase equilibrium for liquid of this mixture is calculated with the Chao-Seader model, because it is usually recommended for hydrocarbon mixtures operating at low or medium pressure.

Table 1. Characteristics of the case study.

Characteristics of the mixture			Constraints	
ID	Component	Feed, mol fraction	Purity, x_i^{pur}	Recovery, x_i^{rec}
A	n- butane	0.05	0.987	0.98
B	n- pentane	0.45	0.98	0.98
C	n-hexane	0.45	0.98	0.98
D	n-heptane	0.05	0.986	0.98

4.1. Analysis performance of DE and BUMDA stochastic algorithms

The main aim of this paper is analyze the performance of two algorithms, DE inspired in natural phenomena and BUMDA based in estimation of Boltzmann distribution. The comparative parameters are effort of computation, time that found solution, quality of solution and behavior along optimization process. In Table 2 we analyze three comparative parameters. The first comparison is effort of computation; i.e. maximum number of function evaluations that each algorithm requires to find the best solution. It is clear that the BUMDA algorithm only needs *15 %* of *NEFmax* of what the DE algorithm requires. The time find a solution, is in direct relation with *NEFmax*, so that the BUMDA is faster than the DE algorithm. The BUMDA only requires 8% of the time that DE algorithm requires.

Table 2. Comparative analysis of best individuals obtained by DE and BUMDA algorithms

Parameter	DE Algorithm	BUMDA Algorithm
Effort of computation $\left(NEF^{\max}\right)$	20,000	3,000
Time of solution $\left(\theta, hours\right)$	100	8
Quality solution $\left(Q, BTU/h\right)$	9425750.75	7153129.14
Quality solution $\left(NT^{total}\right)$	84	71

In Figure 2 there are two sets of point: blue points that represent the best solutions given by the DE algorithm and pink points that are the feasible solutions obtained with the BUMDA algorithm. In this graph, the total number of stages is the axis "x" versus total heat duty shown in the "y" axis. Both variables are the most important in the design of distillation columns, since they show the compromise between size column and its energy consumption. It's clear that the pink points are better than blue points, both in *NT* as *Q*. If we compare the best solution only in terms of energy, the best pink point requires around 2,300,000 BTU/h less of the energy consumption than the best blue point; this behavior is similar in total number of stages. Based on these results, the best

solution obtained by the BUMDA algorithm provides the better compromise to design the distillation train.

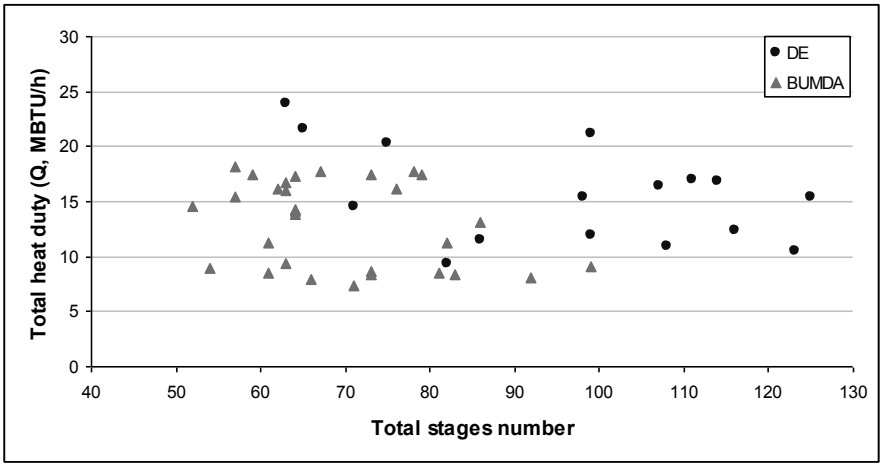

Figure 2. Comparative of the best individuals obtained by DE and BUMDA algorithms.

Finally, based on the results obtained with both algorithms in this case study, the novel stochastic algorithm based on Boltzmann distribution, the BUMDA algorithm implemented by us, is better than the DE algorithm, due to the fact that offers better solutions in less time and requires low computation effort. In addition the performance in optimization process of the BUMDA algorithm presents a high convergence in the best feasible zone and is identified clearly in an intensification zone, which leads to an improvement in the quality of solutions. This study verifies that the approach presented in this paper, BUMDA algorithm with self-adaptive handling constraints technique, is a powerful and robust tool capable of optimizing processes in chemical engineering and is potentially useful in other areas of engineering.

5. Conclusions

In this paper, a comparative study of the general performance of stochastic algorithms to optimize a distillation train is presented. We used two stochastic algorithms: Differential Evolution (ED) and Boltzmann Univariate Marginal Distribution Algorithm (BUMDA). The best solution was found by the BUMDA algorithm. The BUMDA algorithm is better than the DE algorithm because BUMDA is capable of finding the best design with little numeric effort, short computing time and a good success rate.

Dynamic Modelling and Optimal Design of the Solid-Phase Reactive Chromatographic Separation System for Biomass Saccharification via Acid Hydrolysis

Pakkapol Kanchanalai, Matthew J Realff, Yoshiaki Kawajiri*

School of Chemical & Biomolecular Engineering, Georgia Institute of Technology
311 Ferst Drive, Atlanta, GA 30332-0100

Abstract

A dynamic model of the progressing batch reactor as part of the solid-phase reactive chromatographic separation system is presented. The biomass filling and emptying steps in reactor system for two designs are proposed where each operating step is divided into two sub-steps including the transfer period and production period. The operating parameters for the progressing batch reactor with these sub-steps can be estimated from the countercurrent reactor model. The performance of the progressing batch reactor can be predicted from that of the countercurrent reactor model. A minor difference in the sugar yield was found due to the dynamics which cannot be accounted for in the countercurrent model. The proposed filling and emptying steps with the estimated operating parameters from countercurrent reactor can be used as an approximation to optimize the overall solid-phase reactive chromatographic separation system.
Keywords: Biomass hydrolysis, chromatography, reactive separation

1. Introduction

Biomass is a renewable and largely available low-cost source of sugars which can be hydrolyzed and fermented to produce bioethanol or converted to other value-added chemicals. The hydrolysis reaction of biomass using strong acid is one of the common processes; however, the main drawbacks are the cost of acid recovery and the sugar degradation with byproduct formation such as hydroxymethylfurfural (HMF) and furfural which not only reduce the sugar yield but also strongly inhibit the subsequent fermentation process to produce bioethanol.

Solid-Phase Reactive Separation System (SPRSS) has been proposed in our previous work (Kanchanalai et al, 2014) which can potentially improve sugar yield and less byproduct formation from biomass saccharification process via acid hydrolysis. This process integrates the progressing batch reactor (PBR) proposed by Wright et al (1988) and simulated moving bed chromatography (SMB) which has been applied for sugar-acid separation (Xie et al, 2005). Both processes have similar principles of the switching of all liquid inlet and outlet ports to imitate the solid phase movement. SPRSS could also be applied to other system that involves solid reactants.

This work presents dynamic modelling of the PBR system as part of the full PBR-SMB process. Unlike SMB chromatography models which have been developed and validated with numerous operating schemes in past studies, dynamic modelling of the PBR operation is not well-established. Several steps in cyclic operations for PBR such as emptying and loading the solid biomass require several assumptions that need to be

carefully analyzed. We demonstrate that the countercurrent model can represent the dynamic operation of PBR with sufficient accuracy.

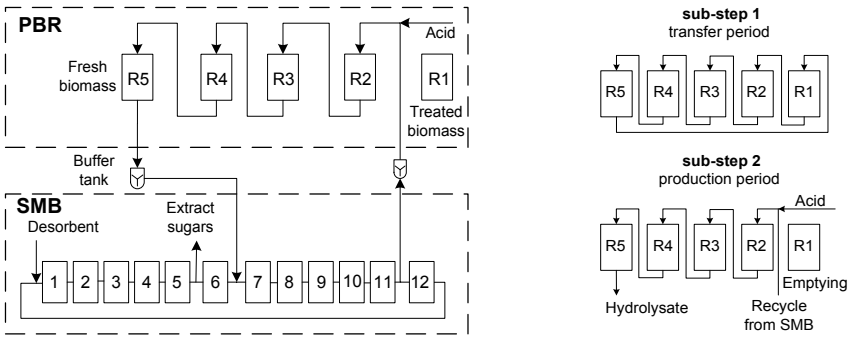

Figure 1. (a) Sequential design of PBR and SMB, (b) PBR operation in sequential design.

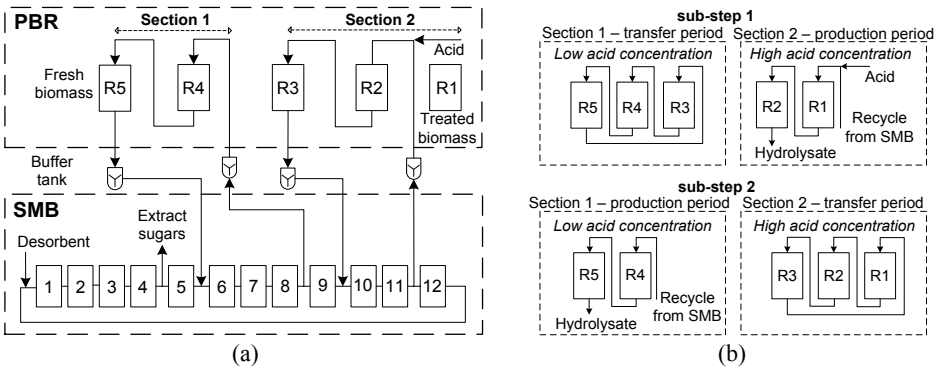

Figure 2. (a) Optimal SPRSS design found from superstructure in our previous study (Kanchanalai et al. 2014), (b) PBR operation in optimal SPRSS design.

2. Solid-Phase Reactive Chromatographic Separation System (SPRSS)

The integration of PBR and SMB for biomass saccharification via sulfuric acid hydrolysis for two alternative designs are shown in Figures 1 and 2. The PBR and SMB is connected in series without interconnecting stream in the sequential design (Figure 1a) while there are interconnecting streams between PBR and SMB in the SPRSS design (Figure 2a), which was found as the optimal solution from a superstructure based on a countercurrent approximation of the dynamic model. Our previous work shows that the SPRSS design shows the potential of improving sugar yield and selectivity over the sequential design due to the higher flexibility in varying the acid concentration (Kanchanalai et al, 2014). In Figure 1a and Figure 2a, both designs consist of five PBRs and twelve SMB columns where we assume that the system has small buffer tanks to connect all streams between these two processes and no reaction occurs in this tank due to the sufficiently small residence time. These tanks are to ensure that the component concentration of the feed streams from the PBR to SMB and that of the recycle streams from the SMB to PBR are constant.

In this study, we validate the countercurrent approximation for the SPRSS model. The dynamic model of SMB chromatography has been well established where the operating parameters can be estimated from that of true moving bed model with proper conversion. A good comparison of the concentration profile between the SMB and true moving bed model have been previously demonstrated (Schmidt-Traub et al, 2013). For the reactor system, on the other hand, such a study cannot be found, while the principles of the process operation is similar to SMB. Several assumptions must be made for the PBR operations such as the biomass filling and emptying steps, which are not captured in the steady state countercurrent reactor model. In this work, we propose two biomass filling and dumping operation corresponding to the two PBR-SMB designs illustrated in Figures 1b and 2b where the operating parameters from the steady state countercurrent reactor model can be used to estimate that of PBR. The dynamic modelling of the PBR including biomass filling and emptying steps is presented in the next section.

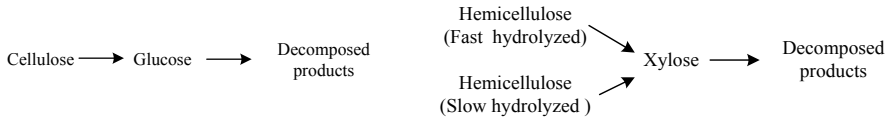

Figure 3. The biomass hydrolysis reaction scheme for cellulose (a) and biphasic hemicellulose (b)

2.1. Dynamic Modelling of the Progressing Batch Reactor

In this work, the biomass is assumed to contain both cellulose and biphasic hemicellulose where the hydrolysis reaction mechanism is shown in Figure 3, and the kinetic model proposed by Saeman (1945) is implemented for all reaction paths which depends on temperature and acid concentration.The mathematical model of a single percolation reactor has been present by Kim et al (1994). In this work, the PBR contain a series of percolation reactors where the mass balances of each component in the solid and liquid phase shown in Eq. (1-2) are applied.

$$\frac{\partial B(x,t)}{\partial t} = r \tag{1}$$

$$\frac{\partial C(x,t)}{\partial t} + u^{PBR}\frac{\partial C(x,t)}{\partial x} = D_{ax}\frac{\partial^2 C(x,t)}{\partial x^2} + r \tag{2}$$

where r is the reaction rate, u^{PBR} is the liquid flow rate in the PBR, and B and C are the solid and liquid component concentration, respectively. It should be noted that the countercurrent reactor approximation can be obtained by replacing $dt = dx/v$ in Eq.(1) where v is the solid velocity, and setting the time derivative term in Eq.(2) to be zero. The above model given in Eq. (1-2) also considers the axial dispersion in the liquid phase with Danckwerts boundary conditions (Schmidt-Traub et al, 2013) where the axial dispersion coefficient D_{ax} is set to 1.4×10^{-4} $\mathrm{m^2/s}$ for all components. In this work, an identical operation shown in Figure 1b or Figure 2b is repeated while performing the liquid port switching in the downstream direction, resulting in a symmetric and cyclic operation. In such an operation, the concentration profiles at the end of each step are identical to those at the beginning of the same step where the entire profiles are shifted in the downstream direction for the length of a one reactor chamber (Kawajiri &

Biegler, 2008). We assume that at $t = 0$, the fresh biomass is loaded at a given initial biomass concentration and is filled with fresh water, and thus the initial liquid concentration of all components are zero.

2.2. Biomass Filling and Emptying

The operations of the biomass filling and emptying steps could significantly affect the sugar concentration and yield from the hydrolysis reaction. In this study, we include the biomass filling and empting step by dividing the PBR operation in each step into two sub-steps consisting of the production period and the transfer period. The PBR in the sequential design (Figure 1b) has the same liquid residence time inside all reactors since there is no interconnecting stream. On the other hand, for the PBR in the SPRSS design (Figure 2b), the process is divided into two sections which have two and three percolation reactors. By having the interconnecting streams between PBR and SMB, the reactor system can have different liquid residence time as well as acid concentration in each section. At the beginning of a step in these two designs, the fresh biomass is filled in R5, which is filled with fresh water while the treated biomass stays inside R1.

The first sub-step of the PBR operation in the sequential design illustrated in Figure 1b corresponds to the transfer period where the acid in R4 flows to hydrolyze the fresh biomass in R5, while the water in R5 goes to R1 which contains the treated biomass. The second sub-step corresponds to the production period where the external fresh acid and the recycle stream from SMB is fed to R2 and the hydrolysate is produced at R5. The treated biomass filled with water inside R1 is also dumped at this step.

For the PBR system in the SPRSS design which has two sections shown in Figure 2b, the transfer and production period occurs simultaneously at different section. In the first sub-step, the transfer process occurs in section 1 (R3-R4-R5) while production process happens in section 2 (R1-R2). In section 1, the liquid with low acid concentration is transferred to hydrolyze the fresh biomass in R5 while the water in R5 goes to the R3. Meanwhile, in section 2, the liquid with higher acid concentration from the fresh acid stream and the recycle stream from SMB are fed to R1 to hydrolyze the treated biomass and the hydrolysate is produced at R2. In the second sub-step, the transfer process is switched to occur in section 2 (R1-R2-R3), while the production process takes place in section 1 (R4-R5). In section 1, the recycle stream from SMB is fed to R4 and the hydrolysate is produced at R5. For section 2, the water in R3 is moved to the R1 before being dumped with the treated biomass. It can be seen that a different number of reactor chamber is allocated in each section. In this operation, the hydrolysis condition of the partially treated biomass in R3 is switched from a low to a high acid concentration and is exposed to a different liquid residence time.

In this proposed filling and dumping the biomass, the operating parameters from the steady state countercurrent reactor model including the liquid interstitial velocity (u_{CCR}) and the biomass interstitial velocity (v_b) can be directly converted to the operating parameters of PBR including the overall switching time (t_{swt}), transfer period (t_{prod}), production period (t_{tran}), and the interstitial velocity of liquid phase (u_{PBR}) from the following equations:

$$t_{swt} = \frac{L_R}{v_b} \tag{3}$$

$$u^{PBR} = u^{CCR} + v_b \tag{4}$$

$$t_{prod} u^{PBR} = t_{swt} u^{CCR} \tag{5}$$

$$t_{tran} + t_{prod} = t_{swt} \tag{6}$$

In the case of SPRSS design when there are two sections inside PBR process, we assume that $t_{tran\text{-}substep1} = t_{prod\text{-}substep2}$, where $t_{tran\text{-}substep1}$ and $t_{prod\text{-}substep2}$ are the duration of the sub-steps shown in Figure 2b.

3. Problem Formulations and Numerical Approaches

This work focuses only on the PBR subsystem for two designs shown in Figures 1b and 2b where the reactor performance is compared with that of the steady state countercurrent reactor. The dynamic models of the PBR with the biomass filling and emptying sub-step for both designs are formulated in the GAMS modeling environment discretizing the time domain with six finite elements by the Radau collocation, and spatial domain with 60 elements by the centered finite difference method. The simulation problems of these two designs are solved where the flow rates and the concentration of all feed streams including the fresh acid and the recycle streams from SMB are fixed at the values in the optimal solutions obtained from the steady state countercurrent reactor and true moving bed chromatography model. The relationship in Eq. (3-6) are used to estimate all operating parameters of the PBR. All values of the model parameters can be found in our previous study (Kanchanalai et al. 2014).

4. Results

The comparison of the reactor system in the sequential and SPRSS designs between the countercurrent reactor and PBR are shown in Table 1. From the table, the conversion of the biomass in both designs between the countercurrent reactor and PBR are very close to each other. However, the sugar yield at the outlets of the PBR is lower than that from the countercurrent reactor. This is mainly because there is some amount of sugar lost during the biomass emptying step.

Figure 4 shows the concentration profile of the liquid phase for SPRSS design at the $t = t_{swt}$ before emptying the biomass in R1. From the figure, it can be seen that there are some amount of sugars and other components remaining inside R1 which are lost when emptying the biomass. Our investigation shows that these losses are caused by the axial dispersion. During the transfer periods of SPRSS (see Figure 2b) where the fresh water is transferred from R5 to R3 in sub-step 1 and then from R3 to R1 in sub-step 2, the sugars and other components diffuse into this portion of water. Consequently, the loss of these components during dumping the treated biomass with the liquid in R1 is inevitable. This phenomenon is not captured in the countercurrent reactor model. The sugar lost during biomass emptying can be recovered later by the SMB system or another separation process. By assuming these sugars can be fully recovered, the total reaction sugar yield (see Table 1) for both designs are higher than that predicted from the countercurrent reactor. The reason for this is that there is a dynamic variation in acid

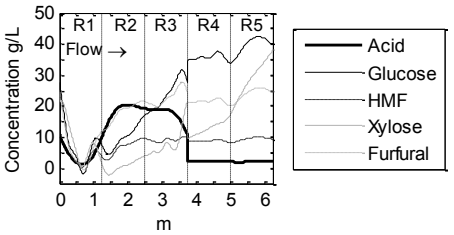

Figure 4. PBR concentration profile in the SPRSS design at $t = t_{swt}$ before biomass emptying.

Table 1. Performance comparisons between the countercurrent reactor and PBR

	Sequential Design		SPRSS Design	
	Countercurrent	PBR	Countercurrent	PBR
Biomass Conversion	85.3 %	84.1 %	94.5 %	94.2 %
Sugar Yield at Outlet	60.7 %	57.8 %	67.9 %	61.5 %
Sugar Lost in Emptying Step	-	10.9 %	-	17.3 %
Total Reaction Sugar Yield	60.7 %	64.9 %	67.9 %	74.3 %

concentration resulting from the axial dispersion in PBR which causes different reaction kinetics compared to that in countercurrent reactor. From the results, the byproduct formation in PBR is observed to be lower than that in countercurrent reactor. The performance of PBR with the proposed biomass filling and emptying steps can be partially predicted using the countercurrent reactor model.

5. Conclusions

The dynamic model of PBR in SPRSS is formulated and the biomass filling and emptying processes are proposed. The operating parameters of the PBR with the proposed configuration can be obtained from the proper conversion of the countercurrent reactor operating parameters. The results shows that the performance of the PBR process can be partially predicted from that of countercurrent reactor where the difference comes from the dynamics that are not accounted for in the countercurrent model. In future work, the full dynamic model of SPRSS with PBR and SMB will be optimized to find the optimal process configurations where the performance results from the proposed biomass filling and emptying steps can be used as an initial guess for the optimization problem.

Life Cycle Simulation for a Process Plant based on a Two-Dimensional Co-Simulation Approach

Mathias Oppelt[a*], Gerrit Wolf[a], Leon Urbas[b]

[a]*Siemens AG, Oestliche Rheinbrueckenstr. 50, 76187 Karlsruhe, Germany, oppelt.mathias@siemens.com*
[b]*University of Technology Dresden, 01062 Dresden, Germany*

Abstract

Simulation plays an important role at multiple stages within the life cycle of a process plant. We expect that in the future, simulation will be integrated into the plant life cycle and will form the backbone of a more integrated engineering process. Engineering creates a virtual plant capable of simulating different aspects and domains. As each specific domain usually requires certain simulation capabilities, multiple specialized simulation tools are used along the life cycle. The ability to reuse existing simulation models throughout the life cycle would be very beneficial. This paper investigates the existing standards for model reuse and co-simulation and describes a basic implementation for co-simulation based on OPC, shared memory and .NET technology.

Keywords: Process Simulation, Virtual Commissioning, Operator Training, Co-Simulation, Model Integration, Process Automation

1. Motivation

The complexity of modern process plants is constantly increasing, and with it the challenges facing the engineering and operation of such plants. The use of simulations can be beneficial to investigate engineering and operational questions without the availability of an actual plant. Today, simulation is already utilized at particular stage swithin the life cycle of a process plant, for instance during the design phase (Bausa and Dünnebier, 2006). At a later stage,it is used for virtual commissioning to test the automation system (Oppelt and Urbas, 2014) and for operator training (Cox et al., 2006). In the operation phase, simulations can be used as assistance systems. Even though the benefits of time, and cost savings, increased quality and improved safety are promising, the use of simulation as an integrated part of the plant life cycle is not standard procedure. Reasons for this include in particular the effort involved in developing simulation models and the fact that the decision to use simulation is not taken from a life cycle perspective (Oppelt et al., 2013; Klatt and Marquardt, 2009). In view of these issues,the reuse of simulation models across the life cycle (horizontally) would be beneficial in bringing about more integrated use of simulation.

Furthermore, different simulation models can represent various parts of the plant. An automated process plant typically includes components such as the distributed control system (DCS), the signals and bus systems, the actuators and sensors and the process. To createa complete virtual plant, these levels must all be available within a simulation model. Consequently,the integration of different simulation models across these levels (vertically) is essential. For further work on the comparison of different model abstraction levels, please refer to (Oppelt and Urbas, 2014).

As simulation models can be realized in different tools, the availability of co-simulation approaches to support a vertical and horizontal coupling of simulation models implemented in different tools is also investigated. This evaluation is based on the requirements for co-simulation such as execution control, data exchange, configuration and management of simulations. The paper compares the ability of the Functional-Mock-Up-Interface (FMI; Modelisar, 2010), Cape-Open (CO; Peshev and Livingston, 2013), IEEE High-Level Architecture (HLA; IEEE, 2010) and Open-Service-Gateway-Initiative (OSGI; McAffer et al., 2010)to fulfill co-simulation needs. In addition, a minimum implementation for a co-simulation setup is described.

The paper investigates the gap between design simulations focused on process modeling (Bausa and Dünnebier, 2006) and simulations for virtual commissioning and operator training(Oppelt and Urbas, 2014). The availability of a suitable co-simulation approach for all simulation use cases along the plant life cycle would enable the greatest possible reuse of existing work and so maximize the return.

2. Aspects of model exchange and co-simulation

2.1. Co-simulation concepts

There are basically three different implementation concepts for model exchange and co-simulation. One solution is to describe the model behavior in a *common mathematical language* (e.g. differential equations). A simulation tool then interprets and solves the equations. This concept of model exchange is realized by exporting and importing models. The work of Schopfer et al. (2004) is an example of this approach.

Co-simulation can be defined as *tool coupling*. In this case at least two independent simulation tools work in parallel and simulate a combined model. The exchange of data and synchronization between the tools are the responsibility of a simulation master. This is either one of the involved tools or a separate application. This principle is used, for instance,by the HLA framework which is described in section 3.2. In contrast to model exchange, this concept includes the connection of the model interfaces but also an interface for control of the simulation tools. The simulation master is responsible for the consistency and the timing of the simulated data within the model. It therefore monitorsthe status of the machines and tools, and also starts, stops and synchronizes the separate processes. Usually this concept is based on proprietary interfaces, but allows all the domain-specific strengths of the involved tools to be used.

A third concept results from a synthesis of both techniques. This is used, for instance, by the FMI (see section 3.1). This is a kind of a *hybrid solution*, where a simulation unit including model and solver is integrated into another simulation tool.

2.2. Co-simulation use cases

The most prominent co-simulation use case involves coupling different simulation tools to simulate certain parts of the plant in one tool and other parts in different tool (see figure 1). As the real plant consists of many different components and processes, so does the virtual plant. For different aspects of the virtual plant, different simulation tools are utilized which need to be combined to realize a complete virtual plant model. This entails the need for a central control, which should also be capable of providing a snapshot of all coupled simulations. A snapshot preserves a certain state of the simulation and enables the user to recreate this state at a later point in time. Advanced

co-simulationis capable of coupling tools dynamically during runtime and also exchanging models during runtime (Oppelt et al., 2013).
A complex aspect of co-simulation is that models can be realized on different levels of abstraction (Oppelt and Urbas, 2014), but need to be combined. The co-simulation environment therefore needs to support data exchange across all abstraction levels. On the detailed finite level, for instance, simulators would also need to exchange data about chemical media. Co-simulation requirements can be differentiated according to three different aspects: (1) simulation execution control, (2) simulation data exchange and (3) configuration of the co-simulation environment.

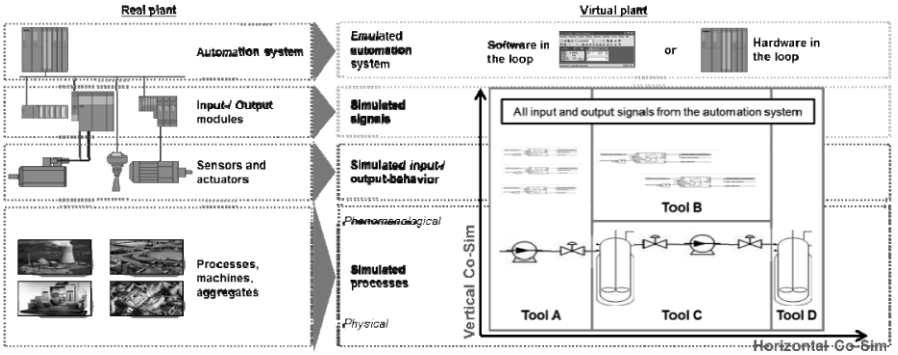

Figure 1: Co-simulation scenario showing vertical and horizontal tool coupling

2.3. Simulation execution control

Co-simulation provides benefit of bringing together a large number of simulation models of different origins. On the system level this "capability comes with the cost and complexity of coordinating all of the computing platforms for the startup, execution, shutdown and artifact collection of the simulation execution." (Snively et al., 2013) On a more detailed level, execution control is concerned with the step-by-step coordination of partial models, to ensure synchronized calculation of the different models.

2.4. Simulation data exchange

The coupled simulation systems need to exchange data during runtime within discrete time steps. This entails exchanging a predefined set of tags or values through standard interfaces. For pure data exchange standards such as OPC DA or shared memory,the technology already exists.

2.5. Configuration of the co-simulation environment

Configuration of the co-simulation environment should be as effortless as possible. Ideally, the standard supports a plug-and-play methodology to connect different simulation systems. The configuration and management tasks include selecting the required resources for the simulation scenario, organizing the resources to build the execution system, and collecting the simulation data.

3. Existing work on co-simulation approaches

There is wide-ranging literature available on co-simulation, including for instance (Yang et al., 2013; Oppelt et al., 2013; Schopfer et al., 2004). In most cases, the existing literature describes a specific implementation and its challenges. This section will compare approaches to co-simulation. The approaches compared were selected on the

basis that the standard can be found in multiple publications and is already used in industrial applications.

3.1. Functional mock up interface (FMI)

The Functional Mock-up Interface (FMI) is designed to be a tool-independent standard to support model exchange and the co-simulation of dynamic models (Modelisar, 2010). The FMI 1.0 standard was first published in 2010. The primary goal was the standardization of model exchange between different simulation tool vendors. A new version 2.0 was published in July 2014. The focus of this version shifts to unit exchange. The concepts of FMI can also be implemented around existing tools similar to a wrapper function.FMI 1.0 mainly addresses the concepts for model and unit exchange. Nevertheless, it is also possible to implement tool coupling with the FMI standard. The specification of FMI focuses on input/output behavior and allows for black box modeling, allowing it to be easily used for simulation on the system and network level. However, it does not support complex and detailed simulation on the finite element level, which is necessary for chemical reaction simulation.

3.2. High Level Architecture (HLA)

High Level Architecture (HLA) is an IEEE standard for modeling and simulation (IEEE 1516). It describes a framework for distributed modeling and simulation by defining connections and interactions between systems (Fujimoto, 2010; IEEE, 2010).

First developed by the American Defense Modeling and Simulation Office, HLA is mainly used for military simulation systems. An HLA system, which is called a federation, consists of one Runtime Infrastructure (RTI) and several connected simulation units, called federates.The HLA specification defines the communication behavior between the components and the RTI. The concept therefore equates to a tool coupling concept in which the RTI is the master of the simulation partners. HLA is an event-based architecture in which the RTI controls and synchronizes all communication between the federates.

3.3. Cape-Open

The Cape-Open (CO) standard was developed for process simulation, both stationary and dynamic (Braunschweig and Gani, 2002). CO provides open, multi-platform interfaces for process unit operations, physical properties, reaction kinetics and numerical solvers. They are maintained by the user-driven organization CAPE-OPEN Laboratories Network (www.colan.org). Major process modeling environments for the process industries have implemented CO interfaces.

3.4. OSGI framework for simulation

The OSGI framework (Open Service Gateway Initiative) was originally designed for component-based software development. It is based on the Java programming language and represents a modular and component-based software standard whose services (bundles) are offered by a dynamic runtime system (McAffer et al., 2010).The bundles of an OSGI framework can be dynamically loaded, unloaded, updated or exchanged during runtime without shutting down the OSGI framework. In the context of a distributed simulation environment, the framework offers remote service plug-ins for communication between different OSGI framework instances on a local computer or on different computers in a network. To enable the OSGI framework as a dynamic and distributed co-simulation framework, a software architecture needs to be developed. Simulator couplers are required to connect simulators. A simulator coupler implements the interface of the simulator for data exchange, synchronization and control flow during co-simulation. For an implementation example, refer to Oppelt et al. (2013).

3.5. Comparison of co-simulation approaches

Table 1 provides a detailed comparison of these four approaches. The results show that no approach currently fulfills all requirements for complete horizontal and vertical coupling of simulation models. The FMI standard is mainly used in discrete applications using Modelica as specific modeling language. HLA focuses its application within the defense industry. CO is used within process industries,where it is deployed for coupling process simulations. CO covers a wide range of interfaces necessary for co-simulation on a network and finite level. The emphasis is clearly on simulation for process design, real-time aspects are not addressed. In comparison, FMI and HLA focus on the co-simulation of models on the system and network level, missing the opportunity to couple finite process models. However, FMI and HLA also support real-time aspects.

Table 1: Comparison of co-simulation approaches

Criteria	Compared standards			
	FMI	HLA	CapeOpen	OSGI
Simulation execution control				
Central start, stop, pause execution control	x	x	PME	x
Virtual time (fast-, slow mode)	p	p	p	p
Real-Time Capabilities	x	x		p
Synchronization	x	x	x	x
Error handling	p	p	x	x
Dynamic model exchange at runtime		p		p
Snapshots (save, load)	x (2.0)	p	PME	p
Simulation data exchange				
Open standards (e.g. OPC)	x		x	x
Shared memory	p			p
TCP / UDP		x	.NET/CORBA	x
Configuration and management				
Simulation project management	p	p	PME	p
Distritution among network	x	x	x	x
Configuration files/tools for automatic setup	p	a	p	p
Know-how protection	x	x	x	p
Model abstraction levels				
Signal level	x	x		x
System level	x	x		x
Network level	x	x	x	x
Finite level			x	x
Standard independence				
Use across industries	Discrete	Military	Process	x
Driven by indepentend organization	Modelica	IEEE	COLAN	OSGI Alliance
Multiple operation system support	x	a	x	x

x: adressed by standard - out of the box use; p: possible by manual implementation; a: third party add on; PME: Process Modelling Environment

Usability is another important aspect. OSGI as a Java framework would not be usable off the shelf without adaptions. Because the effort involved in implementing a federation within HLA is quite complex, HLA has a very high entry threshold and expects any industry application to use the same RTI, which limits flexibility.

Regarding simulation execution control and data exchange, all standards provide good functionality. FMI and OSGI provide the highest functionality on these levels. HLA is limited as regards data exchange, as it only supports TCP/UDP.

4. Minimum implementation of a co-simulation approach

A minimum implementation for a dynamic simulation control system is described in the following. The data exchange between different simulation tools is realized by using either an OPC DA or a shared memory interface. The simulation tool Simit (www.siemens.com/simit) is used as the basis for the implementation. As the data exchange options can be seen as standard technology, the focus will be on the remote control interface usable for dynamic simulation control (Siemens, 2014).The remote control interface (RCI) was developed using .NET technology and is based on the Windows Communication Foundation (WCF). Within the RCI, a handshake protocol was implemented with two different operating modes: synchronous and asynchronous. The interface provides parameters of the control system (e.g. speed) for interface

configuration, and also a set of feedback parameters (e.g. error codes). In addition,information parameters such as the system state, time or the sync mode are provided. Service calls are used to establish or terminate connections between different simulation systems. A live beat supplies information to all the involved tools about the status of the overall system. The interface implementation provides simulation control functions to open or close a project, to open, close, reset, initialize, start or stop a simulation as well as to set the simulation time or calculate only a single step.In addition, interface commands to create or load snapshots are available. For a detailed description of a minimum implementation see (Siemens, 2014).

5. Conclusion and outlook

The paper investigated the current work on co-simulation and illustrates that no real industry wide co-simulation standard currently exists. The availability of co-simulation approaches is limited to specific industries or to specific tools. The paper also looks at closing the gap between design simulations focused on process modeling and simulations for virtual commissioning and operator training. A co-simulation standard would therefore allow theintegrated use of simulation along the plant life cycle with the maximum reuse of existing work. In respect of modular plants and package unit integration, this standard could also form the basis for simulation model integration which is as simple as the integration of a module into the real plant.

Abstract

This work presents a novel systematic approach for the construction of domain ontologies. The suggested approach uses a semi-automatic construction methodology. For this study, parent-child concept pairs are taken from a previous work. Novel contributions include building and completing branches, introducing new relations, and resolving inconsistencies and contradictions. For the process systems engineering (PSE) domain the ISA88 Standard is chosen as a promising starting point for automatic text processing. Finally, this work concludes with a discussion of the ISA88 Standard based on the conclusions that can be obtained from the application of this semi-automatic construction methodology.

Keywords: Domain Ontology, Automatic Ontology Construction, Ontology Construction Methodology, ISA88, Standards.

1. Introduction

There has been a growing interest in the field of PSE for using ontologies as knowledge models (Muñoz, 2011), intelligent data analysis of databases (Roda and Musulin, 2014), intelligent software applications (Morbach et al., 2010) and many other applications, each one using different ontology models. The use of a general domain PSE ontology based on already existing and accepted standards would not only facilitate the development of these and other applications, but also their integration and coordination. Departing from the parent-child concept pairs resulting from a previous work (Farreres et al., 2014), this work describes the systematic procedures used to refine the relationships to be modelled in the core of the ontology. Particularly, an ontology can be defined as "an explicit specification of a conceptualization" (Gruber, 1993). In the field of Computer Engineering, large ontologies for common knowledge have been developed together with tools based on internet databases, reference books and many documents from the Internet

(Vivaldi and Rodríguez, 2002). This is expected to lead to semi-automatic procedures to help experts to develop domain ontologies, although a great effort is still required to filter the noise obtained from extensive indiscriminate searches.

In parallel, expert teams have devoted a commendable effort to produce standards. Using language analysis tools, and in order to combine efforts for creating domain ontologies, the texts defining standards seem very well suited to be taken as a source to synthesize manual and automatic approaches in the most efficient way. Thus, the aim of this work is to investigate the semi-automatic development of domain ontologies in general, and to validate the hypothesis that a document defining a standard is an efficient starting point from which the ontology may be later extended and enriched.

The ISA88 Standard for batch control is a document that is assumed suitable for creating a domain ontology because it is a technical document clearly defining models and terminology, including the explanation of processes, data structures and language guidelines. The assumption is that intelligent selection of texts will reduce noise and allow fast and straight identification of concepts and relations.

In a previous work (Farreres et al., 2014), the ISA88 document was processed using a number of tools, and a set of concept pairs were extracted and manually revised. Each pair was a proposed relation, either between a parent concept and its children, or between a concept and its parts. This study is a continuation of such preliminary work for building a domain ontology. This building process is explained in a systematic way describing the suggested methodology and the quality of the resulting ontology is assessed.

2. Methodology

Common strategies for identifying concepts for a domain ontology manage concepts from the most specific ones to the most general ones (also reverse) or from the most important concepts to the most specific and most general ones (López, 1999 and Corcho et al. 2003). Conversely, this work identifies the concepts from a technical standard that is considered the basis for the domain. As a result, the proposed construction methodology is significantly different from the other strategies, and the ontology is built from these identified concepts by using a semi-automatic construction methodology. The following sections present a brief description of the steps of the methodology.

2.1. Phase-1: Building branches by composing parent-child concept pairs

A core ontology is built using parent-child concept pairs from Farreres et al. (2014). In the case of ISA88 Standard 266 concepts are added with 188 ‘is a’ relations. The ontology is enriched with the meronymy (‘partOf’) relations and 81 doubtful cases are left apart.

2.2. Phase-2: Doubtful cases, introducing ‘partOf‘ relationship and information from the figures in the standard

First, doubtful parent-child concept pairs (e.g. concepts with ‘and’ and ‘or’) are identified and solved manually. Next, graphical information is extracted by a human expert and the newly detected relations and concepts are introduced to further enrich the ontology. The ISA88 Standard contains figures that cannot be processed via automatic pattern matching owing to the fact that figures cannot be processed by the computers. This is revealed as a

difficulty for the automation of the process and it is solved manually processing the standard by a human expert.

2.3. Phase-3: Adding commonsense and ontology pruning

Until Phase-3 knowledge introduced in the ontology was all from the text and graphics of the supporting Standard. However, this may include neither commonsense nor the knowledge shared within a domain that must not be conveyed in a text because of its obviousness. After Phase-1 and Phase-2, conceptual gaps occur as consequence of the lack of explicit commonsense knowledge in the text.

Some simple and straightforward cases of commonsense knowledge are then addressed using a set of pre-established rules for introducing implicit information that can be understood without any explanation. A particular case is identified and solved following the rules 1 and 2. Thus, the UnitRecipe concept, composed of two nouns (1), would be moved as a child of Recipe; and RegulatoryControl, composed of an adjective and a noun (2), would be moved as a child of Control. 141 concepts were refined in this way and additional 'is a' relations are added to the ontology.

$$\text{Noun}_A + \text{Noun}_B \xrightarrow{\text{'is a'}} \text{Noun}_B \quad (1)$$

$$\text{Adjective}_A + \text{Noun}_C \xrightarrow{\text{'is a'}} \text{Noun}_C \quad (2)$$

Another particular case led to the creation of additional 'partOf' relations. Container, Combination, and similar concepts are often extracted as parent concepts from 'is a' relations. However, these concepts indicate the aggregation of further concepts. In this case the actual relation that correctly represents the model is not an 'is a' relation, but a 'partOf' relation. In the case of the ISA88 based PSE ontology, 20 concepts were refined concluding with adding 34 new 'partOf' relations and 22 new concepts.

Another case of commonsense rule will lead to the identification (Zhu et al., 2009) and elimination of redundant relations already presented by other relations.

3. Example of methodology (GeneralRecipe segment)

Figure 1 shows the 'is-a' segment originating in GeneralRecipe after Phase-1 and Phase-2. It is next used as an example to discuss the methodology steps detailed as follows:

i). Container, Collection and Combination concepts: Figure 1 shows GeneralRecipe as a subconcept of Container. As explained in Section 2.3, Container is better modelled by a 'partOf' relation. Figure 2 shows the new added 'partOf' relations.

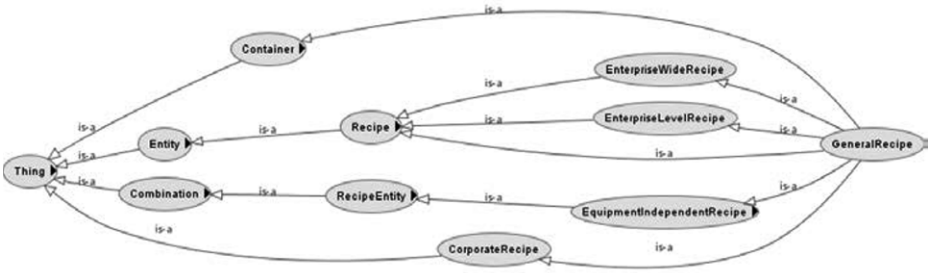

Figure 1. GeneralRecipe segment after Phase-1 and Phase-2

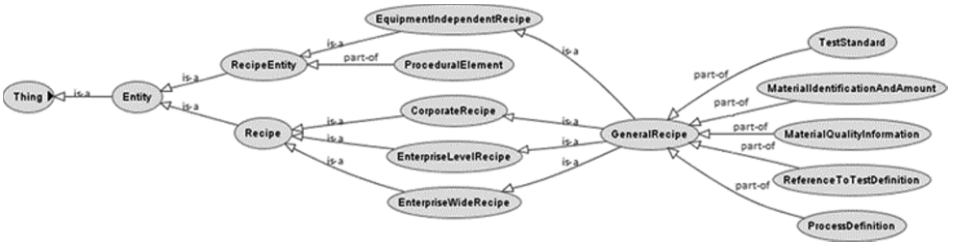

Figure 2. GeneralRecipe segment after Phase-3 (Only 'is a' and 'partOf' relations related with GeneralRecipe segment are represented, in case of clarity)

ii). Introducing commonsense knowledge: In addition, concepts given by compound nouns need reviewing (Section 2.3). For instance, it is apparent that the EnterpriseWideRecipe concept should be moved as a child concept of Recipe as shown in Figure 3a as before. Figure 3b shows the result.

iii). Removing redundant relations: Since there are two ways to reach Recipe from GeneralRecipe, the relation between GeneralRecipe and Recipe can be removed. This redundant relation is shown in Figure 3b.

Finally, Figure 2 shows the final diagram after implementing the proposed methodology.

4. Quality measure results

The direct pattern matching of the raw text after Phase-1 and Phase-2 results in a flat ontology (Figure 4a), lacking commonsense. Although there are no standard metrics for the quality of ontologies, some topological information have been used for measuring. One topological aspect taken into account is the width and depth of the ontology. Figure 4b shows a partial snapshot of the ontology after Phase-2 and Phase-3. It is clear that the first ontology is flat while the second one is deeper and tree-like, which has been considered as a sign of quality and improvement.

Additionally, Figure 5 shows the differences in the number of concepts per level after each Phase. Phase 1 generates an ontology that has most of its concepts at depth 2. After Phase-2 the number of concepts increases but there are few concepts below depth 2. After adding commonsense, the distribution is more reasonable, with a spread number of concepts between level 1 and 4, and a significant queue arriving to depth 6.

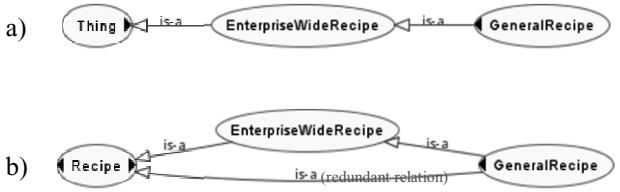

Figure 3. Redundant relations. a) Before introducing commonsense knowledge b) After introducing commonsense knowledge with redundant relation

a)

b)

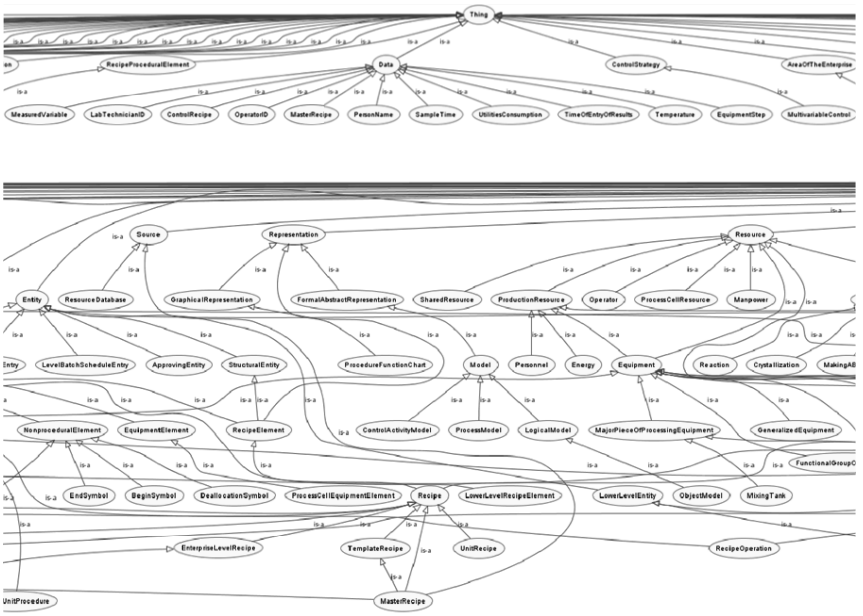

Figure 4. Depth of the ontology. a) After Phase-2. b) After Phase-3

Finally, the improvement obtained by using a text defining a standard (regarding the reduction of noise) is an assumption that can be hardly validated in a quantitative and systematic way. However, the use of another text could provide an illustrative reference. Towards this end, the same methodology was used to process a play of Shakespeare (1611) and nothing was produced: no pattern for the 'is a' or the 'part of' rules is found in the text.

5. Conclusions and future research

This paper proposes a semi-automatic methodology for building ontologies, presents most of the concepts of batch control in PSE by using the ISA88 Standard, and introduces commonsense knowledge to the ontology. The use of technical standards for building domain ontologies has been assumed. Another significant outcome raised in this study is the human expert introduction to the automatic ontology construction. An additional interesting result is that other relations ('input' and 'output') have been detected in addition to the 'is a' and 'partOf' relations for the enrichment process of ontology.

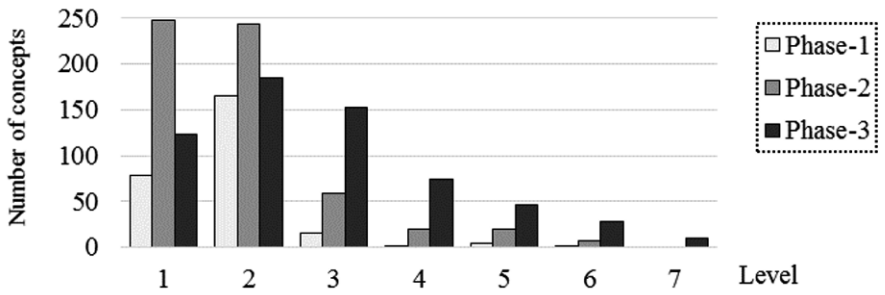

Figure 5. Number of concepts per level

Moreover, the ISA88 Standard consistency could be assessed from the point of view and formalisms of ontology development, and conclusions and guidelines for producing technical standards have been obtained. This includes ambiguous figures, undefined concepts, extended use of synonymy, and use of adjectives in the document which have been identified as problems, not only for the implication of automatic processes, but also for human readers. This contributes an analysis and suggestions for developing technical standards. On the other hand, the ISA88 Standard should be considered as a first case study for a research line, and the learning outcomes from this work are expected to be of practical interest to further ontology developments from other documents (e.g. ISA95).

Further work in this research line includes the enrichment of the ontology by extending the present semi-automatic development of domain ontologies for PSE using other technical documents and automatically searching the Internet to get implicit knowledge. The outcome of this systematic procedure could afterwards be compared to already existing ontologies of the same domain developed manually (Muñoz et al., 2011). Using some similarity metrics in order to validate their completeness. Hence, relevant feedback could be retrieved in order to further improve the systematic approach presented. Furthermore, the findings of this study provide information for developing the methodology as well as improving quality of resulting ontology from ISA88 Standard.

Abstract

Population balance modeling is a widely used approach to describe, crystallization processes, taking into accountnot only the primary phenomena like nucleation and growth, as well asparticle agglomeration and breakage which can be extended to multivariate cases where more internal coordinates i.e. particle properties can be used. The solution of the generated partial differential equation is not trivial due to its hyperbolic nature which causes numerical dispersion and diffusion. The high resolution finite volume algorithms are able to solve multidimensional population balance equations avoiding these unwanted phenomena. Unfortunately, the computational time is significantly larger, compared to e.g. moments based solutions. More recently there is an increased interest to apply parallel computations using GPU-s due to its massively parallel hardware architecture. The current study presents two accelerating possibilities for finite volume solution of population balance equations: compiled C++ code executed on CPU and CUDA C++ code running on the GPU. The case studies demonstrate that the code running on the GPU was between 6-35 times faster than the compiled C++ code and 4-6 times faster than the standard MatLab function. This significant improvement in computational time enablesthe application of model-based control approaches in real time even in case of multidimensional population balance models.

Keywords: population balance modelling, simulation, finite volume algorithm, GPU

1. Introduction

The population balance (PB) modelling approach was introduced by Hulburt and Katz (1964) to describe the population dynamics and thence it have been used in numerous fields of science as meteorology, biology, physics, chemistry and engineering. In crystallization, is the general modelling approach enabling the description of particulate properties such as particle size and shape, a variety of theoretical and experimental works appeared discussing its different aspects. For a process engineer, in order to allow on-line process optimization and control, it is crucial to have an accurate model which is solved with orders of magnitude faster than the real process time. In modern particulate sciences it is essential to control the particulate properties like particle size distribution

(PSD) and particle shape as it can affect significantly the product quality and downstream operations.

From mathematical point of view, the PB is a partial differential equation which may involve integral terms if secondary processes like breakage and agglomeration are also included. A variety of solution methods were proposed, each having its advantages and disadvantages. The high resolution finite volume methods (HR-FVM), introduced by Gunawan et al. (2004) are able tosolve numerically PB-seven with agglomeration and breakage moreovercomputes the PSD without numerical diffusion and dispersion. Thus, from modelling point of view the HR-FVM is perfectly suitable for optimization and control purposes, unfortunately the computational costs may become extremely large.The FVM solution stands on PSD discretization, as presented by Figure 1. For more for details about these methods, see the work of Qamar et al. (2006).

A several attempts were made to improve the computational efficiency of the HR-FVM: Qamar et al. (2007) presented an adaptive mesh strategy making possible to reduce the mesh size, Gunawan et al. (2008) proposed the parallel solution using a master/slave structured CPU cluster. Majumder et al. (2010) developed the Fast HR-FVM method which uses a coordinate transformation to speed up the simulation by maintaining its accuracy but Prakash et al. (2013) exploited the Matlab Parallel Computing Toolbox and Distributed Computing Server capabilities to parallelize the HR-FVM codes on CPU-s. In the above presented methods significant speedup was achieved, however, the increased price of the used supercomputers is a major disadvantage. The massive compute capabilities are generally used in different fields of science, Shane Cook (2012), GPU-s were not used to accelerate the PB equations (PBE) solution. Thus, the aim of this work is to apply GPU acceleration for HR-FVMPBE solution.

2. Methods

Here, the method described by Gunawan et al. (2004) is applied using the same Van Leer flux limiter function in three implementations: (i) in the form of Matlab function (ii) C++ code as compiled .mex function called from the Matlab and (iii) parallel CUDA C++ code in form of compiled .ptx running GPU handled by the Matlab's Parallel Computing Toolbox.It should be noted that when developing the implementations, the Matlab embedding capability was a key factor as is the generally used environment in process engineering.The most important properties of the machine are listed in Table 1: low cost devices are used with optimizing compilers which boosts up the performance of compiled codes. In the following parts, the three implementation methods will be discussed shortly.

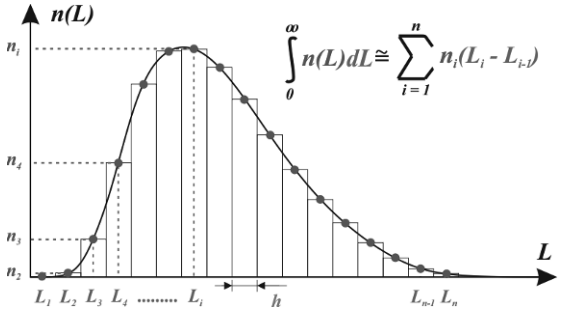

Figure 1. Representation of the finite volume discretisation of PSD

2.1. Implementing in Matlab function

As the MatLab language, due to its flexibility and a variety of engineering applications like Simulink, Optimization Toolbox and Control System Toolbox etc. is widely used in engineering practice, it seems feasible to write the code directly in MatLab language. However, the computational performance compared to the high level programming languages is reduced whichit makes a poor environment for running HR-FVM codes.

2.2. Implementing in C++ code

The C++ language is known as extremely fast high level programming language thus it may be a good environment to implement the HR-FVM. In order to simultaneously profit from the flexibility of MatLab and improved speed of C++, the HR-FVM algorithm is written in C++ code and compiled to.*mex* function, what, in essence, is a special .*dll*which can be called directly from MatLab. The *Gateway function* of the .mex program makes the connection between the MatLab and the crude C++ code. In this case the memory management is handled by the programmer providing extra flexibility when optimizing the program. The operations are still executed serially which, especially for finer meshes can significantly slow down the solution. Parallelizing the code would overload the CPUthus may freeze the machine.

2.3. Implementing in CUDA C++ code

More recently there is an increased interest to apply parallel computing and computations using GPUs, which typically has a hardware architecture consisting of multiple parallel computing units. As the HR-FVM algorithm, from programming point of view is parallelizable, the natural questions rises if the GPU could accelerate the simulation? The Matlab's Parallel Computing Toolbox offers three implementation

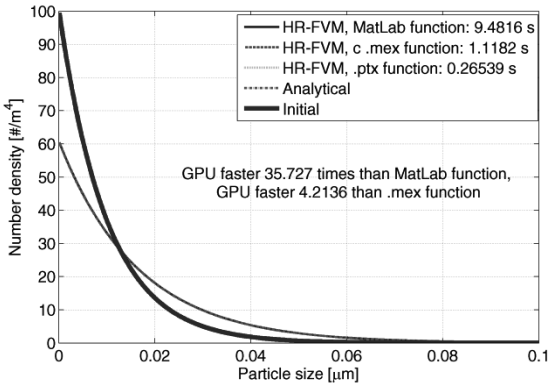

Figure 2. Results of HR-FVM implementations for a constant growth rate problem

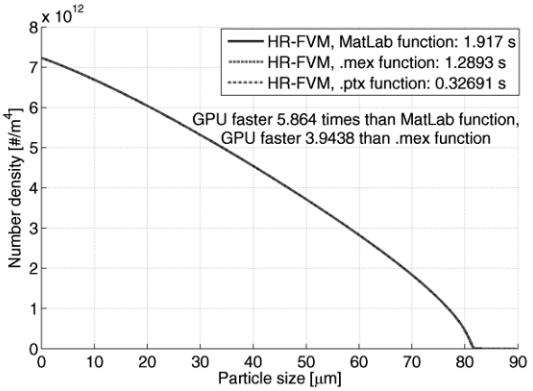

Figure 3. Results of HR-FVM implementations for monodimensional population balance with mass balance, nucleation and size dependent growth

ways to run code on GPU:(i) run built-in MatLab function, (ii) run element-wise MatLab code and(iii) run PTX code as parallel CUDA Kernel object. The PTX code offers the highest flexibility and computing performance which enables for the programmer maximal control of data flow in level of CUDA cores thus here this solution was used. As being the part of Parallel Computing Toolbox, writing a CUDA Kernel object is a comfortable solution for the engineers as the memory management is handled by the MatLab. Consequently, it highly reduces the programming efforts and crude code writing. The parallel code is written by taking into account the specific problems of parallel programming as race conditions and thread synchronization issues.

3. Results and Discussions

The upper discussed three implementations are applied to solve three benchmark cases.These are presented are presented and discussed in the following parts of this article.

3.1. Mono dimensional pure (constant) growth PBE

Let us consider a mono dimensional volume form PB Eq.(1)with growth only:

$$\frac{\partial n(v,t)}{\partial t} + \frac{\partial G(v) n(v,t)}{\partial v} = 0 \tag{1}$$

With$n_0(v) = N_0/v_0 \cdot exp(-v/v_0)$ initial distribution, $G(v)=G_0 v$ linear size dependent growth rate and $n_0(v) = N_0/v_0 \cdot exp[-v/v_0 exp(-G_0 t) - G_0 t]$ analytical solution. Here the parameters given by Gunawan et al. (2004) are used. The results and performance comparison is presented on Fig. 2: the solution curves of numerical solutions practically overlap with

Table 2. Results of HR-FVMimplementations in case solving bi PBE

quantity	MatLab f.	.mex function	.ptx function
μ_{00}[#/m^3]	$2.489 \cdot 10^{20}$	$2.489 \cdot 10^{20}$	$2.488 \cdot 10^{20}$
μ_{10}[μm/m^3]	$7.609 \cdot 10^{21}$	$7.608 \cdot 10^{21}$	$7.605 \cdot 10^{21}$
μ_{02}[μm^2/m^3]	$4.770 \cdot 10^{21}$	$4.770 \cdot 10^{21}$	$4.769 \cdot 10^{21}$
μ_{12}[μm^3/m^3]	$3.523 \cdot 10^{22}$	$3.522 \cdot 10^{22}$	$3.520 \cdot 10^{22}$
Run time (s)	5.1445	0.9954	0.1944

analytical solution. It seems that the C++ code is much faster compared to MatLab function but 4.2times slower than the GPU which can be explained by the fact that all operations are parallelizable which favors for the GPU.

3.2. Mono dimensional PBE with nucleation and growth

A PB with nucleation and growth written for linear particle size take the form Eq.(2):

$$\frac{\partial n(L,t)}{\partial t} + \frac{\partial G(S,L)n(L,t)}{\partial L} = B(S)\delta(L - L_n) \tag{2}$$

This with the corresponding mass balance and temperature profile is a batch crystallization model.In simulations, $n_0(L)=0$ initial distribution, the growth rate is $G(S,L)=0.18\cdot(S-1)^{0.6}(1+0.005\cdot L)$μm/s and$B = 2.64\cdot10^{12}(S-1)^{1.58}$#/m^{3}s nucleation rate is used where S denotes the supersaturation ratio. The temperature dependent solubility is described with $c_s=0.1286-5.88\cdot10^{-3}T+1.72\cdot10^{-4}T^2$equationand the solution is cooled from 32 to 18°C with is 1 °C/min rate.Adaptive time stepping is used to ensure the numerical stability of the algorithm. The results are presented on Figure 3. and can be observed that the computed distribution curves practically overlaps. Unfortunately, here the advantage of GPU is smaller. This can be explained with the presence of serial calculations like temperature and supersaturation calculation, mass balance and time step adaptation. As the GPU cores works on lower frequency (Table 1.), in serial calculations are less effective. However, the 3.9 times acceleration compared to the C++ code still could be beneficial for on-line application purposes.

3.3. Bi dimensional PBE with nucleation and growths

The bi-dimensional PBE with nucleation and growths generate the Eq.(3)

$$\frac{\partial n(L_1,L_2,t)}{\partial t} + \frac{\partial G_1(S,L_1)n(L_1,L_2,t)}{\partial L_1} + \frac{\partial G_2(S,L_2)n(L_1,L_2,t)}{\partial L_2} = B(S)\delta(L_1 - L_{n1})\delta(L_2 - L_{n2}) \tag{3}$$

This is together with the corresponding mass balance and temperature profile is a batch crystallization model. In simulations, a log-normal initial distribution with parameters $L_1 = 5$, $L_2 = 3$, $m_1 = 2$, $m_2 = 1$, $G_1(S, L_1)=0.208\cdot(S-1)^{1.05}(1+0.0001\cdot L_1)$μm/s and $G_2(S, L_2)=0.168\cdot(S-1)^{0.95}(1+0.00011\cdot L_2)$μm/s growth rates of the two characteristic crystal facets and $B = 2.64\cdot10^{-4}(S-1)^{1.38}V_p$#/μm^{3}s nucleation where Vp denotes the total volume of particles - secondary nucleation mechanism is considered - with $c_s=0.1286-9.88\cdot10^{-4}T+6.21\cdot10^{-5}T^2$temperature dependent solubility and the solution is cooled from 32 to 27°C with is 1 °C/min rate. Adaptive time stepping is used to ensure the numerical stability. As the graphical representation of a bivariate PSD is a surface that is not a successful way of result comparison, the moments of the distributions are computed and compared to the standard method of moment (SMOM) solution, introduced by Randolph and Larson (1971). Table 2. contains the comparison of results: all methods are highly accurate and a significant speedup, MatLab function : .mex function : .ptx function = 26 : 5.1 : 1 is achievedas, next to the mentioned serial calculations, moreparallelizableoperationsexist in the algorithm as the growth rates in both directions, respectively, the flux limiter function calculations.

4. Conclusions

In the current work three different implementations of the high resolution finite volume algorithm, namely as a MatLab function, compiled C++ .mex file and compiled parallel

.ptx file (executed on GPU), were studied and presented for solving mono and bivariate PBEs. The performance of different applications is strongly related to the nature of problem: the advantage of compiled .mex file is the faster serial calculation but GPU has a massive parallel architecture which makes it advantageous to perform parallel calculations. For the pure growth one dimensional population balance involving only parallelizable calculations the GPU was with 35 times faster than the Matlab function. The serial calculations are drastically the GPU speedup, for the one dimensional case with mass balance, nucleation and growth the MatLab : .mex : .ptx run time ratio is 5.8 : 3.9 : 1. In bi dimensional case, despite of the presence of serial calculations, the algorithm includes a massive parallelizable part thus the advantage of GPU becomes significant again, with a MatLab : .mex : .ptx run time ratio of 26 : 5.1 : 1. In the current study a low-cost GPU device is used and significant speedup is achieved which makes the method more attractive in application of real time model-based control approaches.

5. Acknowledgments

This paper is a result of a doctoral research made possible by the financial support of the Sectorial Operational Programme for Human Resources Development 2007-2013, co-financed by the European Social Fund, under the project POSDRU/159/1.5/S/132400 - "Young successful researchers – professional development in an international and interdisciplinary environment". Abstract

This paper focuses on the challenges in model development related to model reuse and compatibility and integration of different tools that are used in modelling. A link between two modelling tools, the computer-aided modelling framework of the ICAS system and the modelling environment, MOSAIC, has been established, in order to provide a wider range of modelling capabilities. Through this link, developed models can be exported/imported to/from other modelling-simulation software environments to allow model reusability in chemical and biochemical product and process design. The use of this link is illustrated through a case study.

Keywords: computer-aided modelling framework, model import/export, model reusability, model transfer, modelling environment.

1. Introduction

Computer aided modelling frameworks are gaining increasing attention in model-based studies of chemical and bio-chemical process-product design, as they can contribute by reducing the time and resources needed for model development and model-based applications. However, often a single modelling framework is unable to provide all the needed features, therefore, integration of modelling tools is an option worth considering. Through this integration, process models consisting of complex subsystems that cannot be modelled and simulated in a single general-purpose modelling tool can be handled. Also, the necessary support for model re-use can be provided (Schopfer et al, 2004), as well as offering new capabilities for users to write mathematical models in different formats and formalisms in addition to providing options for model transfer to other modelling-simulation software environments. One of the most time consuming activities for model developers is the exchange of the information between software systems and tools (Kraus et al, 2014). Since process modelling tools usually need different implementations for different modelling objectives, model re-usability

becomes very important. The models provided by a computer aided modelling tool should, therefore, be accessible via a programming interface to other tools (Bogusch et al, 2001). This can be achieved through a computer aided modelling tool that provides a component interface following certain standards, such as, CAPE-OPEN, COM-object, XML, DLL or TXT. This would allow user to exchange and work with a wide variety of models, increasing thereby models reuse. This integration and transfer of models between different tools will allow the use and analysis of models in the most efficient way, depending on the goal of modelling (i.e. model identification, parameter estimation, process design, system representation/understanding, process control, etc.).
The objective of this contribution is to present a general modelling framework of the ICAS system for systematic modelling building through modelling templates, which supports the reuse of existing models via its new model import and export capabilities. This new feature has been developed by establishing a connection with the MOSAIC modelling environment. A brief overview of the new modelling framework with emphasis on the above mentioned capabilities is given below, followed by an application example highlighting the modelling-simulation aspects of a batch reactor and a batch distillation process.

2. Modelling tools

2.1. ICAS modelling framework: template

The purpose of the computer aided template-based modelling framework is to enable the modeller to create a general model for a given system, to be used later to generate problem-specific models. To achieve this, the modeller is systematically guided through the steps of template-based modelling workflows and, at each step, the framework identifies and integrates the required tasks, tools, and database with model library connections (Fedorova et al, 2014; Fedorova et al, 2015). Depending on the modelling needs and goals, the modeller has the possibility to create a new model when the needed problem specific model is not available in the library. The modeller has also the possibility to identify, validate and solve the new models or use existing models from the template library. Furthermore, model templates enable the idea of model reuse as the user can employ the template as a base to build different problem-specific models for different applications. The objective here is to provide structured domain-specific knowledge, to speed-up the model development/derivation process and to improve the model quality. As the template library includes validated models, the creation of a new template-based model will reduce the modelling time and increase efficiency in the subsequent steps of model analysis, model verification and solution (Fedorova et al, 2015).
Figure 1 shows the modelling framework, which involves five main elements: 1) a modelling tool, that includes the modelling template library together with algorithms for model generation (ModDev, Jensen and Gani, 1999); 2) a model library, which provides building blocks for the templates (generic models previously developed); 3) computer aided methods and tools, that include procedures to perform model translation, model analysis, model verification/validation, model solution and model documentation (MoT, Heitzig et al, 2014); 4) model transfer – export/import to/from other application for further extension and application; 5) a user interface that provides the work-flow and data-flow to guide the user through the different modelling tasks.

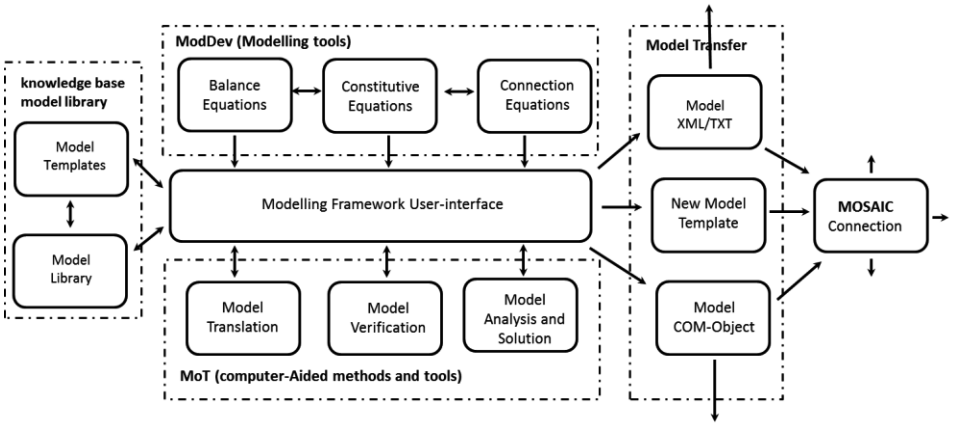

Figure 1. Schematic modelling framework implementation including transfer capabilities.

2.2. MOSAIC modelling environment

MOSAIC is a non-commercial, web based modelling, simulation, optimization, and code generation tool developed at TU Berlin, Germany (Zerry et al., 2004). The MOSAIC models are stored in a platform independent way by using XML/MathML standards and SQL-Databases. All elements of a model (e.g. notations, equations) are exchangeable and reusable. Detailed descriptions of additional features of MOSAIC have been published, focusing on experimental design (Hoang et al. 2013), data management aspects (Kraus et al. 2014) and model integration activities (Merchan et al. 2014). The general structure of MOSAIC is shown in Figure 2.

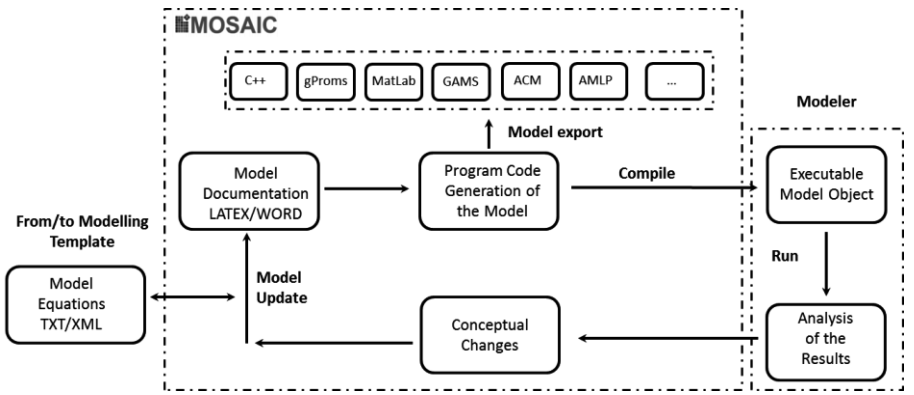

Figure 2. Model transfer interface and general structure of MOSAIC.

2.3. Implementation of the extended features through integration

The objective here is to allow the use of a wide range of programming languages (such as Fortran, C++ etc.), tools based on generic modelling languages (e.g. GAMS, gPROMS®, Matlab®) and domain-oriented tools (e.g. Aspen Plus, Pro II, ModDev) for various modelling needs..

The starting point is mathematical model created in a text editor program and then saved as a text file. The model is then pre-screened and pre-translated to make sure that it is valid, confirming that all model equations are consistent and syntactically correct. The

model transfer capabilities are schematically shown in Figure 1. Several types of formats, such as XML-format and COM-objects, are incorporated to allow the export and import of mathematical models. After the model is imported, it is stored in the modelling template library for further (re)use.
The link between the ICAS modelling framework and the MOSAIC modelling environment is established through a XML schema, which contains a formal description of the structure and elements in the XML files representing the model. This XML schema has been implemented in both ICAS modelling framework and MOSAIC, allowing translation of the model information to the transfer file in XML-format and exchange of these files between tools. Through this link it is possible to translate models into various languages, such as C++, gPROMS®, GAMS, Aspen Custom Modeler® and Matlab® together with a full model documentation. More details on the connection implementation can be found in Tolksdorf et al. (2015).

3. Case study

The application of the ICAS modelling framework and its model transfer capabilities are highlighted through a case study involving the modelling of a batch reactor followed by a batch distillation operation. The model describes the reaction and separation operations in the production of methyl acetate from acetic acid and methanol (Fig. 3). This model is obtained from the library of the ICAS modelling framework and solved using MoT (Fig. 4).

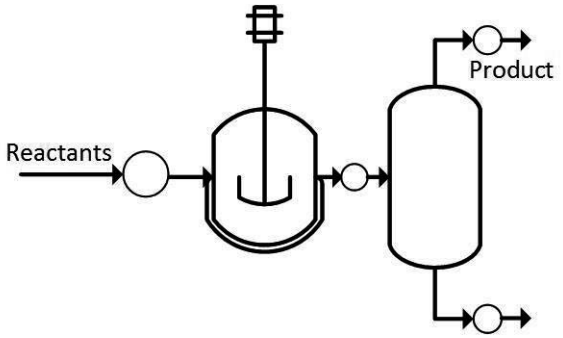

Figure 3. State-task network for batch reactor and batch distillation.

Furthermore, the model is transferred to MOSAIC via XML translation. This translation is done without additional effort from the user. All equations, variables and relations among them, as well as documentation that has been provided, are automatically transferred and implemented.
In MOSAIC, the model can be further translated into various modelling languages, as described in section 2.2.
Figure 5 shows schematic implementation of the transfer process starting from obtaining model from the template library of the ICAS modelling framework, then translating it to MOSAIC modelling environment, where code representation of the model for gPROMS® and Matlab® takes place. Results obtained from external tools are identical to the ones found by ICAS-MoT (see plots in Fig. 4 and 6) and this confirms the successful transfer and use of the new feature.

4. Conclusions

In this contribution a general modelling framework for systematic model development through modelling templates, which supports both, the derivation of models from scratch, and the reuse and further modification/extension of an existing model via its import and export model capabilities have been presented.

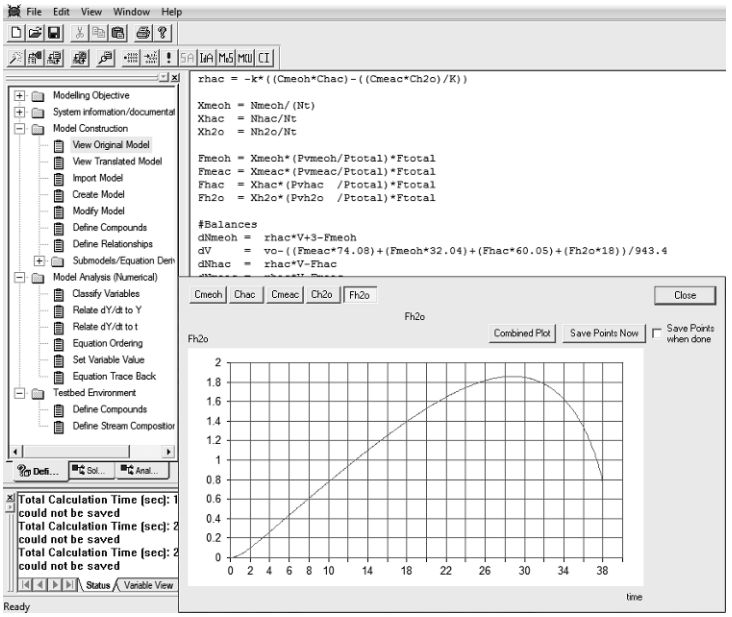

Figure 4. Model implementation in MoT

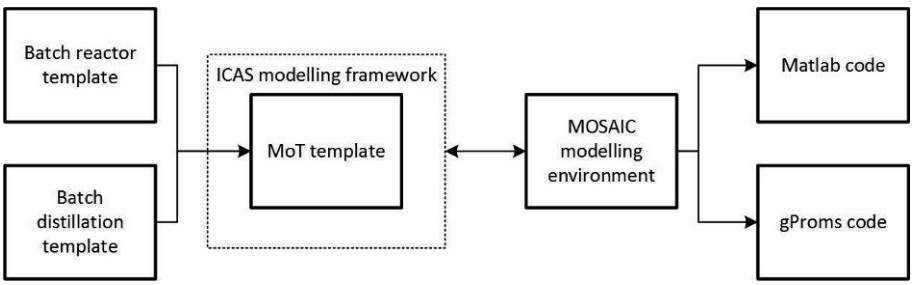

Figure 5. Schematic architecture of model implementation in ICAS modelling framework and its translation to external tools.

In industrial process modelling practice, the average number of modelling and simulation tools used by a work group is approximately five (Kraus et al, 2014). Although the diversity of tools should potentially increase the probability of finding a solution in an efficient manner, it can also lead to difficulties when the models need to be re-used by or shared within different work groups. For this reason an important feature of the tools integration is the capability to import and export the generated mathematical models from/to different modelling tools.

The possibility to translate the model, created in one modelling environment, to a variety of other languages in order to use it in the different modelling tools gives the flexibility to the model development and application process. This allows the model to be shared among modellers, who may be using different tools. Thus, a range of tools can be used for diverse purposes (e.g. model identification, analysis, control strategy etc.) without the need for rewriting the model. Also, by using another tool, a better solution strategy could be employed.

BiOnto: An Ontology for Biomass and Biorefining Technologies

Nikolaos Trokanas[a], Madeleine Bussemaker[a], Eirini Velliou[a], Hella Tokos[a], Franjo Cecelja[a]

[a]*PRISE Group, University of Surrey,Guildford, GU2 7XH, UK*

Abstract

This paper presents design and implementation of the BiOnto ontology in the domain of biorefining. The ontology models both biomass types and composition and biorefining processing technologies. The designed ontology is verified by a case study in the domain of Industrial Symbiosis.

Keywords: Ontological Engineering, Biomass, Biorefining Technologies, Ontology, Semantic Modelling

1. Introduction

In process engineering ontologies are commonly used for knowledge representation. Historically, their potential has been recognised in many different domains such as the biomedical (Musen et al. 2012), legal (Casellas et al. 2005, Lame 2005, Corcho et al. 2005), financial (Alonso et al. 2005), agricultural (Soergel et al. 2006) and chemical and process engineering (CPE).

This paper presents the *BiOnto* ontology, which expands on already developed and implemented processing technology ontology eSymbiosis (Raafat et al. 2013) and represents knowledge on biomass types and composition, as well as on biorefining technologies. To this end, the *BiOnto* ontology provides a reference model interpretable both by humans and computers by classifying biomass in 5 different ways: i) processing characteristics, ii) chemical composition, iii) physical properties, iv) existing standards (such as CEN/TC 335), and v) waste and residue based classification. More specifically, functionality of the *BiOnto* ontology selected by different practical scenarios, which include screening of processing technologies for particular type of biomass, screening the alternative technologies to target material or energy output or production pathway, selecting the best technology to satisfy set economic, environmental and/or social targets, and screening biomass types to supplement another one.. In addition, the *BiOnto* ontology has been demonstrated useful for searching and indexing of biomass information, enabling interoperability between applications, data integration and enabling and enhancing decision making in relation to biomass and biomass processing.

2. Ontologies and Knowledge Modelling

Ontologies are knowledge representation tools that have evolved through the years and are currently researched in the domain of Chemical and Process Systems engineering.

Previous efforts of ontology development in the domain of Chemical and Process Systems Engineering (CPE) have focused on process and process systems design (Zhang, Yin 2008, Bock et al. 2010, Fernandes et al. 2011), supply chain modelling (Muñoz, Espuña & Puigjaner 2010, Muñoz et al. 2012) and industrial symbiosis and environmental decision-making (Trokanas et al. 2013, Trokanas, Cecelja & Raafat

2014, Raafat et al. 2013) among other fields (Morbach, Wiesner & Marquardt 2009, Abanda, Tah & Duce 2013, Panetto, Dassisti & Tursi 2012). This ever increasing use of ontologies is due to their important role in formalising the diverse and volatile information and concomitant opportunity to analyse and understand the knowledge of a domain and respective sharing and reuse of the domain knowledge.

3. The BiOnto Ontology Structure

The BiOnto ontology (Figure 1) structured around two distinct streams/ontologies biorefining domain including biomass types and biorefining technologies. Both ontologies have been modelled in a number of ways forming separate sub-modules which in turn increase its spectrum of use and make the ontology application independent. Figure 1 presents an excerpt of the biorefining technologies module. The expanded sub-module (*ByType*) models processing technologies based on the type of the conversion. The other sub-modules are not presented for the sake of simplicity and presentation.

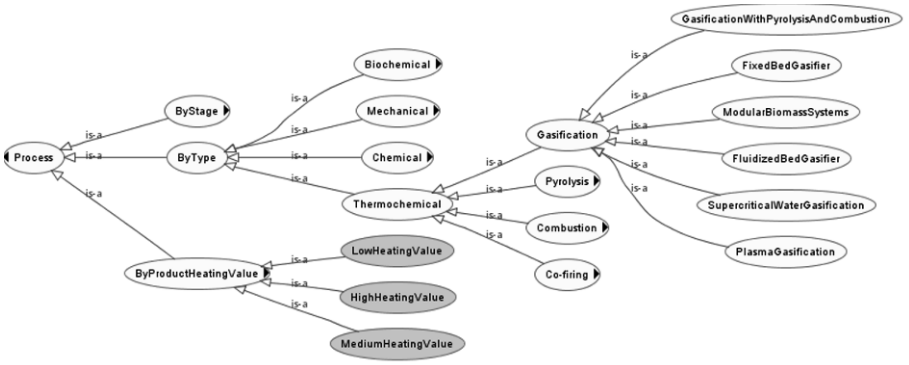

Figure 1 Excerpt of BiOnto Ontology

The BiOnto ontology consists of two main modules: i) Biomass and ii) Biorefining technologies.

3.1. Biomass Module

Biomass is modelled more generally as materials (Figure 2) and includes five identifiable sub-modules. Figure 2 presents the high level of *Materials* (biomass) module and its five sub-modules.

Products sub-module classifies energy and material products such as biofuels, electricity and biochemicals. Concepts under this sub-module are dominantly used used to describe inputs and outputs of biorefining technologies.

PlatformMaterial sub-module classifies platform materials such as syngas, lignin and H_2. These are the intermediate products that can act either as a work-in-progress or as products in cases where biochemical production is the aim.

MaterialByPhysicalForm sub-module classifies all materials of the ontology based on their physical form. This sub-module can be considered as an index.

FeedstockMaterials sub-module classifies biomass as input for the biorefining processes such as animal biomass, herbaceous biomass and aqueous biomass.

OtherMaterials module, classifies all other types of biomass or materials that are not classified. This sub-module is subject to auditing by a knowledge engineer so that *OtherMaterials* are classified in one of the other modules.

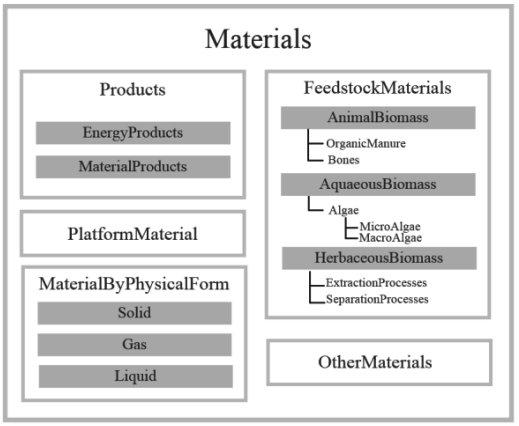

Figure 2 Biomass (Materials) Module

3.2. Biorefining Processing Technologies Module

Biorefining technologies consist of 3 sub-modules (Figure 3): i) ByProcessType, ii) ByProcessStage and iii) ByProductHeatingValue.

ByProcessType sub-module classifies technologies based on the type of conversion which takes place, such as chemical, biochemical, mechanical, thermochemical. This is an intuitive classification and a lot of information is available in literature making this classification the natural starting point.

ByProcessStage sub-module classifies processing technologies based on the stage they occur. Pre-processing technologies include pre-treatment processes such as *Chipping* and *Milling*. Main processing technologies include main conversion technologies such as *Pyrolysis* and *Gasification*. Post-processing technologies include processed such as *SteamReforming* and *WaterGasShift*.

ByProductHeatingValue sub-module classifies processing technologies based on the heating value of their product. The three ranges of heating values are defined as low (>=3, <=10), medium (>10, <=20) and high (>20, <=35). Heating value is modelled in MJ/kg.

Figure 3 presents the high level of the biorefining technologies module and its 3 main sub-modules.

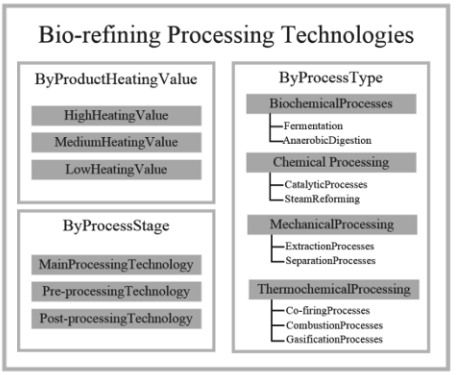

Figure 3 Biorefining Processing Technologies Module

All processing technologies have been classified based on their type during the modelling process and are consequently reclassified under different sub-modules. Reclassification of classes is enabled by the inference capabilities that ontologies offer. Reclassification of processing technologies is demonstrated in Figure 1and Figure 4. To explain, reclassification is apparent for gasification technologies such as *FixedBedGasifier* and *PlasmaGasificication* which have been reclassified as *LowHeatingValue* technologies. This inference is triggered by the specified values of product heating value for each technology.

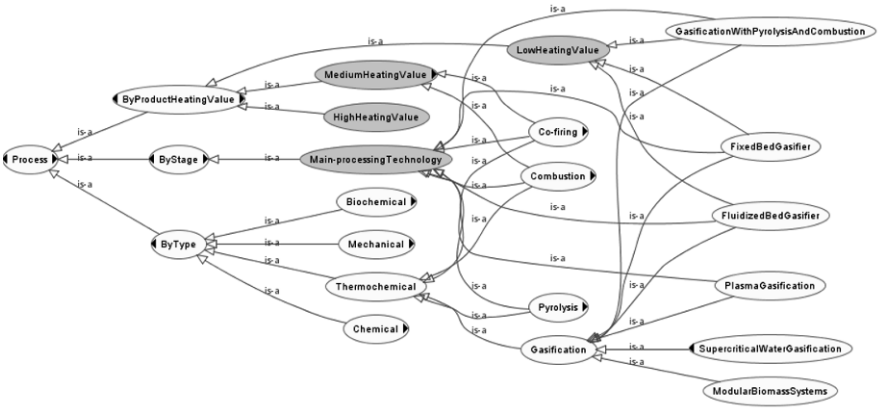

Figure 4 Inferred Ontology Excerpt

Biorefining technologies have been modelled in detail, in an effort to widen the scope of potential applications. Each biorefining technology in BiOnto, has been modelled in terms of feedstock materials, output products and by-products. Operational characteristics have also been modelled for each technology. These include conversion rate, required moisture content, operating temperature and product heating value. This information has been modelled using restrictions on properties. The example of a fixed bed gasifier is presented in Figure 5. The restrictions in Figure 5, describe *FixedBedGasifier* technologies, which is defined having a conversion rate between 60-80%. The same technology has a defined range of product heating value (<=5) that leads to the reclassification of this technology as a low heating value technology.

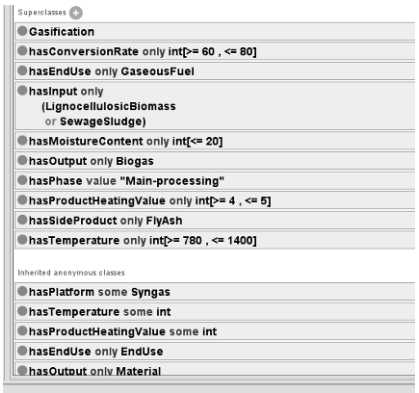

Figure 5 Fixed-bed Gasifier Restrictions

3.3. Properties

The properties used in BiOnto (both object and data type) focus on the operational characteristics of technologies and the compositional (chemical) characteristics of biomass. To name a few, technologies are characterised by their conversion rate (*hasConversionRate*), output (*hasOutput*), input (*hasInput*) and moisture content they can handle (*hasMoistureContent*). Biomass is characterised by its heating content (*hasHeatingValue*), moisture content (*hasMoistureContent*) and composition (*hasLignin*, *hasCelluloce*, *hasHemicelluloce*). Some of the properties are presented in the restrictions of the fixed-bed gasifier in Figure 5.

4. Case study

BiOnto ontology has the potential to be used in many applications such as data integration, semantic search and matching. To validate the presented ontology, we have implemented it in an Industrial Symbiosis platform, previously presented in (Raafat et al. 2013, Trokanas et al. 2012).

In more detail, the ontology was implemented in the Industrial Symbiosis portal and used for registration and matching of resources (in this case biomass) and biorefining processing technologies.

The matching process was initiated by the registration of an anaerobic digestion technology which was matched against a number of biomass types previously registered using BiOnto. The results for the feedstocks matching as inputs of anaerobic digestion technology are presented in Table 1.

Table 1 Matching Results

Resource	Relevance		Name	Quantity	Unit of measure	Valid From	Valid to
Manures	92%		Manure	62,00	Tonnes	01/05/2014	31/08/2015
Corn Stover	85%		Corn Stover	62,00	Tonnes	28/07/2014	27/08/2015
Rice Husk	83%		Rice Husk	135,00	Tonnes	01/01/2015	20/04/2016
Round Timber	79%		Round Timber	240,00	Tonnes	03/06/2014	04/03/2015

Obtained results have been compared and verified with results produced from the established eSymbiosis platform.

5. Conclusions

The presented ontology models biomass and biorefining technologies in detail, allowing the ontology to be used in a range of applications. Validation was performed through a case study in Industrial Symbiosis domain where the ontology was used to collect information from the users and identify symbiotic matches between available feedstocks and technologies. However, BiOnto is open to other applications as well. Future plans include the use of BiOnto to enable model and data integration in biorefining domain and incorporation of the ontology in the decision making process of value chain modelling for biorefineries.

Abstract

Many engineering activities depend on the analysis of the plant connectivity. In particular, process operation requires a thorough understanding of the interconnections between units to be able to evaluate diverse operation scenarios. While some of the relationships between elements are obvious from process descriptions, some others (recycle flows, utility systems, and electrical interactions) are not so easy to spot. The hypothesis is that information regarding these non-explicit connections is already available inside the diagrams and technical documentation of the process. This paper suggests a method for integrating electrical and logical connectivity with process connectivity extracted from "smart P&IDs". Moreover, a prototype tool (Topoviz™) which can be used to integrate, visualise, and analyse plant connectivity is introduced.

Keywords: plant connectivity, graph networks, visualisation, XML, "smart P&IDs"

1. Introduction

Large scale petrochemical facilities are complex systems composed of interconnected processes. The increasing level of automation poses new challenges in the industry as it becomes difficult to extract valuable information when the number of variables in the process grows. Particular challenges are data visualisation, the computational limitations from current tools, and the understanding of complex dependencies amongst process units, especially when these involve different domains. Currently, engineers need to combine information from disparate sources to make inferences about how units, variables and events are related. This procedure has been performed manually, and it typically relies on experience and domain knowledge. Earlier analysis of the engineering workflows and technical documentation for oil and gas production facilities indicates that the understanding of the process connectivity is a valuable resource for activities such as troubleshooting and maintenance planning (Romero and Graven, 2013). The term plant connectivity is used here in its meaning as the physical structure of a network, encompassing the process, electrical and logical links between units inside the network.

A specific problem in troubleshooting activities is related to the analysis of plant connectivity where both electrical and process equipment are involved. As pointed out by Cecilio et al., (2014), it would be meaningful to consider the utilities that service the process for troubleshooting and diagnosis activities. The reason for this claim is that these subsystems also interact with the process through energy and information signals, and therefore disturbances can also propagate via electrical and logical paths. Similar research focusing on the integration of data from different engineering domains has been carried out before. Mordinyi et al., (2012) applied this knowledge to engineering process and lifecycle information. Cui et al., (2010) presented a customized data acquisition method for SmartPlant® P&ID for the integration of process topology with HAZOP.

The physical and material links between process units are contained in the P&IDs, or piping and instrumentation diagrams. P&IDs are "smart" if they are stored in XML files. The extraction of connectivity information from them is a solved problem, as several algorithms have been developed in order to parse information stored in them by under industrial specific standards such as AutomationML (https://www.automationml.org) and ISO 15926 (www.15926.org). On the other hand, electrical diagrams show connections between electrical components, which are usually made by wires. As far as the authors are concerned, there is no evidence of an industrial standard for data integration that can be used in the same way as the ones developed for "smart P&IDs"; hence the extraction of electrical connectivity becomes more difficult and the possibility to automatically extract connectivity information from wiring diagrams is still an open question. Logical connectivity is referred here as the information links between units (signals/interlocks).

In order to offer appropriate support to plant operations and maintenance it is necessary to define a new tool for the visualisation of interconnections between equipment from different subsystems. Figure 1 offers an overview of the different sources of technical documentation that are commonly used in the industry. The example shows how a single item FT-301 (flow transmitter with tag number 301) can be viewed from the different domains and systems, which presents a problem because of the distributed nature of the knowledge. Relevant contextual information readily available by looking at the diagrams and linking them together, is not available in the DCS or other systems used for troubleshooting and maintenance planning. Therefore, a first challenge to be solved is to define an efficient way to integrate and store connectivity information extracted from several places. Commentators suggest that some uses for an integrated connectivity model are: automated fault diagnosis, HAZOP, and maintenance planning (Yang et al., 2014).

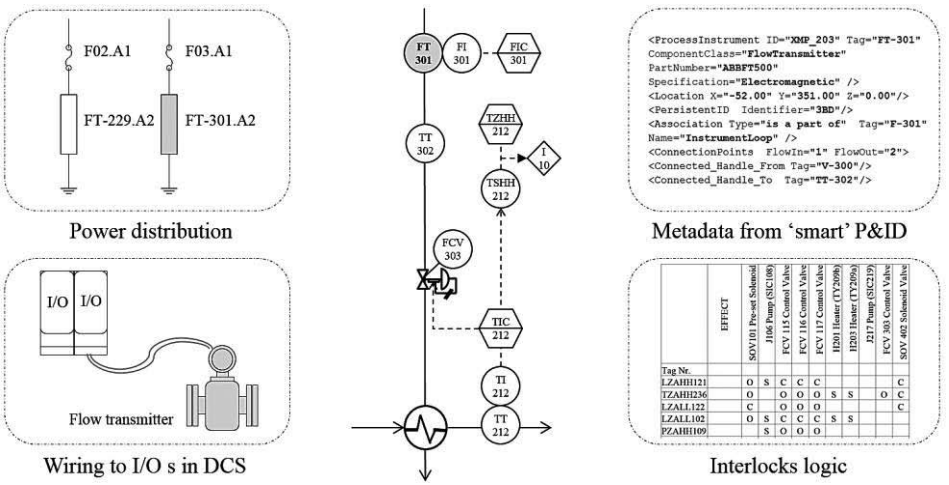

Figure 1. Example data sources, P&ID in the middle was extracted from case study.

The document is laid out as follows: Section 1 has outlined the problem statement and introduced the area of research. Section 2 covers the analysis of relevant literature. Section 3 defines the industrial context and outlines some of the challenges in the petrochemical industry behind the research question. Section 4 describes the methods integrating information about process and electrical connections from different sources. Section 5 presents the tool and the visualisation of a case study, discussing the results of using the proposed methodology.

2. Literature review

Several authors have evidenced that process connectivity extracted from structural models can enhance the isolation and diagnosis of the root-cause in plant-wide disturbances (Maurya et al., 2003; Yang et al., 2014). A number of works have focused on integrating process knowledge with other sources of information. Di Geronimo Gil et al., (2011), for instance, merged first-principles models with process connectivity. Birk et al., (2010) proposed the tool ProMoVis capable of modelling and visualising interdependencies in the control system. A proposal for the integration of P&ID and HAZOP expert systems was carried out by Cui et al., (2010), with the restraint that their customized ontology and middleware not based on any industrial standard. Extending the concept would result in a vast effort to create data acquisition and normalization modules to each data source. Schleburg et al., (2013), more recently devised an algorithm to apply process connectivity from P&IDs for alarm reduction. Nevertheless, all the examples mentioned above look only at process connectivity (material flows), and it is a fact that interconnections can happen via material, information, and electrical flow. Consequently, a problem identified in the literature is that fault propagation analysis must include not only of the process side, but also its auxiliary systems (electrical system, utility and safety). This has been recently addressed by Cecilio et al., (2014) looking at time-series.

The proposed approach is to use the concept of *property-graph* to integrate disparate data sources into a network that is navigable and supports queries. This is achieved by a series of algorithms that are used to parse, integrate and visualise plant connectivity information as a graph network. The methodology reports several advances compared with the previous work on visualisation of connectivity models, including the generation of a novel graph structure that presents several advantages over adjacency matrices, signed digraphs and other object-oriented modelling methods. Furthermore, the algorithms extract connectivity information from electrical diagrams as well as from the P&IDs. The integration of electrical diagrams with process diagrams has never been accomplished before. Thus, the expectation is that the methods proposed here can be combined with data-driven methods and greatly enhance the capabilities of the analysis, for instance, when causes of disturbance originate or are propagated through the electrical system.

3. Industrial context

A concurrent problem linked to the increase in the level of automation is the amount of data available from all the different systems used for automated fault diagnosis. These systems include the process monitoring system, process control and safety systems, as well as a number of proprietary tools and databases available for a particular units. The consequences of abnormal process conditions such as plant-wide disturbances are significant; in the petrochemical industry they are estimated to costs billions of USD dollars (at least 20 as reported by Bullemer in 1994). Surveys confirm that around 80% of these situations are avoidable, and human error causes 40% of them. Manual analysis of the interconnections between units from different systems can be time-consuming and prone to errors, and therefore there is a motivation for the automatic extraction and integration of process and electrical connectivity. A key factor to consider is that the degree of automation achieved depends heavily on the availability of process and electrical diagrams in a computer-readable form. Due to the heterogeneity of engineering documents, e.g. wiring diagrams, equipment layout plans, process flow diagrams and cause-and-effect tables, synchronisation between disciplines may also require a big collaboration effort between discipline experts.

4. Integration of plant connectivity from different domains

The main objective is to be able to enable collaboration across domains, so that experts performing plant-wide diagnosis have access to information about interconnections between process and electrical subsystems. Figure 2 describes the proposed methodology where (1) data is generated by different computer aided engineering tools and then exported to standardized formats, (2) connectivity information is extracted by parsers as node-link relationships, (3) connectivity information from the different subsystems is stored in a graph database, (4) a set of rules is used for querying and searching for propagation paths or connections between items, and (5) a visualisation layer presents the results to the user. As introduced before, the graph database uses the concept of a property-graph, which is essentially a directed graph with properties associated to its nodes and edges.

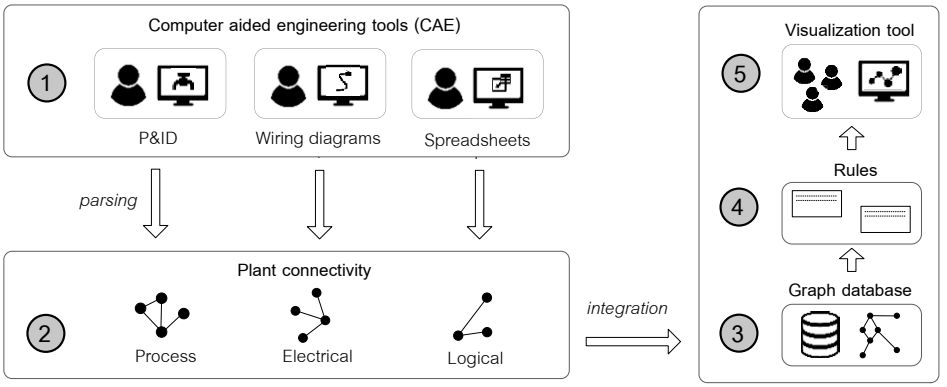

Figure 2. Proposed methodology for integrating and visualising plant connectivity information

Graph databases present an advantage against relational databases (based on tables) because they fit better for exploring data structured as a node-link or tree diagram when relations between elements are significant, and methods for searching and queries require less computational effort. Figure 3 shows an example of the information that can be contained as properties of every node in the network, as well as the source where this information is originated. A property-graph visualisation has the advantage that it can show more information than the tag-number (for example the type of element, location, or subsystem) as well as providing weights and properties in the links between units. Moreover, the graph can be traversed based on the properties attached to nodes and edges.

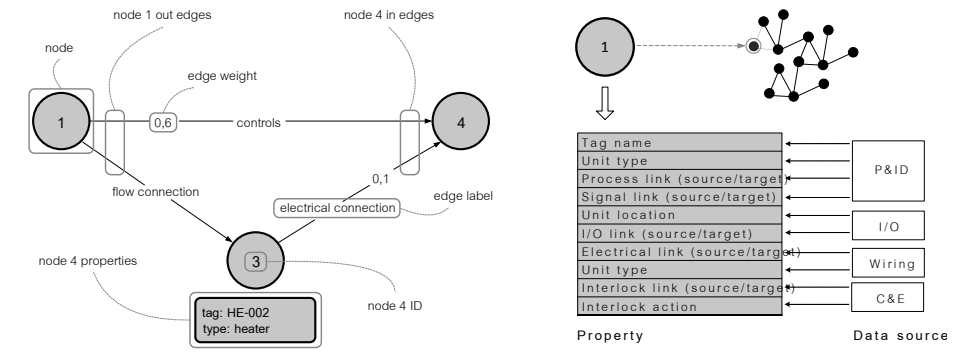

Figure 3. (Right) Main elements of a property-graph. (Left) Example properties from a node.

A ranked shortest path algorithm is use to find feasible propagation paths exploring the graph structure. The aim is to find all paths from element to element along physical, electrical and information flows. The reason for computing multiple propagation paths is because, when dealing with large networks, it is likely that more than one path between two nodes is found, and it is crucial to have them compared in the event of additional constrains. The *K*-shortest path is a generalisation of the shortest path algorithm and was proposed by Hoffman and Pavley (Hoffman and Pavley, 1959). This algorithm not only delivers the shortest path, but also *K* other paths sorted by cost. The use of the Hoffman-Pavley algorithm helps to fulfil the goals by providing all feasible propagation paths that meet the user defined criteria, and the results are sorted as well. Based on that, the engineer can compare that with other indicators (measurements, maintenance history, notifications, work order, to mention some of them) and be supported in fault diagnosis.

5. Prototype, case study, and discussion

The graphical user interface (GUI) from Topoviz™ is shown in Figure 4. As visible, the tool is built as a ribbon window with tab navigation to switch between different visualisations and use modes. A top ribbon (*File* | *Topology builder* | *Troubleshooting* | *Connectivity tools* | *Help*) is used for selecting the module to be used between three: (1) builder, (2) troubleshooting mode, and (3) operations mode. In this example, modules one and two are used in order to generate a network visualisation of the integrated plant connectivity (process + electrical + logical). The case study used is a laborary-scaled process rig from Imperial College London. All diagrams were created by following industrial standards. Autodesk Electrical was used for the single-line and cabinet diagrams, and AVEVA P&ID for the "smart P&ID". Likewise, the methodology can be applied using other P&ID design tools able to export of ISO 15926 and AutomationML compliant drawings. Results in Figure 4 present the successful integration of electrical and process connectivity. This represents an important step for plant-wide disturbance analysis when faults originate or are propagated through the electrical system, or when there is a correlation between elements connected to the same I/O unit in the control system. The nodes visible in the graph visualisation represent units parsed from the P&ID and electrical diagrams. Each of these nodes contains properties which are added as other sources of technical documentation are incorporated to the *Topology builder*. Example properties are unit location, type and parent-child relations with other units. The user gets added information about each node by hovering over it. Properties connected to the nodes or edges can be presented in a tooltip (see Figure 4). Furthermore, the user can search and highlight possible propagation paths in the diagram by using the algorithms mentioned in the previous section. The search bar and selectors on the right side of the interface are used to select elements as "from" and "to" nodes in the graph and then calculate the *k*-shortest paths. The nature of property-graphs allows the system to filter and classify the connections by type (pipe/wire/signal) and to achieve navigation between connectivy informtation from different domains. Finally, the proposed integrated graph stores relevant information into the nodes in the graph, which lowers the computational effor required when performing searches. The concept can be expanded by adding process knowledge and data coming from results of data-driven methods.

An Interactive Framework for Building and Analysing Models of Urban Energy Systems

K. Kuriyan[a]*

[a]*Department of Chemical Engineering, Imperial College, London SW7 2AZ, UK*
k.kuriyan@imperial.ac.uk

Abstract

This paper describes a software framework for building and analysing models of urban energy systems. The framework consists of a technology database and components for model assembly and networking coupled with a graphical user interface. The technology database, which is implemented as a Protégé ontology, describes the available energy conversion, storage and transportation processes. The spatial framework for the model is defined by a cityspace object. Distributed energy demands are specified within this cityspace, and it also identifies potential locations for energy conversion processes and links for resource flows across infrastructure networks. The user interface instantiates and assembles framework objects into an overall object model of the system. The assembled object model can be used to define optimization scenarios for the design of urban energy systems with specific goals and constraints such as minimising investment costs while meeting emission targets. These scenarios can be submitted across a network to a solver on a remote host to obtain an optimal design of the urban energy system. The results are displayed by the user interface at two levels: an aggregate level with key performance indicators and graphical analysis for the city as a whole, and a detailed level showing information about individual cells and flows between cells. The interface also provides charts and summaries for comparing alternative scenarios with variations in emission targets, cost parameters and available technologies.

Keywords: urban energy systems, modelling framework, user interface, optimization.

1. Introduction

UN population estimates show that 54% of the world's population now lives in urban areas and the urbanisation of the world population is projected to rise to 66% by 2050 (UN DESA, 2014). Global energy assessments show that between 56-78% of final energy usage is urban (GEA, 2012). An understanding of urban energy systems is critical to meeting energy sustainability challenges. For the purpose of this paper an urban energy system is defined as 'a formal system that represents the combined processes of acquiring and using energy to satisfy the energy service demands of a given urban area' (Keirstead et al., 2012). The system envelope may include both ex-urban processes for resource extraction, energy generation and transportation, with the associated costs and greenhouse gas emissions, and also potential processes for in-city energy generation and conversion. Models can improve our understanding of urban energy use, and can be used to analyse policy initiatives and infrastructure investments (Morlet and Keirstead, 2013). This paper describes a modelling framework and interactive tool that can be used to build and analyse such models.

2. Modelling framework

2.1. Integrated model

Modelling urban systems involves the analysis of the interactions between several sub-systems. Decomposition of the model into sub-systems is used to make the analysis of the overall system tractable, and also to allow the use of modelling formalisms suited to particular sub-systems. Gray et al. (2012) identify potential "axes of decomposition" for complex systems: functional decomposition along discipline boundaries (e.g. economics, engineering and sociology), control decomposition reflecting boundaries in organizational control (e.g. independent energy production companies, energy consumers and network operators), decomposition in time and space, and decomposition by modelling formalism (e.g. agent models and system dynamics models). Prototype models for land use, activity analysis and resource flow optimization have been developed. The models can be used independently to model specific sub-systems or connected together to form an integrated model of the urban energy system.

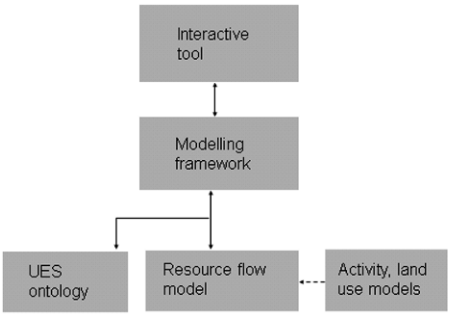

Figure 1 Architecture for modelling framework and tool.

The first component is a land use model which determines an energy efficient spatial layout of the city. The model is posed as an optimization problem to determine the locations of buildings and spaces in which activities are performed and the transportation networks that connect them. Mathematical models for this type of optimization problem are described by Keirstead and Shah (2011). The second component models the behavior of citizens and businesses to determine a spatially distributed pattern of energy demands. Agent-based micro-simulation models for this purpose are described by Keirstead and Sivakumar (2012). The third component is a "resource flow" model which gives the optimal energy strategy for a given pattern of demands calculated from the agent activity model and the set of available conversion and transportation processes. A model based on a hierarchical non-uniform discretization of time can be formulated as a mixed integer optimization problem that is solved to determine an optimal (low cost or low emissions) network of resource conversion, storage and transportation processes which can meet the specified demands while satisfying additional constraints such as carbon emission targets (Samsatli and Jennings, 2013). A simplified model, suitable for cases where a single temporal level is sufficient (e.g. Morlet and Keirstead, 2013), is used in this paper.

Analysis and synthesis of complex systems require an architecture that spans different "views" of the system (Rouse, 2003) exemplified by the three component models. The modelling framework defines abstract model classes that can be extended to implement specific model types. Figure 2 shows how a resource flow model can be implemented as

an extension of an abstract optimization model. A prototype application integrating the use of all three components is described by Keirstead et al., 2009. This paper describes current work on an interactive tool that incorporates a standalone resource flow model.

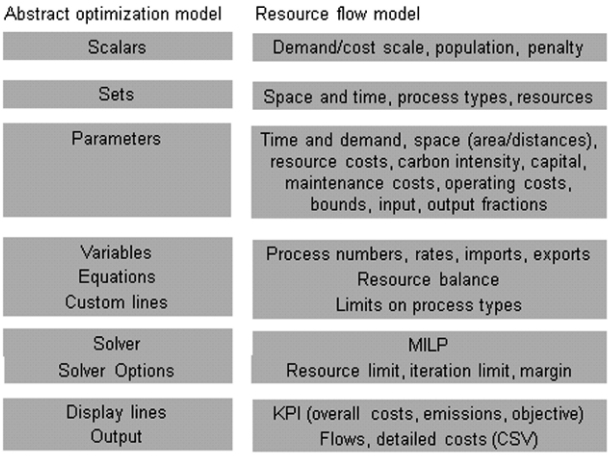

Figure 2 Structure of abstract optimization model and resource flow model objects.

2.2. Urban energy systems ontology.

At the core of the modelling framework is an ontology for urban energy systems (Keirstead and van Dam, 2010). Ontologies can be used to share a common understanding of the structure of information in a domain, to make assumptions explicit and to enable reuse of domain knowledge (Noy and McGuiness, 2001). The urban energy systems ontology is implemented within Protégé Frames (SCBIR, 2009) and fills several roles in the modelling framework. The first is to act as a database for storing the technological and cost parameters of urban energy system objects. The second is to provide consistent class definitions that can be used to transfer information from one model to another. The third is to provide a classification scheme for differentiating between storage, transportation and conversion processes, and also to define sub-classes of these primary classes. This classification is used while specifying attributes of modelling framework objects (e.g. a transportation process requires the use of an infrastructure network) and also in defining menus for technology selection within the user interface.

2.3. Technological framework

The main classes within the ontology are resources, infrastructure and processes. Resources represent both primary resources, such as natural gas, and final resources, such as electricity and heat, that can be used to satisfy the energy demands within a city. Infrastructure classes represent the physical infrastructure of the city such as buildings, roads and energy transport networks including gas pipelines, electricity supply lines and district heating networks. Processes can convert one resource into another, transport a resource from one location to another, provide temporary storage for a resource, or simply act as a sink for disposal of waste resources (e.g. CO_2 or waste heat). This framework is compatible with the construction of State Task Network representations of resource flows in urban energy systems. Resources can be represented as states, while the different types of processes are represented as tasks (Samsatli and Jennings, 2013).

As an example, a CHP unit can consume natural gas to generate district heating and electricity resources which are transported to other locations. The district heating resource can be used to satisfy heat demands in a building by passing it through heat exchangers. The electricity resource can be used to satisfy the electrical demands of households and businesses.

2.4. Spatial and temporal framework

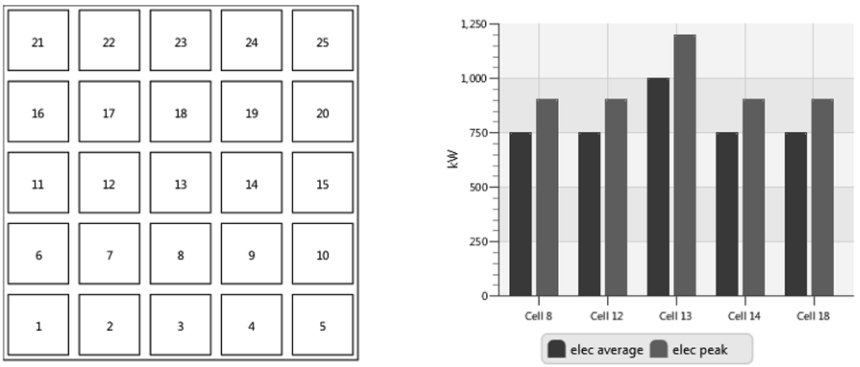

Figure 3 Cityspace with uniform grid and spatially and temporally discretized demands.

Models of urban energy systems require a spatial and temporal framework that reflects the characteristics of urban systems. The modelling framework employs a cityspace object which divides the city into a discrete grid representing possible locations for energy conversion technologies. Edges between neighboring cells represent potential network links for transporting resources. Energy demands are discretised across the cityspace and a set of demand periods representing temporal variations in energy requirements. The demands are specified with a flexible discretization at a single temporal scale consisting of one or more weighted periods (e.g. peak and average daily demands). The weights represent the relative lengths of demand periods, and are used to calculate performance metrics based on annual resource production and usage. Figure 3 shows a cityspace with a uniform grid and the corresponding peak and average electricity demands for the central cells as they appear within the user interface. In general, the cityspace grid cells can be given non-uniform locations and sizes, corresponding, for example, to administrative divisions within a city.

3. Interactive scenario construction and analysis

Typical usage of an urban energy system model involves comparison of scenarios with variations in optimization targets and cost parameters reflecting policy goals and incentives (e.g. Morlet and Keirstead, 2013). A base scenario may be constructed using technologies currently installed within the city for comparison with a future scenario with an emission target that requires the use of a mix of renewables. The interactive tool provides a graphical interface for the construction, execution and analysis of optimization model scenarios. The default costs and technological parameters (e.g. operating rates and resource requirements) for technologies selected by the user are retrieved from the ontology and displayed within the user interface. The parameters can be customized to construct a scenario that reflects local factors and incentives. The

cityspace grid and energy demands are defined in user supplied data files. An overall object model of the city is built by combining the information from the ontology with the scenario parameters and cityspace definition. An algebraic representation of the resource flow model is then assembled and optimized on a remote host on which an appropriate solver has been installed. After an optimized solution has been found the model results are written in output files which are retrieved and stored locally.

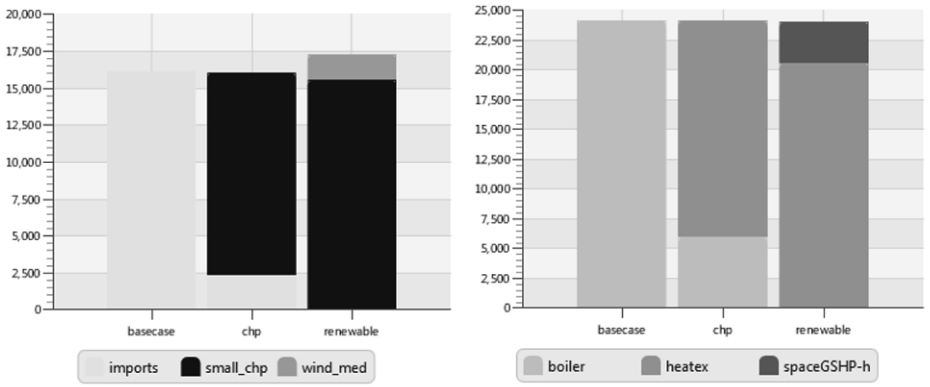

Figure 4 Sources for supply of peak electricity and heat demands (kW).

As an example, three scenarios (basecase, chp, renewable) are constructed for the urban system shown in Figure 3. The objective is cost minimization in all three cases. The basecase scenario does not consider in-city generation of heat and electricity. The chp scenario allows the use of combined heat and power (CHP) generation units to provide district heating and electricity within the city. The renewable scenario imposes an emissions target, includes wind power and solar photovoltaic panels for electricity generation, and ground source heat pumps for heating.

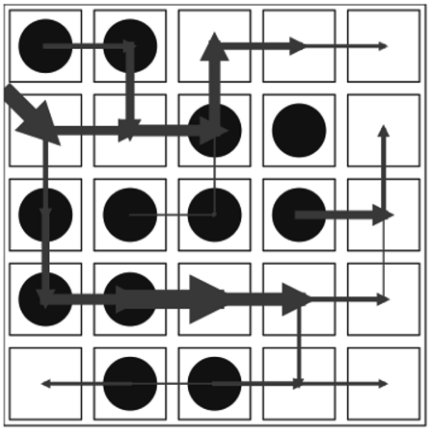

Figure 5 Peak electricity imports, flows and process locations for chp scenario.

Resource supply charts in the user interface show the sources used to satisfy energy demands in the optimized solutions to the three scenarios (Figure 4). In the basecase scenario electricity demands are satisfied entirely by imports, whereas in the chp scenario electricity imports are used only in the peak demand period with CHP units

supplying the rest of the electricity demand. In the renewable scenario, the emissions target is met by eliminating electricity imports and reducing gas consumption through a combination of wind power and ground source heat pumps. The interface has similar charts for resource usage by different technologies, capital cost breakdowns for conversion and transportation processes, costs and emissions associated with resource imports. Detailed results showing process locations, resource imports and flows are drawn as overlays on the cityspace grid (Figure 5).

4. Conclusions

This paper describes a framework of software components for data access, model assembly and remote job submission combined with a graphical user interface. The modelling framework and interactive tool can be used to build optimization scenarios for urban energy systems. The scenarios can be refined by the specification of custom constraints and technology selections. The scenarios can then be solved to determine the optimal energy system design to achieve policy objectives such as carbon emission targets.

Model-based Analysis of Waste Management Systems through a Natural Language Approach

Vassilis Magioglou,[a] Elisabet Capon Garcia,[b] Sara Badr,[b] Antonis Kokossis[a]

[a]*Department of Chemical Engineering, National Technical University of Athens, Athens, Greece*
[b]*Department of Chemistry and Applied Biosciences, ETH Zürich, 8093 Zürich, Switzerland*

Abstract

Waste management systems are complex interactive networks of data, knowledge and models comprising multiple parameters. In these systems the technologies and their models interact with each other in order to fully describe the problem. Inputs and outputs of the models intersect depending on the various parameters. These parameters, such as composition, pH, temperature etc., need to be computed simultaneously in order to select the appropriate processing path prior to model development. Therefore, the the selected path and the waste stream characteristics determine the context of the model. Waste management systems involve non-experts in decisions that require expertise from many disciplines. The need to synthesize the multidisciplinary domains of waste, integrate the knowledge and express them with common natural language terms is outlined by this work. The work builds on recent technology that was produced to synthesize superstructures for integrated biorefineries (Magioglou et al. 2014), which now extends to decision-making and allocation problems for waste management systems. The approach employs ontologies, Java language, OpenBabel library and suggests a natural language framework. Illustrations include an industrial wastewater treatment system of the chemical sector which evaluates the environmental impacts. The framework successfully synthesizes the network and allocates the waste, technologies, streams and auxiliaries along with their parameters.

Keywords: Waste management, ontologies, modelling, automation, waste water,

1. Introduction

Over 4 billion tonnes of waste are generated each year in the 34 countries members of OECD. The environmentally sound and economically efficient management of this waste has to be ensured (OECD, 2013). Waste management systems are complex systems that require multi-objective decision analysis in order to provide a complete and exploitable result. The multi-disciplinary knowledge required to design a management system keeps experts from focusing on integrated models development. These systems involve allocation and planning problems. Experts develop models focused on specific processes, ignoring their broader role in the system and the interaction with other technologies. The study of a single model is not sufficient in a holistic systems analysis. The integration of the relationships between materials, processes and models is examined in this work.

In a waste management system several technologies are involved, thus different levels of decision-making. The technologies are not isolated and interact with each other. The experts develop models individually for each technology. Streams come in and out of the technologies selectively. Each waste stream is required to follow a different treatment and processing path depending on the various parameters values. After each processing step, the output has altered characteristics, which require further analysis to determine the following step (e.g. following model). The interaction of the models in a waste management system is required to provide a complete and accurate overview of the systems functionality and operation.

This work proposes a systematic framework that could be managed by the use of vocabularies and semantic references. Ontologies and Java are employed to establish the models input-output relationships and to further contribute to decision-making based on various quantitative and qualitative criteria. Natural language processing of models is established to facilitate handling and decision-making (Magioglou et al. 2014). Libraries, namely OpenBabel, are applied to further automate various procedures involved in the systems analysis. Promoting waste management systems to automated intelligent systems through ontologies shows great potential in the usability and efficiency. Illustrations of the current approach include an industrial wastewater treatment system of the chemical sector which evaluates the environmental impacts (Koehler et al. 2007). The models describing the system calculate life-cycle inventory parameters as a function of the wastewater composition and the applied technologies. A framework has been designed to develop, visualize the system and enable its semantic use.

2. Methodology

The approach employs system steps to automate the path selection and model development in a waste management system. The methodology is laid out in 4 steps: (1) synthesis stage, (2) nodes development and analysis, (3) semantic models and (4) numerical models development.

2.1. Synthesis and classification

A waste management system is an interactive network of wastes, streams, technologies, pre-treatments, auxiliaries and emissions. These blocks build connections to each other selectively to synthesize the network. The main blocks synthesizing the waste management system are organized and the appropriate connections are established based on their nature and attributes. The main blocks are:

• Waste: waste is the initial stream derived from production facilities and has a defined composition. The characteristics of the waste determine the waste management system to be invoked to provide the desired outcome of the user.

• Streams: the waste streams are input and output of (i) processes, (ii) pre-treatments and (iii) mixing points. Input streams are defined as the streams entering a process, pre-treatment or mixing point. Therefore, output streams are the outcome of a process and have altered characteristics compared to the corresponding input streams. The changes in the stream influence the targeting block to follow, as well as the system itself. Each stream is described by various parameters which determine the potential input.

• Processes: streams head to processes to produce streams with different attributes. The processes operate under certain conditions, with certain wastes within a specific parameters range. A stream is valid to enter the process if the criteria (qualitative and quantitative parameters) defined by the process are satisfied.

• Pre-treatments: pre-treatments are similar to processes. They come before processes and their operation is optional. Depending on the stream characteristics a pre-treatment (e.g. pH adjustment) might be required to make the stream valid for further processing.

The categorized blocks establish connections to each other through the blocks of processes/pre-treatments. The combination of the possible connections results in a complete superstructure representing the waste management system. Secondary blocks (Energy, Emissions, Auxiliaries) are also deployed in the system. The main blocks and connections are demonstrated in Figure 1. The system is not considered as a block itself but it is indirectly related to the process itself.

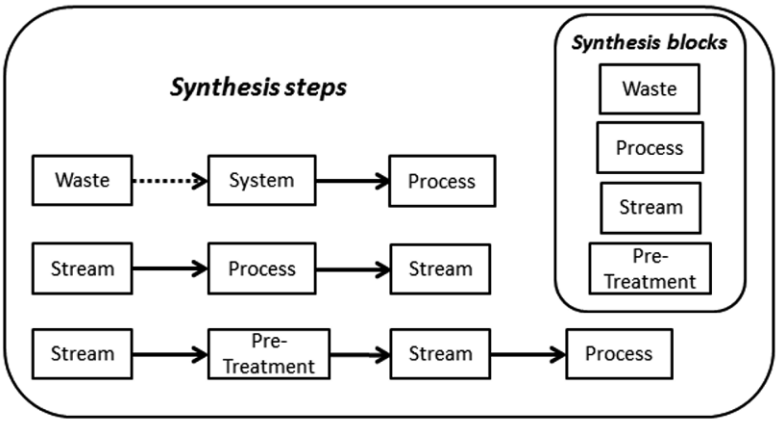

Figure 1. Synthesis procedure for waste management systems

2.2. Nodes development and analysis

Besides one-to-one connections established blocks might develop more complex connections. One-to-many, many-to-one, many-to-many relationships are common in complex networks such as waste management systems. These relationships create decision-making nodes in the network which determine the processing paths of the waste. The nodes increase the number of possible destinations and scenarios in a network. They can either be limited (all outputs of the node must exist) or conditional (not all possible outputs are required in the system). The challenge lies in conditional nodes, where the outputs are not static and logical processing is required. The different types of nodes in a waste management system are shown in Figure 2. The nodes outcome is influenced by quantitative (e.g. pH, waste composition, temperature, cost, water proportion, emissions etc.) and qualitative parameters (e.g. availability of technology, connections, auxiliaries, waste nature and acidity etc.). The selection of the viable but also optimal path depends on multiple interacting parameters. The user may not have adequate knowledge of the required parameters. Therefore, automation is required based on natural language to facilitate and increase the efficiency of the path selection. To establish automation the waste management system needs to be analysed, nodes identified and the respective parameters registered. The conditional nodes define decision-making steps of the system. The data describing the input block of the node will define the output. Hence, the data require an organised flexible structure, which will handle all the possibilities of a node.

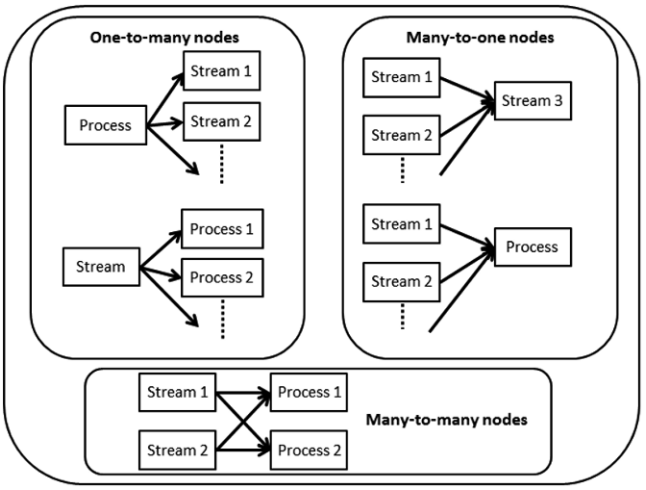

Figure 2. Nodes in waste management systems

2.3. Ontology Engineering

Ontologies are employed to (i) organise the blocks, (ii) establish the connections, (iii) automate path selection and determine the output of nodes, (iv) identify pre-treatments necessity. The blocks synthesizing the system are organised in ontology classes (Waste, Streams, Processes, Auxiliaries, Energy, Emissions, Pretreatments). The connections between blocks are represented by object-type properties. Simple "in" and "out" properties express the inputs and outputs among the blocks of Waste, Streams, Processes and Pretreatments. The class Streams incorporates the different streams coming in and out of processes/pre-treatments and the respective parameters. The classes Auxiliaries and Energy are used to represent the requirements of processes and pre-treatments, whereas Emissions state the emissions type and impact in each process. In addition, data-type properties are assigned, defining values, range of values for different parameters and qualitative statements (e.g. auxiliaries requirements, pH range, acidity, adjustment necessity, composition, units etc.). For example, a process might only be able (or more efficient) to accept acid waste streams with water composition below 40%. The data-type properties are then queried and compared to the conditions of the problem declared by the end-user to provide an accurate and logical output. The connections between the blocks/classes are filtered by the data-type properties leading to different superstructures, thus altered representations of the management system. Additionally, the data-type properties assigned to each of the connected concepts are queried and compared to the input data, to determine whether pre-treatment is required prior to a process, as well as the type and amount of respective auxiliaries. The ontology schema to describe the waste management system is illustrated in Figure 3. The concepts of the ontology have values and qualitative data attached. The data serve as comparing criteria for the nodes and path selection. When the system analysis reaches a node, the ontology is invoked to figure out the optimal processing path the waste stream should follow next. The data-type properties determine the necessity of a pre-treament by checking the boolean property if available ("requirespretreat" or "adjustment"). In case qualitative estimation is not possible, default values or ranges assigned in the ontology are compared to the input of the problem. The data-type properties shown in Figure 3 can vary depending on the decision-making criteria, the availability of data and needs of the examined system.

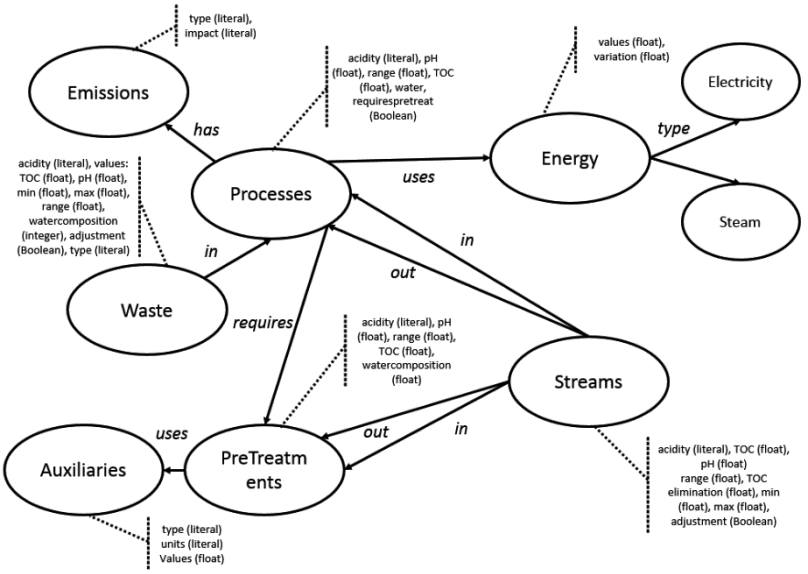

Figure 3. Ontology representation of a waste management system. Arrows show object-type arrows. Dashed lines show data-type properties and their range.

2.4. Models development and deployment

Each process in a waste management system is described by a numerical model for optimization or simulation. Models consist of a core matrix and a case dependent part, where the former is defined by the type of the application, whereas the second depends on the particular case study. Also in a system, the various processes interact with each other, therefore the models are not independent. The output of a specific model could serve as input for the linked process and respective model. For a waste management system in order to be accurate and holistic, the process and model interaction requires integration. The approach relates the problem description to ontology concepts, and then to model concepts. Models input-output relationships and context are deterermined by the ontology resulting in the automation of the models development. This is achieved with the aid of Java language to invoke and link models as well as to handle the transfer of data between ontology and models. SPARQL querying algorithms run at each conditional node to compare the data entered by user and the ontology concepts to determine the optimal problem solution. A different algorithm is also invoked for input stream of a process to compare the stream characteristics with the processing parameters (data-type properties) to determine whether a pre-treatment is required and the respective amounts of auxiliaries. Simultaneously, when interaction between technology models is required the established framework builds models based on prototypes and formats and transfers the data needed. This is achieved by interfering with the models APIs and the deployment of various matching, parsing, writing functions of Java.

3. Illustration

The methodology presented is applied to a wastewater treatment system. The models calculate life-cycle inventory parameters as a function of the waste-water composition and the technologies applied. The established framework develops the system with automated bespoken path selection depending on the composition, water proportion, TOC (Total Organic Carbon), TOC elimination, pH of the initial waste stream. In the

specific waste system analysis, the models require modifications when pH adjustment is needed prior to a process. The framework identifies the acidity of the stream, the technologies that require adjustment and executes the computations to retrieve the type and quantities of the related auxiliaries. MATLAB models that assess environmental impact are invoked and edited accordingly in an automated way. OpenBabel library is used to calculate the atomic composition from the molecules in the waste (SMILES format). Other factors such as density or flowrate are requested to satisfy the specific models needs. In Figure 4 a simple interface for the designed system and a solution of an example for some random values are illustrated.

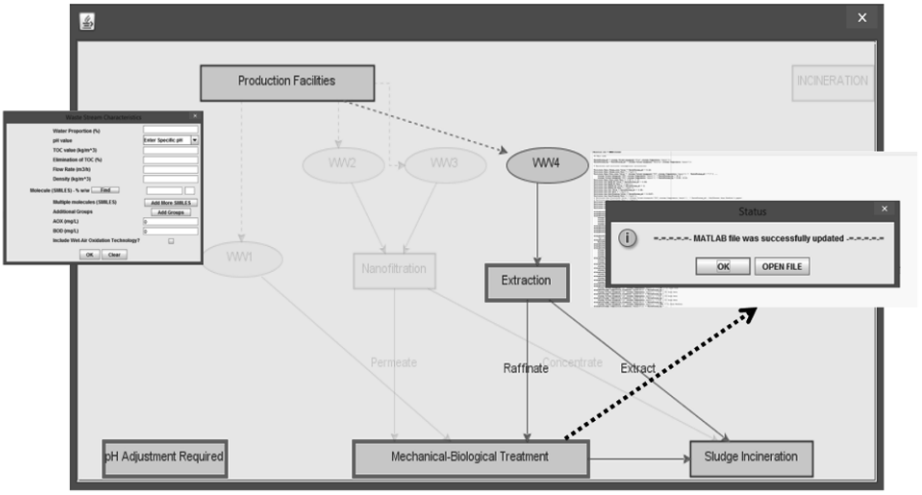

Figure 4. Interface developed for the waste water treatment system

4. Conclusions

The complexity of waste management systems requires a holistic approach that integrates data and models. The paper introduces the use of ontologies to build an intelligent waste management system to handle the multi-objective analysis. Automation through natural language is applied for wider and easier access among the experts. Examination and analysis of the system at a bigger scale provides more explicit and exploitable solutions. The importance of integrating the models interaction in the system is also outlined. Future challenges lie in increasing the involved parameters and complexity of the system, and the inclusion of additional treatment systems.

Abstract

The scheduling function determines the amount of each product to produce, the allocation of equipment and resources to tasks, as well as the sequencing and timing of such tasks, in order to fulfill plan production objectives. A knowledge-based model has been created relying on rigorous analysis of existing process scheduling models. Likewise, a reasoning tool has been developed for matching the system and scheduling task features to previously existing mathematical models. As a result, a model selection can be obtained based on features matching.

Keywords: Scheduling Models; Mathematical Modeling; Knowledge Management.

1. Introduction

The short-term scheduling problem consists of organizing the available human and technological resources in the process plant in order to optimally satisfy customer's demands. Scheduling typically involves decisions on the amount of products to be produced, equipment and resources allocation, production sequence and operations timing, on a weekly or daily basis. A significant amount of models have been proposed in the literature in order to adequately formulate scheduling problems (Floudas & Lin, 2004; Harjunkoski et al, 2014). However, each modeling option can only cope with a subset of the features, and the choice of the mathematical model has an important impact on computational performance. As a result, the model selection and corresponding problem formulation is a formidable task.

From a descriptive perspective, computer science provides with tools for representing the scheduling problem from an abstract conception. For example, artificial intelligence and semantic models, such as ontologies, offer the alternative to represent and share the knowledge of the process and engineering domains. Ontologies are increasingly seen as a key semantic technology for addressing and mitigating the effects of heterogeneities and for enabling semantics-driven knowledge processing. Ontologies are formal structures enabling acquiring, maintaining, accessing, sharing and reusing information (Fensel, 2003).

The goal of this work is to provide a knowledge-based framework capable of determining the best available mathematical models for specific scheduling requirements based on the problem description. Specifically, this work aims to exploit the knowledge found in Operations Research Ontology (Muñoz et al. 2014), by the integration of a decision application and a mathematical scheduling models database. Hence, models capabilities and limitations must be carefully considered for each scheduling problem based on its features and the expected computational performance.
The framework consists of a semantic model based on rigorous analysis of existing process scheduling models. In order to relate the problem features of the real scheduling system to the available mathematical models, a reasoning tool consisting of a decision tree analysis is developed. As a result, the model selection can be automated according to the features matching. Next, the semantic model features and the reasoning tool are described.

2. Scheduling semantic model

The intrinsic complexity of scheduling decision-making has brought forth the development of a wide variety of problem models and solution algorithms. The selection and adoption of a given approach depends on the process plant features and the problem definition and size, among other features. In fact, there is not a unique optimal approach to solve all scheduling problems, and it is highly unlikely to find a universal one at all. Therefore, the main aim of this section is to describe the current scheduling modeling and the developed semantic model.
The starting point when posing a scheduling model consists of defining the problem features, namely the objectives pursued by the scheduling function, the decisions to be made, and finally the elements which represent the system and describe its behavior. Scheduling is the process of arranging, controlling and optimizing work and workloads in a production process. Production scheduling aims to maximize the efficiency of the operation and reduce costs, and backward and forward scheduling are applied to allocate plant and machinery resources, plan human resources, plan production processes and purchase materials.
Scheduling objectives. The objective function measures the quality of the decisions to be made. The objectives traditionally considered in scheduling problems are time related, such as the total completion time or makespan, lateness, tardiness and earliness. However, decisions in chemical industry are usually driven by profitability criteria. Hence, it is necessary to adequately quantify economic criteria in order to reach a high quality decision from an integrative perspective. Therefore, global metrics such as profit, cost or profitability itself should be considered.
Scheduling decisions. The decisions involved in the scheduling function vary according to the plant management needs and depend on the problem features. Anyways, such decisions are highly connected to each other, and to other decision levels, for instance to planning for demand issues or to control for actual processing times. In general, decisions within the scheduling level can be broadly classified in four types:

- Batching. It consists of deciding on the number and size of the lots of products that are to be produced. Therefore, these decisions are directly related to the mass balances and storage management, and so to the planning level.
- Allocation. It involves the assignment along time of tasks to equipment units and other plant resources, such as manpower, electricity and water, according to their availability. Resources are usually finite and product specific, and they may be reusable or not.

- Sequencing. It determines the order in which batches of the different products are to be produced in the different equipment units along the process plant.
- Timing. It concludes the initial and final times at which batches are to be performed. Such decisions highly depend on the process features. Therefore, according to existing intermediate storage policies and the relationship between tasks, production timing may be differently performed inside the whole production time horizon. A key point in batch scheduling consists of the time representation, which depends on whether actions may take place at any time or at some predefined time points. Since actual processing times depend on process conditions, which may be influenced by external disturbances, actual timing decisions may be highly changed from the initial estimation.

Scheduling constraints. Production process features and process plant environment determine the formulation of the scheduling problem. The most fundamental element describing the production process is the product recipe, which contains the information about the amount of raw materials as well as the processing steps with their conditions, such as temperature or pressure, and the times over which they take place. Even though product recipes are usually determined and fixed in the design step, they can potentially introduce flexibility in the scheduling problem, if variable process conditions are allowed.

Depending on the equipment configuration of the plant, the number of batches that can be processed simultaneously varies. In multiproduct batch plants, the final products have an identical recipe structure. Therefore, all products require all steps in the process and follow the same sequence of operations. In contrast, in multipurpose batch plants, the production steps are not the same for all products. Such plants are more flexible and effective for a large number of products produced in small volumes, since equipment items can be fully utilized and vessels cleaned easily.

According to the perishable features of the intermediate products, alternative storage policies can be adopted, namely a zero-wait transfer, a no intermediate storage (if intermediates can be hold up in the equipment), a finite intermediate storage, which may be shared or exclusive, or an unlimited intermediate storage policy. Thus, equipment cleaning and material transfer are two practical issues that may have a significant effect in the scheduling results because they may cause a reduction in the overall equipment utilization.

2.1. Scheduling problem features

From a global perspective, batch production scheduling aims at optimizing the resource utilization of batch manufacturing facilities in order to fulfill customer orders within a specific time horizon. The building block of batch process scheduling is the process recipe, which contains the whole information required to produce the product, as well as the set of processing tasks, i.e. the process flow. The recipe is usually obtained in a design stage prior to the scheduling stage, and the process conditions to perform the product are optimized and fixed for all production batches of a given product. In addition, such information must be complemented with the production facility data regarding equipment and resources, such as manpower, inventory or general services availability; production planning information regarding sales, time horizon, order due dates or prices; and actual plant state. The complexity and variety of the scheduling problems requires effective organization of the aforementioned information in order to improve communication and process efficiency. Next, the most relevant characteristics of the scheduling problem are: (i) material routing, (ii) operation modes, (iii) equipment

assignment and connectivity, (iv) storage policies, (v) material transfer, (vi) changeovers and set-up operations, (vii) batch size and processing time, (viii) demand pattern, (ix) resource constraints, and (x) time constraints.

2.2. Scheduling models classification

The mathematical models which are more widely applied in the literature are presented in Table 1, which contains the summary of the general characteristics of such models along with the critical problem features. For the sake of brevity, the comparison between the formulations is restricted to the aforementioned table.

3. Classification mechanism of the scheduling semantic model

The semantic model classifies the scheduling domain, according to the features described in the previous section for generally characterizing the system. This characterization defines the elements which determine the behavior of the production system. These features (Figure 1) refer to: (i) product, describes whether there is a single final product or multiple final products with different families; (ii) production capacity, refers to the quantity of product; (iii) the size of the company, characterizes the company in terms of single production site or multiple production sites, human resources and economic flow; (iv) supply features, define the raw material availability and reliability; (v) demand features, describe the volume and variability of the demand; (vi) market competition, characterizes whether there is a high or low number of competitors to satisfy the customers; and (vii) environmental regulations, includes the

Table 1. Classification of scheduling models in the literature

Event representation	Time representation		Type of processes		Critical modelling issues	Critical problem features
	Discrete	Continuous	Network	Sequential		
Global time intervals	✔		✔		Time interval duration; scheduling period	Variable processing times; sequence dependent changeovers
Global time points		✔	✔		Number of time points	Intermediate due dates; raw material supply
Unit specific events		✔	✔		Number of time events	Intermediate due dates; raw material supply
Time slots		✔	✔		Number of time slots	Resource limitations
Unit specific immediate precedence		✔		✔	Number of batch tasks sharing units and resources	Resource limitations and inventory
Immediate precedence		✔		✔	Number of batch tasks sharing units and resources	Resource limitations and inventory
General precedence		✔		✔	Number of batch tasks sharing resources	Inventory

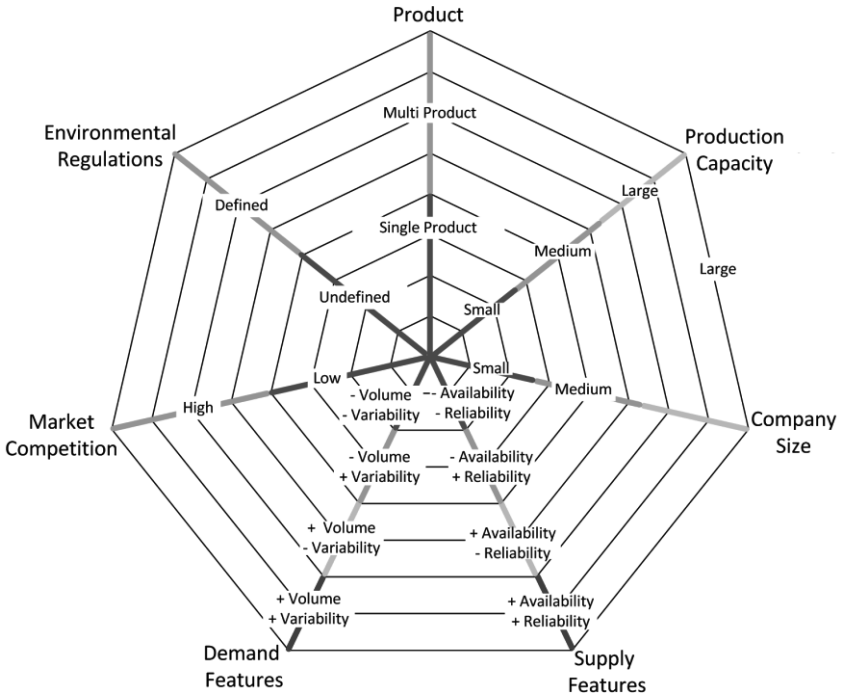

Figure 1. System characterization in terms of the general features

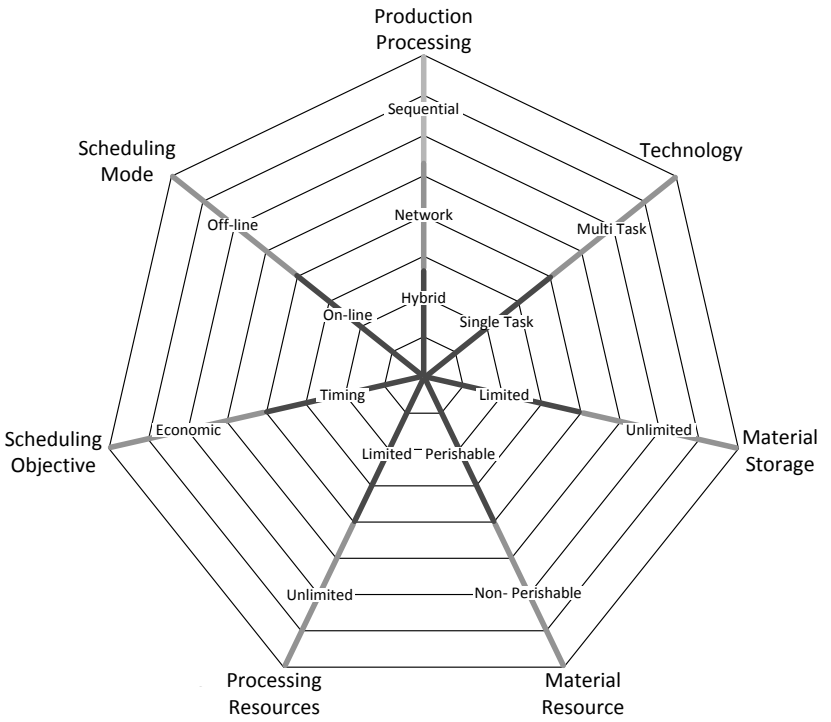

Figure 2. System characterization in terms of the tactical features

limitations or lack of limitations in terms of environmental issues. The tactical features of the scheduling environment are also characterized in the semantic model in terms of the following models (Figure 2): (i) production processing, includes the characterization of the production environment and refers to sequential (single stage, multiple stage, multipurpose), or network (STN, RTN), or hybrid environment; (ii) technology, characterizes the processing units; (iii) material storage, determines the storage (initial, intermediate, final) limitations; (iv) material resource, characterizes whether the resources are constrained in the storage task; (v) processing resources, whether there is a limitation in the resources such as energetic, human, etc.; (vi) scheduling objective, describes the strategy of the scheduling function; (vii), scheduling mode, defines whether the offline mode, that is design, or the online, production plant, mode are pursued. Likewise, the mathematical models have been thoroughly studied and decomposed in terms of their features for understanding which elements take part in the equation models and which features have been included with such models. After this formalization, each model can be characterized from the tactical features to the general features. In order to classify the scheduling problem, we can characterize the system by using the general and tactical features. The reverse path consisting of classifying the process mathematical model can be also addressed from tactical to general features. This matching allows the selection of which model or part of the mathematical model can be reused for formulating a particular production scheduling problem.

4. Conclusions

The developed approach deals with the semantic representation of the process scheduling function. This semantic model relates the problem features with the best mathematical modeling structure given a reasoning stream, consisting of the amount of each product to produce, the allocation of equipment and resources to tasks, as well as the sequencing and timing of such tasks, in order to fulfill certain objectives

In this sense, it has been necessary to develop a reasoning tool for matching the scheduling problem features to the available mathematical models. As a result, a model selection can be obtained based on features matching.

Abstract

The complexity of integrated planning and scheduling models can be tackled with decomposition techniques based on duality and information flows between a master and a set of subproblems. Hence, the information sharing and communication of information from the industrial environments requires flexible structures, facilitating the use of analytic tools and providing higher flexibility for model building in industrial environments. In this work, an ontological framework is proposed to allow the virtualization of systems and processes and to implement a novel Lagrangean decomposition scheme based on hierarchical level decomposition. Indeed, the scheduling and planning sub-problems are created for each facility/supply chain entity and their dual solution information is shared by means of the ontological framework. Two case studies based on a STN supply chain planning and scheduling models are presented to emphasize the advantages and limitations of the proposed approach.

Keywords: Lagrangean Decomposition; Integration; Planning; Scheduling; Knowledge Management.

1. Introduction

In the integrated supply chain (SC) planning problem, several dimensions may be identified, namely geographical distribution, hierarchical levels, and business functionalities (Stephanopoulos, 2011). The performance of SCs results from the synchronization of the material, financial and information flows, based on mass balances, SC capacity and technological constraints, budget limitations, suppliers' capacity, market demand and competition, and customer satisfaction requirements among others, so as to achieve corporate goals efficiently.

The functional decision levels have different space and time scales, but they are intrinsically related to each other since the decisions made at one level directly affect others. In the chemical process industry, two key methodological components of SC management are scheduling and planning technologies. The latter function focuses on

the creation of the production, distribution, sales and inventory plans based on customer and market information while observing all relevant process constraints. In particular, operational plans are aimed to structure future production, distribution and other related activities to reach the business objectives (Kallrath, 2005). According to Kallrath (2002), most of planning problems in the process industry lead to mixed integer linear programming (MILP) or mixed integer non linear programming (MINLP) models and contain the following building blocks: tracing the states of plants, modeling production, balance equations for material flows, transportation terms, consumption of utilities, cost terms and special model features. In fact, the planning model is a simplified representation that is used to predict production targets and material flows over several months or years. At this level, effects of changeovers and daily inventories are usually neglected. This simplification tends to produce optimistic estimates that cannot be realized at the scheduling level (Grossmann et al., 2008). On the other hand, the short-term scheduling function is directly related to: i) the company's planning function which determines the production targets; ii) the process control function which implements and monitors the processes' outputs, and iii) the production process itself by means of the product recipe, which is based on the process stages. Therefore, the integration of process scheduling with other functions is a broad area which poses a number of important challenges. As discussed by Kallrath (2002), the borderlines between scheduling and planning are diffuse and there are strong overlaps between them. Furthermore, the integration between scheduling and planning is increasingly demanded so that facilities can respond quickly to demand fluctuations and better utilize existing resources close to their capacity and actual needs. The economic incentives for the integration of the planning and the scheduling levels are substantial (Grossmann et al., 2008). The goal of the SC planning and plant scheduling problem consists in determining the optimal manufacturing and network distribution policies for the entire SC of a company in order to fulfill a pre-established economic objective.

Lagrangean decomposition strategy has lately received increasing attention for solving the planning problem and its integration with scheduling. This decomposition scheme of the integrated formulation exploits the structure of the full-scale model using mathematical methods. In this work, we address the integrated multi-site planning and scheduling problems using a Lagrangean relaxation approach. Specifically, the decomposition relies on the quantities to be produced at each production site within the SC (hierarchical decomposition), in contrast to other approaches which consider the flows among the SC elements (spatial decomposition), or the flows along time intervals (temporal decomposition).

The Lagrangean decomposition strategy is supported by an ontological framework. The ontological framework manages the information exchange between the master and slave problems required by the decomposition approach. As presented in previous works Muñoz et al. (2013a, 2013b), the ontology also supports streamlining information and data integration along the different hierarchical decision levels which allows the automatic instantiation of analytical systems by gathering and processing data from transactional systems. The aim of the ontology application in this work is to provide a straightforward manner of building, instantiating and solving large scale models by taking advantage of ontologies functionalities. Overall, this work presents a hierarchical-based decomposition strategy based on the functional levels and provides a systematic ontology-based framework for information tracking and transfer, which has not been presented so far in the literature for the integrated planning and scheduling problem.

Next, the integration problem of scheduling and planning is defined as considered in this work. In the methodology section, the mathematical formulation for the planning and scheduling problems, the proposed Lagrangean strategy and the information management environment are presented. Finally, a case study illustrates the algorithm and operation of the knowledge management framework.

2. Problem statement

This work is concerned with the multiperiod and multisite supply chain planning and scheduling problem of multipurpose batch plant facilities. The planning horizon comprises a time span of years. Production plants operate under cyclic scheduling conditions during each year.

The problem assumes a fixed supply chain design.It is assumed that a set of suppliers with unlimited capacity provide raw materials to the different production plants. These production plants and several distribution centers are located in specific geographical sites and deliver final products to the markets. Each production plant produces certain amounts of final products using equipment technologies which have an installed capacity and minimum utilization rate. Production routes are defined in the product recipes, which comprise mass balance coefficients and the utilizationof production resources. The final products may be stored in the distribution centers before being sent to the markets. Each market has a nominal demand of final products, and unfulfilled demand cannot derive in back orders. The price of every product in each market is defined along the time horizon. The available transportation links among the different elements of the supply chain are also provided.

Therefore, the aim of this problem consists of determining: (i) the assignment of manufacturing and distribution tasks to the network nodes; (ii) the amount of final products to be sold; (iii) the amount of material shipped among facilities; and (iv) the detailed batching, sequencing and timing of tasks in each production plant. These decisions are driven by (i) direct cost parameters, such as production, handling, shipping, storage, and raw materials, (ii) indirect expenses, associated with the capacity utilization, and (iii) prices of the final products. The overall goal consists in maximizing the economic performance of the whole supply chain structure. The exchange of information required to build the models and to solve the problem is supported by the ontological framework.

3. Methodology

The multiperiod and multisite deterministic planning model, which provides a framework based on the state-task-network (STN) concept for the planning and scheduling of SCs, is based on the work by Laínez et al. (2009). A cyclic scheduling model (Wuand Ierapetritou, 2004) is applied at each production site. The assumption of cyclic scheduling allows to estimate the production schedule considering uniform demand along the time horizon and availability of the raw materials; which is a reasonable approximation to schedule the yearly operation of a plant. The model adopted in this work relies on the continuous time STN formulation which has been extended to consider cyclic scheduling. Then, the Lagrangean decomposition strategy, which decouples the planning and scheduling decision levels is presented in Figure 1.

Finally, an ontological framework is introduced for the adoption of the solution strategy between the different hierarchical levels to facilitate the problem representation and communication.

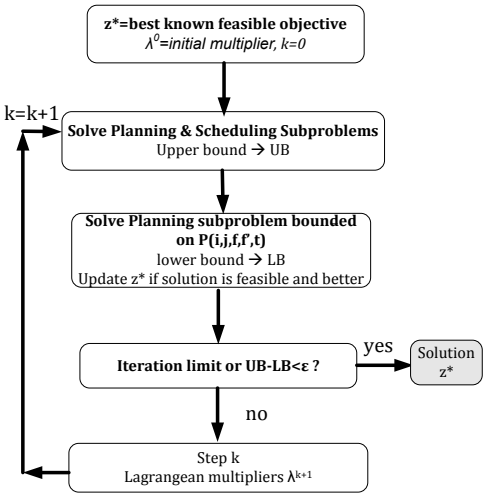

Figure 1. Interaction between the knowledge management framework and the integration strategy considering the Lagrangean decomposition

3.1. Knowledge Management strategy

The ontology is intended to promote transversal process-oriented management enabling interaction among the different functionalities. As a result, databases can be well located and their data are easily available and can be transformed into valuable information. This work uses an ontology-based framework for integrating the planning and the scheduling functions by sharing and communicating the results of the mathematical models in an iterative procedure. The objective is to use such an informationin the Lagrangean decomposition technique. Therefore, this framework allows the communication and management of multiple models and the data flow required for their efficient solution so as to provide support to decision makers in a timely fashion. One key aspect in the decision-making process is information extraction, which should ultimately result in information quality. Information quality refers to the precision of information in terms of the time, content and clarity required for a specific task. Specifically, optimization techniques require accurate information for reaching meaningful results for decision-making. Indeed, the interoperability and exchange of information from different systems and hierarchical levels is one of the most critical aspects in the daily operation of many organizations. This activity can be drastically improved by combining knowledge and expertise management approaches. The workflow of the knowledge management approach adopted in this work is presented in Figure 2. Firstly, the problem is modeled within the ontological structure and the mathematical parameters related to the Lagrangean decomposition are instantiated within the ontology. Next, Lagrangeansubproblems related to the planning and scheduling functions are solved with mathematical programming techniques according to the data contained in the ontological framework. The results from these problems are fed back to the ontological structure, which is updated with the new values. Next, the original planning problem is solved with the upper bounds to the production values obtained in the scheduling Lagrangeansubproblem, and a feasible lower bound to the integrated problem is obtained. The results of the feasible solution are updated in the ontological framework, ant the termination criteria are checked. If these criteria are not fulfilled, the new Lagrangean multipliers are computed and updated in the mathematical parameters of the ontological framework. Therefore, the new planning and scheduling

subproblems are fed with the updated values of the problem, contained in the ontology. This procedure is repeated until one of the termination criteria is met.
The ontological model is managed by means of a high level informatic program; which allows the capabilities for mining data as a decision support system tool by providing information quality at every decision level. In order to provide the optimization models with the input data, Java has been used as a high-level programming language for extracting the data managed by the ontological model.

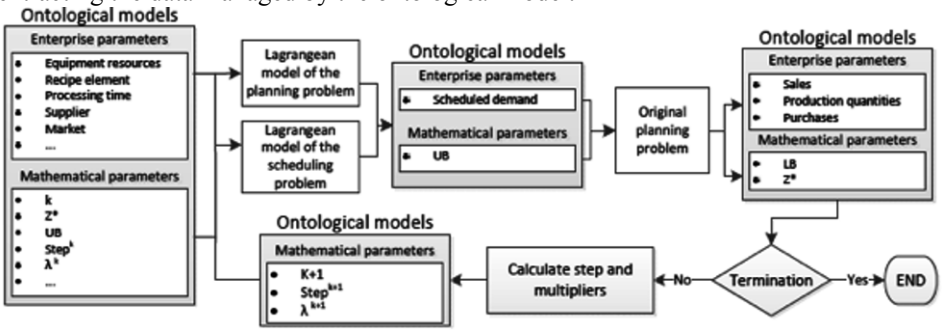

Figure 2. Interaction between the knowledge management framework and the integration strategy considering the Lagrangean decomposition

Therefore, the resulting input files stand for information quality. The code has been built using the platform NetBeans IDE 7.0, and the OWL API has been adopted to access the ontology model from Java.

4. Case study

This case study is based on a supply chain network design-planning problem presented by Laínez et al. (2009). It consists of three suppliers and two installed locations for the processing sites and the distribution centers in a planning horizon of five annual periods. The production process should fulfill the demand of two final products which are sold in six different market locations. Each production plant contains a production process consisting of four equipment technologies, five production tasks and nine states/materials. Two intermediate scheduling storage policies are proposed, unlimited intermediate storage policy (UIS) and zero wait (ZW). The results for the different iterations of the Lagrangean strategy are presented in Figure 3.

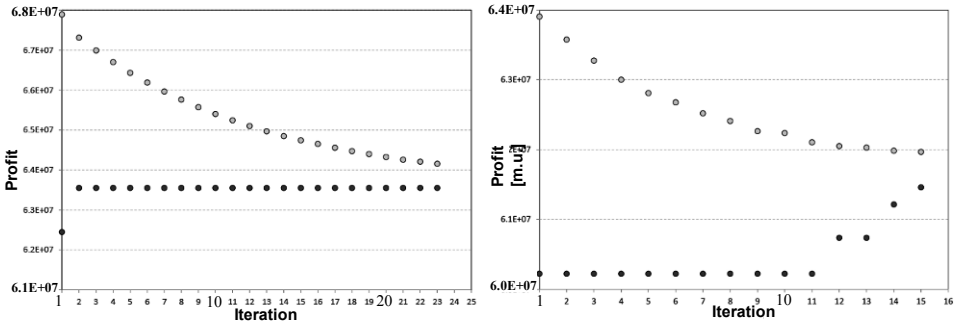

Figure 3.Results of the Lagrangeanstrategy for UIS policy (left), and ZW storage (right).

In the case of UIS, the problem converges after 23 iterations of the Lagrangean algorithm and a total computational time of $2.64 \cdot 10^3$CPU s. The optimal solution (which is represented as the lower bound), increases from the initial iteration. Therefore, the decomposition strategy enables to reach global optimal solutions from the planning perspective, considering the complete detail of the scheduling model. The maximum profit for the SC is $6.33 \cdot 10^7$m.u. In the case of ZW, the problem converges after 15 iterations and a total computational time of $4.33 \cdot 10^3$CPU s. Both the upper and lower bounds change along the iterations, and the decomposition strategy enables to reach global optimal profit value of $6.15 \cdot 10^7$m.u.

5. Conclusions

The developed approach deals with decentralized SC decision-making schemes by using a hierarchical level decomposition.This is of great interest given that the current global economy, in which outsourcing and partnering are the normal mode and SCs with varying degrees of decentralization exist, is the reality that must be addressed. By using a Lagrangean relaxation based approach for decentralized decision making, there is no need of explicit knowledge of sensitive/private information such as production cost functions and operation constraints of every supply chain member, since minimal information (i.e., dual variables and primal variables for the complicating constraints) is interchanged as feedback among SC partners instead. This interchange could be carried out using a technological infrastructure based on the proposed ontological framework.

Abstract

In the last decades, the integration of informatic applications supporting planning, scheduling and control has been a serious concern of the industrial community. Many standards have been developed to tackle this issue by addressing the exchange of data between the scheduling function and its immediate lower and upper levels in the planning pyramid. However, a more comprehensive approach is required to tackle integration problems, since this matter entails much more than data exchange. So, this article presents an ontological framework that provides the foundations to reach an effective interoperability among the various applications linked to scheduling activities.

Keywords: ISA-88, ISA-95, ontologies, scheduling

1. Introduction

Despite over twenty years of research in batch scheduling, advanced scheduling support systems are not very common in the chemical industry yet. In addition, most of the available commercial systems are not based on the solution methodologies that academia has developed. One of the reasons why academic approaches are not adopted in industry is the fact that decision support tools do not integrate with the enterprise and manufacturing applications because they rely upon quite different knowledge representations. In the last decades, the integration of informatic applications supporting planning, scheduling and control has been a serious concern of the industrial community. The ISA-88 (ANSI/ISA, 2010) and ISA-95 (ANSI/ISA, 2000) standards have been developed to tackle this issue by addressing the exchange of data between the scheduling function and its immediate lower and upper levels in the planning pyramid. However, a more comprehensive approach is required to address integration problems, since this matter entails much more than data exchange. In last decade, ontologies have been considered an effective solution to interoperability problems in many domains. Therefore, this article presents an ontological framework that provides the foundations to reach an effective interoperability among the various applications linked to scheduling activities.

The paper is organized as follows. Section 2 points out some of the problems of dealing with multiple knowledge representations in the scheduling domain. Section 3 introduces the ontological approach that is proposed to address integration problems. By means of example, Section 4 describes the ontology that was developed to formalize the ISA-88 standard, which is one of the components of the ontology network that is proposed in this contribution. Finally, section 5 presents some concluding remarks.

2. Different knowledge representations in the scheduling field

Many academic approaches addressing scheduling problems resort to intermediate representations, like the state-task (STN) or resource-task (RTN) networks (See Figs. 1 and 2 of Giménez et al., 2009), before developing the mathematical model that indeed solves the problem. However, this representation does not have a direct mapping to the master data that is usually employed in industry. Thus, the human scheduler has to manually create the STN/RTN graphical models from data that is spread in different tables of the enterprise databases.

On the other hand, in the industrial domain, the most important input for the scheduling problem is the ISA-88 master recipe, which provides the set of data that uniquely defines the production requirements of a specific product batch. Recipes are recursive structures containing five components: *Header, Formula, Procedure, Equipment requirements* and *Other Information*. See for example Fig. 1, which depicts the master recipes of P1 and P2, which are the final products of the STN shown in Fig. 2 of Giménez et al. (2009). Fig. 1 shows that the procedure component of the P1 master recipe is defined in terms of the T2, T1 and T3 operations. The INT3 recipe entity is also shown in Fig. 1 and the ones corresponding to the other intermediates can be found in VH (2014). An analysis of Fig. 1, the material in VH (2014), along with Figs. 1 and 2 of Giménez et al. (2009) shows that these recipe representations are quite different and that a direct mapping is not possible. On top of the recipe information, the scheduling problem needs additional input data, such as demands to be fulfilled, plant topology with unit features, etc. This last type of information is not represented neither in the STN/RTN graphs nor in the ISA-88 recipe model. Usually, industry specifies it in the so called *physical model* proposed by ISA-88, while in academia it is handled in an informal way that is not machine procesable and can lead to misinterpretations.

Having all this input information, a mathematical model is built and then solved. The resulting production schedule needs to be communicated to the adjacent levels in the planning pyramid: (i) to the lower process control layer to materialize batch execution and (ii) to the upper production planning and control (PPC) level for plan management activities. In practice, the results included in the solver output file need to be translated into the *control recipe* (the one that according to ISA-88 standard is employed by the control system to perform batch execution) and into the *operations schedule*, an explicit representation of the schedule according to the ISA-95 standard.

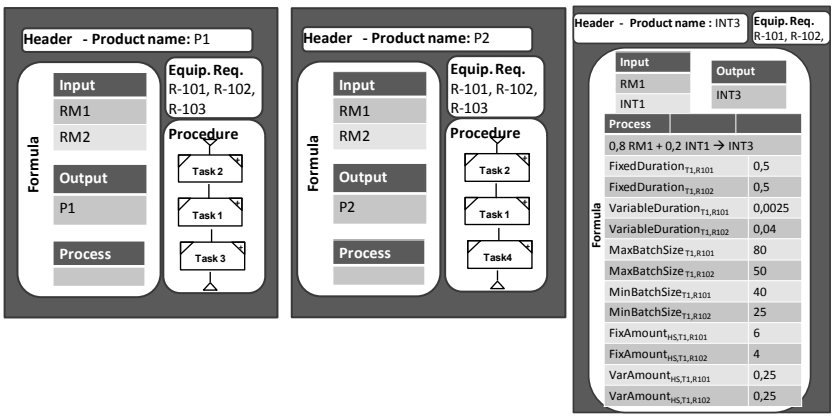

Figure 1. Recipe entities for products P1, P2 and INT3

As a result, it can be seen that in order to perform scheduling activities and to articulate them within the planning pyramid, several knowledge representations and models need to interplay. For instance, to transform a given master recipe into a control one, the procedure that is conceptualized in Fig. 2 would need to be executed (actually, such an approach was never made explicit by researchers devoted to the industrial scheduling field and it is presented in this contribution). Currently, the translation from one representation to another is manually done, in the few cases it is indeed carried out. In fact, none of the academic proposals take into account the automatic translation of the solver output file into representations that are useful from an industrial point of view, i.e. control recipes and explicit schedule representations. In addition to the manual translation workload, these heterogeneous data models employ distinct terms to refer to the same concepts. Besides these semantic issues, since the models are not formal, they cannot be interpreted by a computer and can also be ambiguous. Moreover, an analysis of the ISA-88 and ISA-95 standards (Vegetti and Henning, 2014) reveals some overlappings on the information and activities handled by them (e.g. product definition vs. recipe specification; equipment capability vs. physical model), which discloses some collision points. The problems pointed out in the previous paragraphs are some of the difficulties preventing the integration of scheduling activities within the planning pyramid and, more specifically, precluding the adoption of advanced scheduling approaches in industry.

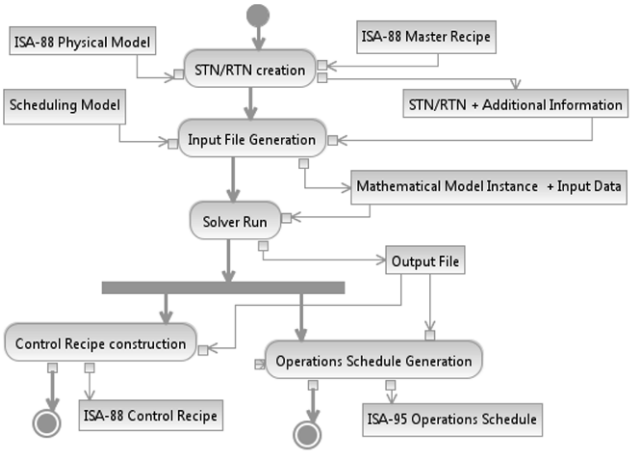

Figure 2. Data manipulation and model translation associated with scheduling

3. Ontological approach that supports scheduling activities

In order to tackle the problems posed in the previous section an ontological approach is addressed in this contribution. An ontology is a "formal, explicit specification of a shared conceptualization" (Gruber, 1993). Ontologies have been recognized as key elements to reach semantic integration, since they provide formal models that establish a consensual and precise meaning to the information communicated among different sources.

Following the interlingua approach (Ciocoui et. al, 2000), this contribution proposes the construction of a network of ontologies (see Fig. 3), having the *Schedule Reference Ontology* (SRO) as a common vocabulary. This network also contains local ontologies that formalize the different sources of information supporting scheduling activities: for instance, it contains ontologies of the ISA-88 and ISA-95 standards, the STN/RTN

representations, of the mathematical programming models (whenever MILP/MINLP-based solution approaches are pursued), of timed automata-based solution procedures, etc. The implementation of this ontology network requires the formalization (triangles in Fig. 3), with a previous conceptualization in certain cases (diamonds in Fig.3), of the various information sources. This is done by means of the OWL (Ontology Web Language; W3C, 2004) and RDF (Resource Description Framework; W3C, 2014) languages. Moreover, the development of ontology alignment agents (circles in Fig. 3), which map concepts in the local ontologies to their definitions in the SRO common vocabulary, is also required. This core ontology plays a central role in the network, acting as a bridge between the different ontologies in the net.

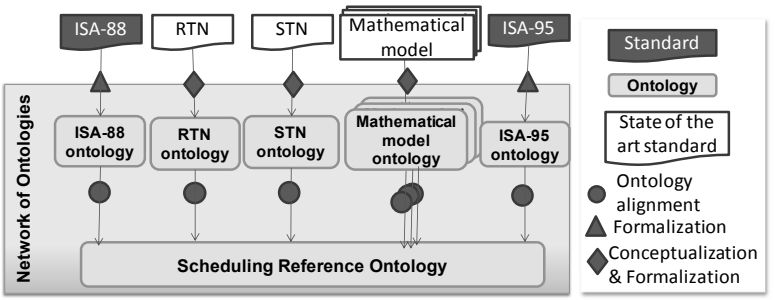

Figure 3. The proposed network of ontologies

The development of the proposed network of ontologies is the starting point for the automatic construction and translation of models that are employed during the scheduling activities. Fig. 4 presents the architecture that is proposed for an application supporting this task, considering the case in which an MILP-based scheduling solution approach is adopted. This architecture has two main components: the RDB2RDF and the automatic constructor and translator (AC&T). The aim of the first component is to create an OWL view of the relational databases that provides information about the master recipe and the physical model. Based on a mapping file and on the ontology network, RDB2RDF creates a populated ontology in RDFS/OWL from these relational databases. The populated ontology is then published by the SPARQL-endpoint, which can reply to the SPARQL queries that are issued from the AC&T component.

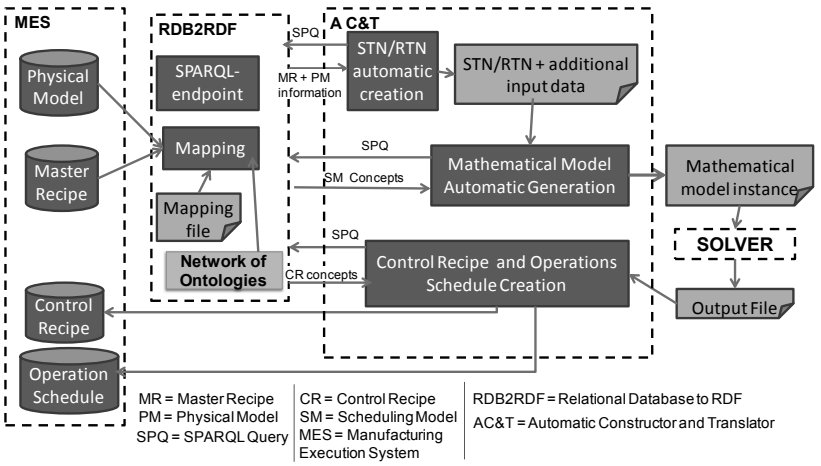

Figure 4. Automatic construction and translation framework

The AC&T component has two objectives. On the one hand, it is responsible for the automatic creation of two representations: the STN/RTN intermediate model and the mathematical model instance, which are the inputs to the solver. On the other hand, it translates the solver output file into the needed control recipes (one per product batch) and the operations schedule models. To execute these tasks, the AC&T component obtains information from the RDB2RDF one through the SPARQL query language. The development of these components is based on JENA, a Java framework for building Semantic Web applications that provides a programmatic environment for RDF, RDFS, OWL, SPARQL and includes a rule-based inference engine. In addition, there are many tools that support the RDB2RDF functions, like the D2RQ platform, Asios' SBRD, RDBtoOnto, among others.

4. Development of the ontology network. ISA-88 example.

The formalization of the ISA-88 standard has been tackled first as it is the data model having the major semantic inconsistencies in its term definitions and because of its central role in scheduling activities. Vegetti and Henning (2014) presented the initial steps towards the formalization of the ISA-88 master recipe, in particular focusing on its recipe procedure component. Therefore, the main concepts in the corresponding ontology are related to recipes and their components. The *RecipeEntity* is the combination of a *ProceduralElement* with associated recipe information, which includes a *Header*, *EquipmentRequirements* and a *Formula* (See VH, 2014). Each *Recipe Entity* is built up of lower-level recipe entities. But these levels should be hierarchically organized according the procedural control model. Therefore, the concepts *Procedure RecipeEntity*, *UnitProcedureRecipeEntity*, *OperationRecipeEntity* and *PhaseRecipe Entity* have been added to the ontology in order to represent recipe entities at *Procedure*, *UnitProcedure*, *Operation* and *Phase* Levels, respectively. All *Recipe Entities,* except the ones at *Phase* level, which do not have components, should include *composedOf* recipe entities belonging to the immediate lower level.

In the remaining of this section, the formalization of the recipe *Formula* component is described for illustration purposes. For space reasons, only a brief sketch of the concepts is shown, along with their definitions. For more details on its OWL implementation refer to VH (2014). According to ISA-88, the *Formula* is a category of recipe information that includes various parameters (see Fig. 1). Therefore, as shown in Fig. 5, a *Formula* is modeled as a parameter set, which may be categorized as inputs, outputs, or process parameters. Parameter values may be simple values, expressions, or references to parameters that are defined at the same level or at higher levels in the associated procedural hierarchy. Values that are expressions may include references to other parameters (*ReferenceTo* association in Fig. 5). An input parameter represents the identification and quantity of a resource required to make the product batch. These resources may be raw materials, energy, manpower or utilities. Moreover, the Resource class may be specialized to take into account others pertaining to specific industrial domains. Similarly, an output parameter specifies a certain material and the quantity that is expected to be obtained from the execution of a recipe. A process parameter details information, such as temperature, pressure, batch size bounds, that is relevant to the product batch. Each parameter is associated with a value type, a unit of measure, a scaling factor and a reference type. The corresponding definitions are given below:

Value type: specifies how the parameter value is interpreted. It includes: basic data types, data sets that define material transactions (transfer, consumption, generation of material); or data series (e.g., a temperature profile that will be tracked).

UnitofMeasure: identifies the engineering units of measure for the Value (e.g., kg, pounds).
ReferenceType: specifies the way parameters are related if the associated parameter has references to others. The types of relations may be: Algebraic or Boolean equations, Product specific entry forms that work on one or more parameters, Deferral of parameters to different recipe entities (at the same or another level), among others.
Scaling Factor: defines the scaling rule, which indicates how the parameter should be scaled with the batch size.

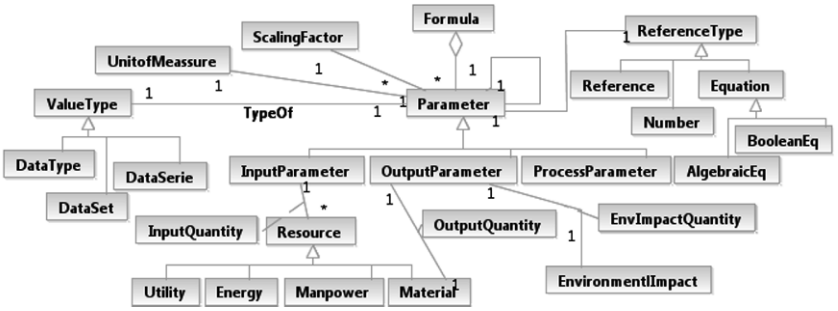

Figure 5. Formula Definition

5. Conclusions

Ontologies support interoperability by providing semantic terminology in a computer understandable format. This article proposes the definition of a network of ontologies to solve the interoperability problems associated with the execution of scheduling activities and their interplay with other functions within the Planning pyramid. This ontology network, whose architecture is presented in this contribution, is the starting point for the automatic construction and translation of models that are employed during the scheduling activities. In addition, one of the main ontologies of this network is described along with its implementation in OWL (VH; 2014).

Constructing an ontology for physical-chemical processes

Heinz A Preisig

Department of Chemical Engineering; NTNU; Trondheim, Norway
Heinz.Preisig@chemeng.ntnu.no

Abstract

An ontology is a formal collection of pieces of knowledge that specify the behaviour of entities in a domain. Our domain is physical-chemical-biological systems, processes that we describe with a set of concepts or principles. These ontologies are not used to reason about the system, but to construct process models that adhere to these concepts, in particular the conservation principles and the behaviour of materials, the geometrical concepts in space and time.

Simplicity of the ontology is a design criteria, both in the definition and implementation of its utilisation. A simple generic structure building on defining the containment as a directed graph, which is populated with tokens. The two enable us to apply our concept in a very broad field of contexts. So whilst we discuss the structure based on physical systems with control, it can be applied much wider. The extension to multi-scale models is or particular interest.

Keywords: model-based engineering, computer-aided, design, operations

1. Why ontoloy-based modelling

Over the past decade this term is increasingly used in science and technology and since by definition the term is context dependent, the usage varies greatly, Adding natural variations in interpretation, it cannot be a surprise that people raise their eyebrows when being confronted with the term. So let us argue on why then we still want to use the term here: Ontologies are loosely defined as the basic knowledge, the template on which we construct and derive the knowledge of a field. Since we attempt to capture the representation of physical systems, we think of ontology to be indeed an appropriate term to use. Our application is in stark contrast to other uses of ontologies, which more lean towards knowledge-based systems. Our application constructs the ontology as a lower triagonal structure, thus the resulting knowledge representation is anything than loose, it is highly structured.

2. The architecture

2.1. Frame

Our objective is to construct an ontology for mechanistic models of physical systems Preisig (2012, 2010). Physical systems live in time and space. The space they occupy is a part of the universe and they move in time.

```
Ontology.physical: frame := [time, space]
```

With this statement we introduced not only a ontology statement, but also an attribute to the ontology, making the ontology context dependent.

2.2. Containment

We further state that space being occupied by the physical system can be subdivided into smaller parts without imposing any further limitations on how "small" this he parts may get. For practical reasons we implement the break-down mechanism as a hierarchical procedure, purely for making the handling of large scale systems feasible; so complexity handling is the issue, but latter is separated from generating an ontology because the model is always the collection of the leave nodes of the hierarchical decomposition.

The process is embedded in its environment thus defining an initial split into two basic parts. The next step is to structure the physical space the plant occupies. The granulation of the process is motivated by time-scale and or some kind of grouping considerations. As mentioned the granulation process is done recursively, which though is not relevant for the ontology in the first place. Without introducing limitations, we specify the environment to consist of infinitely large volumes, and call them *reservoir* thereby following the nomenclature of classical thermodynamics. The observant reader may argue that this will limit the models to constant boundaries. This is not the case as we can always construct a time varying input from a combination of constant reservoirs and perfect control, which though also defines the need for adding control as part of the basic ontology. Once the plant's volume has been divided, one defines the interactions between the different parts across the common boundaries. In the case of a physical process, they will exchange extensive quantities by which means the state of the two interacting volume parts are changing. The interactions carry flow direction information, which must be related to the geometry. Thus we introduce the interaction as directional interaction, physically speaking as a reference co-ordinate. The result is a network of interacting volume elements represented as a directed graph with the nodes being capacities and the arcs representing the exchange of extensive quantities.

We have seen the need for representing control systems. We map them also into a directed graph, though here the nodes represent information processing units and the arcs signals. Again the direction is used to give signals a flow direction.

In both cases we have as a basis a directed graph. So for the ontology we define:

```
Ontology.<context>: containment :: directed graph := [nodes, arcs]
```

The nodes are a list of node identifiers, whilst the `arcs` is a list of tuples each tuple consisting of a tail node identifier and a head node identifier. The `arcs` is thus the incidence list of the graph. At least for physical systems, the graph is a simple one, meaning it has no loops (arcs with identical head and tail). The same usually applies to information systems.

2.3. Tokens

The containment definition together with the frame represent the foundation of the model ontology, whilst the main body is a supergraph of equations and variables. Since the latter is context dependent, the part between must define the context in more detail. We do this by adding one more base component, namely token. The token represents what is living in the containment. In the case of a physical system this will essentially be what is associated with the conserved extensive quantities. The token in a node than gives raise to the definition of the state.

```
Ontology.<context>: tokens := [<token>]
```

with `<token>` representing a context dependent token.

2.4. Index structures

In order to associate the equations to the objects, we introduce index structures, which when implemented will contain two elements, namely a running index and a set. In the ontology we

define the base sets as being the lists of the base objects. Thus there is a index structure for the list of nodes, list of arcs, list of tokens. And since the tokens are living in the network we add product index structures of nodes*tokens and arcs*tokens.

```
Ontology.<context> :
index_structs := [graphs, nodes, arcs, tokens, nodes*tokens, arcs*tokens]
```

2.5. Attributes - colours

In order to enable the specification of the context dependences in more detail, we introduce attributes to all base objects, thus for graph, node, arc and token. The attributes add a kind of ”colour” to objects. They provide the means to further classify the objects and use them in structuring the equation/variable network.

2.6. Variable - equations

The mathematical representation of the model is a super graph of variables and equations.

2.6.1. Completeness

A proper model consists of a ”complete” set of equations and variables. The ontology is the ”mother” of all models, thus it is a type of super structure that captures a range of models, it can be thought of a combination of possible models. It is only when utilising the ontology, the model for the application is being identified or ”extracted” from the ontology. Apparently the term ”complete” is essential and needs to be defined. Models are used for many applications and plant-related problems that are eventually mapped into mathematical / numerical problems that then are solved to get insight into the original plant-related problem. Taking the view of the problem space, the utilisation of the ontology is a priori not defined and a suitable method of guaranteeing ”completeness” must be defined. We found it convenient to define ”completeness” to use simulation as the basis for the definition. It must be noted, though, that this does not constrain the further use of the ontology to simulation. It merely serves the purpose of guaranteeing completeness, and is thus not to be mistaken for instantiation of a mathematical / numerical problem. In general a simulation problem is defined as a set of differential equations augmented with a set of algebraic equations, thus a differential-algebraic problem, whereby differential can also be exchanged with any approximation, such as difference equation or population related description of the dynamic behaviour. A complete simulation problem thus consists of this differential-algebraic system augmented with a set of known parameters, initial conditions and boundary conditions. So we utilise this structure to define completeness: The model is properly specified if the set of equations satisfies a zero-degree of freedom condition given the initial conditions, the boundary conditions and the parameters.

We impose the rule that the definition of the equation set must be done in a lower-triangular manner, meaning that once an initial set of variables is defined, all consecutive definitions can only use what has already been defined. Thus the equation / variable incidence matrix of this bipartite graph is required to be strictly lower diagonal. The ”completeness” condition then implies that we require for each dependent variable a corresponding equation. This makes it possible to guarantee for the completeness of the model in terms of a zero degree of freedom.

2.6.2. Behaviours - variable classes

Often a model is seen as a mapping of the behaviour of the modelled system, though leaving a feel of arbitrariness. Mathematical system theory defines behaviour as a subset of all possible events

in the defined signal space (Willems, 2014, 2007). We use this view defining a set of signal spaces that are in some sense minimal, but add sufficient structure to make the definition of the dynamic system convenient and well aligned with the physical view.

The definition needs a starting point. The starting point is the frame, in our case time and space for the physical containment. Next we define a class of signals called ”state” for the tokens in the capacities. The tokens thus provide us with the philosophical link between the network and the state. The state reflects the minimal information required to predict the future of the system a statement that goes back to Kalman. For the physical systems we base the description on the conservation principles thus define the state as the conserved quantities. The conservation principle balances the system's accumulation of an extensive quantity with the flow across the system's boundary. Thus the second class we introduce is the flows of extensive quantities. In order to allow for the conversion between extensive quantities we also introduce the signal class transposition. The description of transport and transposition is indirectly a function of the state, namely a set of intermediate variables that to a large degree describe the driving forces for the transport and transposition of tokens. Since these intermediate variables are a function of the state, we introduce the term ”secondary state”. To complete the description we also introduce ”parameters” and a class ”incidence” to capture the network structure.

Defined variable classes / types for physical systems:

```
Ontology.physical : signal classes :=
  [state, secondary state, transport, transposition, parameter, incidence]
```

For the information processing systems we use the standard classification of control:

```
Ontology.information : signal clases := [state, input, output]
```

2.6.3. Objects

The variable object is used to form together with operators expressions and equations. The object has a number of default attributes:

- symbol : ID unique at least within variable class. Alternatively globally in variables.
- doc : documentation string
- units : physical units
- index_structs : list of index structures
- type : variable type / class
- equations : list of rhs expressions for the variable

The equation is defined for the variable and not only one equation is allowed, but several. This enables for alternatives, a basic feature of the ontology. The equation is represented as a string of the right-hand-sides, a permissible mathematical expression. The rules for the expression are captured in the definition of a small language for which the definition is to attached to the ontology to facilitate compilation into different target languages.

The rhs-string is to be read by a parser implementing the language definition, build an abstract syntax tree for each of the rhs-expressions, which then can be used to generate different target code using the templates for the target language.

2.7. Parser

Finding a minimal representation is the major challenge in defining the structure of the ontology. This also applies to the language that is used to represent the mathematical expression. At this point in time we believe that we can capture macroscopic systems with the simple language defined below in Extended Backus Naur form using standard regular expressions for the token defintions:

```
token UFunc     : '\b(sqrt|exp|log|ln|sin|cos|tan|asin|acos|atan)\b';
token Root      : '\b(root)\b';
token VarID     : '\w[\w]*'; #matches first word char followed by word
token Index     : '\[.*\]'

expr ::= term { ( "+" | "-" ) term }
term ::= fact { ( "." index "." | "*" index "*" | "\" ) fact }
fact ::= atom "^" ( "+" | "-" ) VarID
atom ::= func | "(" expr ")"| VarID
func ::= unitary_func "(" expr ")"
         | root "(" expr ")"
         | integral "(" VarID "," VarID "," VarID "," VarID ")"
         | differential "(" VarID "," VarID ")"
```

For the different items: the `Ufunc` are the standard unitary functions all of which with exception of the sqrt have an argument with no units. The `root` keyword is used to define implicit equations. `Integral` introduces the integral with the arguments (derivative, integration variable, initial condition, upper limit). For the derivative it is the two variables.

The variable definition `VarID` is composed of characters. There are two operations that depend on the index structure, namely the product `.[IndexID].` and the Khatri-Rao product `*[IndexID]*`. The syntax is including the index structure the operator is reducing.

In the implementation each of the above definition lines will trigger an action which generates a new variable being the result of the operation keeping track of the variables and the applies the rules for the units and the index structures. For example for the addition one gets as a result the sum of the two variables being added, adds the variable to the abstract syntax tree together with the two operands and applies the rule of having equal index structs for both operands which is then also the index structs for the result. The units must be equal and are copied to the result.

By doing so, one builds an abstract syntax tree, which can be evaluated for any output language, given a set of templates one for each of the actions, here term, fact, unitary functions, root, integral and differential.

3. Realisation

The implementation uses probably one of the simplest file formats, namely the cfg file format. It is used for specifying configurations of tasks which fits the purpose of ontologies as base structure. The format is a section keyword `[<section>]` wrapped in rectangular brackets, followed by a series of lines with `<keyword> = <string>` essentially representing a dictionary (Python does load it as an ordered dictionary, for example). The type of ontology we pack into the file name itself. Currently we initialise the ontologies in the configuration files defining the frame, the containment and the tokens. Next we use an special-purpose editor to build the ontology. This editor imposes the rules for the construction foremost it imposes the lower-triagonal definition structure for the supergraph of variables and equations.

4. Oportunities

With the structure as suggested one can think of defining different types of networks and then a separate entity that represents the connection between these networks. In our case it would be the connection between the physical network and the information network. In the real world

these are the sensors and the manipulators. Taking this approach lefts these special objects clearly out and the added structure will be beneficial when controlling the construction of models that involve both types of networks. This thought can also be extended to multi-scale models in which the connections upwards are some agglomeration/averaging mechanisms and downwards design of experiments controlled inputs. So also here a very clear benefit arises from having such a structured approach.

5. Conclusions

We are able to capture process ontologies using a very few structural elements. The design is such that we believe we can capture macroscopic systems and it will also apply to microscopic systems, where the particulate nature of the material description matters. Proof of concept is ongoing and will is done through applications.

The goal was not only wide applicability, but also simplicity. The defined objects are few and the parser for interpreting the strings for the right-hand-side definition of equations is context free and very simple indeed. So the implementation of the parser is very simple and compilation of the expressions into different target languages is also simple indeed.

Where to go from here? Main issue is to implement the ontology in the graphical editor supporting the construction of models using a graphical interface, thus to re-establish the capabilities we generated in 2003 (Westerweele, 2003) but now fully build on the above simple ontology design.

Next will be the extension to particulate models, such as population balances. We do not expect any problems as they all fall into the class we can capture with the given ontology language.

Improved Design Strategies for Flexible Hydrogen Networks

Chuei-Tin Chang, Che-Chi Kuo

Depratmentof Chemical Engineering, National Cheng Kung University, Tainan 70101, Taiwan, R.O.C.

Abstract

Although MINLP models have already been developed for generating the optimal hydrogen networks, improvements are still needed to circumvent their common drawbacks concerning (1) unreasonable unit models and (2) incomprehensive design considerations. These issues are addressed in this study by modifying the conventional formulations so as to produce realistic multi-period designs. In addition to the programming approach, a systematic timesharing algorithm is also devised to manually integrate multiple single-period designs to form a less economical but more flexible structure for operation in different periods. One example is provided to illustrate these two design strategies.

Keywords: Hydrogen network, Multi-period design, Timesharing scheme.

1. Introduction

The development of an efficient scheme for hydrogen integration and distribution in a given refinery is a popular research issue nowadays. Although several MINLP models have already been developed to synthesize the optimal networks, there is still room for further improvements. Specifically, the applicability of available formulations is hampered by two common deficiencies, i.e., (1) oversimplified unit models and (2) incomprehensive design considerations. In the former case, the hydrotreaters and hydrocrackers were unreasonably described in the past according to fixed operating conditions and, also, the steam reforming plant was modelled simply as a hydrogen provider without any provisions for possible recycle. Although Jiao et al. (2012) treated the inlet flow rates and concentrations of hydrogen users as variables, their models were still logically inconsistent since the corresponding outlet conditions were fixed. In the latter case, the often-encountered seasonal variations in model parameters and the design options to add extra processing units were often ignored in the conventional approach. Although Ahmad et al. (2010) proposed a model to generate flexible networks which are suitable for operation in multiple periods, this approach is limited to scenarios in which only the throughputs of hydrogen users were time dependent. This study aims to circumvent all such drawbacks by modifying and improving the conventional model formulations.

2. Problem statement and superstructure

It is assumed in this work that the typical structure of conventional networks can be represented with the sketch given in Fig. 1. The hydrogen producer (which is enclosed in a dotted box), the compressors, the hydrogen users and the fuel gas system are arranged sequentially in different steps, while different units in the same step may be placed in parallel. The goal of the present study can be considered as optimally restructuring this given network with the available units and also a few new ones (such as additional compressors, PSA units and fuel cells) when necessary. Note also that the mathematical programming model for identifying this optimal revamp design can be

formulated on the basis of a superstructure, which is essentially a collection of all possible links between hydrogen sources and sinks. The connection rules for building such a structure can be found in Chiang and Chang (2014). To facilitate model formulation, a distinct label is first assigned to each unit in the superstructure and these labels are then classified and collected in two separate sets to identify their sources and sinks respectively. More specifically,

$\mathbf{I} = \{i \mid i \text{ denotes the label of a hydrogen source in superstructure}\}$

$\mathbf{J} = \{j \mid j \text{ denotes the label of a hydrogen sink in superstructure}\}$

It is important to note that, since the label of every unit may be used to identify both its source and its sink, some elements of **I** and **J** are identical.

3. Improved unit models

Only the unit models of the hydrogen users and the hydrogen producers have been modified in the present work. A summary of the modified formulations is given below:

3.1. Hydrogen using units

As mentioned before, the inlet and outlet conditions in the conventional models were fixed. Since this practice clearly precludes other feasible options which may also be favourable, these constants are replaced with variables in the improved model to facilitate more reasonable consideration. Also, methane was assumed to be the sole impurity in every hydrogen-containing stream in the past. For computation simplicity, the same convention is adopted in the present study and, also, the hydrogen consumption rate of each unit is assumed to be kept at a given value based on the argument that the production rates of fuels and petrochemicals in a refinery are usually predetermined. Such an assumption implies that the overall generation rate of all other gases can also be treated as an unchanged parameter. Consequently, the model constraints at the sink end of a hydrogen user can be written as

$$\sum_{i\in\mathbf{I}} F_{i,sk} = fs_{sk}, \quad \sum_{i\in\mathbf{I}} F_{i,sk} y_i = fs_{sk} ys_{sk}, \quad fs_{sk} ys_{sk} \geq \overline{fy}_{sk}^{\min}, \quad ys_{sk} \geq \overline{y}_{sk}^{\min} \tag{1}$$

where, $sk \in \mathbf{SK}$ and **SK** is a label set for identifying the inlets of hydrogen using units; fs_{sk} and ys_{sk} are variables respectively denoting the total flow rate and hydrogen concentration at inlet sk; $F_{i,sk}$ is also a variable which denotes the flow rate of the stream from source i to sink sk; $\overline{fy}_{sk}^{\min}$ and $\overline{y}_{sk}^{\min}$ are design parameters representing the lower bounds of the inlet hydrogen flow rate and concentration, respectively. On the other hand, the model constraints at the source end can be expressed as

$$\sum_{j\in\mathbf{J}} F_{sr,j} = fr_{sr}, \quad fr_{sr} = fs_{sk} - \overline{f}_{sr}^{\mathrm{H_2}} + \overline{f}_{sr}^{\mathrm{CH_4}}, \quad fr_{sr} yr_{sr} = fs_{sk} ys_{sk} - \overline{f}_{sr}^{\mathrm{H_2}}, \quad yr_{sr} \leq \overline{y}_{sr}^{\max} \tag{2}$$

where, $sr \in \mathbf{SR}$ and **SR** is a label set for identifying the outlets of hydrogen users; fr_{sr} and yr_{sr} are variables respectively denoting the total flow rate and hydrogen concentration at outlet sr; $F_{sr,j}$ is a variable which denotes the flow rate of the gas stream from source sr to sink j; $\overline{f}_{sr}^{\mathrm{H_2}}$ and $\overline{f}_{sr}^{\mathrm{CH_4}}$ are given model parameters which are used to represent the hydrogen consumption rate and the net rate of generation of all other gases, respectively; $\overline{y}_{sr}^{\max}$ denotes the upper bound of hydrogen concentration at source sr.

3.2. Hydrogen production plants

As mentioned before, the steam reforming plant is traditionally treated as a source of the hydrogen network. Since the hydrogen consumption level can be reduced significantly

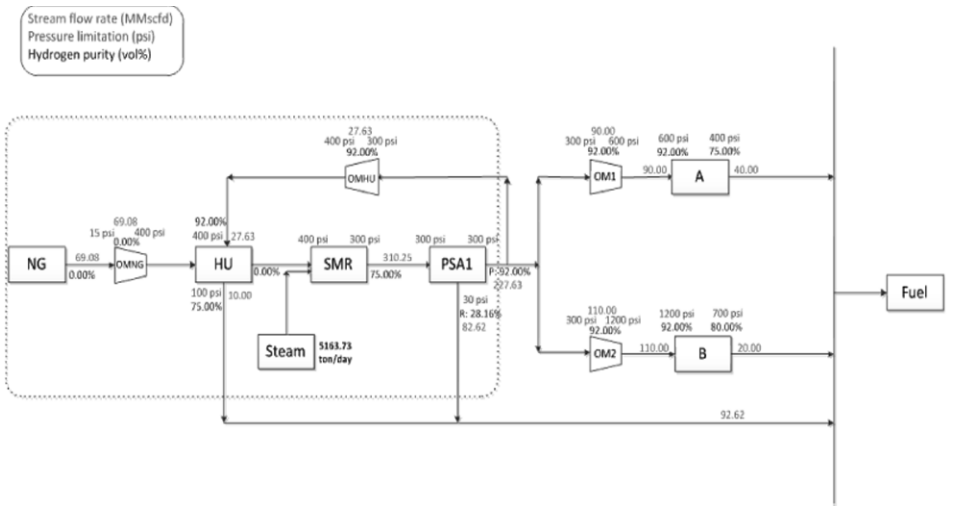

Figure 1. The typical structure of traditional hydrogen networks.

by restructuring the given network, it is desirable to develop schemes that make good use of the consequent overcapacities in the existing units. For this reason, the hydrogen production process is modelled as the following three consecutive steps:

Step I (hydrogenation reactions): The hydrogenation unit is essentially a hydrogen user, which can be modelled in a similar fashion:

$$F_{\mathrm{NG,H2P_I}} \le \overline{f}^{\mathrm{NG}}_{\mathrm{H2P_I}}, \quad \sum_{i\in\mathbf{I}} F_{i,\mathrm{H2P_I}} y_i = \overline{r}^{\mathrm{in}}_{\mathrm{H/N}} F_{\mathrm{NG,H2P_I}}, \quad \sum_{i\in\mathbf{I}} F_{i,\mathrm{H2P_I}} y_i = \overline{y}^{\mathrm{in}}_{\mathrm{H2P_I}} \sum_{i\in\mathbf{I}} F_{i,\mathrm{H2P_I}} \tag{3}$$

where, $F_{\mathrm{NG,H2P_I}}$ is the feed rate of natural gas and $\overline{f}^{\mathrm{NG}}_{\mathrm{H2P_I}}$ is its upper bound; $\overline{r}^{\mathrm{in}}_{\mathrm{H/N}}$ is the proportionality constant used to characterize the linear relation between the feed rates of hydrogen and natural gas; $\overline{y}^{\mathrm{in}}_{\mathrm{H2P_I}}$ is the hydrogen concentration at the inlet, which is fixed at a given value to simplify calculation. The flow rate and concentration of the spent hydrogen stream at the outlet are also fixed at given values. If it is desirable to utilize this stream as a source of the hydrogen network, positive values may be assigned to both parameters. If otherwise, the flow rate of spent hydrogen stream can be set to zero.

Step II (steam reforming reactions): The second group of units represents a complex intermediate step that converts natural gas to hydrogen. In order to simplify computation, all model formulations are approximated with linear functions, i.e.

$$F_{\mathrm{H2P_{II},H2P_{III}}} = \overline{r}_{\mathrm{III/II}} F_{\mathrm{H2P_I,H2P_{II}}}, \quad Z = F_{\mathrm{NG,H2P_I}} / k = Stm_{\mathrm{H2P}} / k' = Pwr_{\mathrm{H2P}} / k'' = Q_{\mathrm{H2P}} / k''' \tag{4}$$

where, $F_{\mathrm{H2P_I,H2P_{II}}}$ and $F_{\mathrm{H2P_{II},H2P_{III}}}$ respectively denote the input and output flow rates of step II, and $\overline{r}_{\mathrm{III/II}}$ is the corresponding proportionality constant; Z is the flow rate of final product of the hydrogen plant which is produced with feed coming solely from step II; k is the proportionality constant that relates Z to the consumption rate of natural gas; Stm_{H2P}, Pwr_{H2P} and Q_{H2P} denote the consumption rates of steam, electricity and heating utility respectively, and k', k'' and k''' are the corresponding proportionality coefficients.

Step III (pressure swing adsorption): Although the PSA unit in the steam reforming plant can be described adequately with a conventional model (Chiang and Chang, 2014), there is an extra need for computing the production rate Z:

$$\overline{y}^{\mathrm{prod}}_{\mathrm{H2P_{III}}} Z = R_{\mathrm{H2P_{III}}} \overline{y}^{\mathrm{out}}_{\mathrm{H2P_{II}}} F_{\mathrm{H2P_{II}},\,\mathrm{H2P_{III}}} \tag{5}$$

where, $\bar{y}_{\mathrm{H2P_{II}}}^{\mathrm{out}}$ and $\bar{y}_{\mathrm{H2P_{III}}}^{\mathrm{prod}}$ denote the known hydrogen concentrations at the outlets of step II and III, respectively, and $R_{\mathrm{H2P_{III}}}$ is the constant hydrogen recovery ratio of the PSA unit in steam reforming plant. This is due to the fact that all sources in the hydrogen network are admissible here.

4. Two effective multi-period design strategies

4.1. Programming approach

The single-period MINLP model can be reformulated for synthesizing multi-period designs. Since the aforementioned unit models are applicable in any period during a year, it is only necessary to introduce an extra subscript p to every process variable and every model parameter so that they can assume different values in different periods. By summing the contributions in all periods, the total annual operating cost can then be determined in a straightforward fashion. On the other hand, to calculate the total capital investment, additional logic constraints should be imposed to determine if new units and new pipelines are needed in the modified design:

$$e_{neq,p}\mathrm{B}_{neq}^{\mathrm{L}} \le \sum_{i\in\mathbf{I}} F_{i,neq,p} \le e_{neq,p}\mathrm{B}_{neq}^{\mathrm{U}}, \quad e_{neq,p} \le e_{neq}, \quad e_{i,j,p}^{\mathrm{pipe}}\mathrm{B}_{i,j}^{\mathrm{L}} \le F_{i,j,p} \le e_{i,j,p}^{\mathrm{pipe}}\mathrm{B}_{i,j}^{\mathrm{U}}, \quad e_{i,j,p}^{\mathrm{pipe}} \le e_{i,j}^{\mathrm{pipe}} \tag{6}$$

where, $e_{neq,p}, e_{neq}, e_{i,j,p}^{\mathrm{pipe}}, e_{i,j}^{\mathrm{pipe}} \in \{0,1\}$ and i, j, neq and p are labels of a source, a sink, a new unit and a period, respectively; $F_{i,neq,p}$ denotes the flow rate of a stream in superstructure between source i and the sink end of unit neq in period p; $F_{i,j,p}$ denotes the flow rate of a stream in superstructure between source i and sink j in period p; $\mathrm{B}_{neq}^{\mathrm{L}}$ and $\mathrm{B}_{neq}^{\mathrm{U}}$ respectively denote the lower and upper capacity limits of unit neq; $\mathrm{B}_{i,j}^{\mathrm{L}}$ and $\mathrm{B}_{i,j}^{\mathrm{U}}$ respectively denote the lower and upper flow-rate limits between source i and sink j.

4.2. Heuristic approach

The above programming approach calls for construction of a mathematical program that minimizes the total annual cost (TAC) under the assumption that the given durations of all periods are fixed. Other than the obvious computational difficulties in solving the MINLP model, the resulting designs are often suboptimal in actual operations since the given period lengths may have to be adjusted in response to unexpected disturbances. A heuristic approach is thus taken in the present study to address this issue. In particular, a single-period model is first constructed and solved to produce the optimal design for each period individually. These individually optimal designs are in general of different structures. A timesharing design strategy is then applied to integrate all such single-period designs so as to reduce the overall capital investment as much as possible while still keeping the operating costs in each period at the desired levels. This integrated design should be considered to be more flexible since it is optimal despite unforeseen schedule changes. In this work, only the PSA units and compressors are allowed to be shared. A systematic manual procedure has been developed to identify the suitable timesharing mechanisms from multiple single-period designs (Kuo, 2014). The detailed steps are omitted here due to space limitation.

5. An illustrative example

The traditional network in Fig. 1 is again considered here. The steam reforming plant consists of a hydrogenation unit (**HU**), the steam reforming reactors (**SMR**) and a purifier (**PSA1**). The other existing units in this network include two hydrogen users (**A** and **B**) and four compressors (**OM1**, **OM2**, **OMNG** and **OMHU**). It is assumed that units **A** and **B** have to be operated differently in three distinct periods according to Tables 1 and 2. The unit costs of natural gas are expected to be 3535, 4600 and 4302

($/MMscf) in these periods respectively. The corresponding costs of electricity and steam also fluctuate. The former are predicted to be 0.18, 0.07 and 0.09 ($/kWh) respectively, while the latter 8.86, 12.51 and 9.06 ($/ton). Two approaches were applied:

(1) To facilitate implementation of the heuristic procedure in subsection 4.2, it is necessary to first produce an "optimal" single-period design for each period. It was found that, if these designs are to be operated respectively in their intended periods, a total of three new compressors (labelled as **NM7**, **NM19** and **NM20**) are required and each is idle in at least one period. One can then manually produce a timesharing scheme in which only the first two are required to be put in use.

(2) By following the programming approach described in subsection 4.1, a multi-period design can also be generated for the present example. For the sake of brevity, only the network structure in period 1 is given in Fig. 2. Note that the idle units are not shown here.

The operating costs, capital costs and total annual costs of all aforementioned designs are compared in Table 3. It can be observed that, by incorporating the proposed model modifications, the TAC of any single-period design is significantly lower than that of the original network. Since any such design is optimal only in one period but may not be suitable for the other time intervals, the proposed timesharing approach should then be utilized to effectively integrate all single-period structures. On the other hand, since a proper trade-off between operating and capital costs can only be achieved with a comprehensive multi-period formulation, the corresponding TAC was found to be the lowest among all options. However, the required optimization run often lasts a very long time which is, in average, 10 times as much as that needed to obtain a single-period design.

6. Conclusions

The conventional programming approach to synthesize hydrogen networks has been modified in this work to circumvent drawbacks concerning unreasonable unit models and incomprehensive design considerations. As an alternative to the brute-force numerical optimization method for producing multi-period designs, a systematic timesharing algorithm has also been devised to manually integrate the single-period designs to form a less economical but more flexible structure for operations in all periods. An example is presented to show the effectiveness of the proposed approaches.

Table 1. Nominal inlet conditions of existing hydrogen users.

Sink	Flow rate in period 1 (MMscfd)	Flow rate in period 2 (MMscfd)	Flow rate in period 3 (MMscfd)	Purity (vol %)	Pressure (psi)
A	90.00	94.00	98.00	92.00	600
B	110.00	112.00	117.00	92.00	1200

Abstract

An integrated reactive distillation process for the production of biodiesel is proposed. The reactive separation process consists of two coupled reactive distillation columns considering the kinetically controlled reactions of esterification of the fatty acids (FFAs) and the trans-esterification of the tri-di and mono glycerides with methanol, respectively. The conceptual design of each reactive distillation column was performed through the construction of reactive residue curve maps in terms of elements. The design of the esterification reactive distillation column consisted of one reactive zone loaded with a solid catalyst (titanium oxide supported on silica TiO_2/SiO_2) and for the trans-esterification reactive column two reactive zones loaded with solid catalyst (hydrotalcites (CHT) and MgO). Intensive simulation of the integrated reactive process including the complex kinetic expressions for the different reactions and the Cubic-Plus Association (CPA) thermodynamic model was performed using the computational environment of ASPEN Plus. Results showed that the amount of fatty acids (FFAs) and water in the oil fed play a key role on the performance of the trans-esterification reactive distillation column while for the esterification column is not significant.

Keywords: reactive distillation, biodiesel production, conceptual design.

1. Introduction

Biodiesel represents a valuable alternative to petroleum derived fuels due to both its renewable nature and its substantially reduced net carbon dioxide emission. This biofuel is conventionally produced through batch or continuous trans-esterification of highly refined vegetable oils with methanol by using homogeneous alkaline catalysts such as sodium or potassium hydroxides or methoxides (Fukuda et al. 2001). The mentioned technology is not compatible with oils which free fatty acids (FFAs) content exceeding a threshold value of about 0.5% by weight. A possible solution to this drawback could be the development of new technologies enabling to employ waste raw materials such as fried oils or mixture of oils from various sources that cannot be treated in the conventional process for their high content in free fatty acids. This perspective discloses the way toward the development of innovative biodiesel production processes such as those based on supercritical methanol (Kusdiana and Saka, 2001), or the two-stage process (Suwannakarn, K. and E. Lotero, 2009). In the two-stage process, the FFAs in the feed are first esterified by acid catalysis to produce alkyl esters. This step prevents soap formation during the second step, which is the trans-esterification of the unreacted

triglyceride with alkali catalyst to obtain alkyl esters. This two-step process may be able to reduce the overall processing time and permit processing of feed stocks with high FFA content. However, the separation of product and catalyst is required in both the acid and alkali catalyzed steps, which again costs time and money. To avoid the separation required in a homogeneous catalytic system, researchers have explored the use of heterogeneous catalysts. Tesser et al. (2010) studied trans-esterification of soybean oil with both basic and acidic heterogeneous catalysts. For basic catalysts, hydrotalcites (CHT) and MgO were used. For acidic catalysts, titanium oxide supported on silica TiO_2/SiO_2 (TS) and vanadyl phosphate $VOPO_4 \cdot 2H_2O$ (VOP) were used. Therefore, it is generally accepted that a process employing a solid acid catalyst, if technically feasible, would be preferred on economic grounds. All of this evidence supports that there exist a need for improvement in the technological and economic feasibility of biodiesel production. Reactive distillation may be considered as an alternative process for biodiesel production. Especially for equilibrium limited and consecutive reactions, reactive distillation is a promising process alternative. Therefore, in the present work, an integrated reactive distillation process for the production of biodiesel is proposed.

2. The Reactive System

The generic esterification reaction of a carboxylic acid (oleic acid in this case) with methanol, producing methylester and water, is schematically shown below:

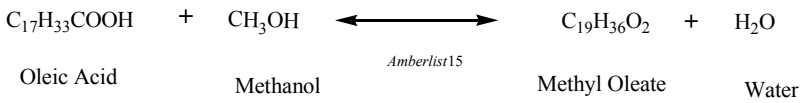

Figure 1. Overall reaction scheme for esterification of oleic acid.

The esterification processes for FFAs abatement are generally promoted by homogeneous acid catalyzed reaction or by ionic exchange acid resins as heterogeneous catalysts. The trans-esterification of triolein with methanol to methyl oleate has been selected as a model process for the trans-esterification of rapeseed oil to produce biodiesel. Figure 2 shows the overall trans-esterification reaction of triolein and Figure 3 shows the stepwise reaction scheme.

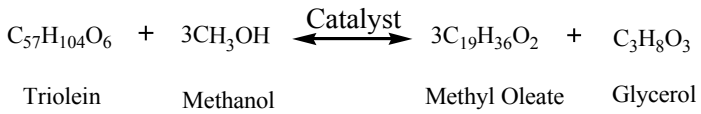

Figure. 2. Overall reaction scheme for trans-esterification of Triolein

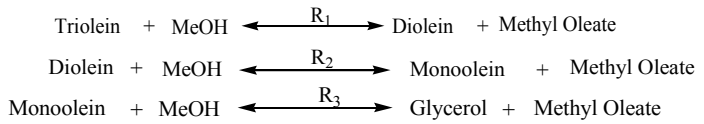

Figure. 3. Stepwise reaction scheme for trans-esterification of Triolein

The reactions described in Figures 1 and 2 can be represented in terms of elements as proposed by Pérez-Cisneros et al. (1997). Table 1 shows the elements definitions and the balanced reactions in terms of such elements.

Table 1. Representation of the reactive system in terms of elements

Reaction	Elements	Reactions in terms of elements
Esterification	A= $C_{18}H_{32}O$	
	B= H_2O	AB + C⇔AC + B
	C= CH_3OH	
Trans-Esterification	A= $C_{18}H_{32}O$	A_3B + C⇔ A_2B + AC
	B= $C_3H_8O_3$	A_2B + C⇔ AB + AC
	C= CH_3OH	AB + C⇔ B + AC

3. Residue Curve Maps and the Integrated Reactive Distillation Process

In this work, the residue curve maps were calculated for each reaction scheme separately following the procedure described by Granados-Aguilar et al. (2008). The heterogeneous kinetic models employed for the esterification reaction and for the transesterification reaction are reported by Tesser et al. (2010) and by Dossin et al. (2006), respectively. For the phase equilibrium computation, the Cubic-Plus-Association Equation of State (CPA) was used with the required parameters reported by Oliveira et al. (2010).

3.1. Esterification Reaction

For the esterification residue curve map a reactive mixture with methanol excess was used as initial composition point (x_{OA}=0.006, x_{MeOH}=0.99, x_{MO}=0.002, x_W=0.002). Figure 4a shows the residue curve map for different values of the reaction-separation parameter (α), which represents the amount of catalyst loaded into the boiling pot. Also, in Figure 4a, (OA) represents the oleic acid, (MeOH) methanol, (MO) methyl oleate and (W) indicates water compounds. It can be observed in Figure 4a that as the amount of catalyst loaded increases (α=0.0001 - 40) the residue curves tend to the AC node, which represents the methyl oleate (MO) pure compound. Figure 4b shows the corresponding liquid composition and temperature profile for the residue curve with α= 40. It can be noted in Figure 5a that the main conversion to methyl oleate occurs between the temperatures 340 K and 450 K, and as the methanol vaporizes and is consumed the remaining liquid phase in the boiling pot is pure methyl oleate.

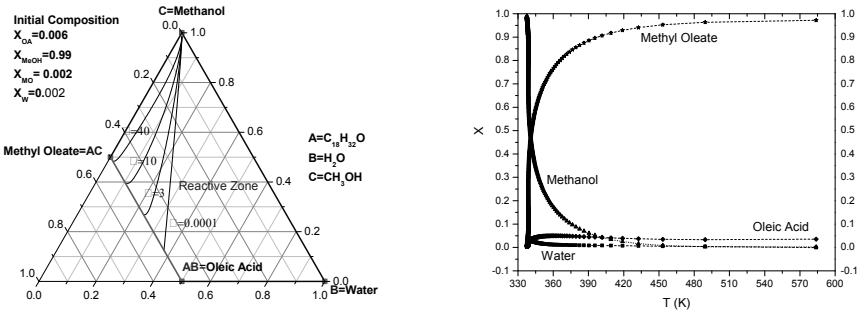

Figure 4. a) Residue curve map for esterification reaction; b) Liquid Composition and temperature profile for the residue curve at α = 40

3.2. Trans-Esterification Reaction

For the trans-esterification residue curve map a reactive mixture with methanol excess was used as initial composition point (xTG=0.04, xMeOH=0.95, xMO=0.004, xDG=0.002, xMG=0.002, xG=0.002). Figure 5a shows the residue curve map for different values of the reaction-separation parameter (α). Also, in Figure 4b, (TG) represents the tri-olein species, (MeOH) methanol, (MO) methyl oleate, (DG) di-olein, (MG) mono-olein and (G) indicates glycerol compounds. It can be observed in Figure 5a that as the amount of catalyst loaded increases (α =0.0001 - 0.01) the residue curves tend to the AC node, which represents the methyl oleate (MO) pure compound. Figure 5b shows the corresponding liquid composition and temperature profile for the residue curve with α= 0.01

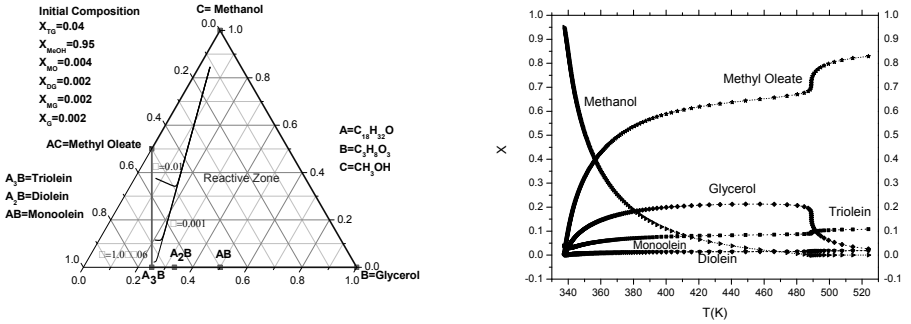

Figure 5. a) Residue curve map for trans-esterification reaction; b) Liquid Composition and temperature profile for the residue curve at α = 0.01

It can be noted in Figure 5b, in opposition to the esterification reaction, that the conversion to methyl oleate increases continuously from 340 K to 490 K, and as the methanol is consumed completely, vaporization of some glycerol occurs leading to an increment in liquid composition of methyl oleate. It should be pointed out that the final mixture in the boiling pot for the trans-esterification reaction is not pure methyl oleate, rather a mixture containing some tri-olein, di-olein and mono-olein should be considered.

4. Intensive Simulation

With the analysis of the reactive residue curve maps and through intensive simulations performed into the ASPEN plus environment a final integrated reactive distillation process to produce biodiesel was obtained. Figure 6 shows the process considering two reactive distillation columns: RDC-1, for esterification reaction loaded with a solid catalyst (titanium oxide supported on silica TiO_2/SiO_2) with one reactive section and RDC-2, for trans-esterification reaction loaded with solid catalyst (hydrotalcites (CHT) and MgO). The firs reactive distillation column (RDC-1) is fed with a mixture of oleic acid and triolein and methanol.

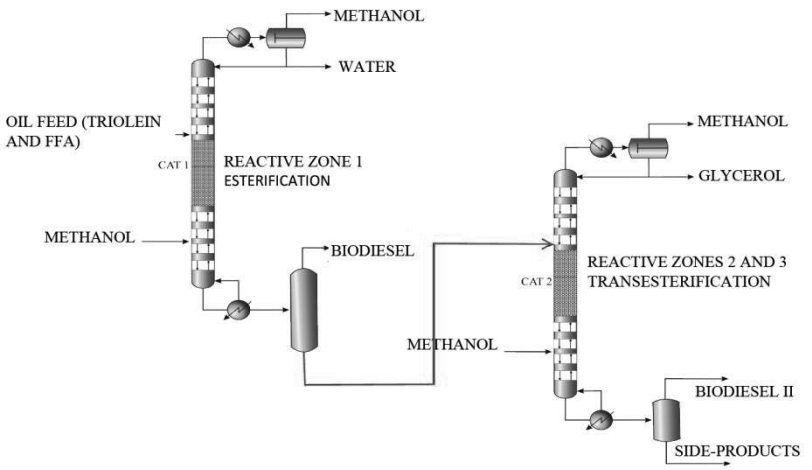

Figure 6. Integrated reactive distillation process for biodiesel production

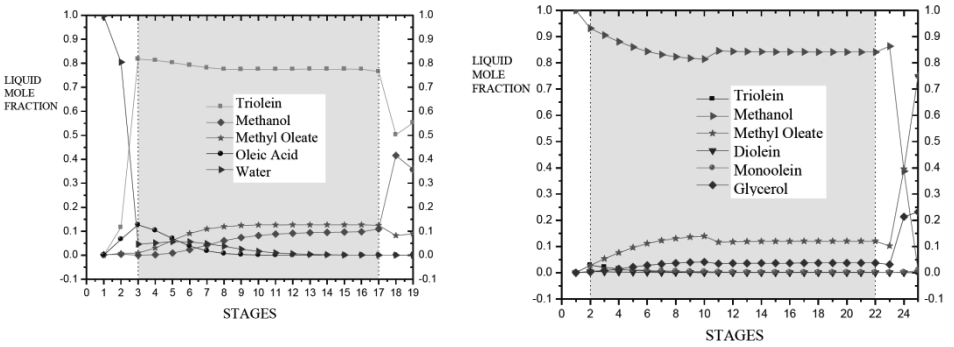

Figure 7. Liquid composition profile a) RDC-1 (Esterification); b) RDC-2 (Trans-esterification)

Table 2 shows the design specifications of the two reactive distillation columns. It should be pointed out that the reflux ratio for the trans-esterification reaction column required is higher than the esterification column and the methanol used is around six times greater. Therefore, it could be concluded that the RDC-2 is more sensitive to changes in the operating conditions. Figure 7a shows the liquid composition profile along the RDC-1 (esterification). It can be noted that the exit stream leaving the bottom of the column is a mixture rich in triolein, methanol and methyl oleate. The Oleic acid is completely consumed and water is vaporized. This bottom stream is further separated in a flash drum and the first biodiesel is produced at the top of the equipment. Figure 7b shows the liquid composition profile along the RDC-2 (trans-esterification). It can be noted that the exit stream leaving the bottom of the column is a mixture rich in methyl oleate and glycerol. The glycerol in the mixture is decanted and separated to produce biodiesel from the trans-esterification column. It is clear that the amount of methanol in

the stages of the RDC-2 must be high in order to achieve complete conversion of the triglycerides.

Table 2. Design specifications for the reactive distillation columns.

Variables	RDC-1	RDC-2
Column Pressure	1 atm	1 atm
Total stages	19	25
Reactive Stages	15 (from 3 to 17)	21 (from 2 to 12 and from 14 to 22)
Reflux Ratio	0.1 (Kmol)	2.5 (Kmol)
Feed Stage (oil)	3	2
Feed Stage (methanol)	18	13 and 23
Oil Feed Flow	14/86 (OA/TG)kmol/h	
Methanol Feed Flow	70 kmol/h	400 kmol/h ; 500 kmol/h
Catalyst loaded in stage	800 (kg)	1000 (kg)

5. Conclusions

An integrated reactive distillation process considering the esterification and trans-esterification reactions has been developed. The reactive residue curves posed in term of elements reveal the optimal operating conditions to render a high purity biodiesel in a coupled reactive distillation process. The complex kinetics and the CPA equation of state have been incorporated into the ASPEN plus environment to perform intensive simulations. Simulation results shown that the trans-esterification reactive distillation column is more sensitive to changes in the operating conditions.

Abstract

A sequential design method is presented for the design of thermally coupled distillation sequences. The algorithm starts by selecting a set of sequences in the space of basic configurations in which the internal structure of condensers and reboilers is explicitly taken into account and extended with the possibility of including divided wall columns (DWC). This first stage is based on separation tasks (except by the DWCs) and therefore it does not provide an actual sequence of columns. In the second stage the best arrangement in N-1 actual columns is performed taking into account operability and mechanical constraints. Finally, for a set of candidate sequences the algorithm try to reduce the number of total columns by considering Kaibel columns, elimination of transfer blocks or columns with vertical partitions. An example illustrate the different steps of the sequential algorithm

Keywords: Distillation, Thermally Coupled Distillation, MINLP, Process Integration, Process intensification.

1. Introduction

Thermally Coupled Distillation (TCD) has acquired a renewed interest because, when compared to conventional systems, it is possible to reach over 30% in energy reduction. Besides, if the search space includes Divided Wall Columns (DWC) important investment savings can also be achieved.

One of the major difficulties in the synthesis involving TCD is that the number of alternatives grows up much faster than when only conventional columns are considered. i.e. for a 5 component mixture there are 203 basic configurations (Giridhar & Agrawal, 2010) if we consider also the internal structure of heat exchangers there are around 10^4 alternatives, and if we consider the thermodynamically equivalent configurations the number of alternatives is around $2 \cdot 10^5$. (Caballero & Grossmann, 2003).

In this work we propose a sequential algorithm, that combines shortcut models (based on Fenske – Underwood –Gilliland (FUG) methods) and rigorous process simulators to the rigorous design of complex TCD sequences. A description of the different stages is as follows:

1. Search in the space of basic configurations (Giridhar & Agrawal, 2010) augmented with the internal structure of heat exchangers (Caballero & Grossmann, 2006). Even

though, consider only the basic configurations, and then optimize the internal structure of heat exchangers usually produce good results, Caballero and Grossmann (2013) showed that the optimal sequence of separation tasks can be lost in a sequential approach. Besides, those authors also showed that DWCs could have an important impact on the total cost of a given sequence and therefore it is convenient explicitly include DWCs in this stage. However, it is important that thermodynamically equivalent alternatives are not taken into account at this stage. Thermodynamically equivalent alternatives share the same sequence of separation tasks and, in most cases; the differences in cost are negligible. Therefore, except for the DWCs, we use an approach based on separation tasks instead of final columns. The final model is a MINLP model. A detailed description of this approach can be found in Caballero and Grossman (2013). Note that the sequence of task must be rearranged in actual columns (see points 3 and 4), that could have a considerable impact on the final cost especially if a configuration with less than N-1 columns is generated.
Besides, in TCD it is common to find several solutions near the optimal one, which must be also taken into account. As a consequence we calculate all the sequences of separation tasks inside a given tolerance, say inside the 10% of the best one.

2. FUG equations assume constant volatilities and constant molar overflow. In actual systems these assumptions not always hold either in a single separation tasks or in different separations. The accumulation of errors could produce inaccurate results. A rigorous simulation (i.e. Aspen-Hysys) allows checking the model and, if necessary, we modify relative volatilities for each separation tasks until we get a good agreement between both models.

3. Selection of the best sequence of columns with exactly N-1 columns (N is the number of key components to be separated). At this point we must take into account two considerations. 1. A thermal couple –two streams, a liquid and a vapour connecting two sections- could induce sections with important differences in diameter. Although it is possible to build columns with different diameters, a column with three or four different diameters did not seem, at least practical. 2. Agrawal and Fidkowski (1998) showed that the sections must be arranged in actual columns in such a way that the vapour flows from higher to lower pressures. The vapour flow between columns can be controlled by a valve. Caballero & Grossmann (2003) showed that for a given feasible sequence of separations tasks it is always possible to get that configuration using N-1 columns. Therefore, in this stage we search for the minimum cost feasible sequence formed by N-1 columns with a single diameter in which the vapour flows from higher to lower pressures. This usually means increasing the diameter of some sections, with its corresponding cost penalty. The feasibility must be checked to ensure that modifications in diameters do not create operability problems (i.e. weeping, flooding, etc.).

4. Selection of the best sequence with less than N-1 columns (Intensification). Some basic sequences of separation tasks allow reducing the number of columns to less than N-1 with a small or moderate penalty in energy consumption. There is a trade-off between the reduction in the investment cost and the increase in the energy consumption. It would be possible to generate all the possible sequences with «reduced number» of columns (Shenvi et al, 2012), and try to select the best one. However a more practical approach consists of studying only the set of best

sequences generated in step 1. If the maximum reduction in investment cost identifies a possible optimal sequence then the intensified sequence is rigorously calculated. Three possible intensification alternatives are taken into account: 1) Kaibel columns (Kaibel, 1984) –separate four key components using a DWC-. 2) Elimination of transfer blocks (Rong and Massimiliano, 2012). These blocks appear in sequences which have columns formed by a single section connecting other two columns. 3) Columns that can be merged in a single shell to form «columns with vertical partitions» (Agrawal, 2001). Or any combination of those.
It is also possible to reduce the number of columns by extracting some products as side streams, but in this case high purity requirements are difficult to get. But it must be taken into account if no high recoveries are necessary.

There are other modifications that could facilitate the operability of the sequence and can be taken into account. DWCs or Kaibel columns can be thermally coupled with the rest of the sequence, which could produce difficulties in the operation. In those cases it is convenient 'decouple' those columns by forcing the existence of a reboiler and a condenser. Shah and Agrawal (2010) suggested that some bi-directional flows (a liquid and a vapour stream exiting from some point in the middle of a column and entering in the middle of another column) can be substituted by a single liquid stream with a small energy penalty, but improving the operability of the column.
Finally, the existence of thermal couples makes that some separation tasks are working far away of their optimal conditions (conditions in which separation task would be operated if there were no interaction with other tasks). That excess of vapour (liquid) in some sections could be use as heating (cooling) media in other parts of the plant (Navarro et al, 2013). But of course, this analysis can be performed only taking into account the whole plant. Alternatively, if the excess of flow is too large (with also large diameters in the actual column) we should consider the possibility of include side heat exchangers. A comprehensive discussion can be found in the work by Navarro et al (2013)
We illustrate all these points with the following example.

2. Example

Consider a mixture of four lineal hydrocarbons; from n-hexane to n-nonane (All relevant data are shown in Table 1).

Table 1. Data for the example.(Rest of physical data from Aspen–Hysys ™ database)

Components	Feed flow (kmol/h)		
A = n-hexane	120	Pressure	1.2 atm
B = n-heptane	90	Feed liquid fraction	1
C = n-octane	60	Vapour Steam cost	14.05 $/GJ
D = n-nonane	30	Cooling water cost	0.354 $/GJ
		Cost data source	Turton et al (2013)

The following constraints have been added to the model in order to generate non-difficult to operate sequences: 1) Divided wall columns must have a condenser and a reboiler. In other words, they cannot be thermally coupled with the rest of the system. 2) The flow transfer between two columns using side streams is forced to be saturated

liquid. 3) We search for actual columns with a single diameter, and configurations for which it is possible to establish a gradient of pressures in such a way that the vapour flows from higher to lower pressures. 4) We consider only columns with a single internal wall.

As commented before we obtained not only the best solution but a set of solutions inside a given tolerance. For this example there are 6 different solutions with a TAC that differ in less than 10%. The best solution obtained corresponds to a fully thermally couple configuration (extended Petlyuk arrangement) with a total annualized cost (TAC) equals to 2261.9 k$/y. If we rearrange the sequence of tasks in actual columns there is an increment of cost, because the increase in the diameter of some sections, to 2336.7 k$/y. (around 3.3%). Figure 1 shows the best solution of stage 1 after the rearrangement in actual columns.

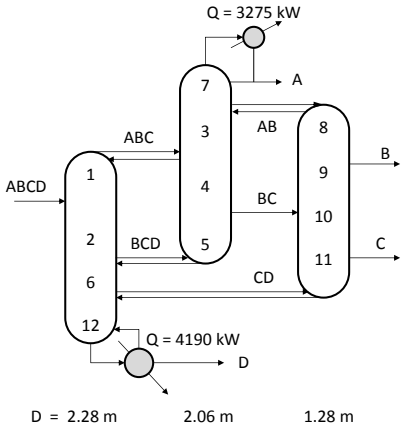

Figure 1. Best solution after steps 1 and 2

A Kaibel sequence can be generated from a fully TCD sequence by removing intermediate mixtures that do not include extreme volatility components (BC in this case). If the energy penalty is not too large the reduction in the number of shells could become the Kaibel column the optimal one. In this example, a simple calculation at minimum reflux conditions shows that there is an energy penalty around 18.5%. Taking into account energy consumption is around the 70% of the TAC we can discard the Kaibel column.

The first, second, third and fourth solutions share the same sequence of separation tasks, and differs each other only in some heat exchangers, therefore we skip here these alternatives (second solution includes a reboiler in the separation BC/CD; the third one includes reboilers in separation tasks ABC/BCD and BC/CD; and the fourth solution a reboiler in ABC/BCD).

Especial mention deserves the fifth solution. For this solution the TAC increases to 2455 k$/y (around 8% higher). In this case it is possible to identify a 'transfer block', which allows reducing by one the number of columns, with almost no penalty in energy consumption, (see Figure 2). We can go a step forward and merge these two columns in a single divided wall column. Remark also that in the final configuration the areas of each section do not need to be modified!

The TAC for the sequence in Figure 2.d is reduced to 2276 k$/y. Therefore, the intensified configuration in Figure 2d has the same TAC than the best sequence formed by N-1 columns (difference around 1%). The final decision on what sequence to build must be based in other kind of considerations.

It is worth remarking that the first sequence with a DWC has a TAC equal to 2821.3 k$/y (around 25% higher). This is due to the fact that we have forced the DWC not to be coupled with the rest of the system. In other words, the DWC must have a condenser and a reboiler (see Figure 3a). Intermediate heat exchangers could have an important impact on the total cost. For example, if for the best solution we force a condenser in the separation task AB/BC (this heat exchanger does not appear in any of the best solutions) the cost increases almost in a 30% (2910 k$/y.)

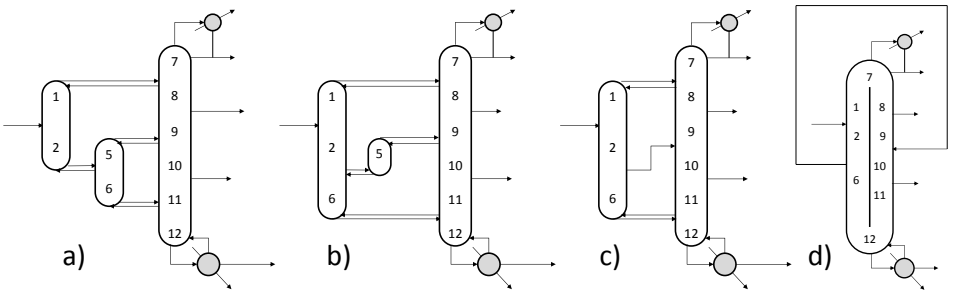

Figure 2. Process intensification for the 5th sequence. a) A feasible arrangement in actual columns. b) A thermodynamically equivalent configuration with a «transfer block». c) Configuration removing section 5. d) Divided wall column thermodynamically equivalent to configuration c.

If we allow the DWCs to be coupled with the rest of the system then the optimal solution is a fully TCD with an internal wall (See Figure 3b).

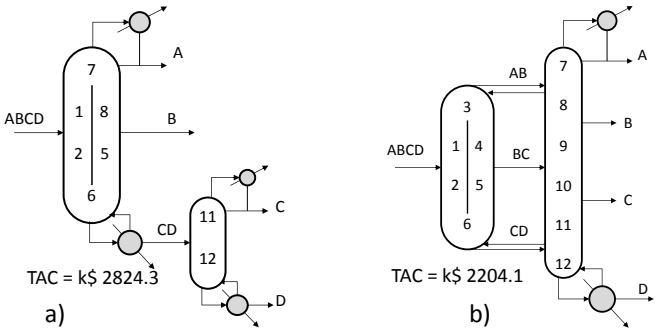

Figure 3. a) Best solution with a divided wall in which the DWC is forced to have reboiler and condenser. b) Best solution if DWCs can be thermally coupled.

3. Conclusions

A systematic procedure for the synthesis and intensification of column configurations for multicomponent distillation is presented. The algorithm starts by searching in the space of basic configurations extended with the internal structure of heat exchangers (reboilers and condensers do not associated to final products). It has been shown that some internal heat exchangers can have a large impact on the performance of the complete system. If this internal structure of heat exchangers is not taken into account there is a large probability of losing the optimal solution. On the other side it is not convenient to explicitly consider, at this stage, the final arrangement in actual columns. This is because there are a potential very large number of thermodynamically equivalent

configurations with similar cost. So a good approach is to use a task based instead of a column based approach.

The optimal sequence of tasks must be rearranged in actual columns. To that end the algorithm takes into account operability constraints and some necessary modification in the diameter of some column sections to avoid building columns with three or more different diameters. Other considerations like limiting the total length can be addressed either by increasing the number of columns or modifying the internals in the column (i.e. tray separation). However, all these modifications must be carefully checked to avoid column malfunctions.

Finally, it is possible try to intensify the total system by reducing the number of column shells. Different alternatives where considered: Kaibel columns, elimination of transfer blocks and merge columns using vertical partitions. However, except in some DWCs, the reduction in the number columns involves a penalty in energy and as a consequence the trade-offs must be carefully studied. But the example shows that these alternatives must be considered

Abstract

Removal of H_2S from industrialgas mixturesis important to avoid operational hazards, and to meet stringent environmental regulationto curb H_2S emission. Zeolites are microporous materialswhich have shown excellent potential as adsorbents for molecular gas separation, and can be applied for separating H_2S from other gases. We apply a multi-scale systems engineering framework to discover or identify highly selective, feasible and cost-effective zeolites for pressure swing adsorption (PSA)-based H_2S separation. Using the *in silico* framework, several new and cost-effective zeolites are identified for adsorption-based H_2S separation. We demonstrate the applicability of the multi-scale approach for H_2S separation fromrepresentative binary gas mixtures such as acid gas (H_2S/CO_2), tail gas (H_2S/N_2), and natural gas (H_2S/CH_4). A key component of the proposed approach is an efficient and hierarchical computational screening that combines selection of materials with advanced process optimization. We anticipate that this approach is suitable for the discovery of novel materials for other molecular gas separation of industrial importance.

Keywords: hydrogen sulfide removal, zeolite, pressure swing adsorption, process optimization, multi-scale systems engineering

1. Introduction

H_2S is a toxic gas found in many chemical and industrial plants, including natural gas processing and utilization, power plants, coal gasification, refineries, petrochemical processing, wastewater treatment, and semiconductor manufacturing. The presence of H_2S in natural gas leads to pipeline corrosion during natural gas transportation. Furthermore, H_2S is one of the major air pollutants found in tail gases and flues gases from chemical and power plants. Removal of H_2S from industrial gas streams with high CO_2 and H_2S concentrations is important due to stringent environmental regulations. Several technologies are available for H_2S removal, which include absorption, adsorption, Claus conversion, catalytic oxidation, catalytic membrane contactor, and microbial treatment.

Pressure swing adsorption (PSA), which involves passing a gas mixture through a column packed with a microporous adsorbent that selectively adheres one gas over others, has been the technology of choice for many industrially important gas separation problems including air separation, carbon capture, and natural gas purification. Microporous adsorbents such as zeolites and metal–organic frameworks (MOFs) have

been shown to be excellent candidates for molecular gas separation for CO_2 capture (Hasan *et al*., 2012a, 2012b, 2013, 2014) and natural gas purification (First *et al*., 2014). There are numerous choices for zeolites as adsorbents, and an efficient computational framework is therefore required to screen for the most promising candidates.

In this work, we apply a multi-scale framework to screen highly selective, feasible and cost-effective zeolites for PSA-based H_2S separation from representative and binary gas mixtures such as acid gas (H_2S/CO_2), tail gas (H_2S/N_2), and natural gas (H_2S/CH_4). We present an *in silico* framework (Figure **1**) that combines zeolite screening with process optimization to identify the most cost-effective materials for these separations involving H_2S. Several materials-centric metrics are used to filter a database of zeolites to a short list of candidates. The PSA process using each of these zeolites is modeled using a detailed system of nonlinear algebraic and partial differential equations. The process topology and conditions are optimized for each zeolite to minimize the total cost of separation, which serves as the final ranking criterion.

2. Screening based on Shape, Size, and Pore Selectivities

Our hierarchical screening procedure (shown in Figure **1**) starts with a three-dimensional pore characterization method to filter the ZEOMICS database of 199 zeolite structures (First *et al*., 2011) to obtain a short list of candidate zeolites as potential adsorbents for H_2S separation. We use three geometric-level metrics: shape selectivity, size selectivity, and pore selectivity. For the case of binary gas mixture, shape selectivity describes the difference in energetic cost of transport of two gases through a zeolite's pores and their networks due to strain and distortion caused by shape and size (Gounaris *et al.*, 2006a, 2006b, 2009; First *et al*., 2013). Shape selectivity is calculated as the absolute difference in Boltzmann factors of the minimum pathway energies of the two gases. The metric of size selectivity was first introduced by Hasan *et al.* (2013) to consider the entire distribution of pore sizes. While shape selectivity is focused on the most dominant pathway through a zeolite, size selectivity is calculated as the relative difference in accessible pore volume between two gases by approximating the gas molecules as hard spheres to determine accessibility.

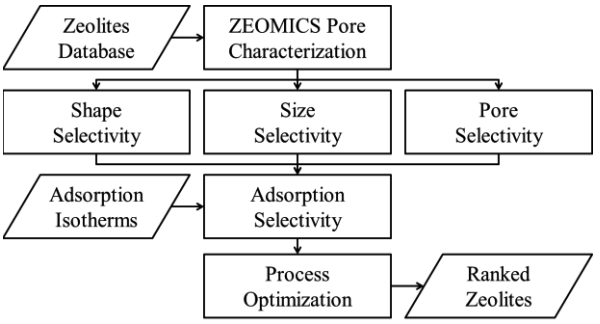

Figure 1. Flowchart of the multi-scale framework for adsorbent screening using combined material characterization and process optimization methodologies.

Pore selectivity is another metric originally proposed for natural gas purification (First *et al.*, 2014). It is calculated as the relative difference in energetically-accessible pore volume. The concept of pore selectivity is based on combining the energetic calculations of shape selectivity with the accessible pore volume calculations of size selectivity.

Each of these metrics is calculated as a number between 0 and 1, with 0 indicating low selectivity and 1 indicating high selectivity. Minimum cut-off values of 0, 0.1, and 0.1 are introduced for shape, size, and pore selectivity, respectively, to filter the full database of zeolites. Out of 199 zeolites, 29 zeolites show shape selectivity, 26 zeolites show size selectivity, and 33 zeolites show pore selectivity higher than 0.1 for H_2S for CH_4/H_2S system. All 33 zeolites which are pore-selective also show shape and size selectivities for this separation. We have also identified 57 out of 199 zeolites which show either shape selectivity, size selectivity or pore selectivity for H_2S removal from CO_2/H_2S.Similarly, 64 candidate zeolites are screenedas preliminary candidates for H_2S removal from H_2S/N_2 mixture, which exhibit either shape, size and pore selectivity.

3. Screening based on Adsorption Selectivity

Adsorption selectivity is determined by performing grand canonical Monte Carlo (GCMC) simulations to calculate the Henry constants for the two gases in each zeolite. The details of the GCMC simulations are reported elsewhere (Hasan *et al*., 2013, First *et al*., 2014). For each system, we consider top zeolites with adsorption selectivitygreater than 10 for further consideration duringdetailed process optimization. The selected zeolites for H_2S/CO_2, H_2S/N_2, and H_2S/CH_4 separation are listed in Table **1**. Note that the reported adsorption selectivities correspond to the more adsorptive component of the two gases present. In zeolites, the adsorption affinities for gases are usually as follows: CO_2> H_2S >CH_4>N_2. Therefore, Table **1** reports the selectivities of CO_2, H_2S, and CH_4 for CO_2/H_2S, H_2S/N_2, and CH_4/H_2S mixtures, respectively.

4. Process Optimization for Pressure Swing Adsorption (PSA)-based H_2S Separation

The PSA process that we consider for H_2S removal is illustrated in Figure **2a**. The feed may pass through a compressor to bring it to the desired adsorption pressure. Then one or more columns packed with a zeolite adsorbent (selected from Table 1) are used for adsorption. For CO_2/H_2S and H_2S/CH_4 mixtures, the clean gas(CO_2 or CH_4) is collected using a desorption vacuum pump. When we separate H_2S from H_2S/N_2 mixture, H_2S is collected using the desorption vacuum pump.

The process is operated using a 3-step PSA cycle (Figure **2b**) consisting of (i) column pressurization, and (ii) adsorption and (iii) counter-current desorption of the more adsorptive gas. During pressurization, the column fills from the feed-end with the feed mixture until the adsorption pressure, P_{ads}, is reached. Then, during the adsorption step, the other end of the column opens and less adsorptivegas exits the column while the more adsorptive gas is adsorbed by the zeolite. Finally, during desorption, the other end of the column is again closed, and the more adsorptive gas is evacuated from the feed-end of the column at the desorption pressure, P_{des}. A typical pressure profile during a cycle is provided in Figure **2b**. Multiple adsorption columns can be used to maximizethe utilization of the feed compressor and the desorption vacuum pump.

The PSA process is modeled using a detailed system of nonlinear algebraic and partial differential equations (NAPDE), which can be found elsewhere (Hasan *et al*., 2012, 2013; First *et al*., 2014). These equations describe mass and energy balances, flow through porous media, temperature and pressure effects, and heat transfer resistance across the column wall (Hasan *et al*., 2012, 2013). A candidate zeolite is represented in the model by parameters describing the adsorption isotherms and heats of adsorption of the gases present in the feed, which are readily available through GCMC simulation.

The model is optimized to identify the column length (L), adsorption (P_{ads}) and desorption (P_{des}) pressures, and adsorption (t_{ads}) and desorption (t_{des}) step durations. The pressurization time is fixed to 20 s (Hasan *et al*., 2012), and the column diameter and number of columns are determined using analytical expressions described in Hasan *et al*. (2013). To efficiently optimize the large, complex process model, an efficient Kriging-based grey-box constrained optimization approach is used (Hasan *et al*., 2013).

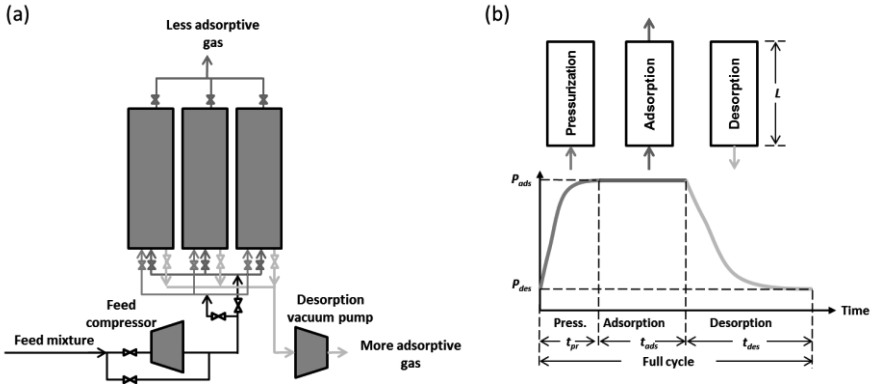

Figure 2. PSA process for H_2S separation: (a) process flow diagram with multiple columns, feed compressor and desorption vacuum pump, and (b) pressure profile of the 3-step PSA cycle, which includes (i) pressurization, (ii) adsorption, and (iii) desorption.

5. Cost-effective Zeolites for H_2S Separation

5.1. H_2S Removal from CO_2/H_2S Mixture

The feed mixture consideredin this problem contains 80% CO_2 and 20% H_2S.The feed flow rate is 0.1 kmol/s. We optimize the total annualized cost (TAC) of the PSA process, where TAC includes the investment, operating and material costs. The optimized results are shown in Table 2. We have identified ABW, LOS, NSI, BIK, MON, AEN and APC, which can remove H_2S and increase the CO_2 purity to 93 – 99% with CO_2recovery of 85 – 92% at reasonable cost.

Table 2. PSA results for the top zeolites for H_2S separation from CO_2/H_2S mixture.

Zeolite	P_{ads}(bar)	P_{evac}(bar)	t_{ads}(s)	t_{evac}(s)	L (m)	CO_2Purit (%)	CO_2Recovery (%)	Cost (MM$)
ABW	1	0.01	9.91	150	1	93	90	3.28
LOS	1.03	0.01	6.58	100	1	98	85	3.27
NSI	1.03	0.01	15	200	1	97	92	3.15
BIK	2	0.01	18.74	300	1	98	92	3.35
MON	2.08	0.01	16.78	150	1	95	91	3.47
AEN	2.31	.005	15.32	231	1	99	88	3.57
APC	2.36	0.01	16.04	150	1	94	89	3.74

5.2. H_2S Removal from H_2S/N_2 Mixture

We have optimized the PSA process for the top zeolites listed in Table **1**. We consider a feed composition of 10% H_2S and 90% N_2. The best zeolite is found to be AWO which can meet the clean gas (N_2) requirement in terms of purity (98%) and recovery (97%). The cost of N2 purification from a feed containing 20% H_2S and with a flow rate of 0.1 kmol/s is $1.51 MM. Therefore, AWO is a promising zeolite for H_2S removal.

5.3. H_2S Removal from H_2S/CH_4Mixture

We consider the feed mixture to be 80% CH_4 and 20% H_2S. This is a challenging problem with high initial concentration of H_2S. We have investigated the top zeolites

suggested by the materials-centric metrics, and found that the zeolite AWO is a promising zeolite which has not been suggested in any previous studies for H_2S separation for removing H_2S from natural gas (CH_4).

6. Conclusions

Using the combined material screening and process optimization methodology, we have discovered several new zeolites for removing H_2S from a variety of industrial gas mixtures with applications in carbon capture, acid gas removal, natural gas purification and tail gas purification. The most economical sorbents, zeolites ABW and AWO, are attractive for use in a PSA process to separate H_2S from sources containing H_2S with high concentrations (as high as 20%). The PSA process can achieve CO_2 purity to 93 – 99% with CO_2 recovery of 85 – 92% for CO_2/H_2S system, 98% purity and 97% recovery of N_2 for H_2S/N_2 system, and more than 90% purity and recovery for H_2S/CH_4 system. The costs of separation are also reasonable.We anticipate that our approach is suitable for the discovery of novel materials for other molecular gas separation.

Abstract

Fusel oil is a valuable byproduct of the fuel ethanol industry that can be used to isolate C6 alcohols and other fragrances and flavor ingredients. In this work we propose two distillation schemes for obtaining isoamyl alcohol from fusel oil: a conventional distillation sequence and a dividing wall column. After validation of thermodynamic models to accurately describe phase equilibria of fusel components (VLE and LLE), a dividing wall column (DWC) separation scheme was developed. Both traditional sequential distillation and DWC system were optimized using differential evolution and tabu list coupled to ASPEN PLUS. Results indicate that significant energy and economic savings can be obtained in the purification of fusel oil (a non ideal mixture) using a DWC scheme compared to conventional configuration.

Keywords: Optimization; fusel; dividing wall column

1. Introduction

Through the years, the production of ethanol by fermentation has increased due to the biofuels demand, and consequently generation of by-products of this industry such as fusel oil has increased as well. Fusel has been characterized as a liquid waste and used as fuel in the boilers within distilleries. It is a mixture obtained as a side cut during ethanol distillation, mainly composed of i-amyl alcohol, water, *iso*butanol, ethanol and other short chain alcohols (C3-C5). These alcohols can be considered valuable raw material for various products of industrial interest such as: biosolventes, extractants, flavors, fragrances, pharmaceuticals and plasticizers, among others. According to different characterizations, major components of fusel oil are isoamyl alcohol, water and ethanol, accounting for ~98% of the total mixture. In this context, two distillation schemes to purify isoamyl alcohol and ethanol were developed. Such schemes were constructed taking into account continuous distillation sequences currently used in ethanol distilleries. A traditional scheme (Figure 1) is comprised of three distillation columns where most ethanol and water are separated in the top of the first column. This stream is sent to a subsequent column where azeotropic ethanol can be extracted on the top and water at the bottoms product. Bottoms product from first column is sent to a third distillation column connected to a decanter, where isoamyl alcohol is obtained as a bottoms pure product.

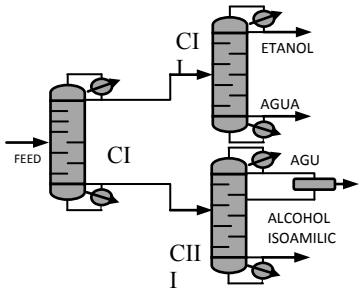

Figure 1. Conventional distillation system for fusel purification.

Dividing wall column has been used in the purification of ternary systems with significantly savings in energy consumption and capital costs over conventional simple column configurations (Hernández et al., 1996). Specifically, the dividing wall column (DWC) has been successfully implemented in many industrial separations (Olujic et al., 2003). In the dividing wall distillation (DWC) scheme proposed in this work (Figure 2), azeotropic ethanol is obtained as the top product of the main column, while isoamyl alcohol is removed from the bottoms product. Water is removed using a side stream connected to a decanter taking advantage of the liquid phase immiscibility

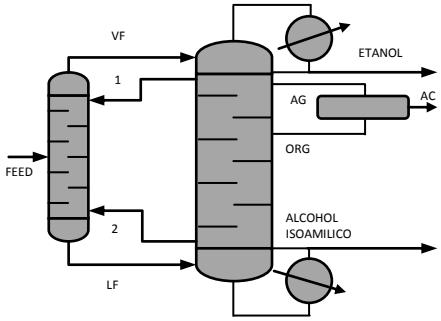

Figure 2. DWC system for fusel purification.

2. Case study

Composition of fusel oil was established according to the analysis performed to six different samples from different sugar mills in Colombia. Samples were characterized by gas chromatography coupled to mass spectrometry. The following components were detected: ethanol, water, n-butanol, isobutanol, isoamyl alcohol and 2-ethylhexanol. The composition of the mixture of study is presented in Table1.

Table 1 Composition of the mixture of study.

T= 25ºC P = 1 atm	
Component	composition % mol
Etanol	0.1258
Water	0.143
isoamyl alcohol	0.7047
n-butanol	0.0139
isobutanol	0.012599
2-ethyl-hexanol	1x10^{-}6

Thermodynamic of phase equilibria was validated by regression of binary and ternary equilibrium literature reports using a NRTL-HOC activity-based model. To obtain the corresponding thermodynamic parameters, NIST equilibrium data incorporated within ASPEN PLUS were used. Using the regression tool included in the same software, VL and LL data were simultaneously fit to accurately model the phase behavior within the distillation system

3. Optimization problem

During optimization of distillation schemes, total annual cost (TAC) minimization was used as objective function. This function takes into account energy consumption, utilities, and column size. The minimization of this objective is subjected to the required recoveries and purities of each product stream, i.e.:

$$\text{Min (TAC)} = f\left(N_{tn}, N_{fn}, R_{rn}, F_{rn}, D_{cn}\right) \quad (1)$$

$$\text{Constrain: } \vec{y}_m \geq \vec{x}_m$$

where Ntn and Nfn are the total number of stages and the feed stages of column respectively, Rrn is the reflux ratio, Frn is the distillate flow, Dcn is the column diameter, ym and xm are the obtained and required purities vectors of the m components, respectively. This minimization implies the manipulation of 14 continuous and discrete variables for each route process, where 5 variables are used for the design of each column. Note that since the product streams flows are manipulated, the recoveries of the key components in each product stream must be included as a restriction for the optimization problem. During each optimization, a Pareto front was generated, plotting the objective function (total annual cost) against the flow of impurities. Impurities flow in each product stream is the sum of the components which are not present in high purity in out flowrate. A list of manipulated variables for both schemes are listed in Table 2.

Table 2 Manipulated variables during process optimization

Manipulated variable	Conventional scheme			DWC	
	CI	CII	CIII	PREF	PETLYUK
number of stages C_n, N_{Cn}	x	X	x	x	x
feed stage in column C_n, $N_{F,Cn}$	x	X	x	x	x
distillate streamflow of column C_n, R_{Cn}	x	X			x
reflux ratio in column C_n	x	X	x		
bottoms streamflow of column C_n			x		x
feed stage of liquid interconnection flow FL in column C_i, N_{FL},C_i					x
feed stage of liquid interconnection flow FV in column C_i, N_{FL},C_i					x
feed stage of liquid interconnection flow FL in column C_i, N_{FL},C_i					x
vapor interconnection flow, FV					x
liquid interconnection flow, FL					x

4. Results

In this section, we present the set of optimal designs in Pareto front, for both schemes: conventional (Figure 3) and divided wall column (Figure 4).

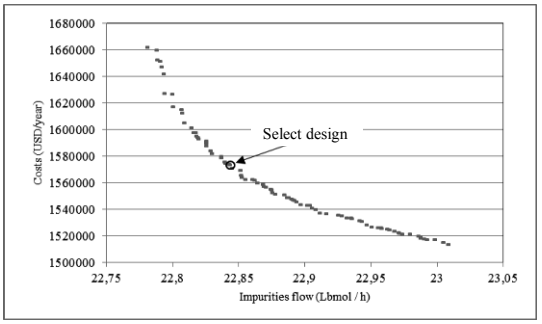

Figure 3. Pareto front of the conventional scheme.

In the conventional configuration, in column CI the number of stages and reflux ratio determine the value of the objective function (TAC) as it is where is performed the separation of water from alcohols including ethanol which forms a minimum temperature azeotrope. Overall, this column represents over 80% of energy consumption scheme. In column CII there is a close relationship between energy consumption, the purity of ethanol and the reflux ratio, due to the higher reflux, there is greater demand for energy and it results in greater purity of ethanol. This was seen as a high purity of ethanol increases energy consumption by 12%.In column CIII was observed the higher flowrate in the bottom stream, the reboiler duty is increased.

Figure 3 shows the Pareto front obtained after optimization, it is clear that both objective functions evaluated are in conflict each other. The Pareto front is formed for several points that accomplish all purity and recovery restriction (84 %, 70 % and 99 % mol). In a general way, the Pareto front consists in three sections, one section where are located designs which have preferably a high number of stages and a high reflux ratio. On the other hand at the end of Pareto front are located some sequences which showed a minor economic impact due to these designs include relative few stages. At the middle of the Pareto front is located a feasible zone, where are designs with suitable values of TAC and impurities flows comparing extremes of plot.

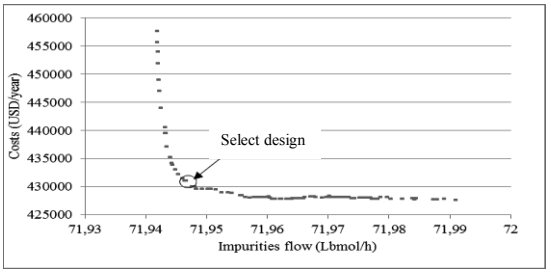

Figure 4. Pareto front Petlyuk scheme.

For the divided wall column, a clear relationship is showed between the reboiler duty and TAC, and high reflux ratio presents a high reboiler duty. Besides, when divided wall column (Figure 4) was evaluated with the same objective functions, and the same restrictions purity of the components of interest, from the Pareto front we appreciate a section with high cost associated to high reflux ratio to achieve a low impurities flow.

Table 3. Design specifications of proposed schemes.

Design specifications						
Equipment		Pref	Petlyuk	CI	CII	CIII
Stages		10	26	16	21	7
Feed stage		8	22	11	15	5

	ISOAMYL ALCOHOL		26			
Feed products	AC		22			
	1		16			
	2		25			
Flow interconnection (Lbmol/hr)	AC		60			
	1		12			
	2		95			
Composition	Ethanol		0.84		0.84	
	Water		0.71		0.72	
	Isoamyl		0.99			0.99
Energy consuption (Btu/h)		8´130,642.04		10´214,657.14		
Costs (USD/year)		430,231.31		1´573,677.43		

Characteristics of the design highlighted in Figure 4 are presented in Table 3. Notice that this design includes few stages considering 50 stages as limit. Nevertheless all purity restrictions were accomplished. As well, Table 3 shows general characteristic of design highlighted in Figure 4 such as stages, reflux ratios and interconnection flows values. This design satisfied in the same manner all restrictions. When comparing both schemes, savings of 73% in the total annual costs (TAC) and a 20% saving in energy consumption are obtained. In order to know purity values through stages in divided wall column, Figure 5 shows a concentration profile, which confirms the high isoamyl alcohol and ethanol purities obtained in this column. This behavior of divided wall column projecting itself as a good alternative in fusel purification due to energy and costs savings.

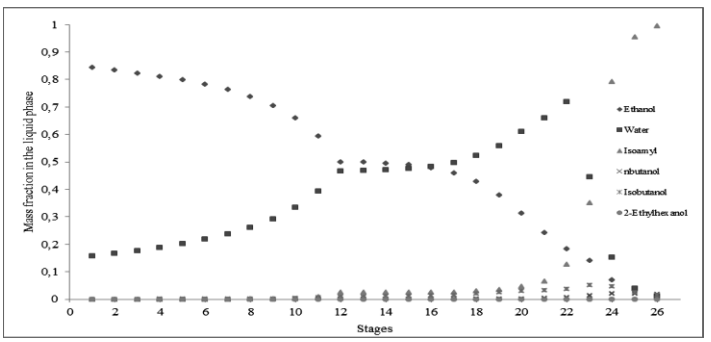

Figure 5. Composition profile for the DWC scheme.

5. Conclusions

In this work, an optimization procedure, based in differential evolution and tabu list coupled to ASPEN PLUS, was proposed for the optimization of complex distillation columns. The results show that divided wall column represents a good option for fusel oil distillation due to the benefits that would be obtained in terms of reduction in total

annual cost (TAC) over the traditional distillation sequence used in industry. The separation of isoamyl alcohol at a high purity and low cost using a dividing wall column represents an excellent option for purification of fusel oil in industry. These results represent a new vision in regard to highly nonideal mixture, where heterogeneous azeotropes are present in multicomponent systems and they are purified in a DWC.

Abstract

This work shows that it is feasible to obtain a high purity of silane over 99% and almost complete conversion of trichlorosilane to silane and silicon tetrachloride by a typical reactive distillation column. Nevertheless, the normal reactive distillation column possesses the shortage of high refrigeration requirement. By removing heat at temperature higher than that at the condenser it is possible to reduce cooling requirements at the condenser. In this work, a superstructure representation, rigorous simulations, and optimization problems were combined to derive optimal reactive distillation columns which can realize heat integration between stages and utilities. The results showed that the installation of two inter-condensers results in the best option with economic savings.

Keywords: Reactive distillation, energy savings, silanes.

1. Introduction

Photovoltaics (PV) use semiconductor materials to generate electricity from solar energy. Semiconductors have electrical conductivities greater than insulators but lower than metals which are good conductors. At low temperatures and high level of purity, they are insulators but at high temperatures and/or when they are doped and excited by sunlight, they conduct electrons. The most commonly used semiconductor element is silicon. Therefore silicon today is the most important material in PV industry. The most well-known chemical route to produce solar-grade silicon is the Siemens process. However, the extremely high consumption of electrical energy as well as the corrosion caused by the byproduct (hydrochloric acid) in some way has limitations in the production of low-cost polysilicon. Other very well known route to produce silane is the disproportionation reactions of $SiHCl_3$ involving the formation of dichlorosilane (SiH_2Cl_2) and monochlorosilane (SiH_3Cl) as intermediates and tetrachlorosilane ($SiCl_4$) as by product (Bakay, 1976) The conventional process for highly pure silane production from trichlorosilane disproportionation is through two reactors and several separation units. However, due to unfavorable chemical equilibrium, this reaction and separation process requires an extremely large recycle ratio and thus the cost of energy as well as

investment is very high. In this context, Reactive Distillation (RD) can be suitable for the disproportionation reactions because it eliminates conversion and phase equilibrium limitations by continuous removal of products from the reaction zone unit (Sundmacher and Kienle, 2003). It can be considered that one of the major disadvantages in using reactive distillation for the disproportionation of trichlorosilane is the low boiling point (-112°C) of the target product at the top of the column (silane) and enforces the use of refrigeration services to condensate it. To alleviate this issue, the use of intermediate condensers can be proposed to reduce the energy consumption. In this work, we investigate the feasibility of applying reactive distillation to the production of silane through the disproportionation of trichlorosilane. The design and rigorous optimization, considering all feasible alternatives, of reactive distillation column with inter-condensers has been studied as a feasible alternative to alleviate this drawback.

2. Case Study

The production of silane (SiH_4) through disproportionation of thrichlorosilane ($SiHCl_3$) in a reactive distillation column has been studied. The reaction occurs in three steps, having as intermediates dichlorosilane (SiH_2Cl_2) and monochlorosilane (SiH_3Cl) and as by-product chlorosilane ($SiCl_4$), as follows:

$$2SiHCl_3 \leftrightarrow SiH_2Cl_2 + SiCl_4 \quad (1)$$

$$2SiH_2Cl_2 \leftrightarrow SiH_3Cl + SiHCl_3 \quad (2)$$

$$2SiH_3Cl \leftrightarrow SiH_4 + SiH_2Cl_2 \quad (3)$$

The L-V equilibrium has been modelled using the Peng-Robinson equation of state (Huang et al., 2013). The reaction occurs in liquid phase, using as catalyst Amberlyst A-21. For the disproportionation of trichlorosilane using such catalyst, a pseudo-homogeneous kinetic model has been proposed (Li, 1988). To model the reactive distillation column, the RadFrac module of Aspen Plus V8.0 has been used. The feed stream has a flow rate of 10 kmol/h of pure trichlorosilane, and enters to the column at 5.5 atm and 50°C. Silane is obtained at the top of the column with a purity of 99 mol%, while silicon tetrachloride is the bottoms product, with a purity of 99 mol%. The condenser operates at 506 kPa, with a pressure drop of 0.5 kPa per stage. A representation of a reactive distillation column is shown in Figure 1a. Since the condenser operates at temperatures lower than 0°C, the use of a refrigerant is necessary, increasing the cost of the separation.

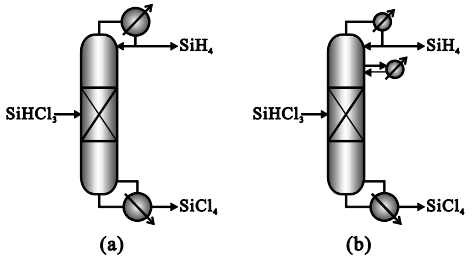

Figure 1. (a) Reactive distillation column, (b) Reactive distillation column with an intermediate heat exchanger.

To reduce the cooling duty at the condenser, the use of intermediate heat exchangers is investigated in the next section. A representation of a reactive distillation column with a single intermediate exchanger is shown in Figure 1b.

3. Installation of Inter-condensers and Inter-reboilers in Reactive Distillation: Optimization Procedure

The vapor stream leaving at the top of a distillation column must be condensed at the lowest temperature condition while the liquid stream leaving at the bottom must be heated at the highest temperature condition. For our reactive column, silane is obtained at the top and it must be condensed at about -78 °C, thus an expensive refrigeration system is required to provide cooling at temperatures below -85 °C. Typically, to avoid condensing at such low temperature levels, the column operating pressure could be increased, however, this option would be impractical because of catalyst deactivation at high pressure. A second alternative, which is exploited in this work, implies cooling at higher temperatures than that at the condenser, allowing the use of less expensive cooling utilities. The cooling and heating utilities used are shown in Table 1 where R1, R2, and R3 denote refrigeration systems at three different temperatures, CHW and CW denote chilled and cooling water, respectively; and MS denotes steam at 6.1 atm.

Table 1. Utilities for cooling and heating.

ID	Inlet temperature (ºC)	Outlet temperature (ºC)	Cost (USD/MWh)
R1	-88	-88	151.94
R2	-30	-30	34.67
R3	-20	-20	28.40
CHW	5	15	15.95
CW	30	40	1.274
MS	160	160	50.58

The selection of the best locations and utilities for heat integration must consider two important features in heat-integrated stages:

1. The heat removed or added at a stage in a rectifying or stripping section is not equal to the net condenser or reboiler duty reduction.
2. The heat removed or added at stages modifies the stage vapor-liquid equilibrium composition, thus the temperature profile changes in the column.

The installation of inter-condensers and inter-reboilers affect both the reaction rate and vapor-liquid equilibrium which results in changes of the equipment size and in operating conditions. A previous work by Huang et al., (2013) studied the disproportionation of trichlorosilane through extensive simulations to find feasible locations and heat loads in inter-condensers. In this work, all the possibilities for cooling at locations other than the condenser and for heating at locations other than the reboiler for a reactive distillation column are comprised in the superstructure shown in Figure 2, which is formulated as an optimization problem.

The adopted objective function, which minimizes the operating cost in a reactive distillation column by finding optimal locations and heat loads in inter-condensers and/or inter-reboilers, is as follows:

$$\min OC = OH\left[\sum_{\substack{i\in REC\\ j\in CU}} C_j^{\text{cool}} Q_{i,j}^{\text{ex}} + \sum_{\substack{i\in HU\\ j\in STR}} C_i^{\text{heat}} Q_{i,j}^{\text{ex}}\right] \tag{4}$$

where *REC* is the set of stages in the rectifying section subject to the installation of a condenser and inter-condensers, *STR* is the set of stages in the stripping section subject to the installation of a reboiler and inter-reboilers, *CU* is the set of cooling utilities, and *HU* is the set of heating utilities. C^{cool} is the cost of cooling utilities while C^{heat} is the cost of heating utilities. $Q_{i,j}^{\text{ex}}$ is the amount of heat exchanged between heat sources *HSO* (i.e., $HSO = REC \cup HU$) and heat sinks *HSI* (i.e., $HSI = STR \cup CU$). Finally, *OH* are the annual operation hours.

Changes in the condenser and reboiler duties due to heat integration at stages in a column are predicted through the use of compensation terms (Alcántara-Avila et al., 2013). Other constraints for the problem are the energy balances, equations for the calculation of the log mean temperature difference (ΔT_{LM}), which is used to determine the temperature driving force for heat transfer in exchangers; and additional constraints to enforce a determined number of heat exchangers in the rectifying and stripping sections and to allocate heat exchangers in feasible heat exchange networks. The log mean temperature difference is used as feasibility criterion for heat integration. The feasibility criterion based on the "Big-M" formulation is as follows:

$$Q_{i,j}^{\text{ex}} - M\Delta T_{\text{LM}i,j} \le 0 \quad i \in HSO, j \in HSI \tag{5}$$

where *M* is a large number.

Since distillation is inherently characterized by a set of nonlinear and nonconvex equations, a simulation software was used to handle them to find optimal values of continuous variables. However, to find optimal values of integer variables (i.e., locations of inter- condensers and/or inter-reboilers) an optimization software was used. Figure 3 shows a flowchart for the proposed iterative procedure, which combines the simulation and optimization software, to find the best reactive distillation column with inter-condensers and/or inter-reboilers. The procedure in Figure 3 was adopted to avoid the solution of complex mixed integer nonlinear and nonconvex mathematical problems.

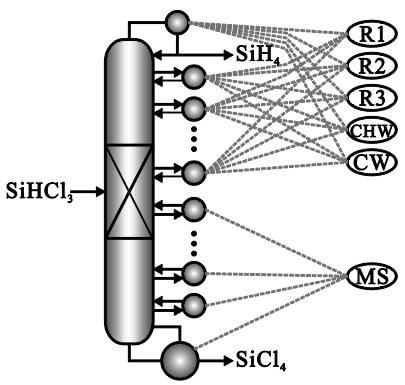

Figure 2. Superstructure representation of the reactive distillation column

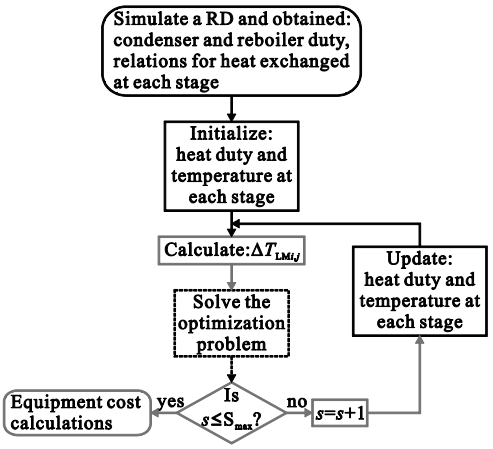

Figure 3. Flowchart of the iterative optimization procedure: Simulation software (solid black lines), optimization software (dasshed lines), interface (solid grey lines).

4. Results

A typical reactive distillation column was investigated first which composed of three sections: the rectifying, catalytic reaction and stripping sections, located at the upper, middle, and lower part, respectively, with the solid catalyst packed in the middle of the column. Trichlorosilane is fed into the column at the middle of the reaction section. Then disproportionation takes place in the reaction section and vaporous product mixture containing light components ascend to the rectifying section while the heavy components descend to the stripping section. Unreacted intermediate products, which rise in the rectifying section towards the condenser, return to the reaction section with the help of the top reflux flow, and unreacted intermediate products, which fall in the stripping section towards the reboiler, return to the reaction section with the help of the boilup stream.

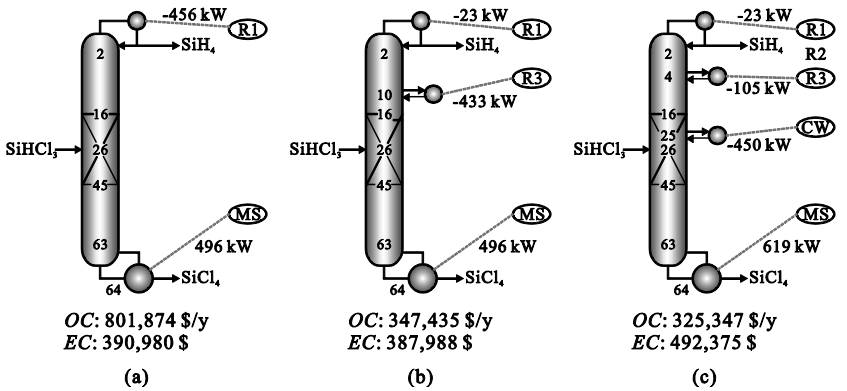

Figure 4. (a) Conventional RD, (b) RD with one inter-condenser, (c) RD with two inter-condensers

To generate the optimal design, the number of stages in the column, the number of reactive stages, the position of the reactive stage, the position of the feed stage, the reflux ratio and the operating pressure were manipulated. The optimum RD column without any intermediate heat exchangers is shown in Figure 4a. The RD with one inter-condenser is shown in Figure 4b, and the RD with two inter-condensers is shown in Figure 4c. The *OC* remarkably drops due to the installation of inter-condensers while the *EC* (Equipment Cost) slightly increases for Figure 4c. In all cases, the liquid residence time of 2.5 s on each stage which is defined as hold-up/liquid-flow-rate. The column is operated at a top pressure of 506.6 kPa with a pressure drop through each stage of 0.5 kPa. The purity of silane in distillate in mole fraction is 0.99. 10 kmol/h of trichlorosilane were fed at 50 °C and 557.3 kPa.

The installation of inter-condensers above the feed stage in the catalytic reaction section (Figure 4c) lowers the temperature profile resulting in higher concentrations of SiH_2Cl_2 and SiH_3Cl in the liquid phase, thus SIH_4 generation is boosted. In addition, although all cases in Figure 4 had the same trichlorosilane conversion (99.25%), the total liquid amount of intermediate species ($SiHCl_3$, SiH_2Cl_2, SiH_3Cl) entering at the top of the catalytic reaction section is 82 kmol/h for Figures 4a and 4b, and 22.7 kmol/h for Figure 4c, respectively. The previous results show how the installation of inter-condensers can effectively reduce the flow rate of intermediate species.

5. Conclusions

It has been proved that it is feasible to obtain a high purity of silane over 99% and a conversion above 99% of trichlorosilane to silane and silicon tetrachloride by the presented reactive distillation columns. The heat removal and addition at stages result in changes of the temperature profile, vapor-liquid equilibrium and reaction rate inside the reactive column. In this work, an optimization procedure was proposed to deal with these changes by iteratively updating the temperature profile and locations of side heat exchangers. In the optimization, the combinatorial problem between stages and utilities was solved while in the simulation, the synthesis problem for the obtained optimal heat integration network was solved. The location of side heat exchangers depend on the estimation of changes in the condenser and reboiler energy requirements due to heat integration, for these purposes, the concept of compensation terms was effectively adopted.

Abstract

In this paper we present conceptual designs of optimal integrated processes for the production of DMF and furfural from biomass, switchgrass and algae. The processes consist of four stages, (1) biomass pretreatment into intermediates such as oil and glucose from algae and glucose and xylose from switchgrass, (2) dehydration of the sugars, (3) HMF and furfural purification and (4) synthesis of DMF out of HMF and FAEE synthesis from oil in the case of using algae. Simultaneous optimization and heat integration is performed for the processes using each raw material. For switchgrass, the use of AFEX pretreatment is recommended for a production of 9 MMgal of furfural and 14 MMgal/yr of DMF. The production cost is $3/kg of biofuel ($570MM of investment cost). When using algae, its composition should be 60% oil, 30% starch and 10% protein to obtain 98 MMgal/yr of biofuels, 16% of DMF, at the cost of $1.98/gal, $0.61/kg of biofuel, requiring $693 MM of investment.

Keywords: Algae, Switchgrass, DMF, Furfural, Mathematical optimization

1. Introduction

Biomass is a rich and diverse raw material for a number of products that have sugars or oil as building blocks. In particular, sugars are the starting block for most biochemical process including bioethanol production. However, we can use sugars to produce added value products and/or intermediates. Furans are a family of chemicals that serve as fuels but can also be used as a building block. Algae biomass comprises lipids, proteins and starch, while lignocellulosic raw materials contain celluloses and hemicelluloses which are a source for pentoses and hexoses. Thus, it is expected we can produce dimethyl furfural (DMF) out of the algae starch, and from switchgrass we should be able to obtain not only DMF but also furfural. Lately, a number of papers have evaluated the production of furan and HMF and DMF from sugars, xylose, fructure or glucose, but all of them start with the sugars without evaluating the production of those sugars from non edible biomass, which is a highly energy and capital intensive stage (Kazi et al 2011, de Ávila & Guiradello 2012). In this work we present conceptual optimal designs for processes from the biomass to furans.

2. Process description

The process is divided into four stages: (1) biomass pretreatment into intermediates such as oil and glucose from algae and glucose and xylose from switchgrass, (2)

dehydration of the sugars, (3) HMF and furfural purification and (4) synthesis of DMF out of HMF and FAEE synthesis from oil in the case of using algae.

2.1. Sugar production from algae

The algae are grown in ponds, harvested using a capillarity based belt. The dry algae biomass is assumed to be composed of oil, up to a maximum of 60 %w/w, starch and protein with a minimum of 10%w/w. On the one hand, the oil, extracted using a hybrid method combining mechanical action and the use of solvents, will be transesterified with ethanol using enzymes. The yield of the reaction is predicted using a surface response model as a function of the excess of ethanol, the load of catalysis and the operating temperature. The excess of ethanol is recovered in a distillation column and the polar and organic phases are separated recovering the glycerol and biodiesel which is finally purified by distillation. On the other hand, the biomass containing the starch and protein is liquefied, 85ºC, and saccharified, 65 ºC, to breakdown the structure into maltose and glucose. (Martín & Grossmann, 2013). Figure 1 shows the flowsheet for the use of algae for the production of DMF and biodiesel.

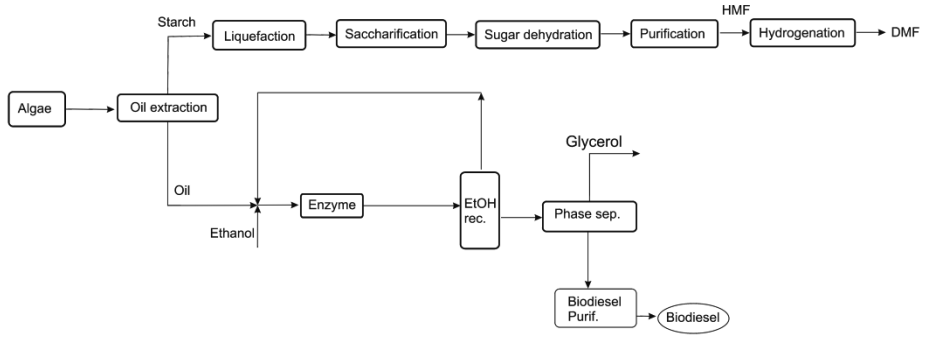

Figure 1.- Flowsheet for the production of DMF and biodiesel from algae

2.2. Sugars production from switchgrass

Two pretreatments are considered for breaking up of the biomass into cellulose, hemicelluloses and lignin, dilute acid and ammonia fiber explosion (AFEX). Once the physical structure of the switchgrass has been broken down, the cellulose and lignocellulose are next hydrolyzed at 50ºC obtaining pentoses and hexoses (Martín & Grossmann, 2012). Figure 2 shows the superstructure for the production of furfural and DMF from switchgrass.

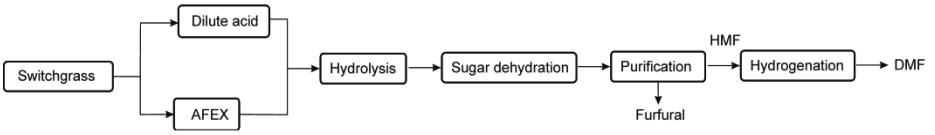

Figure 2.-Superstructure for the production of furfural and DMF from switchgrass

2.3. Sugar transformation into furfural and HMF

The stream containing sugar stream is mixed with butanol, HCl, $CrCl_3$ and NaCl together with recycled streams coming from different separation stages such as the

filter, where the solid catalyst ($CrCl_3$) is recovered, the first distillation column, where mainly water and butanol are recycled, and the distillate of the second distillation column consisting mainly of the same species. The $CrCl_3$ – HCl is the catalyst system and we use a two phase liquid reactor (organic, butanol, - aqueous) to extract the product from the mixture. The NaCl increases the recovery ratio of the products.

In the reactor, the sugars, glucose and xylose, are dehydrated, eqs. (1)-(2). In case of using algae only reaction (1) takes place. The operating temperature and pressure at the reactor are fixed to be 180ºC and 11 bar since it is a common temperature for both sugars to be dehydrated. With this operating conditions the conversion from glucose to HMF becomes 0.67 (Roman –Leshkov et al., 2007) and from xylose to furfural to 0.56 (Marcotulio et al., 2010).

Glucose dehydration: $C_6H_{12}O_6 \rightarrow C_6H_6O_3 + 3H_2O$ (1)

Xylose dehydration: $C_5H_{10}O_5 \rightarrow C_5H_4O_2 + 3H_2O$ (2)

Figure 3 shows the detailed flowsheet for the sugar dehydration process and the subsequent purification process. In case when there is only glucose in the feed, one column is not needed.

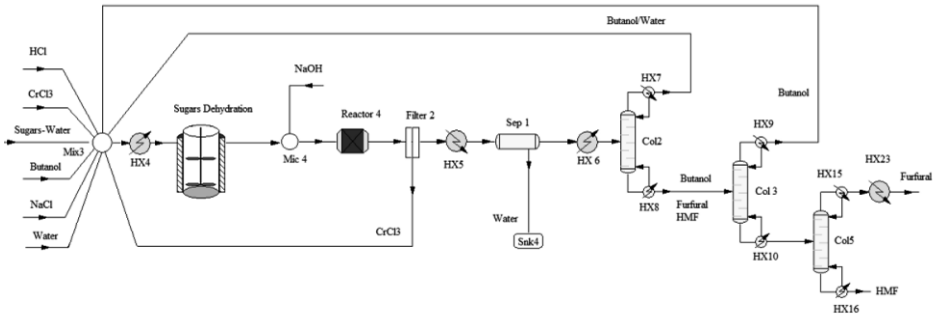

Figure 3.-Sugar dehydration and purification stages

2.4. Products purification.

The purification stage consists of neutralization, filtration, phase separation and a sequence of distillation columns.

The HCl is neutralized using NaOH so that the resulting salt is already in the system. Next, the solid catalyst, $CrCl_3$, is recovered in a filter. After the filter, a phase separation is performed. Based on experimental results from the literature, an operating temperature of 37 ºC is selected (de Álvila et al., 2012) The partition coefficient of the HMF and furfural is taken to be 3 in volume ratio towards the organic phase (Roman-Leshvok, 2009; Roman-Leskov et al., 2007). The polar phase contains butanol, water and NaCl and part of the sugars.

The organic phase coming from the phase separator is distilled. The column operates at low pressure, 0.5 atm, to avoid species decomposition. From the distillate we recover 99,9% of butanol and the water in the feed together with the rest of the sugars. From the bottoms we obtain HMF, furfural and the rest of butanol. A second column recovers

butanol as distillate, and HMF and furfural at the bottoms. Finally, the third column separates furfural to be sold from the HMF that is further used for the production of DMF. In case only hexoses are available, only two columns are needed.

2.5. DMF production from HMF

The production of DMF from HMF is carried out in a catalytic reactor at 120 ºC and 16 bar using CuRu as catalyst. HMF and butanol are fed so that the concentration of the first one is 5% of the liquid mixture. The reactor operates with an excess of hydrogen 12 times the one given by the stoichiometry. The conversion is reported to be 100% (Kazi et al. 2011). The excess of hydrogen is recovered using a flash, and the DMF, butanol and water are sent to a distillation column. The reaction taking place is given in eq. (3). Figure 4 shows the detailed flowsheet for this stage.

$$C_6H_6O_3 + 4H_2 \rightarrow C_6H_8O + 2H_2O \tag{3}$$

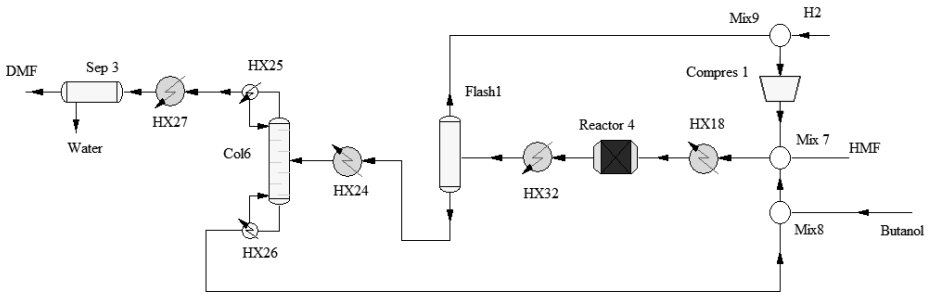

Figure 4.- Production of DMF from HMF

3. Solution procedure.

We formulate the problem for the use of *switchgrass* as raw material as an MINLP where the objective function is a simplified production cost involving the income due to the furfural and the DMF assumed to have a cost of $2/kg and the energy consumed in the process. Due to the fact that there is only one integer variable we decompose the problem into two NLP with 3000 equations and 3600 variables each to solve simultaneously optimize the operating conditions of the pretreatment and heat integrate the entire flowsheet using Duran & Grossmann's (1986) model. In the case of the use of *algae*, the problem is formulated as an NLP with 4100 equations and 5400 variables where the main decision variables are the algae composition, the operating pressures of the distillation columns and the operating conditions of the transesterification reactor. Again simultaneous optimization and heat integration is performed. We use multiple initialization points to solve the problems with CONOPT 3.0 as the preferred solver.

Next, we develop the optimal heat exchanger network using SYNHEAT (Yee & Grossmann 1990). Finally, the cost analysis is performed following Sinnot´s method (Sinnot 1999).

4. Results

4.1. Lignocellulosic based DMF and furfural

If we use lignocellulosic switchgrass as raw material we have as main products DMF and furfural and as byproduct lignin. We consider a price for the switchgrass of \$75/t. AFEX turns out to provide the better performance for a production cost of \$11.3/gal (\$3/kg) versus \$12.15/gal (\$3.20/kg) for the acid based pretreatment with an investment cost of \$570 MM (vs. 764MM). We obtain 23MMgal of products, 9 MMgal of furfural and 14 MMgal/yr of DMF, representing 15% by weight of the initial biomass for the best of the two processes. Due to the need of energy for the process, the lignin produced is fully used to provide part of it

4.2. Algae based DMF

In this case we have as variable the algae composition to produce as main products FAEE and DMF while as byproducts we can obtain glycerol and protein. The algae composition that yields the optimal production facility corresponds to 60% oil, 30% starch and 10% protein, as in previous studies. The reason is that the production of biodiesel is cheaper in terms of energy consumption and investment cost while the use of starch as raw material is much more expensive. The operating conditions at the transesterification reactor are given in Table 1. They match the ones of other integrated processes for the production of biodiesel and starch based products such as ethanol (Martín & Grossmann, 2013).

Table 1.- Operating conditions at the transesterification reactor

	Algae based FAEE + DMF
Temperature(ºC)	30
Pressure(bar)	4 (fixed)
Molar ratio (EtOH/oil)	4.2
Time (h)	8.0
Cat/lipase(%)	13.0
Water added	0.0

The total production capacity of biofuels is 98 MMGal /yr where 81MMGal/yr correspond biodiesel (FAEE) and 17 MMGal/yr of DMF. The investment cost for this facility is high, \$693 MM. In terms of production cost for the main products, namely FAEE and DMF, is \$1.98/gal, \$0.61/kg of biofuel.

5. Conclusions

When switchgrass is used, the preferred pretreatment is AFEX followed by hydrolysis so that the xylose and glucose are available for dehydration. If algae are used, we can not only produce DMF due to the starch within the algae, but also biodiesel that we assume is FAEE for which we need ethanol.

The resulting optimal processes reveal interesting production prices, around \$3/kg if switchgrass is used and \$1.7/gal in the case of producing biodiesel and DMF from algae. However, the energy consumption as well as the water consumption are higher

due to the purification and separation stages for the intermediates. It is technologically feasible to produce furfural and DMF out of algae and switchgrass but at a cost.

The energy consumption of the process is highly dependent on the composition of the mixture in the dehydration reactor. The experimental optimization of the dehydration process is suggested to reduced the amount of butanol so that the separation of the products from the separating agent is less expensive and /or the use of a different agent that has a lower vaporization heat. This can somehow be obtained if the concentration of sugars in the aqueous phase is increased. The concentration of the sugars in the fed can also be adjusted with evaporation previous to the dehydration as long as there is no such need for aqueous phase during the synthesis.

CO_2 as feedstock: a new pathway to syngas

Flavio Manenti[a]

[a]*Politecnico di Milano, CMIC Dept. "Giulio Natta", Piazza Leonardo da Vinci 32, 20133 Milano, Italy. Email: flavio.manenti@polimi.it*

Abstract

A novel pioneering route to synthesize syngas (CO/H_2) from hydrogen sulphide (H_2S) and carbon dioxide (CO_2) is broached. H_2S in acid gases and flue gases rich in CO_2 represent an environmental issue and an industrial cost as neither H_2S nor CO_2 is presently used as a major industrial feedstock or commodity. Acid gases mainly come from desulphurization from fossil fuels, and they cannot be simply released in the atmosphere, due to their toxicity. H_2S is then usually neutralized by conversion to elemental sulphur, with a minor industrial use. Flue gases are massively produced in power, petrochemical and manufacturing plants and CO_2, final combustion product, is generally vented to atmosphere. CO_2 capture and sequestration is still object of a relevant debate and environmental concern. By the new chemical route, potential value of H_2S and CO_2 will be brought out by means of a radically new conversion process: H_2S will be thermally activated in a high temperature reactor and will reduce the CO_2 to produce H_2 via a complex chemical mechanism. Preliminary reactor and process design, along with identification of relevant equipment and operating conditions, carried out using CAPE tools led to initial very promising results. A detailed kinetic scheme, extensively validated in a broad range of oxidation and combustion of sulphur components, further supports this oxy-reduction process, marginally observed also in the Claus process. Complete recycle of H_2S, relevant reduction of CO_2, and syngas production from these pollutants represent the valuable environmental, energy and commercial benefits of the new route, which could also involve a wider field of industrial applications.

Keywords: waste to energy; waste to hydrogen; hydrogen; syngas; CO_2 as feedstock.

1. Introduction

Hydrogen sulphide (H_2S) and carbon dioxide (CO_2) are two of the most critical chemical by-products generated by power, petrochemical and manufacturing plants. First of all, despite their massive production, they do not represent a major feedstock or commodity for subsequent industrial purposes. Then, they are considered pollutants and their venting to atmosphere, when admissible, leads to environmental issues; otherwise, expensive neutralization processes must be adopted. Hydrocarbons, coal and some natural gases contain significant amounts of H_2S and other sulphurous species. H_2S is a poison for industrial and automotive catalysts and a source of corrosion for process equipment. Moreover, if present in fossil-fuels, its combustion products (SO_x) are strong pollutants. Consequently, desulphurization of hydrocarbons and coal, but also biomasses, and sweetening of natural gas are mandatory operations. Due to chemical acid behaviour, gaseous effluents from desulphurization units are commonly called "acid gases"; H_2S content can reach up to 90% by volume. Since H_2S is malodorous and toxic, it can not be vented to atmosphere, but must be properly neutralized. Then, acid gases represent a dangerous and costly waste.

At H_2S concentrations above 40%, the most important and spread neutralization method is based on oxidation of H2S by air (Claus process): the acid gas is fed to a furnace along with a sub-stoichiometric amount of air and then oxidized to sulphur dioxide (SO_2) at high temperature: $H_2S + 1.5O_2 \rightarrow SO_2 + H_2O$. The SO_2 is next reduced by residual H_2S by means of catalytic reactors for obtaining elemental sulphur: $2H_2S + SO_2 \rightarrow 3S(\downarrow) + 2H_2O$. The elemental sulphur is partially used in process industry for producing sulphuric acid; nevertheless, since most portion of sulphur is stocked and commercial demand for sulphuric acid can be weak, the neutralization process represents a significant plant cost. CO_2 is the major responsible for impacts on ecological and environmental system, involving the greenhouse effect. It is produced in conventional combustion processes in all the fossil-fuel-based power plants and in all combustors installed for providing heat to petrochemical, chemical and manufacturing processes. The so-called "flue gas", at ambient pressure and with a CO_2 content normally up to 15% by vol., is generally vented to the atmosphere. On the other hand, capture of CO_2 from flue gas by chemical or physical washing processes leads to questionable issue of disposal. CO_2 is also produced in some petrochemical processes as by-product in the main stream, as in reforming units: catalytic conversion (steam reforming) of a mixture of hydrocarbons/steam to a mixture of hydrogen/carbon monoxide and subsequent water-gas-shift reaction lead to large co-production of CO_2. On the whole, it is estimated that, including non-industrial emissions, a lot of tons per year of CO_2 are released to atmosphere. Due to its thermodynamic stability and low chemical value, CO_2 has presently minor industrial uses; one of its most important consumptions in chemical plants is in urea synthesis. Viable applications of CO_2 are represented by catalytic "dry" CO_2 reforming and catalytic CO_2 hydrogenation. Nevertheless, these have not been successfully applied to industrial scale yet, because of considerable energy consumption and need for large amounts of hydrogen (CO_2 reforming leads to the ratio $H_2/CO = 1$). Direct production of methanol from CO_2 is also a potential route but catalysts and reactors are still in a research phase.

2. A new point of view

H_2S and CO_2 are strongly undesired industrial by-products, to be accounted as a huge cost in the budget of industrial plants. Nonetheless, despite his bad reputation, H_2S is quite an interesting chemical since it contains a highly noble species, the hydrogen. The trouble is how to pull-out H_2 from H_2S. H_2S is the hydrogen richest molecule after methane (CH_4 and hydrocarbons in general), methanol (CH_3OH), ammonia (NH_3), and water (H_2O). Consequently, H_2S should deserve more attention than to be considered just a waste product and then oxidized in Claus plants to obtain elemental sulphur and water. By this conventional approach, hydrogen in H_2S is finally fixed in water and then lost. Besides, as shown in above reforming synthesis reactions, CO_2 is a potential interesting molecule as well since it may work as oxidizing agent. All these considerations have pushed the research to invest for a captive use of H_2S and CO_2, to improve the accounting of these by-products. For recovering H_2, decomposition of H_2S can be an achievable method; proposals date back decades. A complete review of available techniques is presented by Cox et al. (1998). In the same work, thermal decomposition of pure H_2S flowing in a multi-tubular reactor, externally heated by hot flue gas, is specifically discussed; results appear interesting from technological standpoint, but the overall process is not commercially competitive with regard to traditional steam reforming. More recent studies (Villasmil and Steinfeld, 2010) investigated the possibility to obtain H_2 by

thermal pyrolysis of H_2S, driven by concentrated solar energy. Nevertheless, it is general understanding that H_2S decomposition processes are not economically attractive at the present and therefore they are considered an unsuccessful technological approach for bringing out value from waste acid gas. In this paper, proven and mature technology used in the Claus process has been realized to be potential source of innovation by means of CAPE tools. Taking advantage of extensive scientific works and operating experience on acid gas oxidation by air at high temperatures, H_2S and CO_2 have been observed under a different light, like a couple of oxidizing and reducing species; so, reduction of CO_2 by means of H_2S looks to be a promising and valuable new route. Although some aspects are still unresolved, thermodynamics, kinetics and process control of Claus process have been plentifully studied so far; as a consequence, H_2S and CO_2 conversion process starts from a conceptual and technological sound basis. The threefold advantage of recycling acid gas, reducing CO_2 and producing H_2 makes this new synthesis route not only of interest for process/environmental engineering, but also strategic for industrial plants economy.

3. CAPE tools

Contrarily to the conventional way to operate, the proposed process was not identified at the laboratory scale with the observation of main reactions and conversions, but its studies started from modelling and well-established CAPE tools. Conversion of H_2S and CO_2 to syngas is based on a complex reaction mechanism, involving more than 100 molecular and radical species and thousands of chemical reactions. The conversion mechanism consists of the following macro-steps: (1) decomposition of H_2S into radical species; (2) reduction of CO_2 into CO by free radicals; (3) increase of oxygen-based free radicals; (4) formation of sulphurous oxides and inhibition of reverse reaction from CO to CO_2 according to inhibition effect observed by Mueller et al. (2003); and (5) formation of stable SO_2 from SO. An existing package of modular kinetic models, developed and tested by the research group at Chemical Engineering Department of Politecnico di Milano, has been used to predict thermal process behaviour (Manenti et al., 2013). Such a package includes more than 800 chemical species and 30000 reactions, including sulphur and carbon compounds. Chemical reactions are grouped according to the species involved in the process and in hierarchical modules that progressively include families of reactions which makes such kinetic package as viable tool to be extended to new mechanisms and to estimate kinetic parameters of the reactive system by numerical solution of large-scale nonlinear regression. The kinetic package has been validated over several operating acid gas combustors (Manenti et al., 2013). The chemical kinetics has been then implemented in non-ideal reactor models and, next, in process simulations with commercial packages (AspenHysys™). Another CAPE tool adopted in this work for the industrial feasibility study of Section 5 is the GasDS Suite for the dynamic simulation of coal and/or biomass gasification units. Multi-phase, multi-component, and multi-scale phenomena are included in the GasDS model to properly characterize different kinds of gasifiers. More details and industrial examples are given in Ranzi et al. (2014).

4. New process description

The conversion process of H_2S and CO_2, that is oxidation of acid gases by carbon dioxide at high temperature, is a radically new, interesting route for recycling acid gases and CO_2, and therefore for bringing out the potential value of these by-products. Since the conversion takes place at high temperatures, above 1000 °C, the reactive system is of homogeneous and gas-phase type, with chemical thermodynamics and, specially, kinetics

typical of high temperature systems; for this reason, the conversion chamber can be named as "thermal reactor". An alternative approach is the use of a catalytic reactor instead of the thermal one, where the oxidation is not promoted by temperature but by catalytic active sites. At a glance, this may appear attractive and competitive, but a more accurate analysis driven by experience on Claus process, however, leads to consider the catalytic route much more challenging due to the intrinsic nature of reagents. In fact, acid gases are available at different operating conditions and concentrations, and typically they contain also several minor species that act as catalyst poisons and corrosion precursors. Moreover, presence of elemental sulphur in the combusted gas makes difficult the use of conventional catalysts. The thermal process is more robust and tolerant against acid gas inlet conditions and presence of minor species; furthermore, investigation by means of mathematical models of homogeneous gas-phase reactive systems is nowadays reliable. The kernel of the process is a Regenerative Thermal Reactor (RTR, Figure 1a). It consists of a regenerative section, where the inlet feed is preheated by the hot effluent, and a thermal section, where the conversion takes place at high temperature and the oxygen is provided to sustain the process (Fig. 1). The reliable simulation of the RTR can not be carried out using commercial packages since the most widespread process simulators do not include any complex kinetic scheme for high-temperature reaction systems. Some special tools (Manenti et al., 2013), also validated by the field on more than 20 industrial plants, have been used for this purpose. CO_2, H_2S and a small portion of oxygen are supplied to the RTR according to the Figure 1b. The residence time is in the order of 0.4 s at 1.2 bar at a temperature of 1300 °C. Syngas and elemental sulphur are the main products. It is worth saying that the H_2/CO ratio strongly varies with the residence time and the conversion of reactants is related to the RTR operating temperature. The overall reaction for the new process is: $CO_2 + 2H_2S \rightarrow CO + H_2 + S_2 + H_2O$. For instance, considering a high reaction temperature of 1500 °C, 1.5 bar, and 10 kmol/s of CO_2 and 30 kmol/s of H_2S with proper oxygen supply, the outflow molar flows are [kmol/s]: CO_2, 4.47; H_2S, 4.32, S_2, 11.25; H_2, 6.32; CO, 5.40; SO_2, 2.25; H_2O, 19.16; COS, 0.13.
The benefits coming from this new conversion process are different:

- Recycle of acid gases produced by desulphurization units, converting H_2S into a valuable chemical. This has the twofold advantage to neutralize H_2S and bring out a value of acid gases, besides to reduce plant costs and improve processes sustainability.

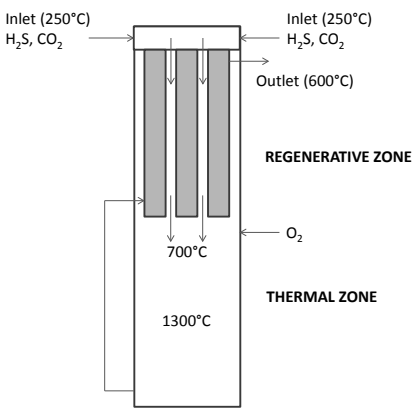

Figure 1a. RTR scheme.

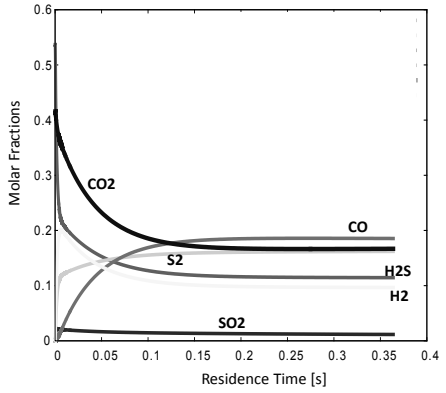

Figure 1b. CO_2/H_2S conversion in the RTR for non-optimal temperature and non-optimal feedstock conditions.

- Recycle of CO_2 as a reactant, and therefore reduction of emissions to atmosphere. CO_2 can be captured from flue gas or taken from separation units installed on main process stream of petrochemical plants.
- Synthesis of syngas or H_2.
- Improvement of Claus process. By means of the new synthesis, the hydrogen contained in H_2S is no longer fixed in water, but is delivered. On the other hand, the sulphur reacts with oxygen to form mainly SO_2. For that reason, the regenerative thermal reactor can be followed by the catalytic conversion from SO_2 to elemental sulphur typical of Claus process. In other words, the overall process can also be seen as a Claus process with a new thermal reactor installed upstream.
- Exploitation of new energy sources without environmental impact. Coal with relevant sulphur content (e.g., Sulcis-Italian coal with 9.5% of sulphur, Inner Mongolia-Chinese coal up to 18% of sulphur) becomes a novel energy/chemical source for low/zero-emission gasification processes.
- Beyond urea and methanol plants, this is a new opportunity to use CO_2 as feedstock.
- Full compliancy with EC Horizon2020 and Energy RoadMap 2030.

From an industrial standpoint, the attractive and promising character of the new process resides in the resemblance with the proven Claus process. This provides not only for a sound basis for process modelling and equipment sizing, but also and specially makes any technological and industrial consideration more concrete. The energy sustainability of the conversion process and mechanical feasibility of equipment are guaranteed by their similarity to H_2S oxidation by air and combustion chamber of Claus units, respectively.

5. Industrial feasibility study: intensification of coal gasification process

The new process is effective in reducing CO_2 emissions and to achieve zero-emissions in different areas, such as gas-to-liquid, methanol synthesis, coal gasification, hydrodesulphurization, to quote a few. Specifically, the selected industrial feasibility study is the coal gasification process using a Texaco's basic layout and a sulphur content of 9.5%. The process line-up simulated using the CAPE tools mentioned above fully integrated with AspenHysys environment is reported in Figure 2. Validation of the GasDS Suite is also given in Figure 3. Coal with sulphur content, steam for gasification and oxygen to sustain the gasification via partial combustion of the coal are fed to the downdraft gasifier of Figure 3a. Water obtained as by-product in the coal gasification is removed in dewatering process. Downstream a sweetening process (MDEA 1) is adopted with a special mixture of MEA/DEA and water to obtain the complete separation of H_2S and the optimal ration of CO_2 to be supplied to the RTR. The remaining portion of CO_2 is sent to the second sweetening process (MDEA 2) for sequestration. The optimal feedstock H_2S/CO_2 from the first sweetening process is then converted in the RTR in syngas. The outflow is sent to the catalytic conversion and the final stream obtained consists of elemental sulphur, water, syngas, and unreacted H_2S/CO_2. After the removal of water and sulphur, syngas and unreacted species could either enter a third sweetening process (MDEA 3) to have direct recycle to the RTR or go back to the MDEA 1 to recovery the additional syngas. It is worth remarking that the only by-product obtained by the process is the elemental sulphur, which is in any case a chemical product with market (30 to 130 $/t according to market price fluctuations of the last years). Considering the lower price of currently unexploited coal with high sulphur content, the additional syngas production, the reduction of CO_2 emissions and the relatively small investment to revamp existing plants, the additional net income for a medium-size gasification process is estimated in the order of 18M€/y.

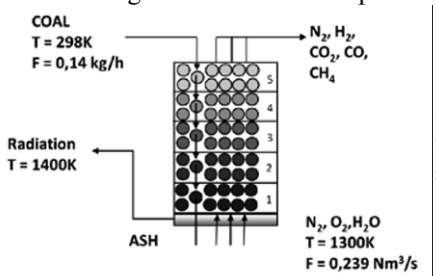

Figure 3a. Downdraft coal gasifier.

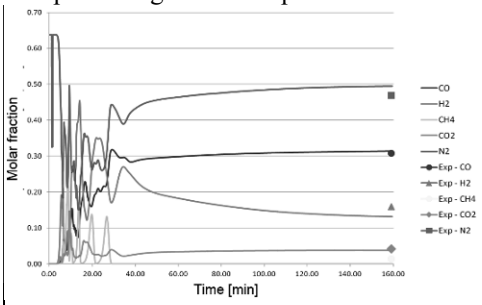

Figure 3b. Model validation (start-up).

6. Conclusions

A novel process to reduce CO_2 and use it as feedstock for chemical/fuel conversion is presented. The process has been studied and engineered using different CAPE tools and then validated by the field, demonstrating its effectiveness and environmental appeal. High conversion of CO_2 and total conversion of H_2S in the oxy-reduction reaction to syngas ensure positive economical impact. The industrial feasibility study on the coal gasification process showed a payback of 2 months for a medium-size plant.

Abstract

For an N-component mixture, a separation sequence with only sharp splits needs the minimum number of N-1 simple columns with 2(N-1) heat exchangers to achieve N pure products. As the number of columns and heat exchangers are the dominant criteria to evaluate a distillation configuration, traditional distillation configurations with only sharp splits have been the preferred alternatives. However, sharp split separations present intrinsic thermodynamic inefficiencies, and one way to reduce these inefficiencies is by means of non-sharp splits. This refers to the possibility of obtaining one product in more than one stream. Moreover, the increasing in both the number of columns and heat exchangers due to the non-sharp splits can be reduced by combining the individual columns and by introducing thermal couplings. In this work, the non-sharp distillation sequence for the separation of a four component mixture of hydrocarbons is considered. Using the aforementioned method, different alternative sequences were designed by the rigorous method with Aspen PlusV8.0, going from 4 to 3 and to 2 columns; then optimized by minimizing the total annual cost by means of a platform consisting in Aspen PlusV8.0 (rigorous simulation) and Visual Basic (stochastic optimizer Differential Evolution), to finally compare the sequences. Moreover, the synthesis methodology used allows deriving two types of intensified systems, the systems with less column sections or the systems with dividing wall columns.

Keywords: non-sharp multicomponent distillation, recombination of column sections, stochastic optimization, dividing wall columns.

1. Introduction

Distillation is one of the most used separation methods in the process engineering and at the same time is responsible of high energy consumptions. According to the U.S. Department of Energy, there are more than 40,000 distillation columns in North America only, and they consume about 40 % of the total energy used to operate refining and bulk chemical industries. Therefore, the research on process synthesis aimed to find new distillation systems with the potential to significantly reduce both energy consumption and capital investment. Defining a simple distillation column as a column with one reboiler and one condenser, this can perform a sharp or a non-sharp split of a mixture. Non-sharp splits refer to a partial or sloppy separation of one or more middle components that are allowed to distribute in the distillate and in the bottom stream. Only sharp-splits configuration allows the minimum number of columns and heat exchangers; thus they have been the preferred alternatives for a quite long time for both academic

research and industrial applications. One way to reduce the high energy consumption of sharp-split systems is to introduce non-sharp splits. However, if non-sharp splits are considered, the corresponding distillation configuration has more columns and heat exchangers than configurations with only sharp splits, leading to an increase in the capital and control costs.

With the introduction of the process intensification concept, several strategies have been proposed for improving the efficiency and environmental-friendly features of different processes. Inside the process separation field, one type of intensified distillation system for multicomponent separations is the dividing wall column (DWC), where the number of shells and the heat exchangers are reduced. The DWCs for ternary separations have been widely studied, and many applications have demonstrated that the energy consumption can be reduced by 30–50 % compared to the conventional columns.

In order to obtain the design for DWCs, the analysis and recombination of column sections, where a column section is defined as a portion of the column not interrupted by mass or energy streams, as well as the inclusion of thermal coupling has the main advantage of relating the design parameters between the original simple column sequences and DWCs. These principles were previously used for the synthesis, design, performance analysis and optimization for mainly ternary mixtures, including side stripper and rectifier configurations, as well as for fully thermally sequences (Fidkowski and Królikowski 1986, Hernández and Jiménez 1996), just to mention a few works. Rong et al. (2003) presented a method which can synthesize all possible distillation configurations with equal to N-1 or more than N-1 columns for an N-component mixture considering both sharp and non-sharp sequences. Moreover, a systematic method has demonstrated to be able to derive the possible distillation configurations with less than N-1 columns for the sharp sequences (Errico et al., 2009). Such distillation configurations with less than N-1 columns for an N-component separation are considered as intensified distillation systems which have the potential to reduce both energy and capital costs. The purpose and novelty of this work is focusing on the intensification of the non-sharp distillation configuration with more than N-1 columns. The objective here is twofold: first, the synthesis of the possible intensified schemes with N-1 or less than N-1 columns is presented, which include the side-stream columns and DWC columns. Second, the design and optimization for all the versions of the considered schemes are implemented for the evaluation of their potential savings in energy and capital costs.

2. Systems synthesis, design and optimization

2.1. Synthesis

In the present work the introduction of thermal couplings together with the possibility of column section recombination were used as a tool to generate the alternative configurations. The reference configuration is reported in Figure 1.a), which first obtained as the feasible distillation configurations with more than N-1 columns in the complete space for an N-component mixture by Rong et al. (2003). Considering only the possibility to introduce thermal couplings in the non-product streams in the first column, three corresponding thermally coupled sequences (TCS) can be generated.

The introduction of the thermal couplings makes some sections movable and recombinable. Then, the thermodynamically equivalent sequences (TES) are obtained. The presence of a single column section in the TES gives the opportunity to reduce the number of columns. If the single column section does not perform a separation task, i.e. is a transportation section, then it is possible to substitute it by a side stream generating

the simple intensified sequence (SIS). Otherwise is still possible to integrate the single section inside the column to which is connected; then dividing wall column (DWC) can be generated. Figure 1 depicts a representative example of the whole synthesis procedure. The evaluation of the separation task of the single column sections were performed through the analysis of the composition profiles.

2.2. Case Study

A 100 kmol h^{-1} of a four component hydrocarbon mixture was considered as a case study to show how the current methodology is implemented for different structures; the authors believe this approach can be extended to other zeotropic mixtures. The composition and the properties of the mixture are presented in Table 1.

All the configurations contained the following features:

- all the components are obtained at the molar purity of 99 %
- only the first column of the sequence performs a non-sharp split
- only the n-hexane is obtained pure in two different product streams
- the split ratios of the intermediate components were fixed at 55 % for n-hexane, and 7.5 % for n-octane; values based on energy consumption via sensitivity analysis.

Table 1. Composition and physical properties of the mixture

Component	x_F
A: C_4H_{10}	0.1
B: C_6H_{14}	0.4
C: C_8H_{18}	0.4
D: $C_{10}H_{22}$	0.1
P (bar)	2
q (feed condition)	1

2.3. Simulation

All the sequences derived from the reference case have been simulated by means of Aspen Plus V8.0. The thermodynamic method selected was the generalized correlation method BK10 that applies for nearly ideal mixtures. The value of the operating pressure for all the columns was defined independently in order to allow the use of cooling water in the condensers. The shortcut design method, based on the Underwood-Gilliland-Winn equations, was used to get the initial parameters, and then these parameters were used in the rigorous RadFrac model. Total condensers, partial reboilers and sieve trays were considered.

A two-step procedure was defined for evaluating the sequences. In the former, all the alternatives were simulated taking the reference case as a basis for the parameters design, and then the reference sequence and the most promising alternative were optimized. However, before the optimization procedure a sensitivity analyses was carried out using Aspen Plus in order to identify the promising alternative via an energy consumption comparison.

2.4. Optimization

The formulation of these problems belongs to a mixed integer non-linear programming problem (MINLP). Among the solver's alternatives, differential evolution (DE) has shown good performances in different theoretical and practical problems. Like others population-based evolutionary algorithms, DE samples the search space, generates new points, evaluate the fitness values and select the best individuals for next generations. The distinctive characteristic of DE is the way the new individuals are generated by means of the scaled difference of random vectors for obtaining a trial vector that will compete against the other individuals of the population.

The DE parameters and stop criterion, as well as the link between Aspen Plus (rigorous process simulations) and Excel (DE coded in Visual Basic) are described in detail in several previous works (Torres-Ortega et al. 2013). The objective function for the final design was to minimize the total annual cost (TAC). The TAC was evaluated following the Guthrie's method (Turton et al. 2004) considering 10 years of investment according to the Eq. (1).

$$TAC = \sum \left[\left(\frac{Capital\ Cost}{Time\ of\ Investment} \right)_i + (Cost\ of\ Utilities)_i \right] \quad (1)$$

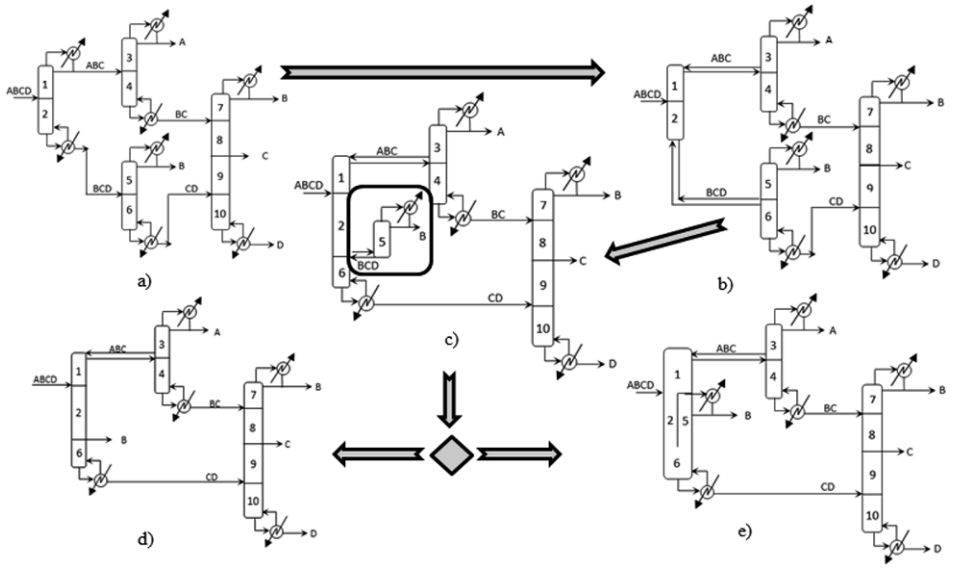

Figure 1.Representative case for the whole synthesis procedure. a) Reference case, and representative derived schemes for: b) TCS, c) TES, d) SIS and e) DWC. In the case depicted, the difference between d) and e) relies in section 5 inside the rectangle of c).

3. Results and discussion

3.1. Simulation analysis

Regarding the energy consumption, the most attractive sequence was the one corresponding to the substitution of both condenser and reboiler of the first column with thermal couplings. Then TES were evaluated and again those obtained from the best TCS presented the lowest energy consumption.

3.2. Simple Intensified Sequences (SIS)

For all the analyzed cases, the single column sections showed a clearly separation function that precludes the possibility to remove these sections and reach the design specifications required. This separation task was more noticeable for single column sections directly related to a product stream than an intermediate section.

3.3. Dividing wall column (DWC)

The derived dividing wall columns from Figure 1a are presented in Figure 2. The energy consumption of these sequences was consistent but slightly lower with their respective TES. However only 4 of the 5 DWC systems, Figure 2.b) to e) presented

lower energy consumption than the reference case and unlike the TES, the DWC arrangements also reduced the number of columns. Again, those derived from the TCS with two thermal couplings reported the major savings.

For intensification purposes, only the systems with energy savings and reduction in the number of equipment were considered for consecutive analyses. Table 2 depicts a more detailed economic analysis comparing the reference case with promising DWCs from Figure 2 b) to e). For the DWC's TAC calculation, the height of the shell was approximated taking into account the total number of stages for the main column and the higher sectional diameter as the overall diameter for the column. The sections just next to the partition wall were considered as complex internal elements, and then an extra factor in the capital cost for these trays was included.

All the promising DWC presented a lower TAC than the reference case. However, the barely improvement in DWC_e can be explained considering the more expensive utility costs associated to a higher pressure in the DWC reboiler. The configuration DWC_d showed the lower energy consumption and TAC; thus it was selected to be optimized together with the reference case.

3.4. Optimization of the reference case and most promising DWC

The modified process variables were related to the number of stages, location of feeds and internal flow division due to the partition wall (in the case of DWC). The own parameters of the DE selected were Cr = 0.8, F = 0.9 for both cases, and Np = 80 and 8,000 simulations for the reference case, and Np = 100 and 9,000 simulations for the DWC. The term Cr stands for the crossover factor, F = mutation factor and Np the population number. Last three rows in Table 2 summarize the main results for the optimal sequences, as well as the percentage of reduction with respect the reference case. According to the data from Table 2, the difference in the energy consumption, the size of the equipment and the TAC were not significantly improved by the optimization from the starting values. However, the alternative DWC configuration moderately outperformed the reference case.

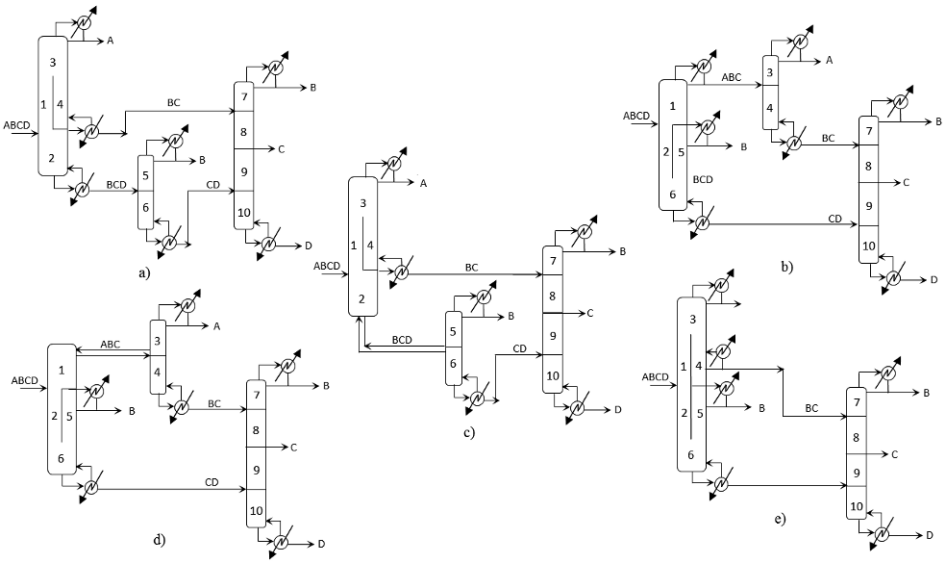

Figure 2. The DWC configurations obtained for the reference case Figure 1a).

Table 2. Economic analysis via sensitivity analysis of the most promising DWC and the reference case, as well as the optimal configuration results. The number in parentheses before the name stands for the number of column shells in every separation train.

Sequence	Total energy consumption [kW]	Capital costs [USD Year^{-1}]	Utility costs [USD Year^{-1}]	TAC [USD Year^{-1}]
(4) RefSC	3023	123742	788638	912381
(3) DWC_b	2804	118012	757772	875783
(3) DWC_c	2679	109302	716633	825935
(3) DWC_d	2567	106138	693910	800048
(2) DWC_e	2737	122582	788890	911472
Optimal (4) RefSC	2950	125382	769985	895367
Optimal (3) DWC_d	2459	115017	673115	788132
% of Reduction	16.6	8.3	12.6	12.0

4. Conclusions

This work has successfully showed that the traditional non-sharp distillation configuration with more than N-1 columns can be intensified into distillation configurations with less than N-1 columns for an N-component mixture. Among the different sub-spaces of the alternatives, DWC showed the highest reductions in both energy consumption and capital costs. Regarding the TAC, the most promising DWC sequence achieved 12 % reduction compared to the reference case. The systematic methodology based on recombination of column sections, sensitivity analysis and stochastic optimization provides a robust and reliable methodology towards looking for the optimal intensified distillation systems.

Deterministic Global Optimization of Multistage Melt Crystallization Processes in Hydroformylation

Christian Kunde[a] and Achim Kienle[a,b]

[a]*Otto von Guericke University Magdeburg, Magdeburg, Germany*
[b]*Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany*
christian.kunde@ovgu.de

Abstract

This paper deals with the deterministic global optimization of multistage melt crystallization processes with application to mixtures of n-/iso-aldehydes resulting from hydroformylation. For this purpose we adopt a process model including experimentally determined parameters from the literature. We extend that model from commonly used countercurrent cascades to arbitrary process configurations and reformulate it for better computational performance. The resulting model is a MINLP due to operational and structural degrees of freedom. Global optima for the process costs with respect to an economical cost function are determined using BARON/GAMS. The results show that there are new process configurations outperforming the conventional countercurrent cascade, depending on parameter values.

Keywords: deterministic global optimization, MINLP, melt crystallization, multistage

1. Introduction

Separation of closely boiling mixtures is a challenging problem in process synthesis and process design. A typical example given by Micovic et al. (2013) is the separation of mixtures of isomers like n/iso-aldehyde mixtures arising from hydroformylation based on renewable resources. Standard distillation is often not favorable due to high process costs. A more efficient separation process for such closely boiling mixtures may be obtained by using melt crystallization either in combination with distillation or as a stand-alone process, as studied by Micovic et al. (2013). To achieve the desired crystal purity, often a multistage melt crystallization process is required. Standard approaches focus on countercurrent crystallizer cascades. However, due to restricted process topology this process configuration tends to be suboptimal. Hence, in the present contribution restrictions on process topology are relaxed also allowing new process configurations which have not been studied so far by other researchers to the best of our knowledge. Optimal operating conditions and optimal process structures are determined simultaneously using mixed integer nonlinear (MINLP) optimization. Due to nonconvexity, standard MINLP solution procedures based on local or stochastic optimization algorithms can not guarantee to find the global optimum, which however is essential for identifying also new and probably counterintuitive solutions. Therefore deterministic global optimization using BARON/GAMS is applied, see Tawarmalani and Sahinidis (2005). A suitable model of a multistage melt crystallization process for the separation of an isomeric mixture of n-dodecanal and 2-methylundecanal by Micovic et al. (2013) is used. The model is adapted to allow arbitrary process topologies and the resulting model complexity is reduced by reformulating the model equations and excluding redundant crystallizer network configurations. The influence of important model parameters on the performance of new process structures is discussed and the results are compared to the standard countercurrent cascade process.

2. Model description

The crystallization model describes the behavior of a binary, eutectic system corresponding to the intended application of separating binary mixtures of the isomers 2-methylundecanal and n-dodecanal. We assume that crystal product impurities can be described by a constant differential distribution coefficient as in Wellinghoff and Wintermantel (1991) and Micovic et al. (2013). The experimental data for mixtures of 2-methylundecanal and n-dodecanal is published in Beierling and Ruether (2012), Micovic et al. (2013) and Beierling et al. (2014). The position of the eutectic point is close to pure 2-methylundecanal, practically only allowing crystallization of n-dodecanal with impurities of 2-methylundecanal.

We consider a crystallizer network with stages $n = 1,\dots,n^{\mathrm{Cr}}$ numbered downwards. Each stage n separates the molar feed flow F_n into the crystal product S_n and the liquid remainder L_n with the molar flows of the impurity denoted as $F_{\mathrm{iso},n}$, $S_{\mathrm{iso},n}$ and $L_{\mathrm{iso},n}$, respectively. The feed of each stage F_n is the sum of all crystal product flows S and liquid remainder flows L connected to that stage and, if applicable for that stage, the crystallizer feed flow $F^{\mathrm{In_{Cr}}}$. The distribution of the crystallizer feed flow and the connections between stages are implemented using binary variables $\beta_n^{\mathrm{In_{Cr}}} \in \{0,1\}$, $\beta_{l,n}^{\mathrm{S}} \in \{0,1\}$ and $\beta_{l,n}^{\mathrm{S}} \in \{0,1\}$, $n = 1,\dots,n^{\mathrm{Cr}}$, $l = 1,\dots,n^{\mathrm{Cr}}$. The variables $\beta_n^{\mathrm{In_{Cr}}}$, $\beta_{l,n}^{\mathrm{S}}$ and $\beta_{l,n}^{\mathrm{L}}$ attain a value of one if and only if the feed enters at stage n, the crystal product output of stage l is fed to stage n and the liquid remainder output of stage l is fed to stage n, respectively.

$n = 1,\dots,n^{\mathrm{Cr}}$:

$$F_n = F^{\mathrm{In_{Cr}}}\beta_n^{\mathrm{In_{Cr}}} + \sum_{l=1}^{n^{\mathrm{Cr}}} S_l\beta_{l,n}^{\mathrm{S}} + \sum_{l=1}^{n^{\mathrm{Cr}}} L_l\beta_{l,n}^{\mathrm{L}}, \tag{1}$$

$$F_{\mathrm{iso},n} = F_{\mathrm{iso}}^{\mathrm{In_{Cr}}}\beta_n^{\mathrm{In_{Cr}}} + \sum_{l=1}^{n^{\mathrm{Cr}}} S_{\mathrm{iso},l}\beta_{l,n}^{\mathrm{S}} + \sum_{l=1}^{n^{\mathrm{Cr}}} L_{\mathrm{iso},l}\beta_{l,n}^{\mathrm{L}}, \tag{2}$$

We ensure that the feed enters exactly one stage by

$$\sum_{n=1}^{n^{\mathrm{Cr}}} \beta_n^{\mathrm{In_{Cr}}} = 1. \tag{3}$$

We make sure that the output flow of each stage is connected to exactly one stage input or one crystallizer product output by

$$\sum_{n=1}^{n^{\mathrm{Cr}}} \beta_{l,n}^{\mathrm{S}} + \beta_l^{\mathrm{S,Out1_{Cr}}} = 1, \quad l = 1,\dots,n^{\mathrm{Cr}} \tag{4}$$

$$\sum_{n=1}^{n^{\mathrm{Cr}}} \beta_{l,n}^{\mathrm{L}} + \beta_l^{\mathrm{L,Out2_{Cr}}} = 1, \quad l = 1,\dots,n^{\mathrm{Cr}}, \tag{5}$$

with $\beta_l^{\mathrm{S,Out1_{Cr}}} \in \{0,1\}$ attaining value 1 if and only if the crystal product output of stage l is connected to output $\mathrm{Out1_{Cr}}$ and with $\beta_l^{\mathrm{L,Out2_{Cr}}} \in \{0,1\}$ attaining value 1 if and only if the liquid remainder output of stage l is connected to output $\mathrm{Out2_{Cr}}$.

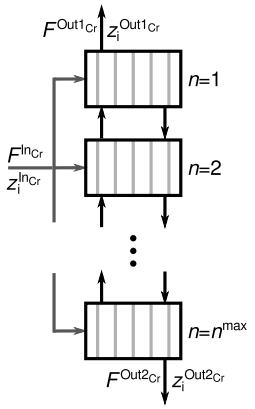

Figure 1: Countercurrent crystallizer cascade with n^{Cr} stages and arbitrary feed stage ($\beta_{l,l-1}^{\mathrm{S}} = 1$, $l = 2,\dots,n^{\mathrm{Cr}}$, $\beta_{l,l+1}^{\mathrm{L}} = 1$, $l = 1,\dots,n^{\mathrm{Cr}}-1$, $\beta_1^{\mathrm{S,Out1_{Cr}}} = 1$, $\beta_{n^{\mathrm{Cr}}}^{\mathrm{L,Out2_{Cr}}} = 1$).

We also require that each stage has at least one input.

$$\sum_{l=1}^{n^{\mathrm{Cr}}} \left(\beta_{l,n}^{\mathrm{S}} + \beta_{l,n}^{\mathrm{L}}\right) + \beta_n^{\mathrm{In_{Cr}}} \geq 1, \quad n = 1,\dots,n^{\mathrm{Cr}} \tag{6}$$

The countercurrent cascade depicted in Figure 1 will serve as the benchmark for any other configuration within this superstructure.

The model equations describing the separation on each stage according to Wellinghoff and Wintermantel (1991) read

$$\begin{aligned} &n = 1,\ldots,n^{\mathrm{Cr}}: \\ &\begin{aligned} S_n &= Y_n F_n, & w_{\mathrm{iso},n} &= k_{\mathrm{int},n} z_{\mathrm{iso},n}, \\ L_n &= F_n - S_n, & x_{\mathrm{iso},n} L_n &= z_{\mathrm{iso},n} F_n - w_{\mathrm{iso},n} S_n, \\ k_{\mathrm{int},n} &= \tfrac{1-(1-Y_n)^{k_{\mathrm{diff}}}}{Y_n}, \end{aligned} \end{aligned} \tag{7}$$

with the yield $Y_n \in [0,1]$, the integral distribution coefficient $k_{\mathrm{int},n} \in [0,1]$ and the molar fractions of the impurity in the feed $z_{\mathrm{iso},n}$, in the crystal product $w_{\mathrm{iso},n}$ and in the liquid remainder $x_{\mathrm{iso},n}$. Note that the distribution coefficient was defined using weight fractions in Wellinghoff and Wintermantel (1991). Weight fractions are equivalent to molar fractions if all chemical species have the same molar mass, as is the case for mixtures of isomers.
With regard to global optimization, it is often desireable to reduce the number of variables and nonlinearities in the model or at least to simplify the nonlinearities. This is done for the crystallization model by reformulating the model using the molar flows of the impurity instead of molar fractions.

$$S_{\mathrm{iso},n} = w_{\mathrm{iso},n} S_n, \qquad L_{\mathrm{iso},n} = x_{\mathrm{iso},n} L_n \qquad F_{\mathrm{iso},n} = z_{\mathrm{iso},n} F_n \tag{8}$$

The resulting equation for $S_{\mathrm{iso},n}$ then reads

$$S_{\mathrm{iso},n} = k_{\mathrm{int},n} Y_n F_{\mathrm{iso},n}. \tag{9}$$

We further introduce new variables $\tilde{k}_{\mathrm{Y},n} \in [0,1]$ and $\tilde{Y}_n \in [0,1]$ as

$$\tilde{k}_{\mathrm{Y},n} = 1 - k_{\mathrm{int},n} Y_n \tag{10}$$

$$\tilde{Y}_n = 1 - Y_n \tag{11}$$

to write the set of equations for the crystallizer that was used for the computational studies in this work.

$$\begin{aligned} &n = 1,\ldots,n^{\mathrm{Cr}}: \\ &\begin{aligned} L_{\mathrm{iso},n} &= \tilde{k}_{\mathrm{Y},n} F_{\mathrm{iso},n}, & S_{\mathrm{iso},n} &= F_{\mathrm{iso},n} - L_{\mathrm{iso},n} \\ L_n &= \tilde{Y} F_n, & S_n &= F_n - L_n \\ \tilde{k}_{\mathrm{Y},n} &= \tilde{Y}_n^{k_{\mathrm{diff}}}. \end{aligned} \end{aligned} \tag{12}$$

Molar fractions are used for the inlet composition $z_{\mathrm{iso}}^{\mathrm{In_{Cr}}}$ and the product specifications $z_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}}, z_{\mathrm{iso}}^{\mathrm{Out2_{Cr}}}$. An interface is implemented by the following equations.

$$F_{\mathrm{iso}}^{\mathrm{In_{Cr}}} = z_{\mathrm{iso}}^{\mathrm{In_{Cr}}} F^{\mathrm{In_{Cr}}} \tag{13}$$

$$F_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}} = z_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}} F^{\mathrm{Out1_{Cr}}} \tag{14}$$

$$F_{\mathrm{iso}}^{\mathrm{Out2_{Cr}}} = z_{\mathrm{iso}}^{\mathrm{Out2_{Cr}}} F^{\mathrm{Out2_{Cr}}} \tag{15}$$

$$F^{\mathrm{Out1_{Cr}}} = \sum_{n=1}^{n^{\mathrm{Cr}}} \beta_n^{\mathrm{S,Out1_{Cr}}} S_n, \quad F_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}} = \sum_{n=1}^{n^{\mathrm{Cr}}} \beta_n^{\mathrm{S,Out1_{Cr}}} S_{\mathrm{iso},n} \tag{16}$$

$$F^{\mathrm{Out2_{Cr}}} = \sum_{n=1}^{n^{\mathrm{Cr}}} \beta_n^{\mathrm{L,Out2_{Cr}}} L_n, \quad F_{\mathrm{iso}}^{\mathrm{Out2_{Cr}}} = \sum_{n=1}^{n^{\mathrm{Cr}}} \beta_n^{\mathrm{L,Out2_{Cr}}} L_{\mathrm{iso},n} \tag{17}$$

Inequalities are added to the model to implement the physical constraint of the eutectic composition x^{eut} and the technical constraint of a minimum cooling temperature. The solid-liquid phase

equilibrium for mixtures of 2-methylundecanal and n-dodecanal given in Micovic et al. (2013) was used to calculate a minimum molar fraction of n-dodecanal $x_{\mathrm{N}}^{\mathrm{min_T}}$ from the minimum cooling temperature. Only one of the following inequalities is active in the model, depending on the parameters.

$$(1-x_{\mathrm{N}}^{\mathrm{eut}})L_n \geq L_{\mathrm{iso},n}, \quad n=1,\ldots,n^{\mathrm{Cr}} \tag{18}$$

$$(1-x_{\mathrm{N}}^{\mathrm{min_T}})L_n \geq L_{\mathrm{iso},n}, \quad n=1,\ldots,n^{\mathrm{Cr}} \tag{19}$$

Without loss of generality we assume that the stages are ordered in terms of purity of the stage feed.

$$F_{\mathrm{iso},n}F_{n+1} \leq F_{\mathrm{iso},n+1}F_n, \quad n=1,\ldots,n^{\mathrm{Cr}}-1 \tag{20}$$

Based on the ordered purity the search space is further reduced by demanding that the crystal output of each stage is not fed to a stage below that stage and that the liquid remainder of each stage is not fed to a stage above that stage. Connecting an output of a stage to the feed of that same stage leads to redundant configurations and is therefore also excluded.

$$\beta_{l,n}^{\mathrm{S}} = 0 \quad \text{for all} \quad 1 \leq l \leq n, \quad n=1,\ldots,n^{\mathrm{Cr}} \tag{21}$$

$$\beta_{l,n}^{\mathrm{L}} = 0 \quad \text{for all} \quad n \leq l \leq n^{\mathrm{Cr}}, \quad n=1,\ldots,n^{\mathrm{Cr}} \tag{22}$$

All potential connections within the crystallizer network used in this work for a fixed number of stages $n^{\mathrm{Cr}}=3$ are illustrated in Figure 2.

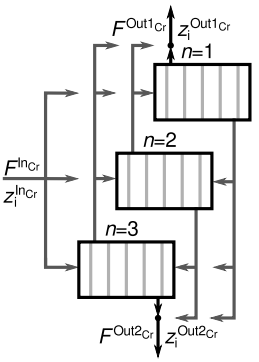

Figure 2: Crystallizer network consisting of $n^{\mathrm{Cr}}=3$ stages with arbitrary configuration.

The process costs are determined according to correlations from Towler and Sinnot (2008). The cost function accounts for annualized installed investment costs of the crystallizer vessel as a heat exchanger, a storage tank for each crystallization stage with the same capacity as the crystallizer and for the energy costs of the process. The dimensioning of the crystallizer is done as in Franke et al. (2008) and the required cooling is calculated according to Wellinghoff and Wintermantel (1991); Franke et al. (2008). Physical parameter values were taken from Beierling and Ruether (2012); Beierling et al. (2014). The resulting cost function can be written in a condensed form as

$$\begin{aligned} cost = (\quad & 86849 \sum_{n=1}^{n^{\mathrm{Cr}}} S_n \text{ s mol}^{-1} + 5215 \\ & + n^{\mathrm{Cr}}(1605.7(\sum_{n=1}^{n^{\mathrm{Cr}}} S_n \text{ s mol}^{-1})^{0.7} + 2123.2) \quad) \text{ \$ a}^{-1}. \end{aligned} \tag{23}$$

3. Results

The results were obtained by applying BARON 11.5.2 (GAMS 23.9.5) to the model described above, minimizing the process costs. CONOPT and CPLEX were facilitated as subsolvers for BARON. The solver options were left at default values except for the termination condition "optcr", the relative difference between upper and lower bound, which was set to 0.000001. In the case of multiple global optima with identical values of the cost function, it should be noted that only one global optimum is found using these options.
The parameters given in Table 1 are chosen to fit the case of constant k_{diff} studied in Beierling et al.

(2014). The value of $x^{\min_T}$ is set according to a minimum cooling temperature above the eutectic temperature. The product specification for $\mathrm{Out2_{Cr}}$ is chosen corresponding to a cooling temperature above the minimum cooling temperature. All molar flow rates are bounded from above by the feed flow rate $F^{\mathrm{In_{Cr}}}$ multiplied by 20.

Table 1: Parameter and domain specifications.

parameter / variable	k_{diff}	$z_{\mathrm{iso}}^{\mathrm{In_{Cr}}}$	$F^{\mathrm{In_{Cr}}}$	$x_{\mathrm{N}}^{\min_T}$	$z_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}}$	$z_{\mathrm{iso}}^{\mathrm{Out2_{Cr}}}$
value / domain	0.08	0.1	1.8838 mol $\mathrm{s^{-1}}$	0.1	$[0, 0.01]$	$[0.89, 1]$

The results for different numbers of stages n^{Cr} are given in Table 2. The countercurrent cascade (see Figure 1) serves as a reference for the evaluation of the optimization results with arbitrary process configurations. The optimal costs for the countercurrent cascade are achieved for $n^{\mathrm{Cr}} = 2$. For configurations with $n^{\mathrm{Cr}} \geq 3$ only the first two stages have a non-zero crystal yield for optimal costs. The optimal costs for arbitrary configurations are achieved at $n^{\mathrm{Cr}} = 3$. Although an additional stage is used the overall costs are reduced by over 2 % compared to the optimal countercurrent cascade. The optimal crystallizer network configurations are depicted in Figure 3.

Table 2: Globally optimal cost values for the countercurrent crystallizer cascade and abitrary crystallizer networks.

number of stages	1	2	3	4	5
countercurrent	infeasible	225468 \$ $\mathrm{a^{-1}}$	230559 \$ $\mathrm{a^{-1}}$	235674 \$ $\mathrm{a^{-1}}$	240776 \$ $\mathrm{a^{-1}}$
arbitrary	infeasible	225468 \$ $\mathrm{a^{-1}}$	220665 \$ $\mathrm{a^{-1}}$	225567 \$ $\mathrm{a^{-1}}$	230101 \$ $\mathrm{a^{-1}}$

The optimal configuration for an arbitrary crystallizer network enables lower overall costs due to a lower crystallization effort $\sum_{n=1}^{n^{\mathrm{Cr}}} S_n$, see Equation (23). This may be explained as follows. The crystallization mechanism used in this work leads to an asymmetric separation, i. e. the purity of the crystal product increases much more compared to the feed than that of the liquid remainder. Using a countercurrent cascade therefore is inefficient due to the mixing of crystal product and liquid remainder with highly different compositions. In arbitrary crystallizer networks there are more degrees of freedom for placing connections to avoid mixing flows with highly different compositions. Consequently, the potential cost reduction depends on the parameters of the model. As an example, lower values of k_{diff} emphasize the asymmetric separation and thereby increase the potential cost savings. Also, the cost reduction seems to be more pronounced if the optimal length of the countercurrent cascade is close to being infeasible. In such a case the yield on each stage is adjusted to fulfill the product specifications and can be used less freely to reduce mixing inefficiencies. Table 3 shows optimization results for $z_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}} \in [0, 0.007]$ with a cost reduction of over 10% compared to the

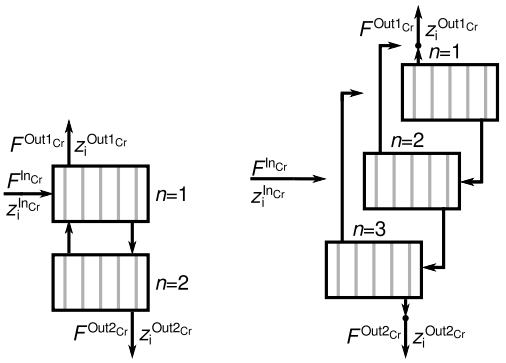

Figure 3: Left: Optimal configuration for a countercurrent cascade ($\beta_{2,1}^{\mathrm{S}} = \beta_{1,2}^{\mathrm{L}} = \beta_1^{\mathrm{In_{Cr}}} = 1$). Right: Optimal configuration for an arbitrary crystallizer network ($\beta_{3,1}^{\mathrm{S}} = \beta_2^{\mathrm{S,Out1_{Cr}}} = \beta_{1,2}^{\mathrm{L}} = \beta_{2,3}^{\mathrm{L}} = \beta_2^{\mathrm{In_{Cr}}} = 1$).

countercurrent crystallizer cascade.

Table 3: Globally optimal cost values for the countercurrent crystallizer cascade and abitrary crystallizer networks with $z_{\mathrm{iso}}^{\mathrm{Out1_{Cr}}} \in [0, 0.007]$.

number of stages	1	2	3	4	5
countercurrent	infeasible	295042 \$ a^{-1}	300804 \$ a^{-1}	306521 \$ a^{-1}	312288 \$ a^{-1}
arbitrary	infeasible	295040 \$ a^{-1}	260752 \$ a^{-1}	265619 \$ a^{-1}	269694 \$ a^{-1}

For the sake of completeness we also report the observed computational time needed to solve the problem cases studied in this work. On a standard desktop computer (Intel® Core™ i7-3770 @ 3.40 GHz) the computational time for the countercurrent cascade is in the range of seconds for $n^{\mathrm{Cr}} \leq 5$. Solutions for arbitrary crystallizer networks require a computational time in the order of seconds for $n^{\mathrm{Cr}} \leq 3$, minutes for $n^{\mathrm{Cr}} = 4$ and hours for $n^{\mathrm{Cr}} = 5$. This increase is caused largely by the combinatorial complexity of the problem.

4. Conclusion

We have presented a suitable model formulation for the deterministic global optimization of melt crystallization processes and applied it to the separation of a mixture of n-/iso-aldehydes, arising from hydroformylation. The results show that the costs of such a process may be reduced considerably by using crystallizer network configurations different from the well-established countercurrent cascade. It is postulated that the mixing of flows with highly different compositions causes inefficiencies in the countercurrent cascade, which can be reduced by using more suitable configurations.

Abstract

Biodiesel production by homogeneous alkali catalysis was simulated in PRO/II ® from crude soybean oil and crude palm oil at industrial level, with ethanol. Actual compositions were assumed and thermodynamic properties were estimated by a group contribution method. The main effluents from biodiesel production are streams rich in unreacted oil, water, ethanol and glycerine. Some alternatives to the treatment of these effluents were proposed, including hydrous or anhydrous ethanol production, production and recycle of pure glycerol and unreacted oil recycle. An economic evaluation was done to find out the potential of each treatment possibility. It was demonstrated that, in the case of Brazil in mid-2014, it was not profitable to produce biodiesel from these oilseeds and ethanol without tax reductions or subsidy, but it is possible to reduce production costs and biodiesel prices with effluents treatment, generating more economical and sustainable plants.

Keywords: biodiesel, effluents treatment, soybean, palm.

1. Introduction

In the last few years, the improvement of environmental concerns, allied with the progressive decrease of the worldwide petroleum production, have motivated the study and development of sustainable energy sources and technologies. In this context, the biofuels arise, among them the biodiesel. Biodiesel is a renewable fuel, normally produced from vegetable oils or animal fats, through transesterification of these components with an alcohol, usually methanol or ethanol. It is biodegradable, nontoxic and its burning emits fewer pollutants than traditional petroleum diesel burning (Zhang et al., 2003a).

Regarding the raw material, vegetable oils and animal fats consist mainly in triglycerides (glycerol and fatty acids esters). They can be obtained from a wide variety of sources. In Brazil, special attention is given to soybean, which corresponded to 78 % of the total raw material used in May 2014 (ANP, 2014). Planting of palm, which is the second most used feedstock to biodiesel production in the world, has tripled in Brazil in the last four years (Neher, 2014). Compared to soybean oil, palm oil has a higher content of free fat acids (FFA), which must be removed before transesterification for biodiesel production (Zhang et al. 2003a).

2. Process Design and Simulation

The simulations were performed in PRO/II ®, developed by Invensys Systems, Inc. Due to the presence of highly polar components, like ethanol and glycerol, the NRTL (Non-Random Two Liquid) model was used to predict the activity coefficients. The

binary interaction parameters that were not present in the simulator's database were estimated from the UNIFAC structures of the compounds (Zhang et al., 2003a; West et al., 2008).

The fatty components (triglycerides, FFA and biodiesel), from both the raw materials, were simulated as pseudo-components. The critical properties, boiling point and acentric factor were estimated by the Constantinou-Gani group contribution method (Constantinou and Gani, 1994). It was assumed an average composition for the oils, based on literature data (Knothe et al., 2005). The other properties were estimated based on the linoleic compounds for soybean derivatives and based on the palmitic compounds for palm derivatives.

The plant capacity was specified as the average production per plant in Brazil in mid-2014. In June, there were 61 licensed production plants, producing a total of 21,167.79 m³/day. It corresponds to about 12,625 kg/h per plant (ANP, 2014).

2.1. Pre-treatment: esterification

Alkali catalysis is the most common way to produce biodiesel. However, before entering the transesterification reactor, the FFA content and humidity must be removed, to avoid the production of soap. Lepper and Frisenhagen (1986) have developed a process to esterify the FFA present in vegetable oils, which was first reproduced in a process simulator by Zhang et al. (2003a) and, later, by other authors (West et al. 2008; Morais et al., 2010). This was the process adopted in this work, which is exposed in Figure 1.

A pure ethanol stream is firstly mixed with the catalyst, H_2SO_4, and then conducted to the esterification reactor, which works continuously at 70 °C and 400 kPa. The esterification kinetics was assumed to be of reversible second order, based on the study of Pisarello et al. (2010). The quantity of ethanol added in the reactor was equal to 15 % in volume of the quantity of crude soybean oil (0.5 % FFA) and 45 % in volume of the quantity of crude palm oil (5 % FFA). This greater amount for palm is needed to displace the equilibrium in the products direction.

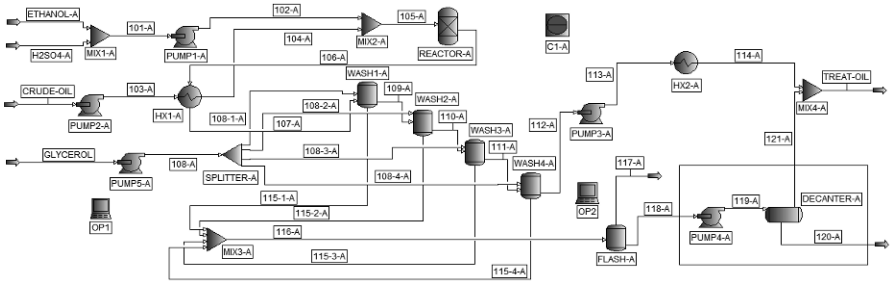

Figure 1 – Pre-treatment module, with (palm) and without (soy) the decanter, indicated by the rectangle

It was necessary a residence time of 0.3 h for the conversion of 50 % of the FFA in soybean oil and 7.1 h for the conversion of 95 % of the FFA in palm oil. After esterification, the oil goes to a sequence of four mixers and settlers (simulated as flash vessels) where a glycerine washing is performed. The objective is to remove all the FFA

and humidity. A flash vessel operating under vacuum (30 kPa) is used to separate glycerine and ethanol. For soy, the ethanol obtained is still under specifications to be sold as anhydrous fuel (ANP, 2011). But the effluent obtained in the palm oil process, which has an ethanol mass fraction of 98.9 %, need to be treated before it can be sold as anhydrous. It is important to note that even if the ethanol could be classified as anhydrous fuel, it cannot be recycled to the esterification reactor, because of the little content of water that could be carried to the transesterification reactor.

There is another difference between the soybean oil process and the palm oil process. Because of the higher quantity of ethanol and solvent needed for washing in the palm oil process, some volume of biodiesel is lost in the extract. To recover this volume, the glycerine goes to a decanter. The biodiesel and the oil recovered in the decanter meet the raffinate stream and go to transesterification.

2.2. Transesterification

The process adopted to perform the homogeneous alkali transesterification is similar to the process used by Zhang et al. (2003a), West et al. (2008) and Morais et al. (2010), showed in Figure 2. Although in the process with methanol it is recommended an alcohol to oil ratio of 6:1 (Freedman et al., 1984), when the vegetable oil is processed with ethanol, a higher ratio is generally used. So, it was adopted a molar ratio of 9:1 in this work. The transesterification reactor works continuously at 50 °C and 400 kPa. An irreversible second order kinetics was assumed, based on the work of Shahla et al. (2012).

Pure ethanol is mixed with the catalyst, NaOH, and is added in the reactor. The same occurs with the pre-treated oil. Based on the contribution of Garnica (2009), who studied these reactions for soybean oil and palm oil in the same conditions, the residence time for 95 % conversion was estimated as 6.6 h for soy, while for palm it was 8.9 h. The reaction product goes to a distillation column, to recover the ethanol excess. The column operates with six theoretical stages, including condenser and reboiler, and reflux ratio of two. It is necessary to operate under vacuum (10 kPa at the top and 30 kPa at the bottom) to avoid degradation of the biodiesel or the glycerol

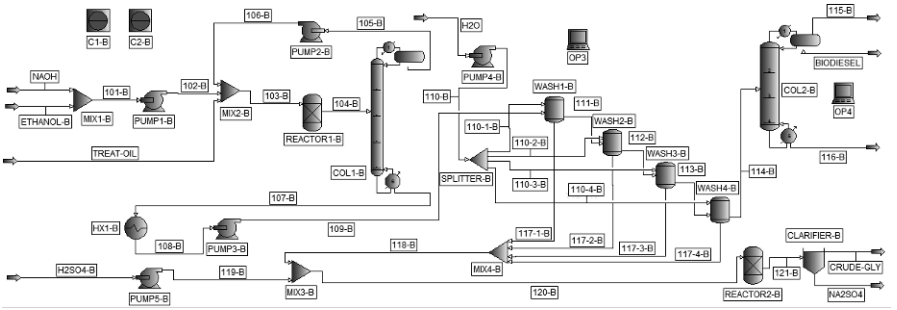

Figure 2 – Alkali-catalysed transesterification module

(Zhang et al., 2003a). Almost 99 % of the ethanol present in the product stream could be recovered and recycled to the reactor. Then, the product goes to a water washing, in a sequence of four mixers and settlers (simulated as flash vessels). The objective is to separate the catalyst and the glycerine. The biodiesel goes to a purification column, which operates with five theoretical stages and under vacuum. The biodiesel produced

in the condenser is under Brazilian and American specifications. The effluent at the top consists of ethanol and water, and must be treated. The effluent at the bottom consists mainly of unreacted oil. The crude glycerine goes to a neutralizer reactor, which also receives the glycerine used in the esterification and a H_2SO_4 load. The reactor works at 60 °C and 110 kPa. After a residence time of five minutes, it is assumed that all the sodium hydroxide reacts with the sulphuric acid, forming sodium sulphate (Na_2SO_4). The solid is separated in a clarifier and the glycerine can be sold as crude glycerine.

2.3. Effluent treatment proposals

The first effluent treatment proposal is the recycle of the unreacted oil obtained at the bottom of the biodiesel purification column directly to the transesterification reactor. The exigency here is just a pump, to put the oil at 400 kPa, and a heat exchanger, to correct the temperature.

The second proposal is the treatment and recycle of the crude glycerine. The glycerine feed a flash vessel, operating under vacuum (30 kPa), which separates the glycerol from water and ethanol. The glycerol obtained has a purity of about 98 % to 99 %. Part of this product can be recycled to the glycerine washing vessels and the rest can be sold as technical grade glycerol.

For both soy and palm, the possibility of mixing the three effluents and producing hydrous ethanol fuel (HEF) was evaluated. This option is showed in Figure 3.

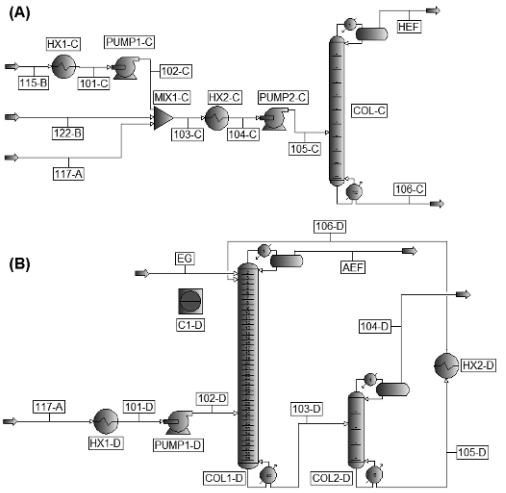

Figure 3 – Treatment of the effluents rich in ethanol
(a) Hydrous ethanol fuel production (b) Anhydrous ethanol fuel production

According to the Brazilian National Agency of Petroleum, Natural Gas and Biofuels (ANP, in Portuguese) specifications, HEF must have an ethanol concentration between 92.5 % and 93.8 %. To obtain this purity, the three effluents feed a column with 12 theoretical stages and reflux ratio of five. Heat exchangers are used to condensate the gaseous effluents, so that they could be pumped up to the column. The column operates

at ambient pressure. At the top, HEF is obtained. The bottom product, rich in water, must be correctly disposed.

The other option is to produce anhydrous ethanol fuel (AEF) from the effluent 117-A of the palm biodiesel plant. According to ANP, AEF must have an ethanol concentration of at least 99.3 %. The process proposed is based on the work of Ravagnani et al. (2010). The effluent feeds a column of 40 theoretical stages and reflux ratio of three, operating at atmospheric pressure. The effluent enters in the column at the thirtieth stage, while the solvent, ethylene glycol, enters at the third stage. The solvent is recovered pure in a six stages column with a reflux ratio of five. The scheme of this treatment module is presented in Figure 3.

3. Equipment Sizing and Economic Evaluation

All the equipment was sized according to empirical guidelines described in Seider et al. (2003). The flash vessels were projected according to Towler and Sinnott (2008). The reactors volumes were obtained multiplying the entering flow rate by the residence time. A headspace of 20 % of the liquid volume was considered. The atmospheric pressure columns were packed with 1 inch carbon steel Pall rings and the vacuum columns with 2 inches carbon steel Pall rings. Equipment that work with sulphuric acid were projected with stainless steel and all the other equipment with carbon steel. The economic evaluation was similar to the works of Zhang et al. (2003b) and West et al. (2008), except by the inclusion of a Lang factor of 4.8, following the guidelines proposed by Seider et al. (2003). Table 1 shows the scenario of prices considered in this work. These were the medium prices practiced in Brazilian foreign and internal trades in the first semester of 2014. Table 2 shows the main economic parameters evaluated.

4. Conclusions

As can be seen in Table 2, it is possible to produce HEF without considerable cost improvements, although AEF production was not economically attractive in this scenario. Unreacted oil recycle contributes with about 5 % of cost reduction and glycerine treatment and recycle contribute with about 10 %. The best results obtained are more economical and sustainable, but without subsidies or tax reductions they were still not profitable in the considered scenario. The authors expect that this work could be a basis for comparison of different biodiesel production technologies and raw materials, aiming more sustainable and even profitable processes.

Table 1. Price scenario in Brazil mid-2014. Medium prices of foreign and internal trades (US$/kg).

RM and Products	Prices	Catalysts and Solvents	Prices	Utilities	Prices

Abstract

This article aims to present a mathematical model for synthesis of a heat-exchanger network (HEN) which can be integrated with a transcritical organic Rankine cycle (T-ORC) for recovering low-grade waste heat from the heat surplus zone of the background process. This work is a direct extension of previous one where the working fluid was operated under subcritical pressure. A T-ORC integrated stagewise superstructure considering all possible match of process hot/cold streams and the re-circulated working fluid is proposed. Based on this superstructure, a mathematical model for synthesizing T-ORC integrated HENs is formulated as a mixed-integer nonlinear program (MINLP), therein the objective is to maximize the net work produced from waste heat in the heat surplus zone below the process pinch. A literature example is solved to demonstrate the application of the proposed model for industrial waste heat recovery. For a given heat source, some organic fluids can be used in both subcritical and transcritical status. After a minor modification, the model can be applied for not only subcritical but also transcritical ORC. Based on the results from the modified model, it is found that the T-ORC-involved HEN can produce higher net power over the heat recovery system where the ORC is operated under subcritical state.

Keywords: Waste heat, Transcritical organic Rankine cycle (T-ORC), Heat exchanger network (HEN), Superstructure, Mixed-integer non-linear programming (MINLP)

1. Introduction

The oil price has increased for several times over the past 20 years. Energy conservation is one of the most visible methods for reducing the energy bill. In industrial processes, there are streams that need heating and streams that need cooling, usually achieved by using hot and cold utilities with some kind of heat recovery. Heat exchanger network (HEN) is the main method to obtain heating and cooling by process streams energetic integration, by using hot streams to heat up cold streams and cold streams to cool down hot streams. In this way, it can reduce the use of external hot and cold utilities. However, a large amount of energy is lost as low-temperature waste heat in industrial and daily processes. Due to the rising cost of energy, effective utilization low-grade waste heat has attracted more and more attention. Organic Rankine cycle (ORC) is widely used to generate electricity from these heat sources. Unlike in a conventional steam Rankie cycle, a low boiling point organic fluid is used as working fluid. Because the organic fluids have lower critical temperatures and pressures, they can be compressed directly to their supercritical pressures and heated to supercritical state before expansion.

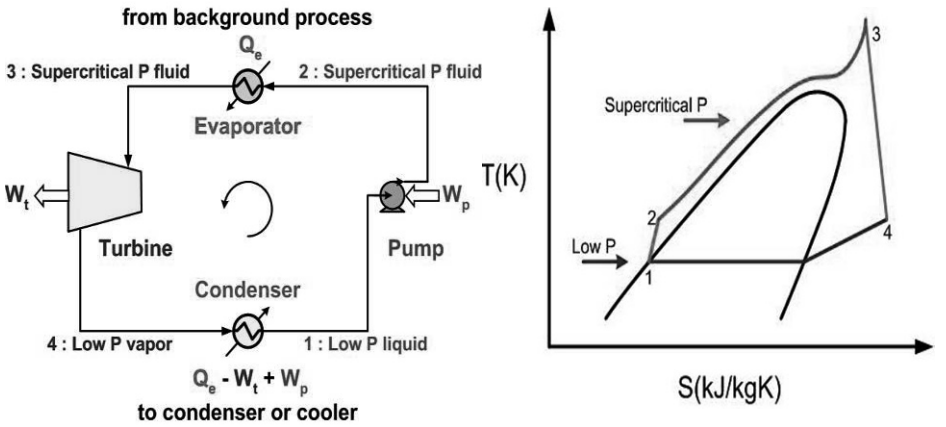

Figure 1a (left) Schematic diagram of transcritical ORC cycle.
1-2: irreversible compression, supply work to the cycle;
2-3: isobaric supply of heat (evaporator);
3-4: irreversible expansion, useful work done by the cycle;
4-1: isobaric removal of heat (condenser);
Figure 1b (right) T-s diagram for a typical transcritical ORC

The heating process of this kind of ORC, which called transcritical ORC, does not pass through a two-phase region like a subcritical ORC, resulting in a better thermal match in the evaporator with less irreversibility, which is confirmed by Saleh et al (2007).This article present mixed-integer nonlinear program (MINLP) model for HENs involving a transcritical ORC for recovery of low-grade waste heat from the background process.

Figure 1 shows the typical transcritical ORC cycle, as well as the temperature-entropy (T-S) diagram. The working fluid is pumped from a lower pressure level (state 1) to a higher pressure level above the critical pressure of working fluid (state 2). Between states 2 and 3 the fluid in supercritical area absorbed the waste heat from background process. The supercritical fluid is expanded in a turbine (state 4). The remaining heat is removed by transferring heat to a cooling medium in the condenser and the complete the cycle.

2. Problem Statement

The problem of integrating a transcritical ORC with the background process can be stated as follows. Givens are a set of hot process streams to be cooled and a set of cold process streams to be heated. The heat capacity flow rates of the process streams, available external hot and cold utilities for heating and cooling, and available dry organic working fluids to be used are also given. It is desired to synthesize an optimal transcritical ORC-integrated HEN to maximize heat recovery among the process streams, while maximizing the recovery of waste heat from the background process for electricity generation.

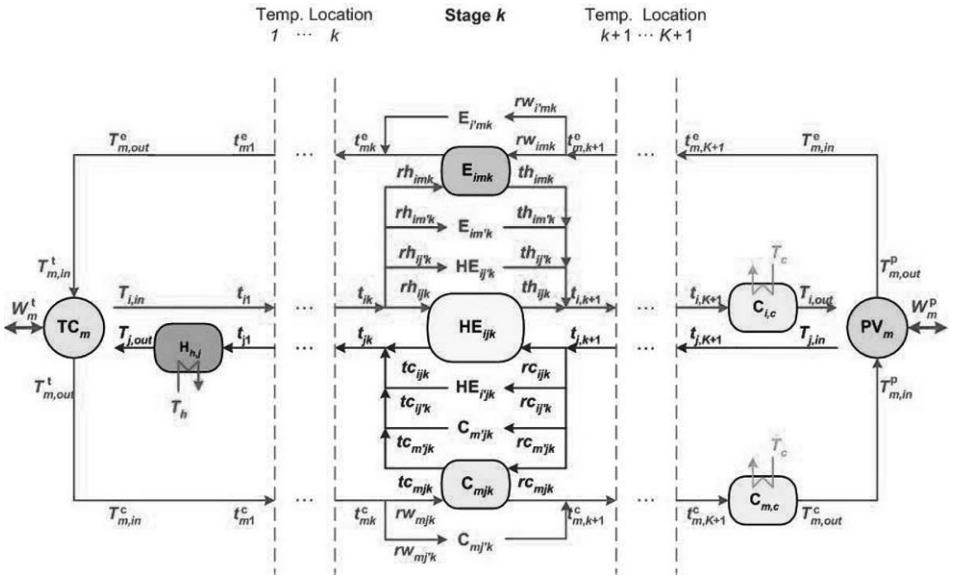

Figure 2. Stagewise superstructure for synthesis of transcritical ORC-integrated HEN

3. Superstructure

Figure 2 illustrates the superstructure for the synthesis of transcritical ORC-integrated HENs for recovery of low-grade waste heat from the background process. This superstructure, an expansion of the stage-wise HEN superstructure of Yee and Grossmann (1990) and Chen et al. (2014), incorporates an ORC and assumes non-isothermal stream mixing.

In the superstructure, HE_{ijk} is the process-to-process heat exchanger; H_{hj} and C_{ic} are the heater and cooler for providing extra hot or cold utilities at the end of process streams; rh_{ijk} and rc_{ijk} are the split ratios for the hot and cold process streams at stage k; t_{ik} and t_{jk} denote the intermediate temperatures; PV_m and TC_m denote the pump and the turbine for working fluid m in the ORC; evaporators E_{imk} and condensers C_{mjk} are used for exchanging the waste heat between the process streams and the working fluid m; t^e_{mk} and t^c_{mk} are intermediate temperatures around the evaporators or the condensers.

4. MINLP Formulation

Mathematical optimization models have commonly relied on the following assumptions for synthesizing HENs:

(1) Heat loss to the surrounding is negligible.
(2) Pressure drops in the pipes and heat exchangers are negligible.
(3) Constant heat capacity flowrates and heat transfer coefficients
(4) Single-pass countercurrent heat exchangers

The objective is to maximize the output net work (W^{net}) from the recovered waste heat, such as shown in Equation (1).

$$\max_{x\in\Omega} J = \sum_{m\in M} W_m^t - \sum_{m\in M} W_m^p \tag{1}$$

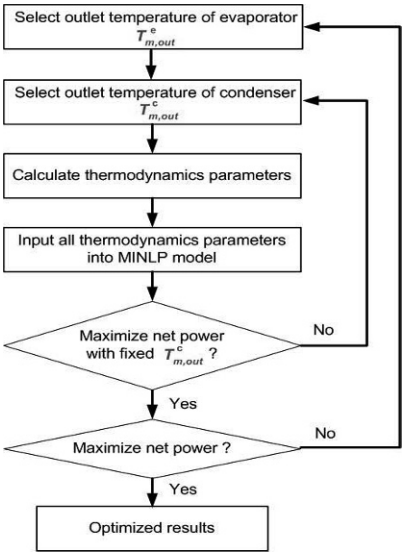

Figure 3. Optimization flowsheet

where W^{t}_{m} represents turbine work of medium m and W^{p}_{m} represents pump work of medium m.

The feasible solution is searched with the limitation of constraints based on the optimization procedure shown in Figure 3. These constraints include energy/mass balances, existence of heat exchangers, temperature difference of heat exchangers, temperature assignments, etc. Under the assumption of the fixed evaporate pressure (P_{max}), there are two remaining design variables for transcritical ORC configuration, which are the evaporator and the condenser outlet temperatures ($T^{e}_{m,out}$ and $T^{c}_{m,out}$). Optimized result can be found by method as shown in Figure 3.

5. Numerical example

The example from the work of Desai and Bandyopadhyay (2009) and Chen et al. (2014) involves three hot and four cold streams with steam and cooling water as the heating and cooling utilities. Given data for the problem, including the inlet and outlet temperatures, heat capacity flow rates, the available utilities of hot and cold process streams are showed in Table 1. The T-ORC is used to recover the waste heat from the heat surplus region of the background process under the pinch temperature 244°C.

Table 2 shows the results by varying two main design variables, the outlet temperatures of evaporator ($T^{e}_{m,out}$) and condenser ($T^{c}_{m,out}$). The net power shown in this table is defined in Equation (2):

$$W^{net} = f \times w^{net} = W^{t} - W^{p} \tag{2}$$

where W^{net}, W^{t}, W^{p}, w^{net} and f are net power output, power done by the turbine, power consumed by the pump, specific net power output and working fluid flow rate. With the selected evaporator outlet temperature $T^{e}_{m,out}$ = 210°C, higher condenser outlet temperature brings more working fluid flow rate and less specific net power output. In similar, with the selected condenser outlet temperature ($T^{c}_{m,out}$ = 102°C), higher evaporator outlet temperature leads to less working fluid flow rate and higher specific

104	107.40	224	167.79	0.918	48.28	7.95	52.29	44.34	9.92	446.58	128.26

net power output. There is a trade-off between working fluid flow rate and specific net power output. The optimized result, which is showed in Figure 4, demonstrates that 44.77 kW net power can be found under $T^e_{m,out}$ = 224^{o}C and $T^e_{m,out}$ = 103^{o}C. Note that 224 ^{o}C is the highest possible evaporator outlet temperature because of the limitation of hot pinch temperature. Compared to the results under subcritical ORC, T-ORC-involved HEN can be operated in higher temperature and pressure, thus can absorb more waste heat and can produce more net work with higher working fluid flow rate.

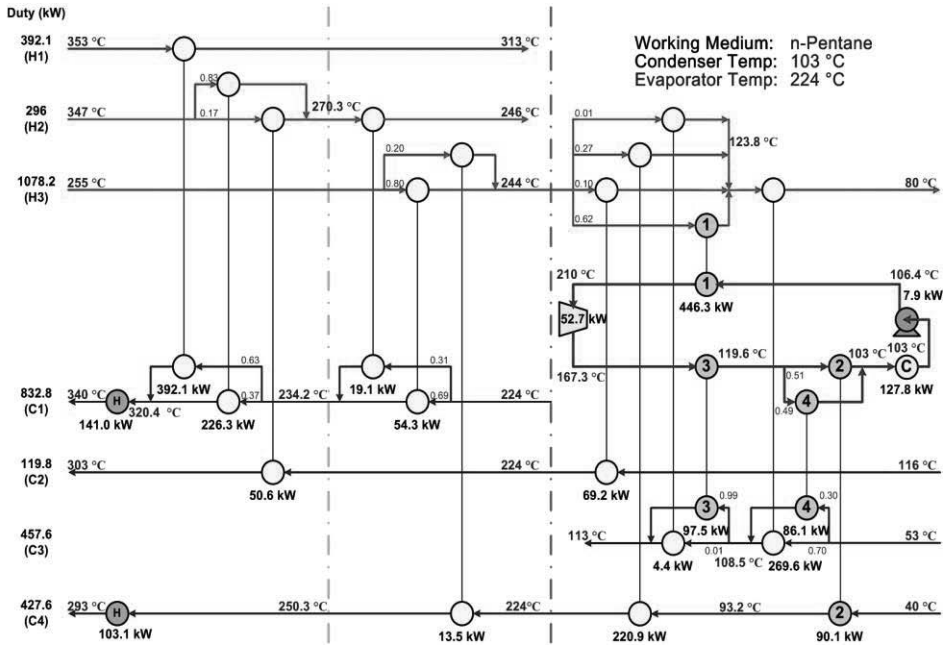

Figure 4. Optimized case with $T^{c}_{m,out}$ = 224 °C and $T^{c}_{m,out}$ = 103 °C

6. Conclusions

A mathematical model for the synthesis of transcritical ORC-integrated HENs has been developed in this paper. Based on a generic stagewise superstructure representation incorporating an ORC and considering non-isothermal stream mixing, the synthesis problem is formulated as an MINLP. A literature example was solved to demonstrates the proposed approach for waste heat recovery from background processes. Based on the results from the modified model, it is found that the T-ORC-involved HEN can generate higher net power over the heat recovery system where the ORC is operated under subcritical state.

Abstract

Process flow diagram of a reactive distillation process for ethyl lactate production is designed and optimized in this study. In an attempt to intensify a process for ethyl lactate production, magnesium lactate obtained directly from fermentation was used, instead of highly purified lactic acid as in a conventional process, as a starting material. Ethyl lactate produced by esterification in the reactive distillation column is purified in a series of fractional distillation columns until its impurity-free aqueous solution is received as a final product. Process optimization is performed using Aspen Plus simulator equipped with RADFRAC module. Sulfuric acid is used as a homogeneous catalyst, and all the kinetic parameters of the esterification reaction are taken from our previous work. Production efficiency of two process schemes was explored. In the first process scheme, ethyl lactate was collected at the top of the reactive distillation column along with other light compounds in the process, i.e. water and ethanol. In the second process, ethyl lactate was discharged from the bottom of the reactive distillation column. Configurations of each operating unit as well as the optimal process conditions were obtained. The first process is more efficient in terms of lactic acid conversion, ethyl lactate recovery, yield, and production rate. The second process, on the other hand, is more beneficial in terms of heat requirement and concentration of ethyl lactate achieved in the final product solution.

Keywords: Lactic acid, Ethyl lactate, Reactive Distillation, Process Design,

1. Introduction

Ethyl lactate ($C_5H_{10}O_3$) is an ester of lactic acid that can be considered as a green chemical due to its nontoxic, biodegradable and excellent solvent properties. It was used in many industries with general application as solvent for production of nitrocellulose, food additive, perfumery, flavor chemicals as well as drug industries (Lewix, 2007).

Conventional production of ethyl lactate is from esterification of lactic acid with ethanol as shown in Eq.(1). The reaction proceeds well in an acid environment so either homogeneous or heterogeneous acid catalysts are normally used to accelerate the reaction. This approach is, however, expensive due to the costly lactic acid separation and purification processes, which has been estimated to be about a half of the total cost for production of highly purified lactic acid (Pereira at al., 2011). Synthesis of ethyl

lactate directly from lactate salts obtained from lactic acid fermentation might help reducing the production cost of this compound (Kasinathan et al., 2010).

$$Lactic\ acid + Ethanol \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ethyl\ lactate + Water \quad (1)$$

In this study, preliminary design of reactive distillation process for production of ethyl lactate from fermentation-derived magnesium lactate is proposed. The process simulation and optimization are performed using ASPEN Plus simulator equipped with RADFRAC module. Process efficiency, evaluated from lactic acid conversion, ethyl lactate recovery, yield and production rate, as well as heat requirement of the process is investigated and compared between two different process schemes.

2. Process description

The process for production of ethyl lactate proposed in this work consists of one reactive distillation (RD) column, where esterification is proceeded, and a series of fractional distillation columns (DIS) to purify ethyl lactate until its aqueous solution that is free from ethanol and other impurities is received as a final product.All the columns are tray-type. Tray diameter and tray spacing of 0.1 m and weir height of 1 in are assumed in this study. Equilibrium stages are numbered down from the top to the bottom of each column. A condenser is, therefore,always the first stage. All the columns are operated under atmospheric pressure.

An acidified magnesium lactate solution is used as a source of lactic acid. Procedure for preparing this solution is described in detail in our previous publication (Daengpradab and Rattanaphanee, 2012). In short, powdery magnesium lactate is mixed with sulfuric acid until it is completely dissolved. Any remained residue is removed by filtration. Water is partially vaporized out of the solution in order to lessen its interference in esterification. Concentrated sulfuric acid, the reaction catalyst, is added into the solution before it is charged into the reactive distillation column in feed stream F1, and ethanol isin feed stream F2, as shown in Figure 1 and 2. Compositionsanalysis of both feed streams is performed. The result is shown in Table 1. It should be noted that the reaction zone in the reactive distillation column extended between these two feed stages.

Production efficiency of the proposed process is determined in terms of lactic acid conversion, as well as ethyl lactate yieldand recovery. These parameters are expressed in Eq.(3), Eq.(4) and Eq.(5), respectively. Ethyl lactate production rate, expressed in grams of ethyl lactate produced per hour of the operation,as well as the ester concentration in the final product are also considered. Process heat requirement, which is evaluated from heat duty of all the concerned process units, is another efficiency-evaluating parameter in this work.

Table 1. Feed composition and molar flow rate.

Feed stream	Component	Normal boiling point (ºC)	Molar flow rate (mol/h)	Mole fraction
F1	Lactic acid	216.63	2.12	0.077
	Water	100.02	23.53	0.859
	Magnesium sulfate	9726.85	1.37	0.050
	Sulfuric acid	274.80	0.38	0.014
F2	Ethanol	78.31	6.35	1

$$\%X_{LA} = \frac{Mole\,of\ ethyl\,lactate\,produced\,in\ RD\,column}{Mole\,of\ lactic\,acid\,fed\,in\ stream\,F1} \times 100 \tag{2}$$

$$\%Y_{EtLA} = \frac{Mole\,of\ ethyl\,lactate\,in\ final\,product}{Mole\,of\ lactic\,acid\,fed\,in\ stream\,F1} \times 100 \tag{3}$$

$$\%R_{EtLA} = \frac{Mole\,of\ ethyl\,lactate\,in\ stream\,TP}{Mole\,of\ ethyl\,lactate\,produced\,in\ RD\,column} \times 100 \tag{4}$$

Production efficiencies of two process schemes are compared. The first scheme is called Process A. Here, ethyl lactate is collected at the top of reactive distillation column, along with ethanol and water, while the heavy components, i.e. magnesium sulfate, sulfuric acid, and unreacted lactic acid are removed at the bottom. In the second scheme, Process B, ethyl lactate is discharged as bottom product of the reactive distillation column together with all the heavy components. Ethyl lactate-containing streams in both processes are subjected to a series of fractional distillation columns, where ethanol is recovered and recycled back to the reactive distillation column and all the heavy components are eliminated. The final product is thus received as an aqueous solution of ethyl lactate.

3. Reaction kinetics

Kinetic parameters of esterification of ethanol with lactic acid in magnesium lactate solution using sulfuric acid as the catalyst were obtained experimentally in our previous work. The detailed procedure was described elsewhere (Daengpradab and Rattanaphanee, 2012).Due to non-ideal nature of the reactive quaternary mixture containing lactic acid (*LA*), ethanol (*EtOH*), ethyl lactate (*EtLA*) and water (*W*), the reaction rate, $-r_{LA}$, is expressed in term of activity (*a*) instead of concentration as shown in Eq.(5). Dependence of reaction rate constant for forward (k_1) and backward (k_{-1}) reaction on reaction temperature followsEq.(6) and (7), respectively.

$$-r_{LA} = k_1\ a_{EtOH} a_{LA} - k_{-1}\ a_{EtLA} a_W \tag{5}$$

$$k_1 = 13300 \exp\left(-\frac{30400 J/mol}{RT}\right) \tag{6}$$

$$k_{-1} = 0.799 \exp\left(-\frac{7022.67 J/mol}{RT}\right) \tag{7}$$

4. Phase equilibria

General equation for vapor-liquid equilibrium (VLE) of a particular mixture at constant low pressure, *P*, and temperature, *T*, is given by Eq.(8), where γ_i is the activity coefficient of component *i*, ϕ_i is the fugacity coefficient, and x_i and y_i are mole fraction of *i* in liquid and vapor phase, respectively. P_i^{sat} is the component's vapor pressure at

temperature, T, and ϕ_i^{sat} is the fugacity coefficient of pure saturated vapor i at temperature, T, and the corresponding pressure, P_i^{sat}.

$$\phi_i y_i P = \gamma_i x_i P_i^{sat} \phi_i^{sat} \tag{8}$$

To account for non-ideal vapor-liquid equilibrium (VLE) behavior of the quaternary solution, the activity coefficient of every component in the liquid phase was calculated using the UNIQUAC model with the binary interaction parameters obtained from Delgado et al., 2007. The vapor phase was assumed to be ideal; therefore, the fugacity coefficients of all the components in this phase are unity.

5. Process simulation

Process simulation and optimization was carried out using Aspen Plus® equipped with RADFRAC module. Design variables are total number of stages, feed location and reflux ratio.

6. Results and discussion

Process flow sheet for Process A, where ethyl lactate is collected at the top of the reactive distillation column, is illustrated in Fig. 1. Composition of each stream in this process is given in Table 2. As seen, magnesium sulfate is totally removed at the bottom of the distillation column. Sulfuric acid and unreacted lactic acid are found along ethyl lactate-containing streams and are completely removed in the second distillation column. The ethanol-free aqueous solution of ethyl lactate is received at the bottom of the third distillation column with its final concentration of 8.27 % by mole of ethyl lactate.

Process B, where ethyl lactate is collected as the bottom product of the reactive distillation column, is depicted in Fig. 2. Stream composition, Table 3, shows that Process B gives the final product as 33.52 % by mole of ethyl lactate, which is much higher than the one obtained in Process A.

Optimal designs for both process schemes are displayed in Table 4 and Table 5. The last fractional distillation column in Process B appears to be the tallest column with the total number of equilibrium stages of 18. Nonetheless, the last fractional distillation column in Process A is the most energy-intensive one.

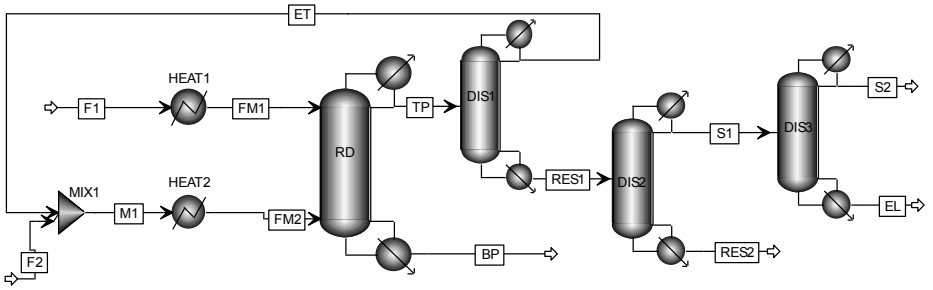

Figure 1. Process flow sheet of Process A, where ethyl lactate is collected in stream TP.

Table 2. Stream composition of Process A.

Description	Stream									
	FM1	FM2	BP	TP	ET	RES1	S1	RES2	S2	EL
Temperature (°C)	110.00	75.00	254.58	84.42	78.40	88.14	87.95	239.77	79.70	99.42
Molar flow rate (mol/h)	27.39	13.45	1.71	39.13	7.10	32.03	31.87	0.15	8.00	23.87
Mole fraction										
Ethanol	0	0.874	0.010	0.247	0.761	0.134	0.134	0	0.535	0
Lactic acid	0.077	0	0.002	0.002	0	0.002	0	0.397	0	0
Ethyl lactate	0	0	0.020	0.052	0	0.063	0.063	0.003	0.005	0.083
Water	0.859	0.126	0.002	0.697	0.239	0.799	0.802	0	0.460	0.917
Sulfuric acid	0.014	0	0.166	0.002	0	0.003	0	0.600	0	0
Magnesium sulfate	0.050	0	0.800	0	0	0	0	0	0	0

Production efficiency of both process schemes is comparatively shown in Table 6. Higher lactic acid conversion as well as ethyl lactate recovery and yield are achieved in Process A. This process also renders the higher ethyl lactate production rate of 233.28 g_{EtLA}/h, while Process B produces 183.35 g_{EtLA}/h.

The superiority of Process B comes in terms of the process heat requirement. This parameter is determined by dividing the total heat duty of concerned process units by the ethyl lactate production rate. In this study, only heat duties of heaters and distillation columns, both reactive and non-reactive, are taken into account. The heat requirement of Process A is 111.768 kJ/g_{EtLA}, which is almost twice higher than that of 70.772 kJ/g_{EtLA} required in Process B.

Another advantage of Process B that is worth to be noted lies in the fact that it gives a much more concentrated final ethyl lactate solution than Process A. This will benefit a downstream processing if further increase in the ester concentration is required.

7. Conclusion

Reactive distillation process for production of ethyl lactate by esterification of ethanol and fermentation-derived magnesium lactate is designed and optimized. Efficiency of two process schemes is studied and compared. Higher lactic acid conversion, as well as ethyl lactate recovery, yield and production rate is achieved in the process scheme where ethyl lactate is collected at the top of the distillation column. On the contrary, when ethyl lactate is collected as the bottom product of the reactive distillation column, higher concentration of ethyl lactate is obtained in the final solution. Heat requirement in the latter process is also found to be lower than the former one.

Abstract

In this study, the tailor-made green diesel blend design problem is mathematically formulated and solved by a decomposition-based computer-aided approach. The green diesel design problem is solved in three main stages to identify the feasible green diesel blend candidates that meet the product property constraints (density, kinematic viscosity, cetane number, higher heating value and flash point) with the desired performance criteria. An optional additives identification step is introduced to enhance the blends. The shortlisted green diesel blends are evaluated on the basis of cost, cetane number and higher heating value. To ensure that the shortlisted candidates have acceptable functional reliability, their compatibility with the engine compartment, engine performance, and emission requirements should be addressed in future works.

Keywords: Lignocellulosic biofuel; Green diesel blends; Computer-aided tools; Mixture design algorithm; Product design

1. Introduction

Tailor-made green diesel blends (the blend of either diesel with biofuel, or of different biofuels) represent one of the most promising solutions to reduce the impact of fuel consumption on the environment while retaining or even improving the performance of diesel fuel. Several studies have clearly demonstrated that biofuels are able to enhance the combustibility of diesel in the engine combustion chamber, and hence, reduce the particulate matter and soot in the exhaust stream (Christensen et al., 2011, Wei et al., 2014). At present, mixtures involving lignocellulosic biofuel (e.g. alcohol, levulinic ester) have been receiving a significant amount of attention. In connection with this issue, one of the main challenges related to green diesel blends involves how to identify the blends that match the blend target properties with the various types of lignocellulosic biofuels.

A systematic computer-aided approach can efficiently address these issues and provide a more efficient solution method than the iterative trial and error approach. The computer-aided technique is able to rapidly narrow down the search space of feasible green diesel blends so that costly and time-consuming experimental work can be reserved for only the most promising candidates (Yunus et al., 2012).

The highlight of this paper is the solution of the tailor-made green diesel blends design problem by using a decomposition-based computer-aided approach, in which the Mixed Integer Non-Linear Programming (MINLP) problem is solved in three main stages: (1)

generation of feasible green diesel blend candidates; (2) generation of the feasible green diesel blends that match the specified target properties, (the design constraints) with or without additives; and (3) ranking of the feasible green diesel blends according to an index of desired performance. Finally, the paper is concluded with suggestions for future work.

2. Tailor-Made Green Diesel Blends Design

The tailor-made green diesel blends are designed by blending commercial diesel with lignocellulosic chemical(s) to reduce the dependency on diesel fuel while mitigating the pollution issue. To ensure that the designed green diesel is able to run the commercial diesel engine without significant reduction in engine efficiency, a set of target properties, as listed in Table 1, should be satisfied. The tailor-made green diesel blends design problem is mathematically formulated (see Table 1), and the problem is solved by using a decomposition-based computer-aided approach. Density, kinematic viscosity and cetane number is calculated using the linear mixing model proposed by (Ariffin Kashinath et al., 2012). The model for higher heating value (Eq.(4)) is taken from (Chen et al., 2009). The flash point of the fuel blends is predicted using the Liaw model (Liaw et al., 2002), and the mixture stability is checked based on the trend of the second derivative of the Gibbs energy of mixing (Eq.(6)) (Yunus et al., 2011). In Table 1, subscripts *i* and *mix* represent the i^{th} compound and mixture; x represents the volume fraction; *C* is the cost; and *n* is the number of components. P_i^{sat} and $P_{i,FP}^{sat}$ are the vapor pressure at mixture flash point and pure compound flash point, respectively. γ_{VLE} and γ_{LLE} are the activity coefficient calculated using the UNIFAC group contribution method for vapor liquid equilibrium (Fredenslund et al., 1975, Fredenslund et al., 1977) and liquid-liquid equilibrium (Magnussen et al., 1981), respectively.

3. Decomposition-Based Optimisation Strategy

3.1. Stage 1: Generation of Feasible Green Diesel Blends Candidates

In this step, the feasible green diesel compounds are generated using computer-aided molecular design technique software (ICAS-ProCAMD). The pure component constraints of the green compounds are first defined according to the benchmark of the existing diesel fuel (Table 2). The potential candidates that satisfy the specific constraints are generated by using ICAS-ProCAMD. Subsequently, the stability of each possible pseudo binary blend is analysed by using Eq.(6).

3.2. Stage 2: Generation of Feasible Green Diesel Blends

The miscible green diesel blends from stage 1 are further tested according to product property constraints. The linear property constraints (density, kinematic viscosity, cetane number and higher heating value) are solved first using Eq.(1) to Eq.(4)), followed by the non-linear property constraint of flash point (Eq.(5)). An optional additive identification step is applied to enhance the blend; for example, the fuel combustion quality can be enhanced by increasing the cetane number. The compatibility of the additive with green diesel blends is verified by using Eq.(6).

Table 2. The requirements of green diesel bio-compounds, translated target properties, and the target value

Requirement	**Target Property**	**Target Value (Pure Component Constraints)**
• Compatible with diesel	Boiling point, T_b	50 °C < T_b< 300 °C
• Enhance engine efficiency • Environmental concern	Choose of chemical types	aliphatic compounds of hydrocarbon, alcohol, ester, ether, aldehyde, ketones, acides
• Liquid at ambient temperature	Melting point, T_m	T_m<20 °C
• Safety	Flash point,FP	FP > 30 °C

3.3. Stage 3: Ranking of Feasible Green Diesel Blends According to Desired Performance Index

The final stage is to select the best solution from all of the feasible blends based on cost and the index of desired performance, which are cetane number and higher heating value. Before considering the cetane number and higher heating value, the following objective function, F_{obj}, is used to identify the binary and ternary fuel blends with minimal cost. The designed green diesel blends must contain a minimum of 10 % of bio-component(s). The composition of bio-component(s) $x_{bio,i}$ is limited to no more than 30 % to ensure that the designed green diesel blend can be used in commercial diesel engines.

$$F_{obj} = \min \sum x_i C_i$$

subjected to

$$\sum x_i - 1 = 0$$

$$0.1 \leq \sum x_{bio,i} \leq 0.3$$

4. Results and Discussion

4.1. The Feasible Green Diesel Blends Candidates

A total number of 6,822 compounds that met the requirements of the pure component constraints were generated in ICAS-ProCAMD. The number of the possible compounds was further narrowed down by comparing the pure component properties with the target property values. Five bio-compounds were selected to illustrate the mixture design algorithm proposed in this paper: ethyl levulinate (EL), butyl levulinate (BL), butanol (BU), pentanol (PEN), and hexanol (HE). The results of the stability test of diesel components with the selected bio-compounds at room temperature (298.15 K) are shown in Table 3. Only the bio-components that are miscible (M) or partially miscible (P) with diesel components were considered as feasible green diesel blend candidates. Based on the previous studies, phase separation only occurred when high concentrations of EL were present in diesel (≥ 15 % of EL) (Wang et al., 2012), while BL can mix with diesel up to 20 % without a miscibility gap at room temperature (Christensen et al., 2011).

4.2. The Feasible Green Diesel Blends

Initially, there were approximately 49,000 possible binary and ternary blend candidates for diesel blending with EL, BL, BU, PEN and HE (with the variation of 1 % blending volume changed). The search space for the feasible blends was sufficiently narrowed down after solving for the linear and non-linear property constraints. For instance, only 49 feasible binary blends were found to meet the linear and non-linear property constraints from the total of 332 possible binary blends. To enhance the fuel combustion quality, a higher cetane number is preferred. Dibutyl ether (DBE) was selected as the cetane enhancer as it is completely miscible with diesel while having a higher cetane number (CN = 91) (Arteconi et al., 2011).

4.3. The Optimum Green Diesel Blends

The best green diesel blends were selected based on cost, cetane number, and higher heating value, as both of these fuel properties are closely related to the fuel combustion quality. The shortlisted green diesel blends with or without additive are ranked according to cost in Table 4. The correlation between cost and the total percentage of CN and HHV loss compared with the conventional diesel is illustrated in Figure 1. All of the shortlisted green diesel blends have competitive cost with the conventional diesel (USD 0.90 per L), except GD 2 (USD 2.33 per L) and GD 4 (USD 1.54 per L). Among the cheaper options (except GD 2 and GD 4), GD 3 and GD 7 have preferable CN and HHV over the other shortlisted blends, especially for the case of GD 3 (see Figure 1). Further testing is essential to evaluate the engine performance and emission of these blends in order to identify the best option for diesel replacement. Meanwhile, the present study has shown that the addition of DBE significantly improved the CN and the HHV of the fuel blends (e.g. GD 3, GD 4 and GD 7).

Table 3. The results of the stability test of each diesel component with the selected bio-compounds

Diesel component	Bio-compounds				
	EL	BL	BU	PEN	HE
n-Decane	P	M	M	M	M

5. Conclusions

This paper presents a systematic computer-aided mixture algorithm for solving the MINLP problem of green diesel blend design using a decomposition-based approach. The search space of the possible green diesel blends was sufficiently narrowed down through an iterative computational technique. Only seven different feasible blends that satisfied all of the target properties with minimal cost are shortlisted at the end of this

study. By comparing the cost, cetane number and heating value, GD 3 and GD 7 have competitive price (USD 0.92 and 1.05 per L, respectively) with diesel (USD 0.90 per L), and preferable cetane number and acceptably high heating value. In order to identify the best solution, its behaviour in the diesel engine, including emission, should be evaluated; this will be addressed in future work.

A Mathematical Programming Targeting Method to Select Treatment Technologies Ahead of Design

Athanassios Nikolakopoulos [a *], Antonis Kokossis[a]

[a]*National Technical University of Athens, School of Chemical Engineering, Heroon Polytechneiou 9, Zografou Campus, Athens, 15780, Greece*
nikolako@mail.ntua.gr

Abstract

The paper proposes a two stage mathematical programming approach for screening wastewater treatment technologies ahead of design, when the limiting concentrations and mass loads of contaminants for a set of water using operations are the only available data. The first stage of the methodology calculates the target for minimum fresh water flowrate further identifying the concentrations and the flowrates of the flows of the wastewater mains. The second stage selects the most effective treatment technologies and calculates targets for minimum wastewater treatment flows. The method is illustrated by a set of examples featuring the different aspects of the problem and characteristics of the solution.
Keywords: Wastewater treatment, Targeting, Water Integration.

1. Introduction

The growing scarcity of water resources and the increasingly stringent legislative framework on discharge limits force the chemical industry to adopt water management practices with ever increasing costs. The minimization of fresh water consumption and waste treatment costs must be synchronized since the effluent flowrates are directly related to the fresh water consumption. Treatment costs depend on the effluent flowrates and the selected treatment processes. Prior to detailed designs it is useful to quantify the target for minimum water consumption and the maximum potential of a wastewater treatment configuration in terms of the selected processes to integrate and minimum wastewater treatment flowrates (Kuo and Smith 1997). Graphical targeting methods (Wang and Smith 1994) are unable to screen treatment technologies and target flowrates for multiple treatment units, while shortcut models for the selection of treatment processes are absent from literature (Bagajewicz 2000, Foo 2009 and Nikolakopoulos et al. 2012). The method proposed in this paper links two transshipment models. The first model (Argaez et al. 1999 and Nikolakopoulos et al. 2013), which targets the flowrate of fresh water, is extended in identifying the flowrates and concentrations of the effluent water mains. The second model (Nikolakopoulos et al. 2014), which originally targets treatment flowrates is extended in screening treatment technologies. The method offers the additional advantage of detecting the critical parameters of the system, where retrofitting changes improve on total cost. The two models are connected by identifying the flowrates and concentrations of the wastewater mains, which are allocated at the *pinch points* of the concentration interval diagram of the residual cascade (Argaez et al. 1999) which in turn correspond to the *pinch points* of the *limiting composite curve* (Wang & Smith 1994). The method is illustrated by a set of examples featuring the different aspects of the problem and characteristics of the solution.

The next section describes the model used for targeting fresh water flowrates and identifying wastewater mains. Section 3 presents the transshipment model for screening

treatment technologies and minimizing treatment flowrates. Section 4 illustrates the method using two examples from literature. The paper concludes in Section 5.

2. Targeting fresh water flowrates and allocating wastewater mains

Let us denote by $I = \{i \mid i = 1,2,...,No\}$ the index set of the water using operations. Associated with each operation are maximum inlet and outlet concentrations $C_i^{in,\max}$ and $C_i^{out,\max}$ respectively. The mass load of the contaminant transferred to each water-using operation is M_i^c. The limiting water flowrate, for the water-using operation i is $F_i^l = M_i^c / \left(C_i^{out,\max} - C_i^{in,\max}\right)$. The index set of concentration intervals is $CI = \{k \mid k = 1,2,...,K\}$, and C_k is the inlet concentration of interval k. The mass transferred from water-using operation i through the k^{th} concentration interval is $W_{i,k}^P = F_i^l \left(C_k - C_{k+1}\right)$, and the residual mass from water using operation i leaving interval k, is $r_{i,k}$. Equations (1-7) are the targeting model for water flowrate F^{fw}:

$$\min F^{fw} \tag{1}$$

$$r_{i,k} - r_{i,k-1} + W_{i,k} = W_{i,k}^P, \ \forall i,k \tag{2}$$

$$\sum_i W_{k,i} = W_k^W, \qquad \forall k \tag{3}$$

$$W_k^W = F^{fw}\left(C_k - C_{k+1}\right), \ \forall k \tag{4}$$

$$0 \le F^{fw} \le F^{fw,U} \tag{5}$$

$$\sum_i r_{i,k} \le y_k M, \ \forall k \tag{6}$$

$$r_{i,0} = r_{i,k} = 0, \ \ r_{i,k} \ge 0, \forall i \ \ and \ \ y_k \in \{0,1\}, \forall k \tag{7}$$

Equation (2) is the mass balances around interval k for every operation i. If $\sum_i r_{i,k} \ge 0$, then k is one of the pinch points. M is a sufficiently large number. If $y_k = 1$, then from (Eq. 6) k is a pinch point; and $KP = \{k^p \mid k^p = 1,...,K\}$ is the index set of all pinch points, including the pseudo pinch K. The total mass of contaminant is $MC^{tot} = \sum_i M_i^c$.

The element that bridges the two targeting models is the allocation of the pinch points at the upper limit of the concentration intervals where the sum of the residuals of the contaminant obtains positive values, while at any other interval the residuals are vanishing. The flowrate in the identified water mains is not influenced by the particulars of the water reuse network. Thus, let $W_{k^p} = \sum_i \sum_{k=k^p-1}^{k=k^p} W_{i,k}, \ \forall k^p$, be the mass of contaminant removed between pinch points $k^p - 1$ and k^p. Then the flowrate of the wastewater main of pinch point k^p is $F_{k^p} = W_{k^p} / \left(C_{kp} - C_{k^p+1}\right), \ \forall k^p$, where C_{kp} is the concentration of the effluent stream k^p. The effluent streams participate at the wastewater treatment optimization configuration to be assessed at the next stage.

3. Screening of treatment processes and targeting treatment flowrates

The design of a waste water network can be described with reference to a set of S_K wastewater mains: $KP = \{k^p \mid k^p = 1,...,K\}$, and a set of S_J treatment processes $J = \{j \mid j = 1,2,...,S_J\}$. Associated with each wastewater main are the original inlet concentrations $C^{in}_{o,k^p} = C_{kp}$. The outlet concentrations of all treated waste streams are equal to the original discharge concentration limits C^{out}_{o,k^p}. The mass load W_{k^p} of the contaminant transferred from main *k*, is already calculated. The minimum water flow rate, MWF_{k^p} for the waste water stream *k* in treatment process *j* is given by: $MWF_{k^p} = W_{k^p}\left(C^{in}_{o,k^p} - C^{out}_{o,k^p}\right), \forall k^p$. Let $IN = \{n \mid n = 1,2,...,N\}$ be the index set of the concentration intervals. C_n is defined as the outlet concentration of interval *n*. The mass transferred from main k^p through the n^{th} interval is given by: $M^P_{n,k^p} = MWF_{k^p}\left(C_{n+1} - C_n\right)$. Similarly, the mass transferred to stream *j* through the n^{th} interval is $M^W_{j,n} = Ft_j\left(C_{n+1} - C_n\right)$. The solution will select a cost effective set of treatment processes and determine the minimum treatment flowrates Ft_j. If fc_j is the fixed cost and $coef_j$ is the coefficient of the variable cost of the j^{th} treatment unit, the problem of selecting treatment processes and minimizing the treatment flowrates is represented by equations (8-14), where u_{n,k^p} is the residual mass of main k^p leaving interval *n*:

$$\min Cost = \sum\left(fc_j x_j + coef_j Ft_j\right) \tag{8}$$

$$u_{n-1,k^p} - u_{n,k^p} + \sum M_{n,j,k^p} = M^P_{i,k^p}, \ \forall n, k^p \tag{9}$$

$$\sum M_{k,j,n} = M^W_{j,n}, \qquad \forall j, n \tag{10}$$

$$M^W_{j,n} = Ft_j\left(C_{n+1} - C_n\right), \ \forall n \tag{11}$$

$$0 \le Ft_j \le Ft^U_j, \ \forall j \tag{12}$$

$$x_j M \ge Ft_j, \ \forall j \tag{13}$$

$$u_{N+1,k^p} = u_{1,k^p} = 0, \ u_{n,k^p} \ge 0, \ \forall n, k^p \ \ and \ \ x_j \in \{0,1\}, \ \forall j \tag{14}$$

The constraint set (9) is the mass balance of the contaminant around each interval. $M_{k,j,n}$ is the mass of contaminant transferred from waste stream *k* to through interval *n* to treatment process *j*. For treatment processes with fixed outlet concentration, before the construction of the concentration intervals the concentrations of all waste streams must be shifted by the minimum of the outlet concentration of the treatment units $C^{out}_{\min} = \min_j\left\{C^{out}_j\right\}$, thus the concentration leaving the treatment processes will have virtually zero value and can be assigned to the first concentrations interval: $C^{in}_{k^p} = C^{in}_{o,k^p} - C^{out}_{\min}$ and $C^{out}_{k^p} = C^{out}_{o,k^p} - C^{out}_{\min}, \forall k^p$. The same shift applies for the inlet and

outlet concentrations of all treatment processes: $C_{s_j}^{in} = C_j^{in} - C_{\min}^{out}$ and $C_{s_j}^{out} = C_j^{out} - C_{\min}^{out}$, $\forall j$. The intervals are defined by the shifted limiting concentrations.

4. Illustrative examples

4.1. Example 1

Table 1 contains the data for four water-using operations (Kuo & Smith 1994) and three waste water treatment processes.

Table 1 Data for example with four water using processes and three waste treatment processes

Water using operations					
Operation No	Contaminant Mass load (kg/h)	C_{in} (ppm)	C_{out} (ppm)	Limiting water flowrate (t/h)	
1	2	0	100	20	
2	5	50	100	100	
3	30	50	800	40	
4	4	400	800	10	
Wastewater treatment processes					
Process No		C_{in} (ppm)	C_{out} (ppm)	Fixed cost K€	Variable cost coefficient K€/t/h
I		50	10	200	15
IIa		900	30	50	10
IIb		900	30	150	8
	Environmental discharge limit		C_e = 20 ppm		

Figure 1a shows the pinch points on the composite curve and Figure 1b shows the resulting water mains that. Treatment processes I and IIb are selected, at cost of 2.5M€.

Table 2 Results for Example 1

Water using operations			Wastewater treatment processes	
Minimum fresh water flowrate		90 t/h	Selected treatment processes	TP I and TP IIb
Water mains	Concentration (ppm)	Flowrate (t/h)	Total cost	2,535 K€
ST I	100	44.3	Wastewater treatment flows (t/h)	
ST II	800	45.7	TP I	90
			TP IIb	64.28

The selection of a TP is sensitive to waste flowrates; if the flowrate of the ST II was 38.46 t/h then TP IIa would have selected instead of TP IIb, with a flowrate of 59.1 t/h.

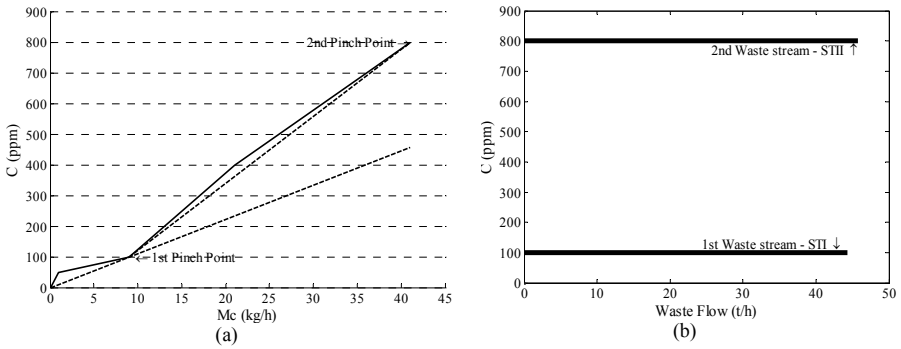

Figure 1 Pinch points and waste streams for example 1

Figure 2 presents an optimal water reuse network for Example 1, where the flows of the two wastewater mains have the same concentration and flowrates as the ones in Figure 1b calculated by solving problem (1-7).

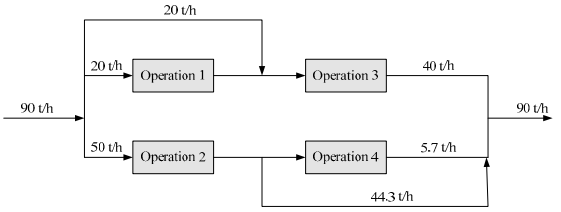

Figure 2 Optimal network for water reuse in example 1 (Smith, 2005)

The pinch points reveal the critical parameters of the water using operations and the treatment units. For example, if the maximum outlet concentration of operation 2, which is involved in the 1st pinch, is increased by 100 ppm, then the minimum fresh water flowrate is reduced by 28% to 65 t/h. This effect propagates to the second stage with an analogous reduction in the treatment flowrates. However a similar increase of the outlet concentration of the 4th operation will have no positive impact.

4.2. Example 2

The data for five water-using operations and three waste water treatment processes are shown in Table 3 (Smith 2005).

Table 3 Example with five water using processes and three waste treatment processes

Water using operations					
Operation No	Cont. Mass load (kg/h)	C_{in} (ppm)	C_{out} (ppm)	Limiting flowrate (t/h)	
1	8	0	200	40	
2	5	100	200	50	
3	6	100	400	20	
4	6	300	400	60	
5	8	400	600	40	
Wastewater treatment processes					
Process No		C_{in} (ppm)	C_{out} (ppm)	Fixed cost K€	Variable cost coefficient K€/t/h
I		200	5	200	15
IIa		1000	50	50	10
IIb		1000	50	150	8
Environmental discharge limit		C_e = 30 ppm			

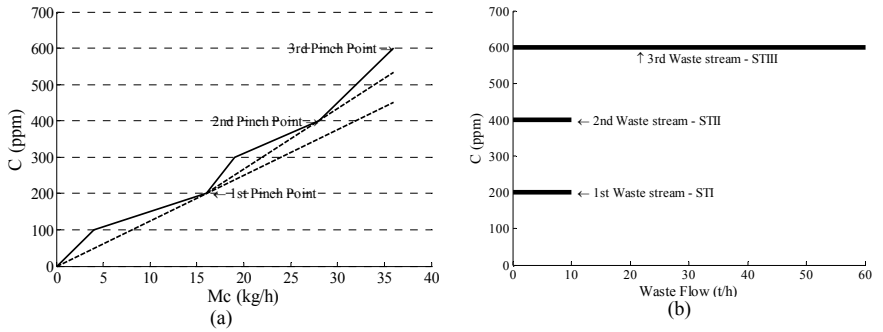

Figure 3 Pinch points and waste streams for example 2

Figure 3a shows the pinch points on the composite curve and Figure 3b shows the wastewater mains that result from this configuration. Treatment processes I and IIb are selected, at a cost of ~2 M€.

Table 4 Results for Example 2

Water using operations			Wastewater treatment processes	
Minimum fresh water flowrate		80 t/h	Selected treatment processes	TP I and TP IIb
Water mains	Concentration (ppm)	Flowrate (t/h)	Total cost	1,986 K€
ST I	200	10	Wastewater treatment flowrates (t/h)	
ST II	400	10	TP I	80
ST III	600	60	TP IIb	54.54

If the flowrate of the ST III was 53 t/h then TP IIa would have been selected instead of TP IIb, with a treatment flowrate of 49.45 t/h.

5. Conclusions

A mathematical programming tool consisting of two interlinked models is proposed for synchronized targeting of fresh water flowrate, screening of wastewater treatment technologies and targeting of treatment flowrates. There is scope to expand the models for multiple water sources, multiple contaminants and treatment processes with removal ratio. Finally, future integration of the two models will offer the possibility to assess the option of regeneration and recycle.

Optimal Structure Synthesis of Ternary Distillation System

Hiroshi Takase and Shinji Hasebe*

Department of Chemical Engineering, Kyoto University, Kyoto 615-8510, Japan
hasebe@cheme.kyoto-u.ac.jp

Abstract

A new process synthesis method for ternary distillation processes is proposed. First the composition space of the ternary mixture is discretized, and each of the discretized compositions is assigned to a module corresponding to a tray of distillation columns. Then, the superstructure connecting all modules by vapor and liquid flow paths is constructed. In the proposed formulation, the liquid composition of each module is determined in advance. Thus, all of the constraints can be expressed by linear equations and linear inequalities even if the vapor-liquid equilibrium is expressed by a complicated function. Finally, by solving the problem formulated as a linear programming problem, the optimal process structure and design condition can be derived. When the composition space is discretized, the optimization result includes unessential flows among modules to satisfy the material and energy balance at the modules. Such unessential flows are effectively removed by prohibiting the ineffective mixing at each module. The developed synthesis procedure was applied to the separation problem of a ternary mixture consisting of benzene, toluene, and o-xylene. The results showed that a process structure close to the Petlyuk column is created without assigning any process structure in advance.

Keywords: Ternary distillation, Process synthesis, Petlyuk column, Optimal design

1. Introduction

As distillation needs a large amount of energy, various energy-saving techniques have been proposed and implemented for energy conservation. For more than two-component separation, the separation sequence is one of the important design variables that affect the possibility of external heat integration, i.e., heat exchange between the top vapor of a column and the bottom liquid of another column. By considering these facts, many researchers have proposed synthesis procedures that optimize the separation sequence, column design and external heat integration (Andrecovich and Westerberg, 1985, Novak et al., 1996). A superstructure is effectively used to formulate synthesis problems as an MILP or MINLP problem. In these researches, a conventional column, rectifying and stripping sections of a conventional column have been used as the building blocks of the synthesis problem.

The other energy conservation method of distillation system is to use thermally coupled columns such as a Petlyuk column or a side rectifier. Synthesis problems, including thermally coupled columns, have also been discussed by many researchers (Sargent and Gaminibandara, 1976, Alcántara-Avila et al., 2013, Caballero and Grossmann, 2014). In these researches, thermally coupled columns and/or their component structures are embedded as building blocks in the superstructure of the

synthesis problem. In other words, a structure having thermally coupled columns cannot be derived if such structures are not included in the model.

To consider flexible process structures, Ghougassian and Manousiouthakis (2012) adopted a tray of a column as a building block of the synthesis problem. By deciding the composition of each tray in advance, they presented the linear formulation for multi-pressure distillation processes of a binary homogeneous azeotropic mixture. Thanks to LP formulation, this procedure has no assumptions about process structure. However, a heat balance was not considered in their model. Takase and Hasebe (2014) extended their formulation so that a heat balance could be embedded in the formulation. In their method, the heat transfer from trays in the rectifying section to trays in the stripping section is considered as well as that between the condenser and reboiler. The developed method was applied to the design problem of internally heat integrated distillation processes of binary mixture. In this research, the method developed by Takase and Hasebe (2014) is extended to a synthesis problem of a ternary distillation system.

2. Method

2.1. Problem formulation

In this research, problems of separating ternary components are studied. The following assumptions are introduced in the problem. The flow rate of feed and its composition are given in advance. All products are saturated liquid, and the specification of each product is given as the lower bound of the concentration of key component. The pressure of the feed is the same as those of products, and the pressure drop in the system is negligible. Several heating and cooling utilities with different temperatures are available, and the utility costs depend on its temperature. The column cost is negligible compared with the utility cost.

For the above conditions, the problem deciding the process structure that minimizes the operation costs is discussed.

2.2. Modules and superstructure of the system

In the proposed design procedure, each tray is treated as a separation module, and the flow paths among these modules are assumed to be not decided in advance. First, the entire range of liquid composition is divided into N_S different compositions. Then, each of the divided compositions is assigned to a module. For a ternary separation problem, the mole fractions of two components must be decided to identify the composition.

In the proposed method, a vapor-liquid equilibrium is assumed between the output vapor and liquid flows at each separation module. As the pressure at each module has been given in advance, the temperature and the vapor composition are uniquely decided from vapor-liquid equilibrium condition. Molar enthalpies of the vapor and liquid are also decided for the output vapor and liquid flows of each module. These values can be calculated before the optimization. Thus, precise thermodynamic models can be used for the calculation of these values.

Figure 1 shows the input and output relationship of a separation module. There are two input nodes. One is the material flow that consists of the mixture of vapor and liquid flows from other modules. The other is the energy flow that shows the heat added to the module. There are three output nodes: liquid and vapor flows and the energy flow. When some amount of heat is removed from a module, it is regarded as energy flow from the module. In the proposed model, heat can be added to or removed from any modules. Therefore, reboilers and condensers are also treated as separation modules.

Feed and products are treated as special modules; the feed module does not have any input flows, and the product modules do not have any output flows. Each module is numbered as follows: The feed module is regarded as module 0, the separation modules are assigned to module 1 to module N_S, three product flows are assigned to module N_S+1 to module N_S+3. In product modules, it is assumed that the boiling temperature of module N_S+1 is the lowest, and that of module N_S+3 is the highest.

The heating and cooling utilities are treated as other types of special modules. Module N_S+4 to module N_S+N_H+3 correspond to heating utilities with different temperatures, and module N_S+N_H+4 to module N_S+N_H+N_C+3 correspond to cooling utilities with different temperatures. A module showing heating utility has only an energy output node, and a module showing cooling utility has only an energy input node.

The feature of the proposed design procedure is that the vapor and liquid flow paths among modules are treated as decision variables. So, this procedure can derive not only conventional distillation systems but also unexplored process structures. Figure 2 shows the superstructure which is adopted in this research. Each box in the figure corresponds to a module. To easily identify the flow connection, each separation module is shown as two divided parts: output part and input part. Thus, two boxes with the same number correspond to the same module. The solid lines, dashed lines, and alternate long and short dashed lines among the nodes are the liquid flow paths, vapor flow paths, and energy flow paths, respectively.

2.3. Mathematical formulation

The total material balances at the feed module, product modules, and separation modules are expressed by Eqs. (1) to (3), respectively.

$$\sum_{j=1}^{N_S+3} L_{0j} = L^F, \quad \sum_{j=1}^{N_S} V_{0j} = V^F \tag{1}$$

$$\sum_{i=0}^{N_S} L_{ij} \geq L^P_{j-N_S} \qquad (j = N_S+1, N_S+2, N_S+3) \tag{2}$$

$$\sum_{i=0}^{N_S} (L_{ij} + V_{ij}) = \sum_{i=1}^{N_S+3} L_{ji} + \sum_{i=1}^{N_S} V_{ji} \qquad (j = 1, 2, \ldots, N_S) \tag{3}$$

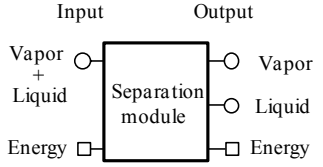

Figure 1 Input-output relationship at a separation module

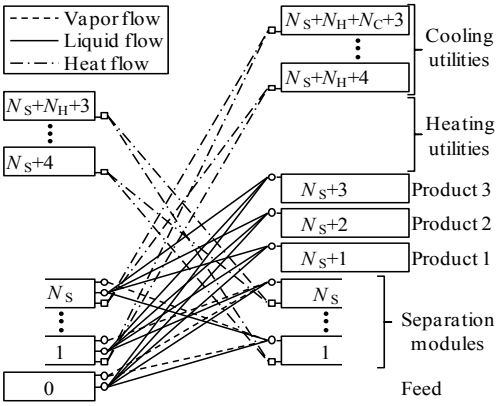

Figure 2 Superstructure of ternary distillation system

where L_{ij} and V_{ij} are liquid and vapor flow rates from module i to module j, respectively. L^{F} and V^{F} are liquid and vapor flow rates of feed, respectively. L_k^{P} is the minimum amount of kth product, and is given in advance. It is assumed that there is no vapor inlet flow to the product modules. The left hand side in Eq. (3) is the sum of inlet flows to module j, and the right hand side of Eq. (3) is the sum of outlet flows from module j.

The enthalpy balance at module j is expressed by Eq. (4).

$$\sum_{i=0}^{N_{\mathrm{S}}} L_{ij} h_i^{\mathrm{L}} + \sum_{i=0}^{N_{\mathrm{S}}} V_{ij} h_i^{\mathrm{V}} + \sum_{k \in U_j^{\mathrm{H}}} Q_{kj} = \sum_{i=1}^{N_{\mathrm{S}}+3} L_{ji} h_j^{\mathrm{L}} + \sum_{i=1}^{N_{\mathrm{S}}} V_{ji} h_j^{\mathrm{V}} + \sum_{k \in U_j^{\mathrm{C}}} Q_{jk} \quad (j = 1, 2, \ldots, N_{\mathrm{S}}) \tag{4}$$

where h_i^{L} and h_i^{V} are molar enthalpy of liquid and vapor flows from module i, respectively. Q_{ij} is the heat flow rate from module i to module j. U_j^{H} and U_j^{C} are sets of heating and cooling utilities which can be used at module j, respectively. By deciding the minimum approach temperature for heat exchange, the content of these sets can be decided in advance.

The specification of the kth product is given as the lower bound of the mole fraction of key component, x_k^{P}, and the corresponding constraint is expressed by the following inequalities:

$$\sum_{i=0}^{N_{\mathrm{S}}} L_{ij} x_{ij} \geq x_{j-N_{\mathrm{S}}}^{\mathrm{P}} \sum_{i=0}^{N_{\mathrm{S}}} L_{ij} \qquad (j = N_{\mathrm{S}}+1, N_{\mathrm{S}}+2, N_{\mathrm{S}}+3) \tag{5}$$

Since the composition is discretized in the proposed method, it is difficult to strictly satisfy the component balance at each separation module. Thus, the component balance at each separation module is given by inequality constraints:

$$-\varepsilon \leq \frac{\sum_{i=0}^{N_{\mathrm{S}}} (L_{ij} x_{ik} + V_{ij} y_{ik}) - x_{jk} \sum_{i=1}^{N_{\mathrm{S}}+3} L_{ji} - y_{jk} \sum_{i=1}^{N_{\mathrm{S}}} V_{ji}}{\sum_{i=0}^{N_{\mathrm{S}}} (L_{ij} + V_{ij})} \leq \varepsilon \quad (j = 1, 2, \ldots, N_{\mathrm{S}},\ k = 1, 2) \tag{6}$$

where ε is a parameter which shows the maximum acceptable error on the composition. (y_{i1}, y_{i2}, y_{i3}) is the vapor composition which is equilibrium to (x_{i1}, x_{i2}, x_{i3}).

In this research, we assumed that the column cost is negligible compared with the utility cost, and that the objective function, PI, is expressed by

$$PI = \sum_{k=1}^{N_{\mathrm{H}}} \left(c_k^{\mathrm{H}} \sum_{i=1}^{N_{\mathrm{S}}} Q_{N_{\mathrm{S}}+3+k,i} \right) + \sum_{k=1}^{N_{\mathrm{C}}} \left(c_k^{\mathrm{C}} \sum_{i=1}^{N_{\mathrm{S}}} Q_{i,N_{\mathrm{S}}+N_{\mathrm{H}}+3+k} \right) \tag{7}$$

where c_k^{H} (c_k^{C}) is the unit cost of kth heating (cooling) utility.

All of the equations and inequalities in Eqs. (1) to (7) are linear. Thus, the problem is formulated as a linear programming problem.

2.4. Prohibition of ineffective mixing

When the problem formulated in the previous section is solved, the obtained result has many flow paths among the modules. Some of them are caused by the effect of the discretization of the composition space. To avoid ineffective mixing at a module, flow paths that satisfy the following conditions are prohibited.

$$L_{ij} = 0 \ \text{ for } {}^{\forall}(i,j) \in \left\{ (i,j) \,|\, (\boldsymbol{x}_j - \boldsymbol{x}_i)^{\mathrm{T}} (\boldsymbol{y}_i - \boldsymbol{x}_i) > 0,\ i, j = 1, 2, \ldots, N_{\mathrm{S}} \right\} \tag{8}$$

$$V_{ij} = 0 \ \text{ for } {}^{\forall}(i,j) \in \left\{ (i,j) \,|\, (\boldsymbol{x}_j - \boldsymbol{x}_i)^{\mathrm{T}} (\boldsymbol{y}_i - \boldsymbol{x}_i) < 0,\ i, j = 1, 2, \ldots, N_{\mathrm{S}} \right\} \tag{9}$$

where $\boldsymbol{x}_i$ and $\boldsymbol{y}_j$ are vectors that show the liquid and vapor compositions of the output of module j. The qualitative meaning of these constraints is that the vapor of a module must flow into the module whose composition is richer in lighter components, and the liquid must flow into the module whose composition is richer in heavier components.

3. Case Study

The proposed method was applied to the separation problems of a benzene, toluene and o-xylene mixture. The feed is the saturated liquid of equimolar mixture of three components and its flow rate is 300 kmol/h. The pressure is assumed to be 101.3 kPa in entire system. The specification for each product is 0.80 for key components, and the flow rate of each product is 100 kmol/h. Only a kind of heating utility is available and its cost coefficient c^{H} is 11.0 \$/GJ, and only a kind of cooling utility is available and its cost coefficient c^{C} is 0.25 \$/GJ. The pitch of composition discretization is 0.025.

First, the vapor composition, temperature, and vapor and liquid enthalpies are calculated for each module. These values are calculated by the NRTL fluid package of Aspen HYSYS®. Then, Eq. (7) is minimized under the linear constraints of Eqs. (1) to (6) and Eqs. (8) and (9). CPLEX 12.5® was used for optimization.

The result is expressed in Fig. 3. The left figure shows the liquid flow paths, and the right figure shows the vapor flow paths. The obtained result still has many flows whose flow rates are very small so as to adjust the material balance. Thus, in Fig. 3, the flow paths whose flow rate is less than 10 % of product flow are not depicted.

In Fig. 3, separation modules are classified into six groups circled by dashed lines. When each group of modules is treated as a column, the process structure in Fig. 4 is obtained. In Fig. 4, solid and dotted lines express liquid and vapor flows, respectively. There are many vapor and liquid flows among the columns. However, by merging five columns, columns 2, 3, 4, 5 and 6, in Fig. 4, the structure shown in Fig. 5 is obtained. This structure is almost the same as the Petlyuk columns except that the obtained structure has several bypass flows among the columns.

4. Conclusion

A systematic synthesis method of a ternary distillation system was proposed. In the method, a tray is treated as a module, and the vapor and liquid flow paths are treated as design variables. By discretizing the composition space of the ternary system and assigning each composition to a module, all the constraints were expressed by linear equations. As the synthesis problem was formulated as a linear programming problem, the optimal structure could be obtained even when the problem size became large. The developed method was applied to the synthesis problem of a benzene, toluene and o-xylene mixture, and a process structure similar to the Petlyuk column was obtained. In the proposed method, there are no constraints on the flow paths among trays. Thus, the proposed method has a high possibility of generating innovative structures which are not derived by human experience.

In the current model, the column cost is not included in the objective function because a large number of 0-1 variables are needed to express the tray number of a process structure. Furthermore, there is no guideline on how to discretize the composition space. This guideline is essential, when purer products are requested or when azeotropes exist. These problems are regarded as future works.

Optimization and Analysis of Chemical Synthesis Routes for the Production of Biofuels

Douglas Allan, W. Alex Marvin, Srinivas Rangarajan, and Prodromos Daoutidis*

University of Minnesota, 421 Washington Avenue Southeast, Minneapolis 55455, USA
daout001@umn.edu

Abstract

In this work we extend a recently proposed method to concurrently select biofuel blends which satisfy ASTM standards and their optimal synthesis routes by using thermochemistry based post-processing analysis to compare these routes. Gas phase thermochemistry, estimated from group additivity, was used to calculate the equilibrium extent of reaction for each synthesis step. Situations of reaction, phase, and site coupling were subsequently identified to overcome equilibrium limited steps and reduce the number of reaction systems required. This method can aid process designers in screening and ranking large numbers of potential biofuel candidates and synthesis routes simultaneously from an energetic, thermochemical, economic, or kinetic standpoint.

Keywords: Optimization, Reaction network, Biofuels, Thermochemistry, Coupling

1. Introduction

Ethanol is currently the world's most common biofuel, with over 88 billion gallons being produced worldwide in 2013 (Renewable Fuels Association, 2014). However, its miscibility with water, lower heating value, and the high vapor pressures of ethanol-gasoline mixtures are significant drawbacks to its use as a gasoline replacement. Therefore, other oxygenates that can be derived from biomass have been proposed as alternate fuel components, such as 1-butanol and dimethylfuran (Christensen et al., 2011). Furthermore, olefins and alkanes that can be blended with gasoline can also be synthesized from biomass (Bond et al., 2010). To design blend components and their synthesis routes from biomass, Marvin et al. (2013) proposed a method to find the optimal synthesis route of a fuel additive that would be blended with an existing blendstock to create gasoline which satisfies ASTM specifications.

This method combines two chief components: a rule-based reaction network generator, RING (Rangarajan et al., 2012), and a mixed integer linear programming (MILP) problem. The former takes a set of biomass-derived oxygenates identified as possible platform chemicals (Bozel and Petersen, 2010) and uses reaction rules to exhaustively generate a network of reactions and intermediates that upgrade biomass to a plethora of compounds including the desired biofuel blend components. These reaction rules include aldol condensation, to create carbon-carbon bonds, dehydration, to break carbon-oxygen bonds, and (de)hydrogenation to remove oxygen, increase molecule size and saturate or unsaturate bonds as desired. This reaction network, represented by a stoichiometric matrix, is then used in the optimization problem. The optimizer solves the MILP problem subject to blending constraints. The objective function minimized is the total energy loss-the difference in low heating values between reactants and products-which is empirically

linked to the overall process economics. Thermodynamic data was generated for all the intermediate compounds using group contribution methods. A combination of group contribution methods and experimental data was used to ensure the resultant blend satisfied ASTM standards.

In this work we extend the above method by providing metrics and process analysis features to compare and contrast the multiple routes. At the algorithmic level we add post-processing to automatically identify equilibrium-limited reactions. Subsequently, we scan the solutions for possible site, phase, and reaction coupling. These features are applied to the gasoline blend networks generated in Marvin et al. (2013).

2. New Post-processing Features

We start by calculating the equilibrium extent of reaction, X, for each synthesis step in the gas phase, aiming to identify reactions and process conditions with strong equilibrium limitations (i.e. low X). The following expressions are used to this end:

$$exp\left(-\frac{\Delta G_j}{RT}\right) = \prod_i (y_i P)^{\nu_{ij}} \; ; \qquad -\frac{\Delta G_j}{RT} - \sum_i \nu_{ij} \, ln(P) = \sum_i \nu_{ij} \, ln(y_i) \tag{1}$$

$$y_i = \frac{n_i}{\sum_i n_i}; n_i = |\nu_{ij}|X \;\; if \; \nu_{ij} > 0; \; n_i = |\nu_{ij}|(1 - X) \; if \;\; \nu_{ij} < 0 \tag{2}$$

where y_i is the gas phase mole fraction of species i, n_i is the number of moles of species i, ν_{ij} is the stoichiometric coefficient of species i in reaction j, ΔG_j is the Gibbs free energy of reaction j, R is the ideal gas constant, P is the system pressure, and T is the system temperature. Since y_i increases monotonically with X for reactants and decreases monotonically for products, the right hand side in the second equation in (1) increases monotonically with X, and the left hand side must be maximized to maximize X. The only maxima with respect to pressure arise at the lowest or highest pressures in the optimization region, in accordance with Le Chatelier's principle. For temperature, there is the possibility of non-boundary optima. Taking the first two partial derivatives with respect to temperature we get:

$$\frac{\partial}{\partial T}\left(-\frac{\Delta G_j}{RT} - \sum_i \nu_{ij} \, ln(P)\right) = \frac{\Delta H_j}{RT^2} \; ; \quad \frac{\partial}{\partial T}\left(\frac{\Delta H_j}{RT^2}\right) = \frac{1}{RT^2}\frac{\partial \Delta H_j}{\partial T} - \frac{2\Delta H_j}{RT^3} = \frac{\Delta C_{p,j}}{RT^2} \tag{3}$$

where ΔH_j is the enthalpy of reaction j and where $\Delta C_{p,j}$ is the constant pressure heat capacity of reaction. The extrema with respect to temperature, therefore, occur when $\Delta H_j = 0$, and in order for an extremum to be a maximum, $\Delta C_{p,j}$ must be negative. Group contribution methods are used to calculate the heat capacity of each species. In the particular gasoline blend application, the search for maxima was limited to the range of 450-550 K, in order to balance concerns of phase change on the low end and thermal decomposition on the high end. With these restrictions in place, only 0.3% of the reactions in the network and only a single reaction in the top ten synthesis routes, have maxima which do not lie on the boundary of the temperature range. Equilibrium extents of reaction were calculated at 1 bar at 450 K, the optimal temperature, and 550 K using Newton's Method under the assumption of stoichiometric feed. Once the optimal Xs were obtained for each candidate synthesis route, the worst X and the number of reactions with optimal $X < 0.2$ were identified.

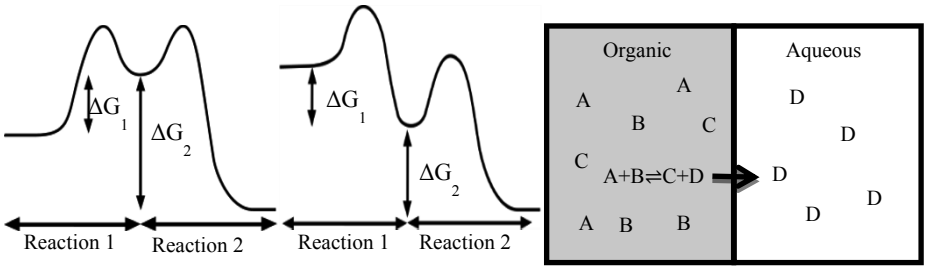

Figure 1. Free energy diagrams demonstrating reaction coupling (left) and site coupling (middle), and a diagram of phase coupling (right).

Many of the reactions can potentially have their *X* enhanced through coupling (Simonetti and Dumesic, 2009) to mitigate equilibrium limitations and to reduce the number of reactors/reaction systems required. Three possibilities arise: (a) reaction coupling wherein a spontaneous reaction consuming the products of an equilibrium-limited reaction can drive the equilibrium forward, (b) phase coupling - differences in hydrophobicity of reactants and products allow for in situ product separation, thereby driving an equilibrium-limited reaction forward or reducing cost of separation, and (c) site coupling whereby two equilibrium-favored reactions are combined in a single process. All of these are illustrated in Figure 1. For site coupling, the intermediate species needs to be consumed mostly or entirely in order to avoid creating a separation challenge. For reaction coupling, the second reaction must be spontaneous enough to increase the overall *X* of the two reactions. As a result, a free energy criterion can be chosen for the second reaction of both types of coupling. For the application here we chose: ΔG_2<-20 kJ/mol. It should be noted that the criterion for reaction coupling identifies potential candidates and the success of the coupling ultimately depends on the kinetics. For phase coupling, octanol-water partition coefficients (log P values), calculated using group contribution methods for all species, were used as a measure of hydrophobicity. Three criteria were used to establish phase coupling: that no two reactants have a difference in log Ps greater than 0.5, that at least two products have a difference of log Ps greater than 1, and that, excluding water, a difference of log Ps greater than 0.5 exists between reactants and products. The first ensures that the reactants do not have tendency to phase separate, the second ensures that the products do, and the third ensures that the coupling assists in separation.All situations which fulfill these criteria are automatically identified and reported in the optimization output, alongside the underlying thermochemistry.

3. Analysis of Gasoline Additives Synthesis Routes

The utility of these post processing steps will be demonstrated by applying them to the same system as in (Marvin et al., 2013). From the optimization results, four synthesis routes are presented here. Figure 2 contains the synthesis routes to create the blends listed in Table 1. These synthesis routes particularly show examples of potential coupling. All of these routes require some external hydrogen source. The two sources of hydrogen identified by the optimization are the decomposition of glycerol or methanol into hydrogen and carbon monoxide. The carbon monoxide is converted into more hydrogen using the water-gas shift reaction. Note that in the second sequence, the ethanol in the final blend comes from the hydrogenation of acetaldehyde. Many of these reactions have been proposed in the literature (see Marvin et al., 2013).

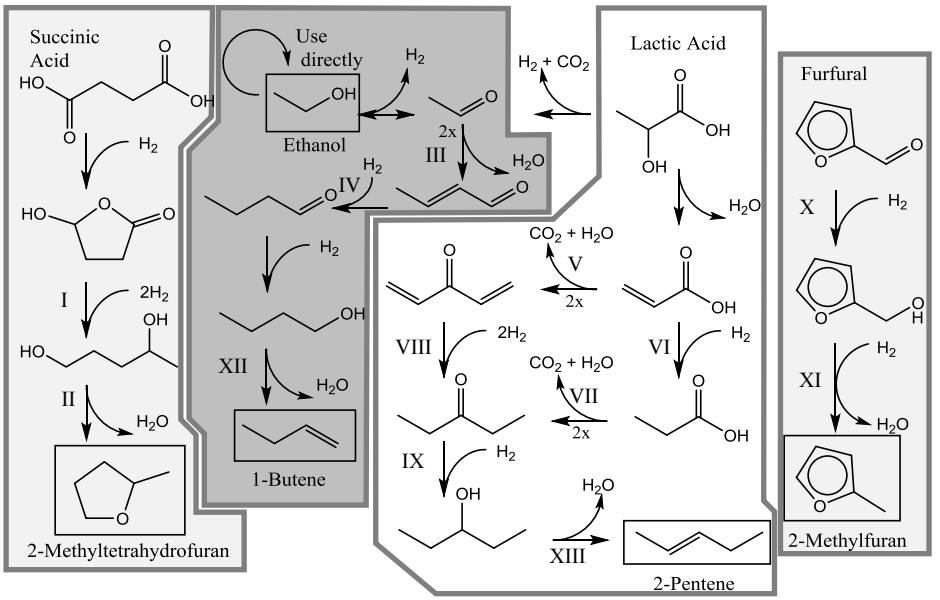

Figure 2. Diagram of the chosen synthesis routes.Note that "2x" denotes a dimerization reaction. Certain reactions are numbered for easy reference in the text.

Reaction I has $X < 10^{-4}$ at both 450 and 550K. It does have a favorable enthalpy of reaction, but this is overbalanced by the loss of entropy from the consumption of two gas phase molecules. This suggests a condensed phase reaction at much lower temperatures and high pressures, but that might not be sufficient to achieve an adequate *X*. Reaction II is equilibrium favored, and could potentially help drive Reaction I if they were conducted together, although reducing temperature and increasing pressure would probably still be required. Reaction II also has optimum *X* at 456 K, and as such is the

Table 1. Reactant and blend fluxes for the four presented blends. The same blendstock used by Marvin et al (2013) is used here.

Synthesis Route:		1	2	3	4
Reactant flux in 10^{-3}mol/min	Ethanol	3.79		1.00	4.01
	Lactic Acid		4.73		
	Succinic Acid				1.23
	Furfural			0.61	
Blend flux in 10^{-3}mol/min	Ethanol	1.05	1.06	1.00	1.08
	1-Butene	1.37	0.65		1.46
	2-Pentene		1.18		
	2-Methylfuran			0.61	
	2-Methyl THF				1.23
	BOB	7.95	7.56	8.22	6.93

only reaction presented here with a non-boundary optimum. The synthesis route from acetaldehyde to 1-butene is important to all but one of the pathways presented here. The aldol condensation of acetaldehyde (Reaction III), however, is equilibrium limited, with $X = 28\%$ at 550K. Its equilibrium cannot be manipulated by changing pressure. However, it has potential for both reaction and phase coupling. 2-Butenal is lipophilic, with a log P equal to 0.76. As a result it will phase separate from the released water, and the equilibrium can be driven forward. Second, the hydrogenation of 2-butenal's carbon-carbon double bond (Reaction IV) is very thermodynamically favorable, and by carrying out these reactions together, the first step's equilibrium can potentially be driven forward. The self-ketonization and hydrogenation of acrylic acid (Reactions V through IX) to make 3-pentanol is a sequence which could benefit from site coupling. As is shown in Figure 2, options exist for the order of the ketonization and hydrogenation. Thermodynamics allow for the site coupling of the self-ketonization of acrylic acid with the subsequent hydrogenation of the carbon-carbon double bonds. However, it is simpler to site-couple the hydrogenation steps together. Finally, the consecutive hydrogenation of furfural into 2-methylfuran is an instance of site coupling identified by both our method and Yan et al (2014). Reactions XII and XIII are spontaneous at both 450K and 550K, but the large difference in log P between reactants and products suggest that they could be carried out at much lower temperatures and without a subsequent extraction step using phase coupling.

From an equilibrium perspective, Route 4 seems to be infeasible. Significant work is needed to achieve an adequate X in Reaction 1, and the other three routes are much more promising. In Routes 1 and 3, the dehydrogenation of ethanol has $X = 18\%$ at 450K, but can be run at 550K for a much better $X = 71\%$. In Route 2, the hydrogenation of 3-pentone has $X = 2\%$ at 550K, but can achieve 22% at 450K and would improve at lower temperatures. Kinetic considerations favor high temperature reactions, but safety considerations favor milder conditions. Routes 2 and 4 contain 13 and 10 reactions, respectively, while Route 1 only contains 5. However, Route 2 synthesizes its own ethanol from lactic acid while Route 1 uses ethanol as a reactant. Route 4 contains

Reaction	ΔG_{rxn} (kJ/mol)	ΔH_{rxn} (kJ/mol)	ΔS_{rxn} (J/(molK))
I	47.8	-47.4	-190.

III	14.2	7.8	-12.8
IV	-66.2	-125	-119.
V	-60.7	4.4	130.
VI	-74.1	-136.	-125.
VII	-55.0	8.8	127.
VIII	-142.	-268.	-252.
IX	8.2	-56.5	-129.
X	8.2	-54.1	-125.
XI	-102.	-101.	1.7

Table 2 (left) contains ideal gas reaction thermochemistry calculated at 500K for selected reactions. Table 3 (bottom) contains the calculated log P values for selected species.

Species	Log P
	0.21
	0.76
	0.78
	1.58
	1.17
	1.97

Route 1 within it, supplementing Route 1's blend with 2-methyltetrahydrofuran. It should be noted that the high number of reactions in Routes 2 and 4 come from parallel, not serial reactions. Not counting hydrogen generation reactions, at most 5 reactions occur in series in Routes 1, 2 and 4, and only two occur in series in Route 3. This analysis has focused on equilibrium properties, but information about reaction kinetics would be necessary to determine what operating temperatures and pressures are feasible.

4. Conclusion and Future Work

Reaction thermochemistry was used to evaluate different synthesis routes for biofuel blends on the basis of equilibrium extent of reaction (*X)* and potential for coupling. The conditions which give optimal *X* for an ideal gas reaction system were derived and the optimal *X* for the reactions present in these synthesis routes were found. Reactions with low *X* were identified, and potential instances of reaction, phase, and site coupling were identified to help compare synthesis routes. Routes 1-3 are all viable based on equilibrium concerns, and they all benefit from moderate amounts of coupling. The final decision between those routes would require a more detailed analysis of kinetics as well as analysis of feedstock costs. The current objective function only takes into account the synthesis route's absolute heat duty, and a more complicated objective function could factor in feedstock cost and equilibrium concerns. Each reaction's thermochemistry and *X* are automatically calculated prior to the optimization, so a complex objective function could easily factor in a term penalizing equilibrium-limited reactions.

Design and Economic Evaluation of Coal to Synthetic Natural Gas (SNG) Process

Bor-Yih Yu and I-Lung Chien

[a] *Department of Chemical Engineering National Taiwan University Taipei 10617, Taiwan*

Abstract

In this work, the steady state design and the economic evaluation for coal to Synthetic Natural Gas (SNG) process are rigorously studied. For those countries which lack energy resources, importing natural gas is very costly due to the requirement of liquefaction and compression. SNG holds very similar composition and heat value to typical natural gas, and can be used as a replacement directly in industrial and home usages. Thus, producing SNG from gasification route will be an attractive alternate for those countries which lack energy sources. From the simulation results, the plant-wide energy conversion efficiency is about 60.38%, and the SNG production cost is 11.433 (USD/MMBTU).

Keywords: Coal; Synthetic Natural Gas (SNG); Process Simulation; Economical Evaluation

1. Introduction

Natural gas has long been considered as a cleaner energy source all over the world, due to its lower C/H ratio. In Taiwan, there are several natural gas power plants that provide electricity to local industries, with over 1300 MWe generated each year. The largest natural gas power plant is in Datan, Taoyuan, which has six NGCC cycles and produces about 438 MWe, to support the electricity needed in northern Taiwan. Thus, natural gas utilization is important in our country.

However, over 99% of annually energy source depends on importation in Taiwan. For Natural gas, it is imported in form of Liquefied Natural Gas (LNG), and the requirement of liquefying and pressurizing makes the importation price expensive (ranged from 15~18 USD/MMTU). Compared with LNG, coal has good advantages of lower price, great abundance, and easier transportation. These advantages lead to the fact that coal is the major energy source used annually in Taiwan. Thus, the route that converts coal into SNG is expected to have both practical and economical advantages. SNG is a product with similar composition as natural gas, which can be used as a replacement of natural gas directly.

In this work, the design and the economical evaluation of a plant-wide coal to SNG process are illustrated. The conversion process starts from gasification to form syngas, and the syngas is then passes through the treating section, including Water-Gas-Shift Reaction (WGSR), Acid Gas Removal (AGR), and finally methanation section to form SNG. The possible heat integration strategy and waste heat recovery in/between different parts are also proposed to produce electricity for using inside the coal to SNG plant. After designing, the plant-wide economical evaluation is studied based on the proposed economic model. The SNG production cost is calculated and compared with the importation price of LNG in Taiwan.

Although the concept of gasification-based process has been proposed earlier, the overall detailed analysis of the plant-wide process with rigorous modeling for each part inside the process is rarely found. The primary aim of this work by the authors is to provide a baseline analysis for coal to SNG process for Taiwan, and any other country holds similar situation as Taiwan. Due to the recent decrease of oil price, there might be other alternative ways to generate syngas for producing SNG. The authors are welcome possible improvement and suggestions for further design of the plant.

2. Design of Coal to SNG Process

The overall block flow diagram for Coal to SNG process is illustrated in Figure 1. The plant-wide process is describing in detail separately in the following subsections. In this work, Aspen Plus V7.3 is used for simulation. The reactions included in the system are listed in Table 1, while the coal properties are listed in Table 2. The detailed information for the process is illustrated in the work by Yu and Chien (2015).

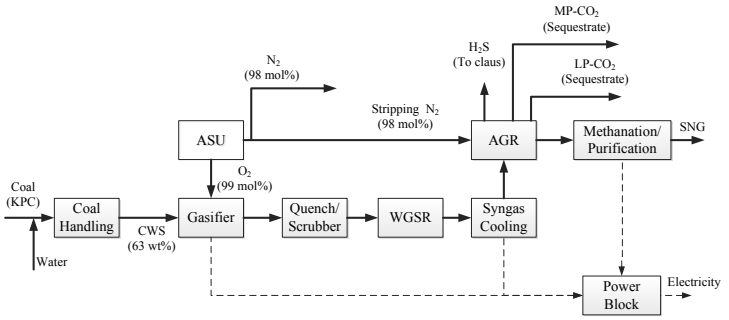

Figure 1. Overall block flow diagram of coal to SNG process.

2.1 Coal Handling

In coal handling section, the coal is uploaded from the silo, dried, crushed, screened, and then transported to plant. In this SNG plant, the gasification system is operated by a slurry-feed, entrained flow gasifier. Thus, a step for slurry preparation is necessary. The processed coal sample in this work is Kaltim-Prima coal (KPC) from Indonesia, which actually imported in Taiwan annually.

2.2. Air Separation Unit and Gasification

Cryogenic separation is used to produce large quantities of pure oxygen and nitrogen. The whole process can be divided into four blocks, including Main Air Compressor (MAC), further compression, Main Heat Exchanger (MHE), and rectifying section. The purity of the oxygen product is assumed to be 99 mol%, so that the amount of inert compounds sent into gasifier could be decreased to let the heat value of final SNG product meet regulation. For nitrogen product, it can be used in recovering the physical solvent in AGR, as well as in ammonia plant downstream. The purity of nitrogen product is set as 98 mol%, with the remainder to be 0.93% Ar and 1.07% O_2.

For gasification system, an industrial scale, slurry-feed, entrained flow, oxygen blown gasifier is used to convert coal into syngas. It is simulated by a simplified 1-dimensional kinetic gasifier model proposed by Yu and Chien (2015). The processed coal flow rate is 240 (ton/hr), with two gasifier trains operate in parallel. The residence time inside

gasifier is assume to be 3 seconds, the operating pressure is 56.7 (bar). The coal particle is assumed to be homogeneously spherical, with 80 (μm) diameter.

At gasifier outlet, a Radiant Syngas Cooler (RSC) is used to cool the syngas. High temperature syngas is slowly cooled by heat exchange with cooling medium, thus an amount of heat could be recovered as medium (or high) pressure steam. Due to the low cooling rate for radiant quench, some reversible reactions, mainly WGSR, is expected to continue even if the raw syngas has already left gasifier. The raw syngas is cooled to 866 K in RSC as suggested by Tampa Electric Company (2002).

After RSC, a water quench unit is used to cool the syngas to its dew point. The outlet temperature of syngas after water quench is 472 K. The low temperature quench water is having direct contact to syngas, which makes it cool quickly without any remaining reactions. After the water quench, a scrubber is used to wash out the solvable components in raw syngas.

2.3 Syngas Treating Section: WGSR, Syngas Cooling, AGR, and methanation

In this work, the H_2/CO ratio is adjusted to 3.5 by WGSR to enhance the reaction rate of methanation stage. Besides, the sulfur content in coal is appeared in the form of carbonyl sulfide (COS) in syngas, it will also be hydrolyzed to hydrogen sulfide (H_2S)

in WGSR stage. The reaction catalyst for COS hydrolysis is aluminum-based, while the catalyst for WGSR is Mo/Al_2O_3, which will not deactivate under the presence of sulfur.

Because WGSR is exothermic and the reactor is operated in adiabatic mode, the reacted syngas should be further cooled to the operating temperature in AGR. The cooling step is separated into three stages, and part of the waste heat could be recovered by generating different levels of steam. Process condensate contains water and other soluble contaminants that removed from the syngas, which need to be further treated before disposed or recycled.

In Acid Gas Removal (AGR) process, H_2S and CO_2 are captured in two stages. The captured H_2S could be sent into Claus process for sulfur recovery, which is not considered in this work, while CO_2 is assumed to be compressed and sequestrated. In this work, SELEXOL process is used for AGR, in which a mixture of diethylene glycol is used as the solvent. For simulation, PC-SAFT is chosen as the thermodynamic model, with the binary interaction parameter cited from literature, and the aspen built-in DEPG component is used to represent the solvent (Field and Braisington, 2011). The capturing targets are assumed to be 99.7% for H_2S and 92% for CO_2.

The operation of AGR process is complex, with many operating variables to be determined. Thus, in order to simplify the problem, several assumptions are made. First, the temperature of DEPG solvent is assumed to be 283 K. Second, the pressure for the H_2S absorber is set at 5.17 MPa, while 3.03 MPa for CO_2 absorber. Third, the pressure level of the regenerative flash units is assumed to be 1.9/0.9/0.15 (MPa). Finally, because the boiling point of DEPG solvent is very high, the thermal regeneration is expected to operate at a vacuumed pressure (0.02 MPa).

In optimization works, three design variables are selected to study, including the total stage of H_2S absorber (NT_{H2S}), total stage of CO_2 absorber (NT_{CO2}), and the pressure of the concentrator (P_{CONC}). The objective function for AGR is minimized total annual cost. Based on the above assumptions, the optimized opeating condition will be at NT_{H2S} equals to 60, NT_{CO2} equals to 14, and P_{CONC} at 2.21MPa.

In methanation reaction section, a configuration with four adiabatic reactors in series and inter-stage cooling is arranged to react the treated syngas from AGR to form SNG. The possible reactions and the references for kinetic data are also listed in Table 1. The overall process could be roughly divided into two stages, High Temperature Reaction (HTR) stage and Low Temperature Reaction (LTR) stage. This is because methanation reactions are exothermic, thus the reaction equilibrium is favored to the product side at lower temperature.

After the two-staged methanation reaction, the produced gas still contains some CO_2 and H_2O, thus another separation step is required. In this work, molecular sieve is used to separate 99% of remaining CO_2 and all water inside the SNG product as suggested by DOE/NETL (2011). The treated SNG is then compressed to the pipeline pressure, and cooled to required temperature. The molar composition of final SNG product is 95.5% CH_4, 4.2% for combination of N_2 and Ar, while CO is only 7 ppm. The high heat value of SNG product is 36.06 (MJ/m^3), which matches the regulation.

2.4 Power Block

The waste heat inside the system is recovered by generating different level of steam through a Heat Recovery Steam Generator (HRSG). Most of the generated is used to

drive steam turbine for producing electricity, while the remainder of them could be used in the SNG plant. Apart from the SNG product, the net electricity produced (29.15 MW) is viewed as the bonus from the plant-wide process.

2.5 Summary

The overall energy conversion efficiency for this SNG plant is at 60.39%; for energy that transferred from coal to SNG, it is at 58.66%.

3. Economic Evaluation

In According to open literature (Chen, 2005; DOE/NETL, 2011), the items to be studied include capital investment (CAPIN), fixed operating and maintenance cost (Fixed O&M cost), and variable operating and maintenance cost (Variable O&M cost). Each part is explained in detail separately.

In this study, for CAPIN calculation, the cost parameters and terminology used are based on the methodology developed from Electric Power Research Institute (EPRI). The input parameters, the calculation stage, and the items for calculating capital expense for coal to SNG plant include direct and indirect construction costs, general facility cost, engineering & home office fees, project and process contingency costs, royalty fees and start-up costs.

For calculating Fixed O&M, The items studied in this part are operating labor cost, maintenance cost, taxes and insurances, and administrative and support cost. For Variable O&M, the items studied are fuel price, maintenance material cost, consumable cost, and also the profit of by-products. Here in this work, the coal price sold by Tai-power company in Taiwan is used. The primary by-products are sulfur and electricity for this SNG plant. However, KPC is coal sample with very low-sulfur content, thus the credits for selling sulfur is omitted in this work. The consumables included the cost for WGSR catalyst, methanation reaction catalyst, and DEPG solvent that used in AGR.

In this work, a simpler financial structure is assumed that only inflation rate and capital depreciation are accounted. It is assumed that the operation target is that the payback period for capital investment is 20 years, with 3.5% inflation rate during the operation period. All the capital investment will be linearly depreciated in 20 years. According to Gibsin Engineers, Ltd (GIBSIN), a Taiwan-U.S. joint venture consulting company, these assumptions will be corresponded to the investment regulation for public enterprises in Taiwan.

The results for CAPIN, fixed O&M and variable O&M are listed in Table 3. The detailed information for the economics is also illustrated in the work by Yu and Chien (2015).The production cost is calculated in US dollar per unit heat value of SNG, thus the overall energy conversion efficiency will also influence the results of economical evaluation. Here in this work, the calculated SNG production cost is at 11.433 (USD/MMBTU), which is much less than the LNG import price in Taiwan (15~18 USD/MMBTU). If this SNG plant could be co-operated with other country that has large amount of coal reserves, the SNG production cost will become even lower. It seems to be economically attractive for Taiwan in the foreseeable future.

Table 3. Energy and Economic calculation results

Economic Calculation Result		**Energy Calculation Result** (unit: MW)	
CAPIN	3.871	Energy input (Coal)	1690.45
Fixed O&M	1.276	Energy Output(SNG)	991.63
Variable O&M	6.286	Energy Output (Electricity)	29.15
Total Cost	11.433	Overall Energy Conversion	60.38(%)
(Unit:USD/MMBTU)		Coal to SNG Energy Conversion	**58.66(%)**

4. Conclusions

In this work, the plant-wide Coal to SNG process is rigorously studied. Coal is first converted to syngas through gasification, adjusted composition by WGSR, cleaned though AGR process, and reacted to form SNG through methanation reaction. A waste heat recovery system is also studied to produce different levels of steam, and then it is used in the SNG plant or to generate electricity for auxiliary use. From economical evaluation, the cost to produce SNG is at 11.433 (USD/MMBTU), which is much lower than the price to import LNG in Taiwan. Thus, to establish a SNG plant will have practically and economically advantages in the near future.

Abstract

An industrial park is a cluster of multiple company individuals, so there is requirement to develop specific reuse strategies to improve the utilization of resources across plants. Differing from the direct reuse strategy of 'unit-based' mode which is originally proposed for intra-plant water integration, this article presents a 'plant-based' mode for water allocation within industrial parks. Wherein, mixers and splitters are involved to present the mixing, transmission and splitting operations for reusing streams across plants. Such that, the mixing possibilities can also be investigated and many redundant solutions can be avoided by considering the number limit of inter-plant stream connections at the building stage of network superstructures. On base of this mode, both direct and direct-indirect-mixed integration problems are studied in this study. Superstructures are established and mathematically formulated aiming to the minimum fresh water consumption. At last, an example from literature is illustrated. With the obtained results, the effectiveness of the approach has been successfully demonstrated.
Keywords: inter-plant, allocation, water network, industrial park, superstructure

1. Main Text

Nowadays, the shortage and pollution of water have become serious barriers to the development of human society. As a promising way of planning individual plants, industrial parks can provide more opportunities for resources saving and sharing, as well as the centralized treatment of waste. So exploring the reusing possibility in industrial parks, especially investigating the allocation, using and regeneration by breaking process or plant boundary limits would be very meaningful for the global saving and pollution reduction of water in process industries.

Olesen and Polley (1996) carried out the earliest water integration study for inter-plant problem in 1996. However, an extensive discussion about this issue was mainly concentrated in last seven years. Wherein, Lovely et al. (2007) proposed an optimization approach so as to reduce the water consumption and discharge in pulp and paper plants. Later, source-interception-sink representation was used by Castro et al (2012) to retrofit existing networks for eco-industrial parks. Chew and his co-workers have conducted a series of works about inter-plant water integration, including the proposing of direct and indirect integration schemes (Chew et al. 2008), an automated targeting technique based on pinch technology (Chew and Foo, 2009), and the application of game theory (Chew et al. 2009). In order to improve the practicability of system, Chen et al. (2010) presented a mathematical model for integration by placing central and decentralized water mains within and between individual plants. Boxi et al.

(2012) studied a multi-objective optimization problem, in which the fresh water, regenerated water as well as the connection number were minimized. Then in the recent reports, the flexibility and multi-period water planning problem of industrial parks have been discussed by Montastruc et al. (2013), Bishnu et al. (2014) and Avios (2014).

In mentioned works, the 'unit-based' mode would generate many redundant solutions when having connections limits for streams. To avoid this defect and also to consider the allocation of water from plant but unit, a so called 'plant-based' mode is proposed in this study. Based on this mode, the direct integration and the mixed integration, which is studied as the combination of direct and indirect integrations in this work, are both developed for synthesis.

2. Problem Statement

Aim of the work is to make an optimal management of water, respecting to the overall consideration of process requirement of each plant in an industrial park. In this study, the water network synthesis task is illustrated via an industrial park example from Olesen and Polley (1996) and Chew et al. (2008). Table 1 has shown the flow rate and concentration limits of 15 water sources and 15 sinks in example. These sources and sinks, being distributed into three individual companies (A, B and C) as indicated, will be schemed to constitute the intra-plant networks as well as the inter-plant portion. Synthesis purpose is to achieve an optimal network for the park, where all water sources are well managed to satisfy the requirement of sinks. Within the numerous alternatives, the selected network should feature the minimum fresh water consumption and the lowest inter-plant delivery amount of water.

Table 1. Limit data of example

water network	sink SK_j	flowrate F_{SK} ($t \cdot h^{-1}$)	concentration C_{SK} (ppm)	source SR_i	flowrate F_{SR} ($t \cdot h^{-1}$)	concentration C_{SR} (ppm)
A	1	20.00	0	1	20.00	100
	2	66.67	50	2	66.67	80
	3	100.00	50	3	100.00	100

	8	15.63	80	8	15.63	400
	9	42.86	100	9	42.86	800
	10	6.67	400	10	6.67	1000
C	11	20.00	0	11	20.00	100
	12	80.00	25	12	80.00	50
	13	50.00	25	13	50.00	125
	14	40.00	50	14	40.00	800
	15	300.00	100	15	300.00	150

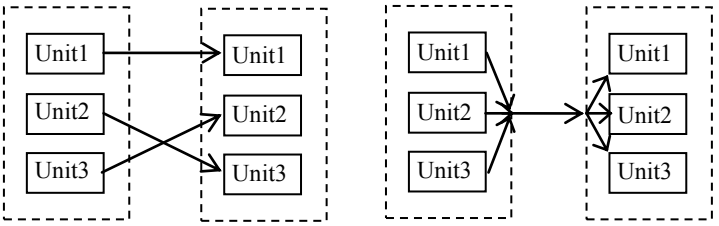
3. Method

3.1. Proposing of plant-based mode

Resource sharing is one of the most important characters of industrial parks. To promote sharing, the distribution of materials between companies should be studied. In previous works, the 'unit-based' mode was always directly applied to manage the inter-

plant water, through building direct connection from a source unit to a sink unit as Figure 1-(a) shows. However, this will on one hand limit the participation of sources because there usually has number constraint toward the stream connections between plants. And on another hand, will generate many infeasible solutions because of the excess inter-plant connections during synthesis. To avoid above defects, a so called 'plant-based' mode is proposed in this study.

A basic structure of 'plant-based' mode is presented in the schematic diagram of Figure 1-(b), in which the sources of a same plant are intensively delivered to another plant and distributed to sinks as shown. Such that the allocation/reuse of water between plants is no longer directly dependent on the outlet streams of sources but that of plants. In another words, the monitoring on each source is moved to the outlet of each plant. This change of allocation/reuse will produce more possibilities for crossing-plant streams especially when their number is strictly limited. Jump out of Figure 1-(b), it's worth noting that the mixing and splitting points of each plant can be multiple if allowed. In this study, the proposed 'plant-based' mode is applied to construct networks for the optimal synthesis.



(a) Unit-based mode (b) Plant-based mode

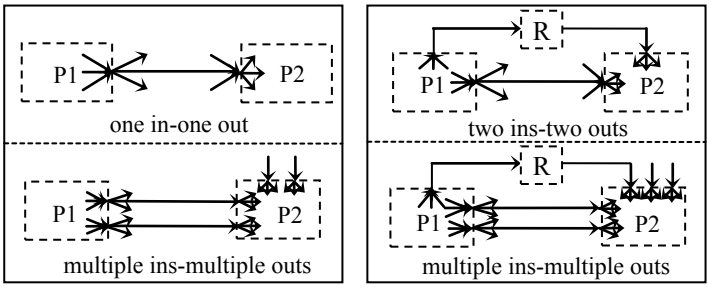
Figure 1. Sketch of inter-plant allocation modes

3.2. Direct and mixed integration superstructures

Define direct integration of reuse are only carried out via cross-plant pipelines, while the indirect kind must go through a centralized regeneration unit. In this article, direct integration and the mixed integration which combines direct and indirect allocation together are both studied to design the water networks within industrial parks.

On basis of 'plant-based' mode, the superstructures presenting cross-plant allocation for direct and mixed water integration are displayed in Figure 2-(a) and (b), respectively, wherein the allocation superstructures for plants are not detailed because they follow a general allocation pathway of 'unit-based mode'. In 'plant-based' mode, cross-plant steams are intensively collected and distributed through mixers and splitters. This way, the in and out steams of plants are able to be used to define superstructure schemes when considering connection complexity. Two typical scenarios are both provided in Figure 2-(a) and (b). For direct integration, 'one in-one out' scenario means one collected stream at most will run out of a plant, then after the inter-plant allocation, one collected stream at most will enter a plant. To investigate more in and out alternatives, the bottom half of Figure 2-(a) has given a scenario having multiple inlets and outlets for a plant. Regeneration operation (indicated with R) is considered in mixed water integration in this study. Add R into Figure 2-(a), then the two scenarios of mixed integration superstructures are presented as Figure 2-(b) shows. Through analysis, two major features of the proposed superstructures can be condensed into:

(1) the number constraint of inter-plant stream has been considered at the building of network superstructure, so there will not generate many redundant solutions.
(2) by adjusting the numbers of mixing and splitting operations, the superstructures in this paper are able to cover the all 'unit based' connection possibilities.



(a) Direct integration (b) Mixed integration

Figure 2. Sketch of direct and mixed integration

3.3. Synthesis and optimization

Alternatives consisted in network topologies of Figure 2 should be investigated and contrastively analyzed in order to do an appropriate decision-making for planning. To carry out this work, mixed integer non-liner programming mathematical models are formulated respecting to the superstructures of different design scenarios. The optimization process is carried out in two steps, where the fresh water consumption is obtained at first and the inter-plant water flow rate is minimized on its basis then. The inter-plant connections between plant and plant, as well as between regeneration unit and plant, should comply with the number constrain. The final results should tell the network details, including concentrations, flow rates, inter-plant stream number, network structure, fresh water consumption, as well as the collection and redistribution of water among individual plants.

4. Problem Solutions

The optimization problem mentioned in Section 2 was solved by means of CPLEX GAMS. In which, the 'one in-one-out' superstructure of direct integration and 'two in-two out' superstructure of mixed integration are both implemented and coded for synthesis. To get rational results from the consideration of actual practice of transportation, set lower boundaries to cross-plant flow rate and intra-plant flow rate as 5 and 0.5 $t \cdot h^{-1}$, respectively.

Apply the two-steps optimization procedure to minimize fresh water consumption and inter-plant water flow rate orderly, then the direct integration results are obtained and summarized in Table 2. At a same inter-plant connection number it can be noted that, the minimum fresh water requirements received in this study are all no larger than that in literature, and the total inter-plant water flow rates follow about the identical relation if the fresh water consumptions are close (as the cases of connection number=2 and 4 indicate). These results can demonstrate the ability of centralized operations (mixing and splitting) on providing more stream options for their reusing into other plants. Figure 3 showing is the network structure of connection number=3 in this study.

Table 2. Results comparisons

content	literature (Chew et al. 2008).			this paper		
minimum fresh water /t·h^{-1}	316.3	316.4	314.4	316.3	314.4	314.4
minimum inter-plant water /t·h^{-1}	61.2	78.5	97.0	61.7	87.8	74.1
inter-plant connections	2	3	4	2	3	4

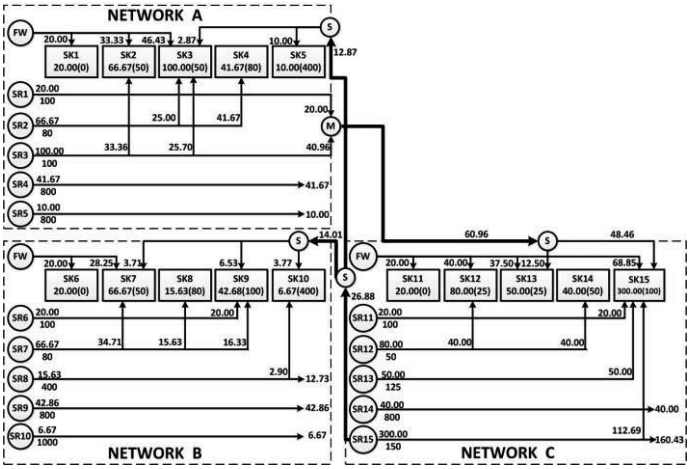


Figure 3. The optimal water network for direct integration

Figure 4. presenting is the optimal network of mixed integration at regeneration rate of 0.5, unit cost of 1.160 $ for per kg removed impurities (Chew et al. 2008). This network features of 138.5 t·h^{-1} fresh water consumption and 557.5 t·h^{-1} inter-plant water. This mixed integration has considered the possibilities of direct reuse, however none exists between any two plants in Figure 4. Observe Figure 3 and Figure 4, then one common feature can be found that: the two networks both have mixers (presented by M) and splitters (presented by S) involved rather than having only direct unit-to-unit inter-plant connections. Thus results can show the necessity of considering mixers and splitters, and also demonstrate the reasonability of the 'plant-based' method.

5. Conclusions

A 'plant-based' mode has been developed for inter-plant water allocation of industrial parks in this work. By involving mixers and splitters, this mode is able to include more inter-plant reuse possibilities and also reduce redundant solutions at the building stage of network superstructures. On its basis, both direct and mixed integration were studied for synthesis, wherein the network superstructures of several scenarios have been presented. Finally for verification, an example adopted from literature was solved for illustration, and the results indicated that the involving of mixing and splitting operations would generate a better solution.

Energy-saving design and control of a hybrid extraction/distillation system for the separation of pyridine and water

Yi-Chun Chen, [a] I-Lung Chien[a*]

[a]*Department of Chemical Engineering, National Taiwan University, Taipei 10617, Taiwan*
ilungchien@ntu.edu.tw

Abstract

In this study, design and control of a hybrid extraction/distillation system for the separation of pyridine and water are studied. The same separation has been studied in the previous paper (Wu et al, 2009) by using the design of a heterogeneous azeotropic distillation system where a two-column heterogeneous azeotropic column system was devised making use of the new minimum-boiling azeotrope between toluene and water. A further intensified dividing-wall column was recently proposed by Wu et al. (2014) to thermally-couple the two columns for further reduction of the overall reboiler duty.

In the hybrid extraction/distillation design, pyridine is extracted from aqueous solution by using N-propyl formate as a solvent in an extraction column. Combining two strippers with the extraction column, a simple hybrid extraction/distillation process can be devised achieving the same product purity specifications as the original design. By comparing the optimized design of this newly proposed system with the previously mentioned heterogeneous azeotropic design, significant reductions of 58.8 % in the total annual cost and 65.6 % in the steam cost can be obtained. Furthermore, in comparison with the complex design of dividing-wall column system, this proposed hybrid extraction/distillation system can still significantly save total annual cost and steam cost by 41.2 % and 50.8 %, respectively.

The plant-wide control of the proposed system is also studied. Overall control strategy with tray temperature control loops are proposed for the plant-wide control structure. The dynamics results show a trade-off between economical design and controllability due to selecting of an optimal solvent flow rate at low constraint in the design stage. However, the case with 20% more solvent (which results in 6.15 % more total annual cost than the optimized case) is capable of holding product qualities under various feed disturbances by a proposed plant-wide control structure.

Keywords: hybrid extraction/distillation system, plant-wide control, separation

1. Introduction

The use of hybrid extraction/distillation system is a very promising process design, allowing significant energy reduction for the separation of azeotropic mixtures without a reboiler. In this study, a pyridine and water separation system that was studied by Wu and Chien (2009) will be used as a demonstrating example to investigate the energy-saving potential of the hybrid extraction/distillation system.

In Wu and Chien (2009), a two-column heterogeneous azeotropic column system was devised making use of the new minimum-boiling azeotrope between toluene and water. However, from residue curve maps and material balance lines of this system, potential economical pitfall of this heterogeneous azeotropic distillation processes can be predicted due to large recirculation rate inside the system. In Wu et al. (2014), a dividing-wall column design for the same separation system was proposed to thermally-couple the two columns for further reduction of the overall reboiler duty. Nevertheless, the design flowsheet and the control structure are more complex and more interactive than the conventional column system. In this study, a conventional design of hybrid extraction/distillation system is proposed. Moreover, economical analysis and energy consumption of the proposed design are compared with that of the previous mentioned heterogeneous distillation design and the dividing-wall column design.

Besides the issue on energy-saving, dynamics controllability of the hybrid extraction/distillation system will also be closely examined. Certain amount of solvent is necessary for the extraction process. Less solvent leads to less total annual cost (TAC), but reduce the controllability of the system. Thus, a trade-off between economical design and controllability is observed for this studied system.

2. Conceptual Design and Simulation Details

The hybrid extraction/distillation system includes a liquid-liquid extraction column following by two strippers, as shown in Figure 1. Liquid-liquid extraction, which is also known as solvent extraction, is a method to separate compounds based on their relative solubilities in two different immiscible liquids, usually water and an organic solvent. For the extraction process in the proposed design, pyridine is extracted from aqueous solution by using N-propyl formate as a solvent in a countercurrent extraction column. The extract contains most pyridine and solvent and is further purified in a stripper (named STRIP1) to obtain high purity pyridine as bottom product; the raffinate contains very little pyridine and mostly water will also be purified in a stripper (named STRIP2) to obtain high purity water as bottom product. Top vapor products of both strippers will be cooled down by coolers separately, and fed into a decanter where two liquid phases will form. The organic phase contains mostly the solvent, and is treated as recycled solvent used repeatedly in the extraction column; the aqueous phase contains almost the same composition as the raffinate, and thus is combined with raffinate stream as the feed to STRIP2. Two specifications are met for all simulations. The bottoms of STRIP1 is kept to be 99.9mol% pyridine, and the bottoms of STRIP2 is kept to be 99.9mol% water.

There are four design variables for the proposed design flowsheet which are total number of trays for each stripper, total number of extraction column stages, and the ratio of extraction solvent and fresh feed flow rate. The ratio of extraction solvent and fresh feed flow rate is the most important design variable, and should be assigned as the outer-most variable in the optimization procedure. All product specifications are met in the optimization steps. Figure 2 shows the simulation result. Note that from Figure 2, the optimized case reaches a low constraint for the system. When using less entrainer, no more converge run can be obtained because certain amount of entrainer is necessary for extraction process. Thus, this optimized case would not be able to handle feed composition disturbance in dynamics simulation. A trade-off between design and control should be used in this case and will be discussed in the next section.

Table 1 compares the total annual cost (TAC) of the optimized results for hybrid extraction/distillation system, heterogeneous azeotropic distillation system, and dividing-wall column system. All the calculations are based on the TAC calculation basis in Luyben (2013). TAC calculation includes annual total operating cost, total capital cost divided by a payback period assumed to be three years. Operating cost includes the cost of steam, cooling water, and solvent; capital cost includes the costs of columns, vessels, and heat exchangers. Compared the optimized design of the hybrid extraction/distillation system with the previously mentioned heterogeneous azeotropic design, significant reductions of 58.8 % in the total annual cost and 65.6 % in the steam cost can be obtained. Furthermore, in comparison with the complex design of dividing-wall system, the proposed hybrid extraction/distillation system can still significantly save total annual cost and steam cost by 41.2 % and 50.8 %, respectively.

total capital cost	1000$/yr	1335.46			1442.90		1025.06	
TAC	1000$/yr	1839.16			4510.80		3159.43	

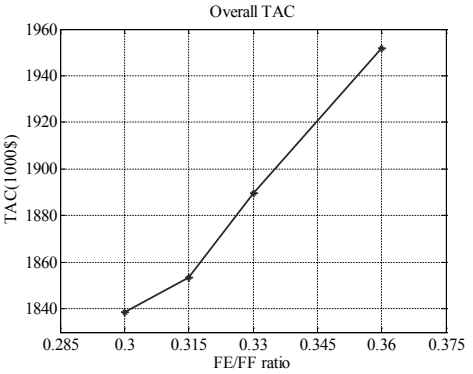

Figure 2. Summary of TAC plots at various FE/FF ratio

3. Control Strategy Design

In this section, dynamics and control of the hybrid extraction/distillation design is examined. As we mentioned above, the optimized case reaches a low constraint for the design flowsheet as shown in Figure 2. Once there is an increase of pyridine in feed, the system will not be able to converge, and thus the optimized case would not be able to handle disturbances. When increasing entrainer flowrate to 360 kmol/h, the case is able to hold product specifications despite disturbances from throughput and feed composition changes by the proposed plant-wide control structure. Figure 3 shows the TAC minimized case when the ratio of extraction solvent and feed flowrate fixed as 0.36. Although this case in Figure 3 has greater TAC (6.51% increase) than the optimized case result in Figure 1, this design case should be able to handle feed composition disturbances. We will examine the dynamic responses under throughput and feed composition changes in the followings.

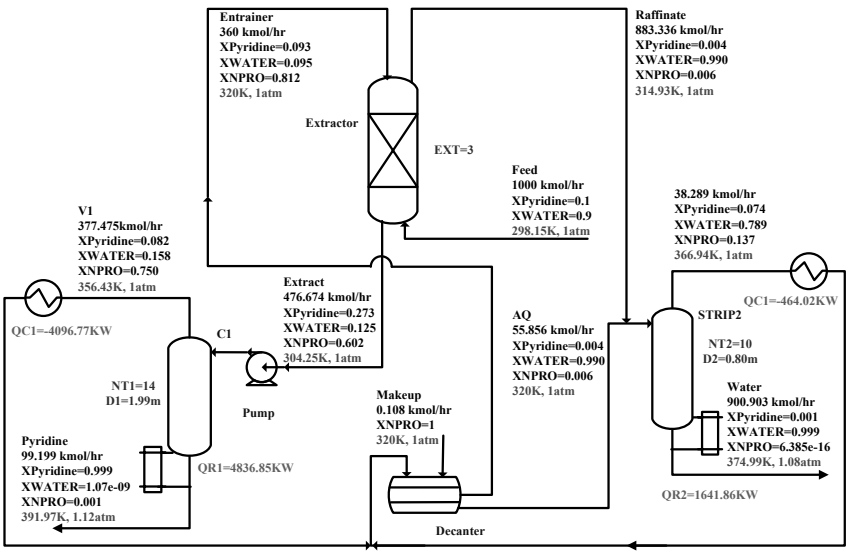

Figure 3. Optimized Flowsheet under FE/FF=0.36

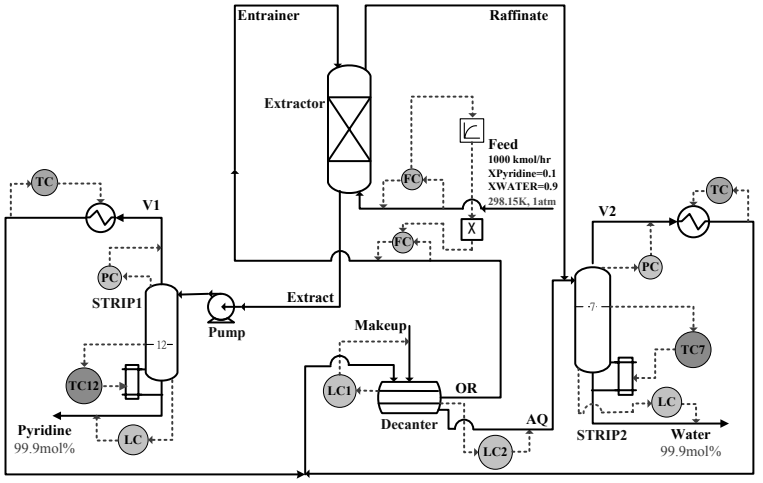

Figure 4. Proposed Overall Control Strategy

The overall control strategy as shown in Figure 4 is developed to hold both specifications in spite of feed flowrate and composition deviation. In control strategy development, no online composition measurement is necessary. It will be inferred by tray temperature control strategy. There are ten inventory control loops included level controls, temperature controls, pressure controls and flow controls. A ratio scheme between feed flow and entrainer flow is established and ten minutes lag is added to smooth out the dynamic response. With the information of closed-loop and open-loop sensitivity tests, the 12th stage temperature of STRIP1 and the 7th stage temperature of STRIP2 are selected to be controlled by reboiler duties. The temperature control loops contain 1-min deadtimes and are tuned by Tyreus-Luyben tuning rules.

The set point of temperature controller is further investigated. To hold both specifications, we pre-investigate the value of set-point of temperature controllers during throughput change as shown in Figure 5. Figure 6(a) displays the responses of ±20% in throughput change. For throughput change, temperature set point values are manually adjusted according to the result of pre-investigation in Figure 5. The two products purities returned quickly back to their specifications. Figures 6(b) gives responses for ±20% composition change of pyridine in feed. The two controlled temperatures returns quickly to their set point values and the two products are still maintained at high purity.

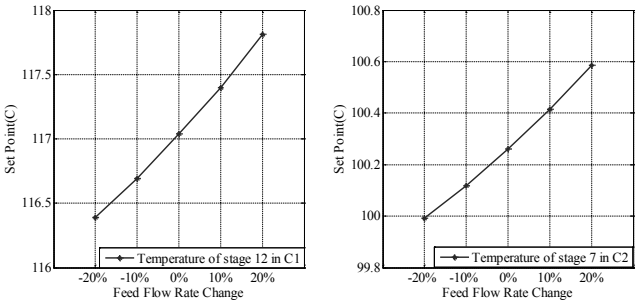

Figure 5. Set-point Values of Tray Temperature Control under Throughput Change

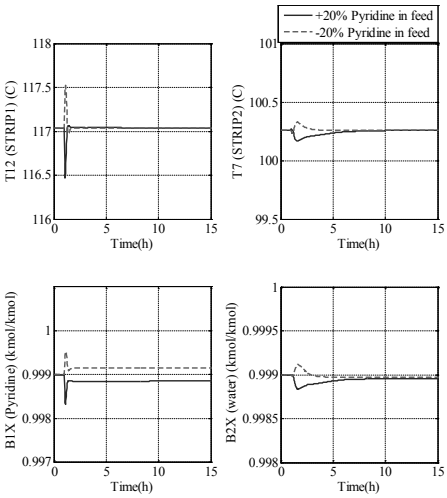

Figure 6(b). Responses of ±20% pyridine in feed

4. Conclusions

Design and control of a hybrid extraction/distillation system for the separation of pyridine and water are studied. In the extraction column, N-propyl formate has been selected as the solvent. Compared with the previously mentioned heterogeneous azeotropic design and dividing-wall column system, significant reductions in the total annual cost and in the steam cost can be obtained.

The dynamics results show a trade-off between economical design and controllability. With the adjustment of solvent flow rate, proposed plant-wide control structure is capable of holding product specifications despite disturbances from throughput and feed composition changes.

Abstract

Recent technologies for biobutanol production by fermentation have resulted in higher final biobutanol concentrations, less fermentation by-products and higher volumetric productivities during fermentation, together with less energy intensive separation and purification techniques. These new technology developments have the potential to provide a production process for biobutanol that is economically viable in comparison to the petrochemical pathway for butanol production. This study compares four different possible process designs for purification of biobutanol by means of a multiobjective optimization process having two objective functions: the total annual cost (TAC) as an economical function and the associated eco-indicator 99 as an environmental function.

Keywords: biofuels, biobutanol, thermal coupling, process synthesis.

1. Introduction

With the depletion in petroleum resources, an increasing attention has been paid to the research of new energy sources. The use of biofuels for transport is becoming very relevant for a number of reasons, such as environmental concerns relating to climate change, depleting fossil fuel reserves, and reducing reliance on imports (Wingren et al., 2003). This is leading to international, national and regional focus on alternative energy sources. In the EU, the transport is responsible for an estimated 21 % of all greenhouse gas emissions (Searchinger et al., 2008). More than 90 % of the total transport emissions are due to the road transport. Biofuels, processed from biomasses, which are considered as a renewable resource, are suggested as a direct substitute for fossil fuels in transport. Thus, the current research and development drivers are the identification of potential renewable energy sources or biomass feedstock and their processing in order to produce alternatives to fossil fuels in transport, such as biobutanol.
The aim of this work is to perform the process design, multiobjective optimization and comparison of different possible process routes for industrial scale biobutanol production. Process modelling in Aspen Plus was performed and the optimization was conducted using the stochastic optimization method Differential Evolution with Tabu list, having two objective functions, the total annual cost as an economic objective,

whereas the environmental objective function is measured through the eco-indicator 99 based on the LCA methodology.

2. Hybrid extraction-distillation process

The combination of extraction and distillation is considered as one of the most promising separation alternatives for the ABE purification (Van der Merwe et al., 2013). The extraction column is located after the fermentor, the mass separation agent or extractant, is fed from the bottom and the fermentation broth from the top. The raffinate phase contains water and traces of acetone, butanol and water. The extract phase contains the extractant, acetone, butanol and ethanol. The selection of the extractant is of meaningful importance for the economy of the process because directly affects the composition of the extract phase. It is possible to generalize that a good extractant, besides its economicity and low toxicity, should have a high distribution coefficient for the butanol and a high selectivity between butanol and water.
The extract phase obtained from the extractor is feed to the distillation section where acetone, butanol and ethanol can be recovered following different arrangements, with simple and/or complex columns. The liquid-liquid extraction may eliminate the request of azeotropic distillation making the process more competitive compare pure distillation flowsheets. The nine configurations reported in Figure 1 are considered and compared in the present study.

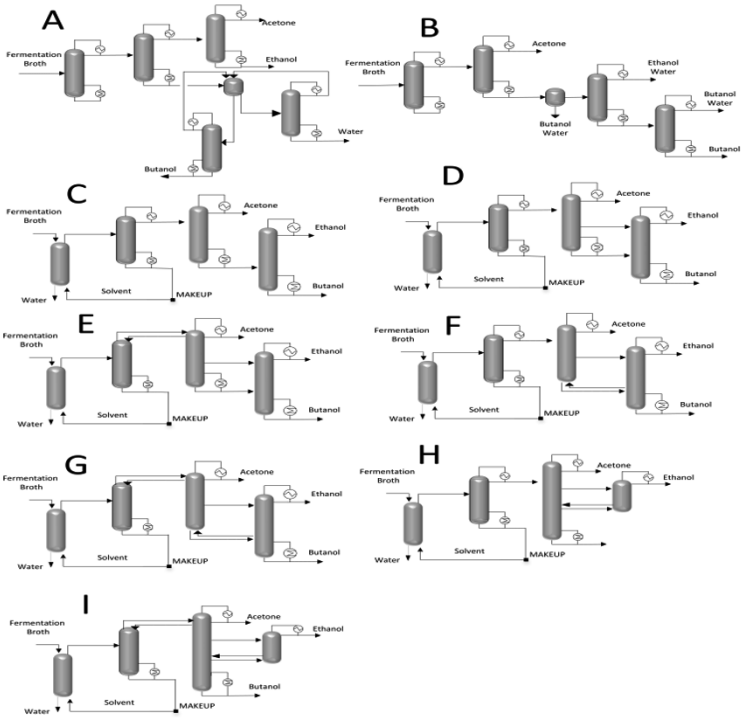

Figure 1. Sequences considered for the biobutanol production.

3. Case study

All sequences in Figure 1 were subject to a rigorous optimization, all these design cases were initially simulated using Aspen Plus process models. Note that these process models were robust and thermodynamically rigorous. According to Van der Merwe et al. (2013) and Chapeaux et al., NRTL-HOC was the most accurate thermodynamic model for the calculation of the physical property available for the components used at the specified conditions. It was assumed that all process designs have the same stream feeds except LLE design where it was added hexyl acetate as extractant. The feed composition reported by Wu et al. (2007) was used. The required purities are 99.5 wt % for biobutanol, 98 wt % for acetone, 94 wt % for ethanol and 95 wt % for the solvent recovered.

4. Optimization problem

The optimization of the biobutanol purification section is essential to run a biobutanol industry that can effectively compete with the current butanol derived from the petrochemical route. Moreover the environmental impact must be also taken in count in order to satisfy all governmental restriction.

4.1 Economic objective function

The objective function is the minimization of the total annual cost (TAC), which is directly proportional to the heat duty, services and the columns size. The minimization of this objective is subject to the required recoveries and purities in each product stream, i.e.:

$$\text{Min (TAC)} = f(N_{tn}, N_{fn}, R_{rn}, F_{rn}, F_{vn}, D_{cn}) \quad (1)$$
$$\text{Subject to } y_m \geq x_m$$

where N_{tn} are total column stages, N_{fn} is the feed stages of all streams in column, R_{rn} is the reflux ratio, F_{rn} is the distillate fluxes, F_{vn} is the vapor flow in interconnections at coupled sequences and D_{cn} is the column diameter, y_m and x_m are vectors of obtained and required purities for the m components, respectively. This minimization implies the manipulation of 22-26 continuous and discrete variables for each configuration, where 5-7 variables are used for the design of each column. Note that since the product streams flows are manipulated, the recoveries of the key components in each product stream must be included as a restriction for the optimization problem. In the configuration reported in Figure 1(a) the acetone, biobutanol and ethanol must be recovered; while in the configuration of Figure 1(b), the acetone and biobutanol must be recovered.

4.2 Environmental objective function

The environmental indicator is measured through the eco-indicator 99 based on the methodology of the life cycle analysis (Geodkoop and Spriensma, 2001) and is stated as follows:

$$\textit{Min (Eco indicator)} = \Sigma_b \Sigma_d \Sigma_k \delta_d \omega_d \beta_b \alpha(b,k)$$

Where β_b represents the total amount of chemical b released per unit of reference flow due to direct emissions $\alpha(b,k)$ is the damage caused in category k per unit of chemical b released to the environment, ω_d is a weighting factor for damage in category d, and δ_d is the normalization factor for damage of category d.
In the eco-indicator 99 methodology, 11 impact categories are considered:

1. Carcinogenic effects on humans
2. Respiratory effects on humans that are caused by organic substances
3. Respiratory effects on humans caused by inorganic substances
4. Damage to human health that is caused by climate change
5. Human health effects that are caused by ionizing radiations
6. Human health effects that are caused by ozone layer depletion
7. Damage to ecosystem quality that is caused by ecosystem toxic emissions
8. Damage to ecosystem quality that is caused by the combined effect of acidification and eutrophication
9. Damage to ecosystem quality that is caused by land occupation and land conversion
10. Damage to resources caused by the extraction of minerals
11. Damage to resources caused by extraction of fossil fuels.

These 11 categories are aggregated into three major damages categories: (1) human health, (2) ecosystem quality, and (3) resources depletion. These 11 categories are aggregated into three major damages categories: (1) human health, (2) ecosystem quality, and (3) resources depletion.

5. Global stochastic optimization strategy

In order to optimize the processes routes for biobutanol production, a stochastic optimization method, Differential Evolution with Tabu List (DETL) was used. Differential Evolution (DE) has its basis in Darwin's natural selection theory, and is similar to genetic algorithms (GAs) except for one important factor: several GAs, particularly earlier versions, encode decision variables as bit strings whereas DE encodes them as floating-point numbers. Srinivas and Rangaiah (2007) showed that the use of some concepts of the metaheuristic tabu can improve the performance of DE algorithm. In particular, the tabu list (TL) can be used to avoid the revisit of search space by keeping record of recently visited points, which can avoid unnecessary function evaluations. A comprehensive description of the DETL algorithm is provided by Srinivas and Rangaiah (2007).
The implementation of this optimization approach was made using a hybrid platform using Microsoft Excel and Aspen Plus. The vector of decision variables (i.e., the design variables) is sent to Microsoft Excel to Aspen Plus using DDE (Dynamic Data Exchange) through COM technology. In Microsoft Excel, these values are attributed to the process variables that Aspen Plus need. After simulation it is done, Aspen Plus return to Microsoft Excel the resulting vector. Finally, Microsoft Excel analyzes the values of the objective function and proposes new values of decision variables according to the stochastic optimization method used. For the optimization of process routes analyzed in this study, we have used the following parameters for DETL method: 200 individuals, 300 generations, a tabu list of 50 % of total individuals, a tabu radius of

0.0000025, 0.80 and 0.6 for crossover and mutation fractions, respectively. These parameters were obtained through a tuning process via preliminary calculations. The tuning process consists of performing several runs with different number of individuals and generations, in order to detect the best parameters to allow better convergence performance of DETL.

6. Results

In Figure 2 the results for the sequences of Figure 1(a) and 1(b) are reported. Only conventional columns are involved in separation and purifications of solvents. Pareto front from sequence 1(b) has a lower TAC and Eco 99 compare to the sequence 1(a), however it must be considered than in sequence 1(b), some part of biobutanol is wasted in the decanter, which means that recovery of biobutanol can not reach the target of 95 wt %.

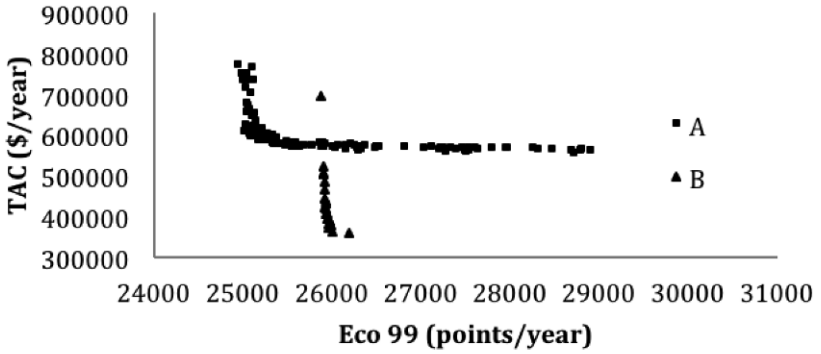

Figure 2. Pareto fronts from sequence of Figure 1(a) and 1(b).

In Table 1 the results of the TAC and the Eco-indicator 99 for all the alternatives considered, were reported. In general it is possible to notice that all the configurations with one or two thermal couplings are able to outperform the TAC and the Eco-indicator 99 of the classical configurations. Among all, configuration 1(h) reports the lowest value of TAC together with the second best environmental indicator.

Table 1: TAC and Eco 99 index for all the configurations of Figure 1.

Process Design	TAC ($/y)	Eco 99 (points/y)
A	580658	25351
B	363832	26009
C	128176	12975
D	133791	14974
E	104868	11056
F	123413	11499
G	107022	11729
H	101026	11434
I	108580	11168

7. Conclusions

A set of nine possible separation sequences for the biobutanol separation has been presented. Pure distillation alternatives together with liquid-liquid extraction plus distillation were considered and compared. The inclusion of thermal coupling in some liquid-liquid extraction based sequences reduced significantly the economic and environmental impact measured by TAC and Eco-indicator 99, comparing with some other sequences that do not include thermally coupling or a liquid-liquid extraction.
Compare to a pure distillation alternative, a liquid-liquid sequence with one thermal coupling was able to reach a 83 % reduction of the TAC together with 55 % reduction of the environmental indicator. This decreasing in economic and environmental issues, combined with other research efforts, could lead to be more profitable the use of biobutanol as an alternative energy source.

Abstract

To optimize the sensory product attributes by changing the processing conditions or product recipe was the main objective of this research. A mathematical framework was built containing process and sensory models. First, a typical mayonnaise production line was modeled. The line consisted of two mixing steps; in mixer 1 the objective was to prepare an oil-in-water emulsion; while in mixer 2 the required product specifications had to be reached. The droplet size and emulsion viscosity were coupled in the processing model for mixer 2. The physicochemical emulsion properties were subsequently correlated to the sensory attributes with a Neural Network. This allowed us to estimate panel scores on sensory attributes. Second, an optimization case study was formulated with the objective to increase mayonnaise creaminess while fixing the oil concentration to a minimal value of 0.65 w/w. The overall result was that the creaminess could be increased by 22 %, but at the expense of other sensory attributes.

Keywords: optimization, mayonnaise, sensory attributes

1. Introduction

It has been a long term goal of many fast-moving consumer goods companies to optimize the sensory profile of their products. Fast-moving consumer goods (FMCG) are products which are frequently purchased, consumed on a daily basis, have a low cost-price and are sold in large quantities; for example, foods, drinks, detergents and cosmetics. The sensory perception of these types of products determines why a consumer favors one product over another. During panel tasting sessions products are rated on sensory attributes such as mouth feel, taste, odor and appearance, which together form the sensory profile of a product. The physics and physical chemistry of the product influence its sensory perception. Many studies in the past have been focusing on relating the sensory attributes to physicochemical product properties (see e.g. Maruyama et al., 2007; Terpstra et al., 2009; Van Aken et al., 2011). What has been lacking until now was a relationship between the sensory attributes and the formulation and processing of the product. Eventually the manufacturer would like to manipulate the sensory profile by changing the recipe and/or processing conditions.

In this context a mathematical framework was built which was able to estimate panel scores on sensory attributes for mayonnaise from formulation and processing decisions.

Mayonnaise is an oil-in-water emulsion stabilized by egg yolk. Other important ingredients are vinegar, salt, sugar, mustard and water. Because the original mayonnaise contains dispersed 70 – 85 % vegetable oil, mayonnaise behaves as a semi-solid with viscoplastic and time dependent properties (Perissini et al., 1998). Mayonnaise is often modelled as a Herschel-Bulkley liquid, see e.g. Singla et al., (2013). In literature there are relations available which explain emulsion viscosity, yield stress and elasticity based on oil fraction and droplet size distribution. When the oil phase is decreased, for low fat products, the continuous phase must be structured with food additives to mimic the behavior of the full fat mayonnaise.

A typical mayonnaise production process consists of two mixers, see Figure 1. The first mixer is a fed batch system, where the oil phase is slowly added to the water phase to ensure an oil-in-water emulsion. The second mixer is usually a high shear mixer, which breaks up the oil droplets to reach the required specifications. While breaking the oil droplets the viscosity of the emulsion increases which influences the emulsion flow and in turn the rate of droplet breakup. Modeling this interaction is stipulated by Janssen and Hoogland (2013) as the top of the modeling hierarchy in terms of complexity and solving the problem in full detail remains far out of reach for practical industrial cases. There are mixers available which operate in the laminar regime and therefore need only one parameter to describe the flow. When a mean field viscosity model is opted for, the interaction between emulsion flow and droplet breakup should be feasible, even in an optimization context.

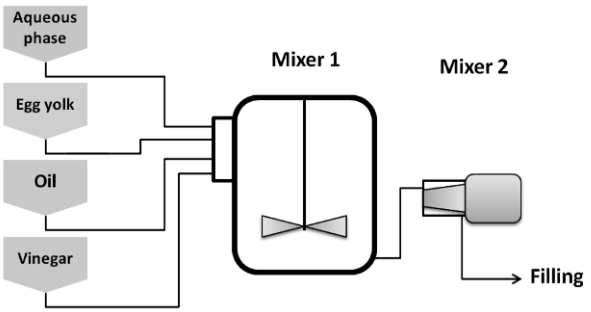

Figure 1: Simplified flow diagram of a typical dressings production line

2. The Framework

The optimization framework connects the processing variables and the product recipe on the left to the sensory attributes on the right, via several interconnected models, see Figure 2. All the models used in the framework will be briefly discussed here:

2.1. The population balance model (f_1)

A population balance tool was used to estimate the emulsion droplet sizes coming out of the second mixer. The inlet droplet size, coming out of Mixer 1, constitutes the initial condition for the population balance. It was experimentally shown that the initial droplet size distribution did not have a significant impact on the outlet droplet size, therefore it was deemed unnecessary to model mixing step 1. The breakage and coalescence rates were similar to those published in Maindarkar et al. (2014). The population balance was integrated over the axis of the mixer head so that at every length step the emulsion viscosity was recalculated using the mayonnaise viscosity model (f_2).

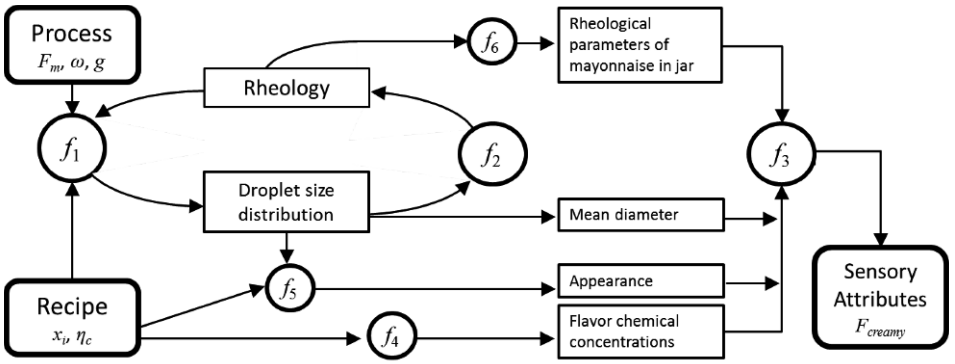

Figure 2: Detailed optimization framework; the arrows indicate the flow of information; the circles are the mathematical functions and the boxes are the variables

2.2. Mayonnaise rheology models (f_2)

To model the mayonnaise viscosity the empirical model of Jansen et al. (2001) was applied. This model is based on a modified Cross model, which contains a viscosity plateau at very low shear rates, a shear thinning region and a high shear plateau. The free parameters in the model are fitted to actual mayonnaise viscosity data. The yield stress and the elastic modulus were calculated using the models of Scheffold et al. (2013). The yield stress is an input parameter for the viscosity model and the sensory model (f_3). The elastic modulus is only an input for the sensory model. The other rheological variables needed for the sensory model are: the critical modulus; the tangent of the phase angle; the shear thinning index; the viscosity at 50 s^{-1}, which is a characteristic for in-mouth shear; and the Stevens value, which is the force necessary to push a grid through the mayonnaise.

2.3. The sensory model (f_3)

An artificial neural network model was selected as the best model from a range of statistical models, see Dubbelboer et al. (2014). The neural network correlates the physicochemical properties to the sensory attributes. The model inputs are rheological variables, mean oil droplet size, yellow index (appearance) and concentrations of flavor chemicals. The model has 25 different outputs estimating the panel scores on various sensory attributes.

2.4. Models predicting flavor chemical concentrations (f_4)

The concentrations of flavor chemicals were detected by Mass Spectrometry and were found to be linear with the amount of added ingredients, except for the pH.

2.5. Model to predict color based on droplet size distribution and recipe (f_5)

Emulsion color is very much affected by droplet size and the ingredients. There are mechanistic models available which are able to estimate emulsion color based on oil droplet size and concentrations up to 20 % (Chantrapornchai et al., 1998). The present case only considers mayonnaises with more than 65 % oil. Besides that many mayonnaises contain food colorants and no information was available which could correlate the concentration of colorants to the yellow index. For the time being the average yellow index was used from the dataset.

2.6. Model describing the increase in product structure due to the setting of mayonnaise in a jar (f_6)

The proteins from the egg yolk are known to gel the emulsion (Kiosseoglou, 2003), which takes roughly 1 to 2 days. The mayonnaise gains in structure while it stays in the

jar. Before it reaches a consumer the rheological properties have changed. Currently there are no models available taking this effect into account. Therefore the rheological properties attained directly after mixing were correlated to the sensory attributes.

3. The case study

The framework models are able to estimate scores on 25 sensory attributes. The case study presented here focuses on the optimization of one particular attribute which is mayonnaise creaminess. Therefore the cost function predicts the sensory score as would be given by a tasting panel. A correlation was found between the oil content of mayonnaise and the panel scores on creaminess see Figure 3. The framework was used to answer the following question: can product creaminess be increased while the oil concentration is kept to a minimum? Here 0.65 w/w is the minimum according to the standard of identity in some countries like US. Besides that the rheology for high internal phase emulsions acquires its characteristics around and above the maximum packing limit of hard spheres.

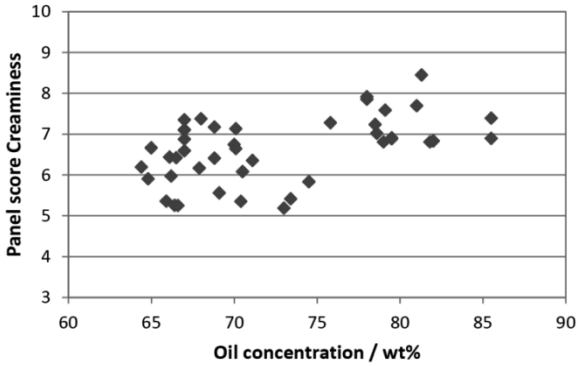

Figure 3: Creaminess scores by a panel on various types of mayonnaise versus the oil concentration

4. Optimization

The optimization problem has the following structure:

$$\max \quad Y_{creamy} = f(x_i, \eta_c, F_m, \omega, g)$$

subject to:

$$\sum x_i = 1$$

$$x_i > 0$$

$$10^{-3} \leq \eta_c \leq 10^{-1} \text{ Pa·s}$$

$$25 \leq F_m \leq 100 \text{ kg/h}$$

$$3{,}000 \leq \omega \leq 10{,}000 \text{ rpm}$$

$$0.2 \leq g \leq 0.64 \text{ mm}$$

It is the objective to maximize the model output creaminess, Y_{creamy}, which is basically an NLP. The model inputs are the formulation variables, x_i, as mass fractions; the continuous phase viscosity, η_c, because there is not a good correlation available to estimate this quantity based on the recipe; and the processing variables: flow rate F_m,

rotor speed ω, and gap size, g. For the optimization case x_{oil} was fixed to 0.65 w/w. The first step in the optimization of the framework a Genetic Algorithm (GA) was used from the MATLAB global optimization toolbox. Then, in the second step, the outcome of GA forms the initial guess for the simplex search method using the fminsearch algorithm with constraints also from MATLAB. From 100 optimization runs the 10 highest creaminess scores were evaluated.

5. Results and discussion

The maximum creaminess score found in the optimization was realized by the input values listed in Table 1. The 10 highest optimization runs had all the same combination of input variables except for 2 runs which were only slightly off. The maximum creaminess score of 7.3 for a 65 wt% oil mayonnaise was an increase of 22% compared to tested mayonnaises with similar oil content. The average creaminess score of mayonnaises in the range 80 – 85 wt% oil was 7.3. This showed that it is possible to increase product creaminess for 65 wt% oil mayonnaises. It appeared that mustard was not beneficial for the sensory attribute creaminess. It does, however, not mean that mustard should be removed from the recipe because other sensory attributes like taste might be influenced by the mustard flavor content.

The vegetable oils used in mayonnaise and dressings contribute the most to the cost price of these types of products. Lowering the oil content while maintaining same product quality is one of the major challenges in the development of mayonnaise and dressings. Also from a sustainability point of view it is desirable to limit the use of vegetable oils. The oil phase gives structure to the products, i.e. an increase in viscosity, elasticity and yield stress. When the oil phase is reduced the loss of structure must be compensated by the viscosity of the continuous phase or the droplet size distribution.

Table 1: optimization results

Product formulation variables	Optimized values	Dimensions
x_{oil}	0.65	w/w
$x_{egg\ yolk}$	0.04	w/w
$x_{vinegar}$	0.01	w/w
$x_{mustard}$	≈ 0	w/w
x_{water}	0.3	w/w
η_c	0.023	Pa*s
Processing variables		
F_m	25	kg/h
ω	10,000	rpm
g	0.64	mm
Model output		
Y_{creamy}	7.3	
$D32$	2.2	µm

The optimization results showed that the viscosity of the aqueous phase had to increase to 23 times that of pure water. With all the components already present in the aqueous phase, the viscosity rises to about 10 times that of pure water. Therefore the aqueous phase must be structured with food additives such as starches or gums to increase the creaminess score of 65% oil mayonnaise. The addition of thickeners could very well influence the perception of creaminess and other attributes. Unfortunately the effect of additional thickeners is not yet included in the sensory model. Likewise the effect of salt and sugar addition on the sensory attributes has not been quantified. Salt and sugar are part of most mayonnaise recipes and are likely to influence the sensory perception of the product.

6. Conclusions

A mathematical framework was presented in this work which could optimize sensory attributes of mayonnaise by changing the product recipe and/or processing variables. Although the framework did not yet contain all desirable correlations it was put to the test by a case study. The case study involved the optimization of mayonnaise creaminess scores while fixing the oil level to a minimal value of 0.65 w/w. An optimum was found by comparing 100 optimization runs. According to the optimization the creaminess scores of mayonnaise containing 0.65 w/w oil could be increased by 22%. However, this meant virtually removing all mustard flavor components and thickening the aqueous phase. Removing the mustard components might have detrimental effects on other sensory attributes and thickening the aqueous phase with food additives could result into other sensory effects. The next step would be to test the result of the framework, from mayonnaise formulation and production to panel tasting sessions.

Abstract:

The synthesis of indirect work exchanger network (WEN) based on transshipment model is first studied considering the compression ratio and expansion ratio as the variables in this paper. Compared with superstructure method, the transshipment model is simpler to obtain the minimum utility consumption taken as the objective function, which is also easier to get the optimal WEN configuration in which the number of units is minimized. The proposed approach for WEN synthesis is a linear program model applied to isothermal process. All the streams are divided into several pressure intervals, also called sub-networks. Then the energy balance is calculated in each sub-network according to the analysis of work cascade in isothermal process. In addition, the adjacent intervals are merged according to the proposed merging rules in order to decrease utility consumption and optimize the network structure. Finally, this method is proved to be feasible and effective by an example.

Keywords: indirect work exchanger network; transshipment model; process synthesis; compression/expansion ratio

1. Main Text

Energy is a major concern in the 21st century, the worldwide demand of which is predicted to rise by 57% during 2004-2030 (Del et al., 2010). The two common forms of energy in chemical plants are heat and work. As work is much more expensive than heat, which also has higher energy quality, work exchanger network is an important part of energy recovery system, the design level of which will have significant influence on energy consumption in process system.

Work can be exchanged between work sources and work sinks through indirect work exchangers. In the indirect work exchanger, the energy is exchanged in two steps: the pressure energy of work sources is converted to mechanical energy through turbines at first and further converted to the pressure energy of the work sinks through compressors (Liu et al., 2011, 2014). Shin et al. (2007) proposed a mixed integer linear programming method to optimize boil-off gas (BOG) compressor operations targeting the minimization of the total average energy consumption in an LNG receiving and re-gasification terminal. M.S.Razib et al. (2012) proposed a superstructure for the WEN

configuration and developed a MINLP to minimize the total annualized cost for a constant speed of the single shaft on 2-stream single-shaft-turbine-compressor (SSTC) units. Furthermore, Viviani C. Onishi et al. (2014) introduced a multi-stage superstructure to optimize WEN configuration with heat integration simultaneously at a constant speed of the single shaft for SSTC.

Based on the literature researches, no study on the integration of WEN with multiple streams in the indirect work exchanger using transshipment model has been reported. Hence, we employ the transshipment model with work cascades taken into account and formulate the synthesis of work exchanger network as a linear program in isothermal process. Also an example is used to demonstrate the benefits of this method.

2. Problem Statement

A set of gaseous streams at high pressure (HP) and low pressure (LP) are present in a chemical process, with known volume flows, inlet pressure and outlet pressure. In addition, the work efficiency and the maximum compression/expansion ratio are also provided. The main objective is to synthesize an optimized WEN with the minimum utility consumption and the number of units minimized through work recovery between HP and LP streams, utilizing turbines and compressors running on a common shaft. Compression ratio, expansion ratio, inter-stage pressure, energy requirement and number of units are variables in the synthesis of this work exchanger network. Also for purpose of simplifying synthesis process, we assume the following:

(1) All streams are in ideal gas phase.
(2) Only isothermal reversible compression/expansion is considered.
(3) The work efficiency is constant in different pressure intervals.
(4) The condition of temperature constrain is not taken into account.

3. Model Formulation

3.1. Sets definitions

The following sets are defined to meet the requirements for the development of the model:

$HP = \{HP_i / i = 1,2,...,N_H\}$, N_H is the number of high-pressure streams.

$LP = \{LP_j / j = 1,2,...,N_L\}$, N_L is the number of low-pressure streams.

$SN = \{SN_k / k = 1,2,...,K\}$, K is the number of pressure intervals.

1.2 Division of pressure intervals

The first step to establish the transshipment model is to divide all the pressure of streams into several intervals, marked as SN_k. Since no pressure difference constrain is demanded for work exchange, a new strategy is proposed in accordance with the maximum compression ratio $CR_{\max}$ and the maximum expansion ratio $ER_{\max}$ rather than that in the HEN. This strategy for division of pressure intervals guarantee that one high-pressure stream matches with one low-pressure stream through one SSTC unit. The pressure intervals consist of two pressure endpoints of all the streams and the constructed intermediate pressure, arranged in a sequence pressure values from high to low. The intermediate pressure of all streams is constructed as follows.

$$P_{HP_i}^{\text{int}} = P_{HP_i}^{OUT} \times ER_{\max} \tag{1}$$

$$P_{LP_j}^{\text{int}} = P_{LP_j}^{IN} \times CR_{\max} \tag{2}$$

$$P_{HP_i}^{OUT} \le P_{HP_i}^{\text{int}} \le P_{HP_i}^{IN} \tag{3}$$

$$P_{LP_j}^{IN} \le P_{LP_j}^{\text{int}} \le P_{LP_j}^{OUT} \tag{4}$$

3.2. Compression and expansion analysis in sub-networks

As mentioned above, the essence of work exchange between high-pressure streams and low-pressure streams for SSTC is analogous to threshold problem of HEN, which means that only one kind of utility (pressurization utility or depressurized utility) is used for the synthesis of WEN. In each pressure interval, the inlet and outlet pressure of all streams are limited between the minimum and maximum value of the inlet and outlet pressure in the WEN. Additionally, the pressure relationship in these sub-networks is presented as follows.

$$P_{HP_i,IN} = P_{HP_i,k} \quad (HP_i \in HP, k \in K) \tag{5}$$

$$P_{HP_i,OUT} = P_{HP_i,'k} \quad (HP_i \in HP, k' \in K, k' \ge k) \tag{6}$$

$$P_{LP_j,IN} = P_{LP_j,k} \quad (LP_j \in LP, k \in K) \tag{7}$$

$$P_{LP_j,OUT} = P_{LP_j,'k} \ (LP_j \in LP, k' \in K, k' \le k) \tag{8}$$

Let $W_{HP_i,k}$ be the energy extracted by turbines while $W_{LP_j,k}$ is energy required by compressors. In addition, consider $W_{PU,k}$ and $W_{EU,k}$ as pressurized and depressurized utilities. Hence, the transshipment model is represented as Figure 1.

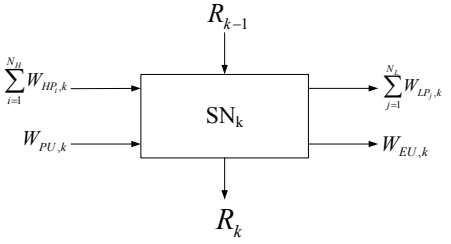

Figure 1: Work exchange in pressure interval k

In conclusion, the objective function and constrains can be obtained as follows according to the above analysis.

$$\min Z = \sum_{k=1}^{K} (W_{PU,k} + W_{EU,k}) \tag{9}$$

$$\sum_{i=1}^{N_H} W_{HP_i,k} + W_{PU,k} + R_{k-1} = \sum_{j=1}^{N_L} W_{LP_j,k} + W_{EU,k} + R_k \tag{10}$$

$$\mathrm{W}_{\mathrm{HP_i},k} = -P_{i,k} V_{i,k} \ln\left(\frac{P_{HP_i,k,t}}{P_{HP_i,k,s}}\right) \cdot \eta \tag{11}$$

$$\mathrm{W}_{\mathrm{LP_j},k} = -P_{j,k} V_{j,k} \ln\left(\frac{P_{LP_j,k,t}}{P_{LP_j,k,s}}\right) \tag{12}$$

$$R_0 = R_K = 0 \tag{13}$$

Where the R_k, $W_{PU,k}$, $W_{EU,k}$ are all non-negative.

3.3. Merging of adjacent pressure intervals

Although the minimum utilities can be worked out based on the proposed transshipment model, an excess of units have to be utilized in order to recover more work, which results in a complex work exchanger network. Therefore, it is essential to reduce the number of units with utility consumption unchanged. And then a new strategy is proposed to solve this problem, which is the merging of adjacent pressure intervals. A stream existing in any of the original pressure intervals being merged is contained in the new interval. All properties of these streams keep the same while the pressure drop ratio in the new interval is enlarged. However, this new pressure drop ratio must be equal or lesser than the required maximum compression/expansion ratio. Furthermore, the work recovery between work sources and work sinks does not change, which indicates no redundant utility is needed.

4. Case Study

Table 1: Stream data for the case

Stream	P_{IN} (MPa)	P_{OUT} (MPa)	F ($dm^3 \cdot s^{-1}$)
HP_1	5.734	2.217	990.49(outlet)
HP_2	3.114	0.196	763.37(outlet)
LP_1	0.244	5.734	725.52(inlet)
LP_2	0.113	2.217	504.71(inlet)
LP_3	1.735	3.114	832.77(inlet)

In this example, WEN is designed to allow work integration between two high-pressure streams (HP_1, HP_2) and three low-pressure streams (LP_1, LP_2 and LP_3), the problem data of which are presented in Table 1. In this case, we set some variables equal to const where the efficiency is 0.85 and both the maximum compression ratio and expansion ratio are 3. For ideal gas, the product of pressure and volume for all streams in different pressure intervals is identical. Subsequently, all the pressure value of streams are divided into 12 pressure intervals and then the above model is employed to solve each sub-network taking the minimum utility as the objective function. The minimum utility consumption is 551.71kW, less than 557.90kW of Zhou et al. (2011). However, more

than 30 units are needed to complete the work exchange in the WEN. Hence, the optimized work cascade diagram is illustrated as Figure 2 according to the proposed strategy with the purpose of reducing the number of units. The corresponding work exchanger network configuration is shown as Figure 3.

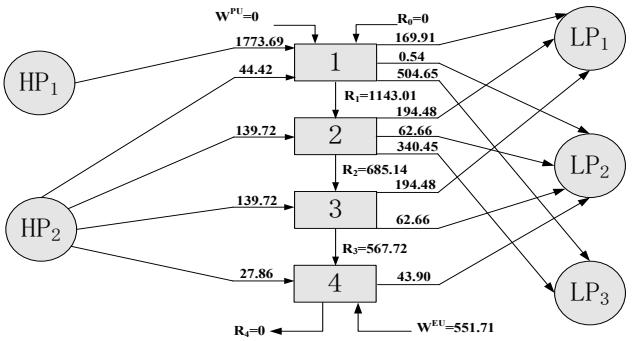

Figure 2: The optimized work cascade diagram for the case

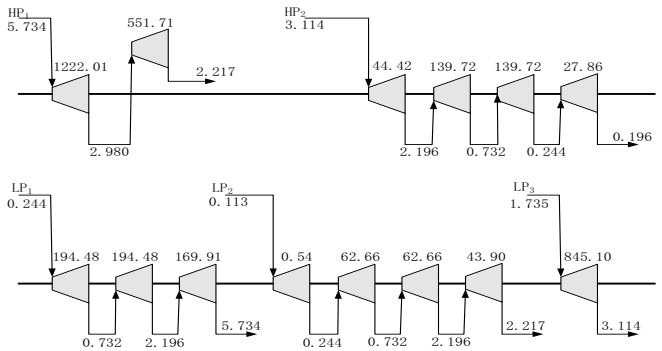

Figure 3: The work exchanger network for the case

5. Conclusions

In this paper, a new optimization methodology for synthesis of WEN based on transshipment model was first proposed, by introducing division of pressure intervals and putting forward pressure-interval merging principles to reduce the number of units and optimize WEN configuration. Finally, a numerical example from literature has been studied and the satisfactory solution justifies the feasibility of the proposed method.

Abstract

Utilization of CO_2 feedstock through CO_2 conversion for producing valuable chemicals as an alternative to sequestration of the captured CO_2 is attracting increasing attention in recent studies. Indeed, the methanol production process via thermochemical CO_2 conversion reactions is considered a prime candidate for commercialization. The aim of this study is to examine two different options for a sustainable methanol plant employing the combined reforming and CO_2 hydrogenation reactions, respectively. In addition, process improvement strategies for the implementation of the developed processes are also considered. The two methanol plants are developed using Aspen Plus®, the commercial process simulator. The net CO_2 flows and methanol production costs are evaluated using ECON® and compared with those of the conventional methanol plant, which uses two-stage reforming. It is verified that the combined reforming process has to be integrated with the existing conventional methanol plant to obtain a reduced CO_2 emission as well as lowered production costs. On the other hand, the CO_2 hydrogenation based methanol plant could achieve a reduction of net CO_2 emission at a reasonable production cost only with utilization of renewable energy resources (hydroelectric power and biomass) for the H_2 feedstock.

Keywords: CO_2 conversion, Methanol production, Sustainable process design, Process integration, Renewable energy utilization

1. Introduction

As CCUS (Carbon capture, utilization and storage) is becoming a popular R&D theme due to the mounting concerns about climate change, CO_2 conversion has attracted much attention lately. Basically, the aim of CO_2 conversion is to utilize the concentrated CO_2 (from CO_2 capture) as a feedstock to produce valuable chemicals via various conversion processes including thermochemical reaction, electrochemical reduction, photo-catalytic reduction, and bio-enzymatic reduction (Adebajo and Frost, 2012; Taheri Najafabadi, 2013). However, for CO_2 conversion to become widely practical, significant hurdles will need to be overcome. Slow kinetics and high energy demand associated with most CO_2 conversion reactions can lead to high economic penalties and additional CO_2 emission.

In spite of much research done on CO_2 conversion reactions in recent years, works on their process development, optimization, and analysis of their economic feasibility and impact on reduction have been scarce. In this paper, two thermochemical CO_2 conversion reactions, namely the combined reforming and CO_2 hydrogenation, are investigated. Designs of sustainable methanol plants employing these reactions and the conventional methanol plant are developed, respectively. Moreover, the net CO_2 flow and economic feasibility, crucial factors for sustainable process development, of the two methanol plants are compared. Finally, for those infeasible cases, either in terms of net CO_2 flow or economics, strategies are suggested to make them feasible.

2. Process description

In this study, three methanol production processes are developed and compared with one another. Two of the three utilize CO_2 as feedstock and the third represents a conventional process for methanol production. In the conventional process, syngas (the mixture of H_2 and CO) is produced through two-stage reforming (steam reforming and partial oxidation) and methanol is synthesized from the produced syngas (Dahl et al., 2014). The combined reforming (also referred to as mixed reforming or bi-reforming) can also produce syngas for methanol synthesis as in the conventional case, but it uses CO_2 as well as methane as feed and there is only one reforming stage combining the steam reforming and dry reforming steps (Holm-Larsen, 2001; Olah et al., 2009). Finally, methanol can be synthesized from CO_2 hydrogenation using CO_2 and H_2 (Van-Dal and Bouallou, 2013). The reactions taking place in each of the three processes are listed in Table 1.

The two CO_2 conversion reactions (see Table 1) are based on mature technologies already tested in large scale and therefore have the potential for further development. Most other CO_2 conversion options are currently in small-scale experimental stage. For example, a commercial-scale methanol plant (3,030 MTPD) adopting combined reforming has started up in Iran in 2004 (Aasberg-Petersen et al., 2008) and another commercial methanol plant (5 million liters per year) adopting CO_2 hydrogenation has been successfully launched in Iceland in 2011 (CRI, 2011).

Flowsheet simulations of the three methanol plant have been developed in Aspen plus® with the design specifications taken from Holm-Larsen (2001), Van-Dal and Bouallou (2013), and Dahl et al. (2014), respectively. The feed and reactor (including the primary reformers and the CO_2 hydrogenation reactor) operating conditions are optimized further through the simulator (see Table 2).

Table 1. Three different reactions for the methanol production

	Reaction equation	Operating conditions
Combined reforming	$CH_4 + H_2O \rightarrow 3H_2 + CO, \Delta H^\circ = 206.3$ kJ/mol	850~950 °C
	$CH_4 + CO_2 \rightarrow 2H_2 + 2CO, \Delta H^\circ = 247.3$ kJ/mol	20~30 bar
CO_2 hydrogenation	$CO_2 + 3H_2 \rightarrow CH_3OH + H_2O$	200~300 °C
	$\Delta H^\circ = -49.32$ kJ/mol	50~100 bar
Two-stage reforming	$CH_4 + H_2O \rightarrow 3H_2 + CO, \Delta H^\circ = 206.3$ kJ/mol	850~950 °C
	$CH_4 + 0.5O_2 \rightarrow H_2 + CO, \Delta H^\circ = -35.6$ kJ/mol	20~30 bar

Table 2. Feed and operating conditions of three methanol plants

	S/C_nH_m	CO_2/ C_nH_m	O_2/ C_nH_m	H_2/CO_2	T (°C)	P (bar)
Combined reforming	1.79	0.29	-	-	950	22.5
CO_2 hydrogenation	-	-	-	3.00	200	70
Two-stage reforming	1.80	-	0.46	-	890	25

3. Process evaluation and results

In principle, net CO_2 flow and economic feasibility are essential criteria for discussing the feasibility of CO_2 conversion processes.

$$Net\ CO_2\ flow = \sum_i F_{CO_2,i}^{Generated} - F_{CO_2}^{Input} \quad (1)$$

The feasible CO_2 conversion process must achieve a reduction of net CO_2 flow defined as in Eq.(1). Here, the input flow ($F_{CO_2}^{Input}$) is being converted while the generated CO_2 ($F_{CO_2,i}^{Generated}$) is the amount emitted through purge (direct emission) and/or produced for energy used by the process (indirect emission) (Frauzem et al., 2015). Also, positive profit should be guaranteed, based on the mass and energy balance information of the process simulation. The cost of each methanol plant is evaluated by using ECON®. For the costs and energy supply, the equivalent of CO_2 generated is calculated. For the CO_2 feedstock, it is assumed to be captured at a H_2 plant (Metz et al., 2005). H_2 is produced via steam methane reforming (SMR) (Bartels et al., 2010), and the power demand is supplied from the conventional gas-fired power plant (U.S. EIA, 2013). Also, the natural gas is assumed to be 3.915 USD/MMBTU.

Table 3 lists the net CO_2 flow and the corresponding methanol production costs. However, its net CO_2 flow is positive because of the high heat demand in the reformer that resulted in significant CO_2 emission from the reformer furnace (accounting for 92.8 % of total emission, see Table 4). The CO_2 hydrogenation based methanol plant generates the most CO_2 because of the large demand for H_2 which is very expensive and gives significant indirect emission of CO_2 (97.8 %, see Table 4). Therefore, both of the CO_2 conversion based methanol plants are not feasible as is, and follow-up strategies are required.

Table 3. Net CO_2 flow and the methanol production cost of the three methanol plants

	Net CO_2 flow (kg_{CO2}/t_{MeOH})	Production cost ($/$t_{MeOH}$)
Combined reforming	253.56	227.68
CO_2 hydrogenation	1,202.07	596.72
Two-stage reforming	311.36	260.31

Table 4. CO_2 flows of three methanol plants

	CO_2 input rate (kg_{CO2}/t_{MeOH})	Direct CO_2 emission		Indirect CO_2 emission	
		Rate (kg_{CO2}/t_{MeOH})	Portion (%)	Rate (kg_{CO2}/t_{MeOH})	Portion (%)
Combined reforming	375	583	92.8	45	7.2
CO_2 hydrogenation	1,456	60	2.2	2,599	97.8
Two-stage reforming	0	264	84.9	47	15.1

4. Strategies toward the sustainable CO_2 conversion process

A new standalone installation of neither of the developed methanol plants utilizing CO_2 seems promising owing to their positive net CO_2 flow and/or too high production costs. To make them more attractive, process integration and utilization of renewable energy sources are considered.

4.1. Process integration of the combined reforming-based methanol plant with an existing methanol plant

Although an economic advantage is seen from the combined reforming based methanol plant, the problem is that more CO_2 is released from the process than the input amount. Instead of an independent implementation, if integration of two methanol plants in operation, a conventional methanol plant and the CO_2 conversion process, is considered, actual reduction of CO_2 emission can be achieved. In fact, both the conventional methanol plant and the combined reforming based methanol plant produce the syngas necessary for synthesizing methanol. Therefore, for given methanol production capacity, the syngas production rate from the two-stage reforming processing section can be reduced and the reduced amount can be supplemented by the combined reforming section. This "process integration" strategy is illustrated in Figure 1.

For various integration ratios (0.1~0.7, ratio 0.7 means 70 % of original syngas production rate at the two-stage reforming process is generated by combined reforming process and returned to the methanol synthesis section), several performance indices including the CO_2 abatement rate, CO_2 credit benefit, and the methanol production cost saving have been calculated and given in Table 5. Here, 4.63 EUR/t_{CO2} of carbon credit is applied in the calculation of the carbon emission credit benefit.

Consequently, increasing the process integration ratio (producing more syngas by the combined reforming process) leads to a decrease in CO_2 emission and an increase in the production cost saving. The reason is that syngas production via combined reforming is less costly and also emits less CO_2 than the two-stage reforming.

Eventually, depending on the desired CO_2 reduction rate, the proper integration ratio can be decided. This way one can obtain a more sustainable solution without any economic sacrifice. In addition, extra income may be earned from the carbon emission credit trading but it is rather minor (0.166 USD/t_{MeOH} for 50 % integration) at the current rate of carbon emission credit.

Table 5. CO_2 and economic-related performances with respect to the integration ratio

Integration ratio	0.1	0.3	0.5	0.7
CO_2 abatement rate (%)	1.82	5.45	9.09	12.7
Carbon credit benefit \$/tMeOH	0.0332	0.0997	0.166	0.233
Production cost saving \$/tMeOH	0.765	2.30	3.83	5.36

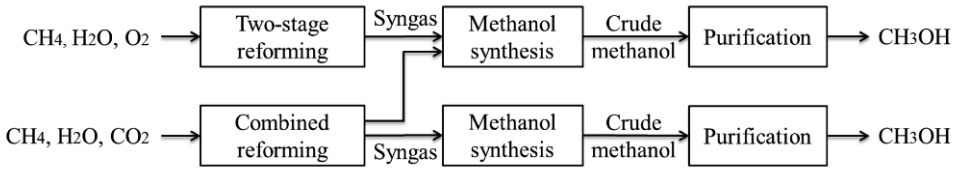

Figure 1. Schematic diagram of the integration of two methanol plants

4.2. Utilization of renewable energy sources for the CO_2 hydrogenation based methanol plant

Large demand of H_2, which is both expensive and laden with sizable CO_2 footprint, is the biggest hurdle to achieve a more sustainable solution for the methanol production via CO_2 hydrogenation. Instead of the conventional H_2 production via SMR, utilization of various renewable energy sources is an alternative worthy of consideration. Here, six different renewable energy sources for H_2 production are considered (Bartels et al., 2010; Yumurtaci and Bilgen, 2004): biomass, hydroelectric power, nuclear power, photovoltaic, solar thermal power, and wind power. For each case, the calculated net CO_2 flow and methanol production cost are plotted along with those of the SMR based H_2 production case and the conventional methanol plant case in Figure 2.

Most cases utilizing H_2 from renewable energy sources result in a reduction of net CO_2 flows except for the photovoltaic case. On the other hand, reasonable methanol production costs (less than 400 USD/t_{MeOH}) are obtained only in the case of hydroelectric power and biomass based H_2 production. The other cases are not found to be economically competitive because of their currently high power generation costs. Therefore, methanol production via CO_2 hydrogenation with H_2 production using hydroelectric power or biomass based is a more sustainable choice in terms of both the CO_2 flow and economic feasibility, at least at the current stage of development. Most likely, the wind and solar thermal power based H_2 production options can also become economically feasible if their power generation costs decrease further in the future.

5. Conclusion

CO_2 conversion technologies are currently attracting much interest due to the mounting concerns on climate change. To argue for the feasibility of CO_2 conversion processes, two promising reactions for methanol production, combined reforming and CO_2 hydrogenation, have been investigated. Plants employing the two reactions were designed and their net CO_2 flows and methanol production costs were evaluated and compared with those of the conventional methanol plant. The combined reforming based methanol plant showed an economic feasibility but it is found to release more CO_2 than it utilizes as input. In particular, direct CO_2 emission from the reformer furnace accounts for more than 90 % of the total CO_2 emission. For the case of CO_2 hydrogenation based methanol plant, the main problem was found to be the large demand for H_2 and its high cost and large CO_2 footprint. Since building a new installation of a standalone CO_2 conversion process based on these reactions is found to be not sustainable, two strategies to make them more sustainable have been investigated. First, integrating the combined reforming process with a methanol plant using the conventional two-stage reforming technology resulted in reduction of CO_2 emission as well as the methanol production cost saving. For the CO_2 hydrogenation based case, utilization of various renewable energy resources has shown to decrease the indirect CO_2 emission at the H_2 production step. In particular, use of the hydroelectric power or biomass in producing the required H_2 has led to a more sustainable solution. The interested reader can obtain the calculation details and simulation results by contacting the corresponding author.

Abstract

In this study, optimal design of algal biorefinery using microalgae with respect to techno-economic criteria is studied. A systematic methodology using superstructure-based optimization is used to this end. A superstructure representing a wide range of technologies developed for processing microalgae to produce end products is formulated. The corresponding technical and economic data is collected and structured using a generic input-output mass balance models. An optimization problem is formulated and solved to identify the optimal designs. The effect of uncertainties inherent in economic analysis such as microalgae production cost, composition of microalgae (e.g. oil content) and biodiesel/bioethanol market prices is considered. New optimal processing paths are found with potential of producing higher amount of biodiesel. Last, the methodology is intended as decision support tool for early-stage concept screening to enhance the future development of algal biorefinery.

Keywords: Algae biorefinery, superstructure-based optimization, process synthesis.

1. Introduction

Sustainability in particular resource availability is a serious challenge to economic growth of chemical/biochemical industries. This motivates the development of technologies for utilizing more sustainable and renewable feedstock. This study is focusing on microalgae as an alternative renewable platform for manufacturing biofuels and co-products.

In development of algal biorefinery, there are a number of alternatives potentially available to choose from depending on types of microalgae and the processing technologies used to produce biodiesel, glycerol, ethanol and protein-based compounds. One of the challenges in identifying optimal algal biorefinery concept is the underlying uncertainties in data used for comparison and evaluation. These include the volatility of market prices, process conversion factors and yields inherent in new technologies. Therefore, it is important to use a systematic methodological approach at early stage design phase to identify the optimal designs under uncertainties.

In this study, a systematic framework that uses superstructure-based optimization is used to identify the optimal algal biorefinery concept. The study considers the effect of uncertainties in raw material composition and product prices on the decision making as well. First, a superstructure representing design space of algal biorefinery is developed containing various types of microalgae and subsequent pretreatment, reaction and

separation technologies to produce biodiesel, ethanol and protein-based compounds.. Subsequently, the database (generic model and parameters and data) is collected The superstructure which is formed by the combination of the alternatives (types of feedstock, technologies, and products) together with the collected data, is then mathematically formulated as optimization problem and solved to identify the optimal designs with respect to techno-economic constraints . Further product market prices and algae oil content uncertainties are analysed for robust decision making purposes.

2. Framework

2.1. Step 1: Problem formulation: (i) problem definition; (ii) superstructure definition and data collection; (iii) model selection and validation.

The first step consists of defining the problem scope by selecting objective function and optimization scenarios with respect to economic/business metrics, engineering performance, or sustainability criteria. The superstructure (processing network) is also defined and the necessary data are collected. The model selection and validation task is then performed, i.e. a consistency check. Each processing technology is simulated in GAMS to reproduce the collected results to verify the input parameters and models used prior to the optimization problem.

2.2. Step 2: Uncertainty characterization.

In this step, the domain of uncertainty is defined and characterized. Monte Carlo simulation and Latin Hypercube Sampling with correlation control are then used to sample uncertain data. The sampling of uncertain data yields the potential scenarios that are to be analyzed in the next step.

2.3. Step 3: Identification of optimal designs under deterministic basis.

The optimization problem which is formulated in step 1 is performed and solved in this step using the nominal values for the parameters – in case a parameter is characterized by a certain statistical distribution (hence uncertain input) then its mean value is used here. The result in this step is the deterministic optimal processing path, i.e. yielding one optimization scenario on the basis of mean value of the input data.

2.4. Step 4a: Identification of optimal designs under uncertainties (deterministic problem)

In this step, the deterministic optimization problem is performed separately for each sample generated from the uncertainty domain (in Step 2). The results are the probability distribution of the objective function value and the frequency of occurrence of the optimal processing path candidates that are selected for given uncertain inputs.

2.5. Step 4b: Identification of optimal designs under uncertainties (stochastic problem, sample average approximation)

In this step, the optimization problem is modified as a stochastic programming problem by including uncertainty domain (inputs, parameters, etc). To this end, the objective function is reformulated as to minimize or maximize the expected value of the objective function over the uncertain domain.

2.6. Step 4c: Identification of optimal designs under uncertainties (stochastic problem, optimal flexible network)

In this step, the optimal trade-off between the investment cost and the ability of the network to adapt its structure in order to mitigate the negative consequences of the uncertainty is identified. The problem is reformulated as a two-stage stochastic programming problem. This step is beyond the scope of this study.

3. Identification of algae biorefinery optimal designs

In this section, synthesis and design of algal biorefinery networks under uncertainty was performed using the systematic framework presented in earlier section.

3.1. Step 1: Problem formulation: (i) problem definition; (ii) superstructure definition and data collection; (iii) model selection and validation

The problem statement was formulated as the identification of optimal biorefinery concepts with respect to techno-economic specifications under a specific objective function aiming at maximizing company earnings. The superstructure (Figure 1) of the algae biorefinery processing network was generated producing biodiesel and co-products by processing microalgae cultivated by raceway pond with 1300 tpd (the same basis as Pacific Northwest National Laboratory, Jones, et al., 2014). The superstructure has 4 four main processing steps consisting of 12 harvesting technologies; 4 pretreatment technologies; 4 extraction technologies; 6 transesterification alternatives; and 4 conversion technologies of co-products, resulting in total of 1920 alternative processing paths. The data collection including model verification was performed against the experimental data published prior to the identification of optimal processing paths in the next steps. This step was performed in the previous study (Cheali et al., 2014a) to form the basis in this study.

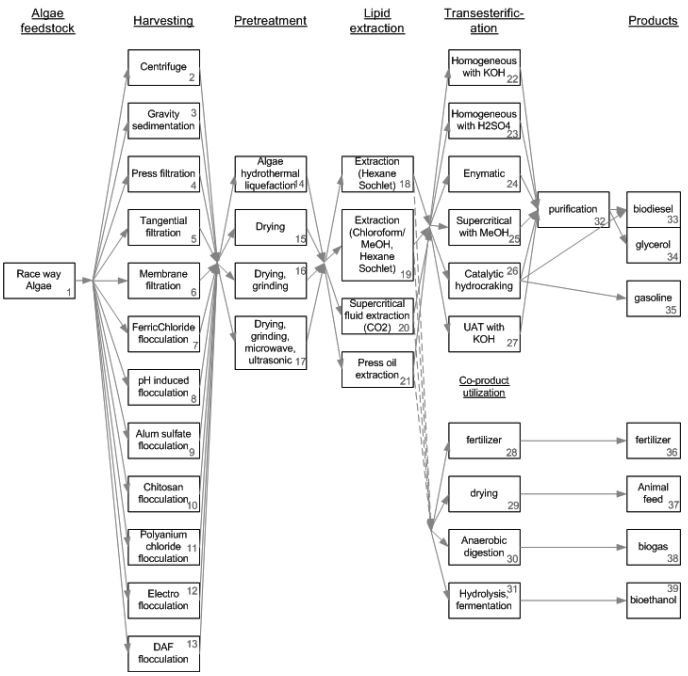

Figure 1. The superstructure of algae biorefinery processing networks

3.2. Step 2: Uncertainty characterization.

In this study, the uncertainties of market prices (biodiesel and bioethanol prices) and oil content in microalgae were identified as the important sources of uncertainty affecting the decision making. Other potential sources of uncertainties (i.e. yields, reaction conversions, efficiencies) were not considered due to low values of uncertainties

reported. A summary of the input uncertainties and the correlation coefficient if available used in this study is presented in Table 1. These data forms the input uncertainty domain, which were then sampled to generate 200 samples of the uncertain inputs. Latin Hypercube Sampling (LHS) technique was used to this end.

Table 1. Input uncertainty and correlation control coefficient

	mean	**Std**	**Reference**	
Biodiesel price ($/kg)	1,43	0,07	EIA	
Bioethanol price ($/kg)	0,72	0,08	USDA	
	min	**Max**		
Oil content (Raceway pond)	7,5	22,5	Alabi et al. (2009)	
Raw algae cost ($/ton)	300	560	Jones et al. (2014)	
Correlation matrix				
	DO	EtOH	RC	Algae
Biodiesel price (DO)	1	0,194	0	0
Bioethanol price (EtOH)	0,194	1	0	0
Oil content (RC)	0	0	1	0
Algae cost	0	0	0	1

3.3. Step 3: Identification of optimal designs under deterministic basis.

In this study, the objective function was defined as maximizing the operating profit (MM$/y) for the biodiesel scenario. The formulated MIP/MINLP was solved in this step under the deterministic basis (mean input values), in particular, maximizing Earnings Before Interest, Taxes, Depreciation and Amortization (EBITDA). The optimization solutions are presented in Table 3. The results show that a new optimal processing paths was found compared to the case study from PNNL report (Jones et al., 2014).

Objective function:

$$\max. EBITDA = Revenue - Expenses\ (excluding\ interest,\ taxes, depreciation\ and\ amortization$$

3.4. Step 4a: Identification of optimal designs under uncertainties (deterministic problem)

In this step the 200 samples generated from the LHS sampling were used as the input data for the MIP/MINLP problem, resulting in 200 optimal solutions. The full results were then analysed to identify the optimal solution under uncertainty. As presented in Table 2, two processing paths were selected under uncertainty.

From the 200 considered scenarios under uncertainty, network 1 and network 2 are identified as the best candidates. Moreover, network 1 resulted in higher EBITDA, however, standard deviation is slightly higher compared to network 2 meaning that further analysis should be performed to mitigate the impact of uncertainties such as flexible network solution.

Table 2: The frequency of selection of the optimal processing paths for 200 input scenarios under uncertainties

Network no.	Processing path	Frequency of selection	EBITDA (MM$/a)	Std.
1	Algae, hydrothermal liquefaction, transesterification with H_2SO_4	130/200	351	26
2	Algae, hydrothermal liquefaction, transesterification with KOH	70/200	316	25

3.5. Step 4b-4c: Identification of optimal designs under uncertainties (stochastic problem, sample average approximation and optimal flexible network)

The mathematical formulation used in Step 3 and Step 4a were reformulated as stochastic programming and solved in this step. Table 3 presents the optimal solutions (processing paths and operating profits) under uncertainty. As regards the optimal network solutions under uncertainty, the process topologies selected were slightly different from the deterministic case, which was the trade-off between conversion and utility cost (higher conversion but more expensive using H_2SO_4), therefore confirming the robustness of the deterministic solution and a strong impact of uncertainties.

Table 3: Optimal solutions under uncertainty

Solution	Network	EBITDA (MM$/a)	Capital cost (MM$)	Operating cost (MM$/a)		
				Microalgae cost	Natural gas	Catalyst/Chemicals
Optimal network (Step 3)	Algae, hydrothermal liquefaction, transesterification with H_2SO_4	316	252	190	6.6	4.5
Network under uncertainty (Step 4b)	Algae, hydrothermal liquefaction, transesterification with KOH	314	252	190	6.6	3.8

To sum up, based on the techno-economic analysis of optimal biorefinery network presented in the previous steps of the methodology, the network presented in Figure 2 is found as the optimal solution both under deterministic case and under uncertainty in particular market uncertainties. Hence the result from optimal flexible network (Algae, hydrothermal liquefaction, transesterification with H_2SO_4 and KOH) is the recommended as the best candidate among the design space for further research and development efforts.

Moreover, it is important to note that 90% of biodiesel production cost is related to the microalgae production cost (1300 tpd of microalgae, 190 MM$/y) which is much higher compared to lignocellulosic biomass (67 %, Cheali et al., 2014b). Furthermore, at the same capital investment, algal biorefinery has a lower production capacity compared to lignocellulosic biorefinery meaning that it is significantly more capital intensive and expensive to realize with the current cost of microalgae production (Jones et sl., 2014). However, biodiesel yield is higher, 51% for algal biorefinery and 28% for lignocellulosic biorefinery (Cheali et al., 2014b).

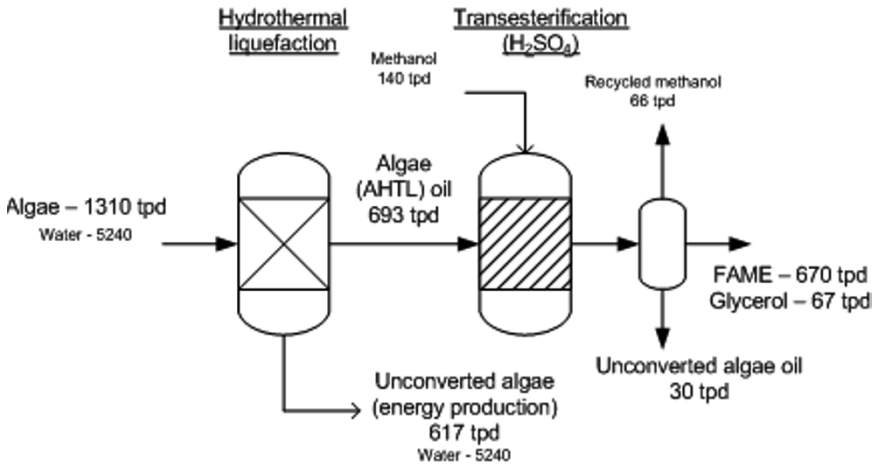

Figure 2. The optimal processing network (simplified flowsheet)

4. Conclusion

In this study, the systematic framework for synthesis and design of processing networks under uncertainty was applied for designing optimal algal biorefinery processing networks. A new optimal processing path was identified which includes the following processing scheme: hydrothermal liquefaction and transesterification with acid (H_2SO_4) or KOH. Moreover, the solutions under deterministic basis and under uncertainties in product market prices, algae cost and oil content are slightly different. These confirm the strong impact of oil content in algae and biodiesel market prices for algae biorefinery processing networks. It is also important to note that the microalgae cost is around 90% of the biodiesel production which indicates that research and development efforts need to focus to bring down the production costs of microalgae by and large.

Using the framework, many processing network alternatives are generated and evaluated at their optimality resulting in the identification of the optimal processing paths. The generated database and superstructure provides a versatile process synthesis toolbox to support designing future and sustainable algal biorefinery.

Abstract

This paper deals with the design and optimization of the Sabatier process for the production of methane from renewable sources with emphasis on the reactor section. It is designed to produce Synthetic Natural Gas (SNG) ready to be injected into existing natural gas grids after downstream drying of the gas via water absorption in glycol. The investigated process configuration is a cascade of polytropic fixed bed reactors with intermediate condensation steps for water removal. The temperature profile and feed conditions of the reactors are optimized simultaneously together with the design parameters of the process, thereby minimizing the production cost of (SNG). It is shown that a cascade of three tube bundle reactors with two intermediate condensation steps is the best process configuration in terms of production cost and practical implementation.

Keywords: Dynamic optimization, CO_2 utilization, H_2 storage, Methanation, Reactor design, Process economics.

1. Introduction

Meeting future energy demands and ensuring sustainable energy supply are two main challenges modern societies are facing. Depletion of fossil fuel reserves, geopolitical struggles, continuous increase of fuel prices, and environmental concerns are factors that push the development of efficient technologies which can exploit renewable energy sources, in particular wind and solar energy. However, electricity generated from these sources is characterised by significant fluctuations posing challenges to the electrical grid. To overcome this, electricity in excess is stored such that it can be fed into the grid at a future point. Unlike batteries and pumped hydro storage which can provide only limited capacities (Stolten et al., 2013), mass storage of surplus electrical power can be realized by converting it into gas. Due to its high selectivity (100%), efficiency (80%), positive impact on environment, and the existing infrastructure for natural gas storage and distribution, the Sabatier process is considered an attractive power-to-gas process route. It converts CO_2, obtainable from biogas plants or coal-fired power plants, by use of H_2, producible by water electrolysis, to synthetic methane which can be used as a fuel or a chemical feedstock whenever needed. The main reaction is:

$$\mathrm{CO_2 + 4\,H_2 \Leftrightarrow CH_4 + 2\,H_2O} \;\; ; \;\; \Delta_R H^0 = -165 kJ/mol$$

In this work we aim at designing and optimizing the Sabatier process with focus on the reactor. The optimal reaction concept is identified from a process-wide perspective to account for its coupling with the other units in the process. This is done by applying our

Elementary Process Function (EPF) methodology (Peschel et al., 2010). Using this flux-oriented approach, the reactor and process design parameters are identified from the solution of a dynamic optimization problem. The objective is to minimize the production cost of SNG which has to meet the following gas grid quality specifications: $0 < x_{out,\,H_2} < 0.02,\ 0 < x_{out,\,CO_2} < 0.05,\ 0.95 < x_{out,\,CH_4} < 1, 0 < c_{out,H_2O} < 200\ \mathrm{mg/m^3}$ (see: DVGW G260/A, 2013; DIN 51624).

2. Optimal Reaction Concept and Process-wide Optimization

2.1. Sabatier Process

Since reducing the number of purification steps can have significant impact on reducing the overall cost of the process, the downstream processing of SNG in the considered design is limited to a final drying step using glycol. The selectivity of the methanation catalyst is normally very high (almost 100%) such that CO separation is not an issue here. But the H_2 conversion must be more than 99 % to meet the product specifications. The whole process thus consists of two main parts: reaction section and drying section.

2.2. Optimal Reaction Route

The design of an optimal reactor based on our EPF methodology follows three decision levels. Predefined devices are avoided on Level 1; instead a general fluid element in the thermodynamic state space is considered. The fluid element is manipulated over time by unlimited mass and heat fluxes such that one obtains optimal profiles of the state variables (e.g. T, x_i), i.e. the optimal reaction route. By investigating the potential of the different options for flux manipulation, the best possible reaction concept can be identified. On Level 2, the effects of mass and heat transfer limitations are taken into account and practically realizable control variables for flux manipulation are determined. On Level 3, the best control variable profiles are technically approximated and additional non-idealities are considered based on a detailed reactor model.

Due to the proposed layout of the Sabatier process and the given constraints (X > 99 %, quality specifications), dosing of the reactants CO_2 and H_2 during the reaction turns out to be not favorable, whereas extraction of products is inevitable in order to overcome thermodynamic limitation of the methanation reaction. According to our knowledge, no simple technology for extracting CH_4 from CO_2/H_2 mixture exists so far. Thus, CH_4 extraction is not an option here. But several methods are available for extracting water either continuously or in discrete manner, namely via hydrophilic membranes or simply by condensation. In addition to water removal, since the Sabatier reaction is highly exothermic, intensive cooling is necessary. This leads to one technically possible integrated concept, namely a reactor section with simultaneous water extraction by use of active cooling. For the sake of brevity, the integration concept developed on Level 1 will not be outlined in more detail here. Instead, the next focus is on Level 2, namely on a process system which applies intermediate condensation steps for water extraction and heat removal during the methanation reaction.

2.3. Model Formulation on Level 2

2.3.1. Reactors

We consider a cascade of polytropic tube bundle reactors with interstage condensation. The reactors are assumed to be randomly packed with spherical pellets. Optimization variables for each reactor of the cascade are: inlet temperature (573 K $\leq T_{in} \leq$ 673 K), inlet pressure (5 atm $\leq p_{in} \leq$ 10 atm), tube diameter (1 cm $\leq d_t \leq$ 5 cm), length of reactor (0.3 m $\leq L \leq$ 10 m), and inlet composition of the first reactor ($0.79 \leq x_{H2,in} \leq 0.81$, $0.19 \leq$

$x_{CO2,\ in} \leq 0.21$). The particle diameter of the catalyst in the tubes is an optimization variable which was varied such that $d_t / d_p \geq 10$.
The tubular reactors are described using a 1D pseudo homogeneous plug flow model. The component mass balances, Eq. (1), and the energy balance, Eq.(2), are given by:

$$\frac{d(\rho_i v_i)}{dz} = \left(\rho_c \frac{1-\varepsilon}{\varepsilon} M_i \right) \sum_j \nu_{ij} r_j \tag{1}$$

$$\rho_g C_p \frac{dT}{dz} = -\left(\frac{4}{d_t \varepsilon} q + \sum_j \Delta H_j r_j \rho_c \frac{(1-\varepsilon)}{\varepsilon} \right) \frac{1}{v_i} \tag{2}$$

The reaction rate expressions r_j for the main reaction (methanation) and the main side reaction (reverse water gas shift) are taken from the work of Xu and Froment (1989).
The heat transfer between the reactor and the coolant was described by

$$q = \alpha_w (T - T_c) \tag{3}$$

where T_c, bounded between 550 and 700 K, is used to control the heat flux q. The heat transfer coefficient across the wall of the reactor is calculated using the correlation given by Yagi et al. (1959). Ergun's equation was used to estimate the pressure drop:

$$\frac{dp}{dz} = -\left(150 \mu_g \frac{(1-\varepsilon)^2}{d_p^2 \varepsilon^3} + 1.75 \frac{v_s \rho_g (1-\varepsilon)}{d_p \varepsilon^3} \right) v_s \tag{4}$$

2.3.2. Condensers
Each condenser is represented by two heat exchangers in series: the first uses steam as coolant while the second uses liquid water. The phase separation in the condenser is calculated using a standard equilibrium flash model (see e.g. Biegler et al., 1997). At equilibrium, the dew point equation must be satisfied. The temperature and split factor defined as $\xi_i = n_{i,vapour} / n_{i,feed}$ $(0 \leq \xi_i \leq 1, 298 \leq T_{cond} \leq 400K)$ are optimization variables while the condensation pressure p_{cond} is set equal to the reactor pressure upstream. The phase distribution constants, $K_{i,cond} = y_{i,cond} / x_{i,cond}$, are calculated using temperature- dependent correlations (Fernandez-Prini et al., 2003) which also account for the solubility of the gaseous components in the liquid phase.

2.3.3. Downstream Dehydration Process
Since natural gas distribution grids require extremely low water content, downstream drying of the generated SNG is indispensable. Several technologies are available for drying natural gas. The most widely used technology is the dehydration of the gas by water absorption using triethylene glycol (TEG). This technology is easy to operate, cheap to install, and the TEG regeneration requires a relatively low amount of energy. In order to estimate the size of the water absorption column and further operating conditions of the glycol unit, we used correlations proposed by Bahadori and Vuthaluru (2009) who calculated the water removal efficiency as a function of the following optimization variables: number of theoretical stages, circulation rate and glycol purity

which is a function of boiler pressure and boiling temperature (Bahadori et al., 2014). The boiler uses steam for heating the glycol-rich solution. The pressure of the absorber column was fixed at 41 bar, the inlet temperature of the wet gas at 311 K and that of the lean glycol at 317 K.

2.3.4. Compressors and Heat Exchangers

The heat exchangers considered are counter-current tube-shell exchangers. The heat exchange area is calculated in terms of the heat duty, mean logarithmic temperature difference, and the heat transfer coefficient. While the heat duties are calculated based on energy and mass balances, overall heat transfer coefficients can be estimated in dependence on the heat transfer media and typical flow conditions.

The outlet temperature and theoretical electric power consumption of the gas compressors are calculated by assuming ideal isentropic compression. The resulting brake power is estimated with the help of compressor and motor efficiencies. Sizing the heat exchangers and compressors is done using the method reported in Biegler et al. (1997).

2.4. Process Optimization

The objective is to minimize the production cost of the proposed process for a given volumetric SNG production rate of 891 m_N^3/h. The production costs include the raw materials, operating costs, and investment costs of the main utilities (heat exchangers, compressors, reactors, glycol water absorption unit). Typical values for the costs of raw materials, electricity, steam, and cooling water are used. The plant is assumed to operate for 10 years, 330 days a year. The investment cost of the sized equipment is estimated using power law correlations developed first by Guthrie in 1969 (see e.g. Biegler et al., 1997), corrected by use of cost updating factors (Chemical Engineering Plant Index, 2012). As mentioned earlier, three different reactor cascades with different number of intermediate condensation steps (1 -3 steps) are investigated and compared on the basis of the production costs of the overall process. Each reactor of the cascade is assumed to consist of 500 parallel tubes filled with catalyst as sketched in Figure 1.

The resulting optimization problem was solved using CONOPT 3.14 G in AMPL. It can be stated as follows:

$$\min_{DoF} \; Cost$$

s.t:

- Component balance equations
- Energy balance equation
- Pressure drop equation
- Chemical reaction kinetics
- Heat transport kinetics
- Ideal gas law
- Inequality constraints (e.g. $d_t/d_p \geq 10$)
- Shortcut models for other process units(e.g.condensers, compressors,absorber)

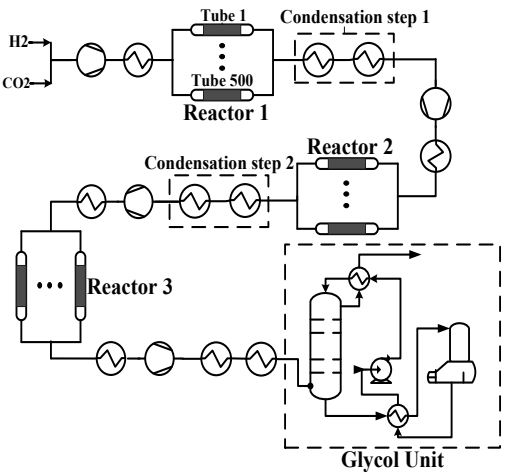

Figure 1: Process flow sheet: Cascade of 3 reactors, each with 500 parallel tubes, and 2 intermediate condensation steps.

3. Results

Although increasing the number of condensation steps enhances the performance of the reactor cascade, as reflected by the space time yield (STY=4.1; 8.8; 10.1 mol/(m^3 s), for 1,2 and 3 condensation steps, respectively), it is not always beneficial on the economical level. The results in Figure 2 shows that having two intermediate condensation steps instead of only one step reduces the production cost by around 440,000 USD. However, adding one condensation step (i.e. 3 intermediate condensation steps with 4 reaction segments) leads to an increase of the cost by more than 2 million USD. This is due to the fact that the incremental enhancement in the performance of the reactors decreases with increasing the number of condensation steps. Beyond two steps, this enhancement does not compensate the increased investment and operating cost for the additional equipment needed (e.g. heat exchangers).

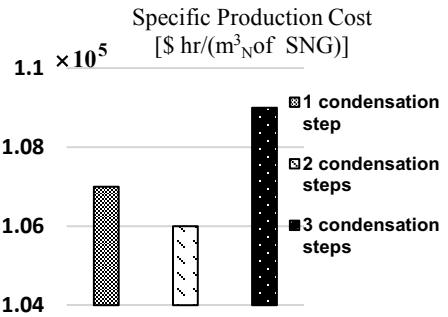

Figure 2: Specific production cost of the process for different number of condensation steps in the reactor cascade.

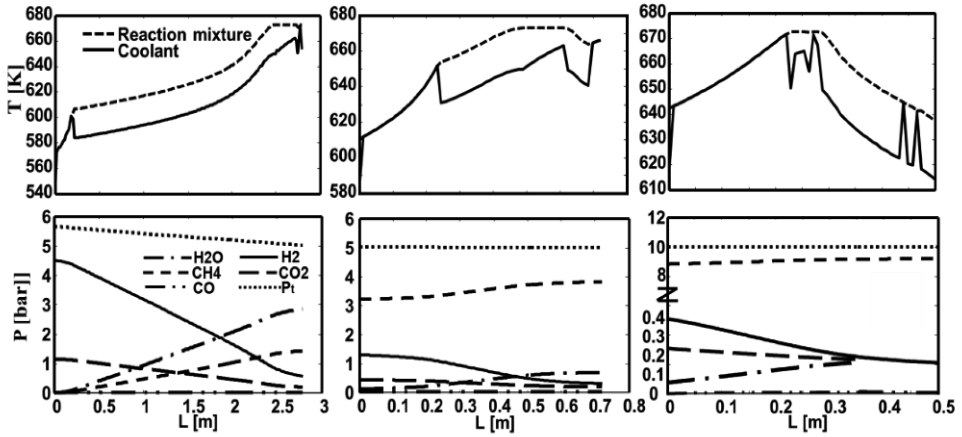

Figure 3: Optimal temperature profiles (upper row), total pressure and partial pressures (lower row) in the tubes of the three reactors (from left to right: reactors 1, 2, 3).

Thus, the best process configuration is a cascade of three tube bundle reactors with two intermediate condensation steps. The optimal temperature profiles of the coolant and reaction mixture in the tubes of the three reactors are presented in Fig. 3. These profiles can be approximated using a combination of adiabatic operation and active cooling using cocurrent (reactor 1 and 2) and counter current (reactor 3) heat exchange. The oscillations of the coolant temperature in reactor 3 are difficult to realize technically. They can be either approximated using countercurrent heat exchange or by partly adiabatic operation. Figure 3 also shows the partial pressure of the different components as well as the total inlet pressure. The optimal inlet pressure of the first and second reactor is 5.6 and 5 bars respectively. Although a higher pressure is favorable from the kinetic as well as from the thermodynamic perspective, a low pressure should be preferred since it reduces the cost of compression. However, the optimal inlet pressure of the third reactor is equal to the upper bound (10 bars) which shifts the methanation

equilibrium towards the product, thereby achieving the desired high level of H_2 conversion (X > 99%), and also increases the reaction rate. Furthermore, a high pressure in the last reactor reduces the power for gas compression to 41 bars, which is a typical pressure level in the absorber column of the glycol unit. The results also show that the concentration of the reactants increase due to intermediate condensation, leading to a sudden increase of reaction rates in the next reactor. The mole fraction of methane at the end of the reactor cascade is 94.7%. This increases further after drying the produced gas in the glycol unit such that the SNG quality requirements are met. Due to the condensation steps, the gas entering the absorber contains a low amount of water. For this reason only two theoretical stages are needed to purify the produced SNG.

4. Conclusions and Outlook

In this work, we design and optimize a process producing SNG from H_2 and CO_2. It consists of reaction section and a drying section. The cost optimal reaction section is a cascade of three fixed bed tube bundle reactors with two intermediate condensation steps for water removal. The results clearly show the importance of considering the coupling between the reaction section and the other process units when determining the optimal process operating conditions. Several advantages of water extraction in the reaction section are visible: (1) overcoming the thermodynamic limitation of the methanation reaction, (2) enhancing the chemical kinetics, and (3) reducing the energy duty of the glycol unit used for final gas drying. Within the reactor tubes, optimal temperature profiles should be realized in order to follow the optimal reaction route. In the future, we will compare the here proposed process configuration with a reactor equipped with an integrated hydrophilic membrane for in situ water removal. Based on this comparison one can step into detailed reactor design (Level 3 of our EPF methodology).

Abstract

Pinch technology is one of the commonly used energy-saving technologies in chemical industries. We have proposed a simulation framework using multiagent into the design of heat exchanger network (HEN) to save the energy usage and to reduce the emissions of greenhouse gases. We set up several HEN Design Agents and each agent had different strategy to search candidate segments of HEN to modify. In our previous study, HENs for only a single process was optimized by the multiagent system at a time. However in general, there are some abutting chemical processes in a site. The inter-process heat integration, that is heat giving and heat receiving between a process and the others, is effective for energy saving in addition to the internal heat integration in a single process.

In this study, we introduced Coordinator agent within the multiagent framework to achieve both inner-process and inter-process heat integration simultaneously.

Keywords: Multiagent system; Coordinator agent; Pinch technology; Heat Recovery; Heat exchanger network;

1. Introduction

Design of heat exchanger networks (HENs) is one of the important levers to save the energy consumption and to reduce emissions of greenhouse gases, in chemical industries. Although the concept of pinch technology is involved in some process simulation software, the skilled engineers' considerations are still necessary to obtain preferable HENs. We have proposed a multiagent oriented framework for HENs design using pinch technology (Kimura 2010, 2012). We have set up several kinds of agent, for example "Project Manager", "Energy Cost Manager" and "HEN Design Agent". And also we have set up some different strategies to HEN Design Agents. In our previous study, our multiagent system could design only a single process at a time. However, there are some abutting chemical processes in a site. Inter-process heat integration or total site heat integration is starts to garner attention. Cheng et al. (2014) proposed a game-theory based optimization strategy and demonstrated their method with a vinyl chloride monomer process. Onishi et al. (2014) proposed a multi-stage superstructure using MINLP to synthesize work exchange and heat integration simultaneously. Liew et al. (2014) developed Total Site Heat Storage Cascade, which can transfer the heat

between several batch processes. In their work, the detailed information of sub processes is necessary to provide to make integration scheme. However in the point of information management, information sharing is not always enthusiastic.

In this study, coordinator agent is introduced to our multiagent framework in order to achieve heat integration both respective sub processes and inter-process simultaneously. And also coordination mechanism is investigated.

2. Multiagent Framework

2.1. Agent framework

We have developed a multiagent framework with "Pinch technology" to design energy-saving chemical processes. In our previous study, HENs for only a single process was optimized at a time. However, there are several adjoining chemical processes in a site, several sub processes in a plant. In order to achieve inter-process heat integration, we introduced new agent named coordinator agent who accommodates heat from a certain sub process to another sub processes. Figure 1 shows the outline of our multiagent framework with coordinator agent. There are three multiagent systems, namely there are three sub processes A, B and C—which are represented by dashed shapes. In each sub process, there are one project manager, one targeting agent, one equipment cost

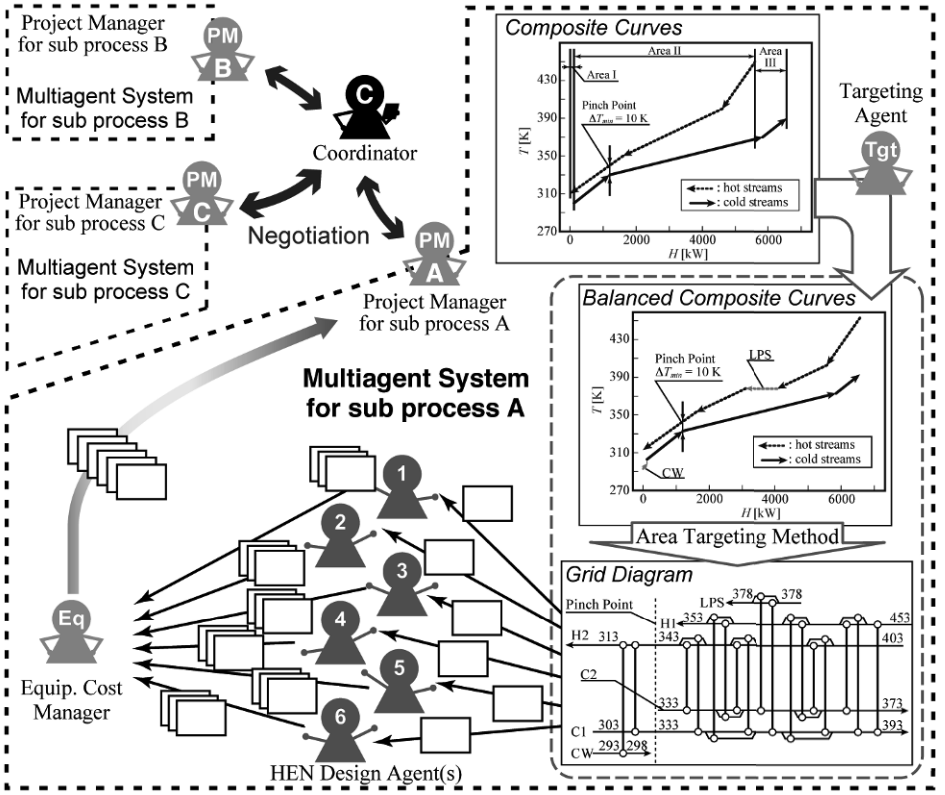

Figure 1: Schematic diagram of multiagent system with coordinator agent.

manager and some HEN design agents. Each multiagent system is able to optimize heat exchanger network for a single process. And process managers negotiate with coordinator agent based on their own result of the internal heat integration.

2.2. Negotiation protocol

Figure 2 shows an outline of communication sequence for the coordination mechanism. In the figure, there are three Project Managers named "PM-A", "PM-B" and "PM-C" for sub processes A, B and C respectively. For each sub process, there are also some agents (e.g. Targeting Agent, Cost Manager, Heat Exchanger Network Design Agent) to design and optimize its own heat exchanger network, but they are omitted in this figure. Each Project manager, named PM-A, PM-B or PM-C, sends a "Heat Demand" message—which contains the specification and quantity of utility— to the coordinator after the planning of the its internal heat integration. In the figure, PM-A needs to consume the high-pressure steam (HP) by 1.3 MW, PM-B can supply the HP by 18.9 MW and PM-C needs to consume the HP by 25.0 MW. When coordinator receives the Heat Demand messages from all the project managers, coordinator starts negotiation sessions with each project manager. Firstly, based on the heat demand from PM-A, coordinator sends a "Negotiation" message to PM-B to ask whether the HP (from PM-A) by 1.3 MW is receivable. Then, PM-B recalculate its internal heat integration and resend "Heat Demand" message with altered quantity of utility (-18.9 MW + 1.3 MW = -17.6 MW). After that coordinator sends other "Negotiation" message to PM-C to ask whether the HP by 17.6 MW can be supplied. If PM-C replies negative, coordinator starts another negotiation session based on the heat demand from PM-B.

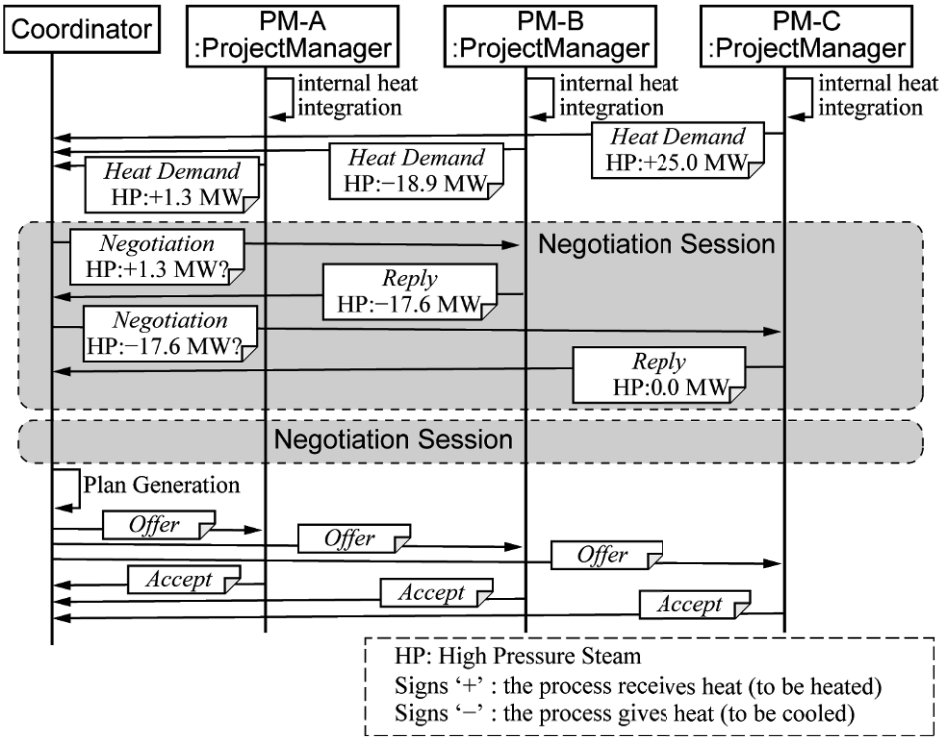

Figure 2: Communication sequence of coordination mechanism.

After the negotiation sessions, coordinator makes several inter-process heat integration plans by the matching between heat demands on the plan generation step. Then, coordinator sends “Offer” message to all the project managers with one of the heat integration plans. If coordinator receives "Accept” messages from all the project managers, the coordination is completed. If not, coordinator offers another plan, one after another. When the consensus obtained among coordinator and project managers, project managers respectively call their own Heat Exchanger Network Design Agents for HEN design based on the accepted inter-process heat integration plan.

3. Simulations and Results

3.1. The target process

3P-1 problem was applied to the above-mentioned multiagent system to achieve inter-process heat integration. This problem was originally introduced by Ahmad et al. (1991) and altered marginally by Hui et al. (1994). There are three sub processes—in other words “region”— A, B and C in the 3P-1. And there are certain distances between these three sub processes. The stream data of each sub processes are shown in Table 1(a)–(c), and the available utilities are shown in Table 1(d). Flue gas is a heating utility and chilled water is a cooling utility. Both HP-ex and HP-cycle mean ‘High Pressure steam’. HP-ex is a heating utility introduced from external energy plant. HP-cycle can be used not only as a heat giving (heating) utility but also as a heat receiving (cooling) utility to achieve the in-direct heat transfer between sub processes.

Table 1: Stream data of three sub processes and available utilities for 3P-1 problem.

(a): Sub process A

Stream Name	Temperature		*CP* [MW/°C]	Heat load *ΔH* [MW]
	Inlet T_{in} [°C]	Outlet T_{out} [°C]		
HotA1	250.0	120.0	0.30	39.00
ColdA1	185.0	220.0	0.50	17.50

(b): Sub process B.

Stream Name	Temperature		*CP* [MW/°C]	Heat load *ΔH* [MW]
	Inlet T_{in} [°C]	Outlet T_{out} [°C]		
HotB1	500.0	120.0	0.25	95.00
ColdB1	139.0	500.0	0.15	54.15
ColdB2	20.0	250.0	0.10	23.00

(c): Sub process C

Stream Name	Temperature		*CP* [MW/°C]	Heat load *ΔH* [MW]
	Inlet T_{in} [°C]	Outlet T_{out} [°C]		
HotC1	120.0	119.0	15.0	15.00
HotC2	200.0	30.0	0.20	34.00
ColdC1	110.0	160.0	0.25	12.50
ColdC2	200.0	201.0	25.0	25.00

(d): Available utilities.

Utility Name	Temperature		Annual cost [£/kW-y]
	Supply T_s [°C]	Return T_r [°C]	
Flue gas	1000.0	550.0	100.0
HP-ex	300.0	300.0	80.0
HP-cycle	300.0	300.0	120.0
Chilled water	5.0	6.0	10.0

3.2. Simulation result

Table 2 shows the utility distribution results, that is heat demands, after the internal heat integration of each sub process (i.e. before “negotiation session”). In the table, the above numeric numbers in a cell represent heating/cooling demands where the sign ‘+’ means consumption of the utility in its sub process, in contrast, the sign ‘–’ means providing. The below numeric numbers with parenthesis in a cell represent annual utility cost (or annual sales). Due to the internal heat integrations, the utility usage and

costs are minimized individually. However the net amount of annual utility cost for entire plant is over three million pounds.

Table 2: Utility distribution results for 3P-1 problem before inter-process heat integration.

Utility Name	Sub process			Net
	A	B	C	
Flue gas [MW]		+1.65		+1.65
(Cost [k£/yr])		(165)		(165)
HP-ex [MW]	+1.30		+25.00	+26.30
(Cost [k£/yr])	(140)		(2,000)	(2,140)
HP-cycle [MW]				0
(Cost [k£/yr])				(0)
Chilled water [MW]	+22.80	+19.50	+36.50	+78.80
(Cost [k£/yr])	(228)	(195)	(365)	(788)
Amount cost [k£/yr]	(332)	(360)	(2,365)	(3,057)

After the negotiation sessions among coordinator agent and three project managers, coordinator agent obtained nine feasible alternatives of inter-process heat integration plans out of 115 suggestions. Table 3 shows two alternatives of the inter-process heat integration. As compared with table 2, HP-cycle is used both in the plan 1 and 2 of table 3. Sub process B provides HP-cycle by 18.90 MW for sub process C instead of the chilled water demand. And the demand of HP-ex of sub process C is decreased in the both plans of table 3. Also the demand of HP of sub process A is changed from HP-ex to HP-cycle in the plan 2. As a consequence of the negotiation among coordinator agent and three project managers, the net amount of annual utility cost for entire plant is reduced more than half. Although the amount utility cost of entire plant and the cost sub process B are drastically reduced, the costs of sub processes A and B are the same or increased from table 2. In these cases, coordinator agent and project manager of sub process B are willing to agree to these plans. In contrast, project managers of sub processes A and C resist these plans because of the increasing utility costs.

Table 3: Utility distribution results for 3P-1 problem after inter-process heat integration.

	Plan 1				Plan 2			
	Sub process			Net	Sub process			Net
	A	B	C		A	B	C	
Flue gas [MW]		+1.65		+1.65		+1.65		+1.65
(Cost [k£/y])		(165)		(165)		(165)		(165)
HP-ex [MW]	+1.30		+6.10	+7.40			+7.40	+7.40
(Cost [k£/y])	(140)		(488)	(592)			(592)	(592)
HP-cycle [MW]		-18.90	+18.90	0	+1.30	-18.90	+17.60	0
(Cost [k£/y])		(-2,268)	(2,268)	(0)	(140)	(-2,268)	(2,112)	(0)
Chilled water [MW]	+22.80	+0.60	+36.50	+59.90	+22.80	+0.60	+36.50	+59.90
(Cost [k£/y])	(228)	(6)	(365)	(599)	(228)	(6)	(365)	(599)
Amount cost [k£/y]	(332)	(-2,097)	(3,121)	(1,356)	(384)	(-2,097)	(3,069)	(1,356)

4. Conclusions

In this study, “coordinator agent” had been introduced to the multiagent framework in order to achieve inter-process heat integration. And also the communication protocol

had been investigated. The results shows that it was possible to obtain several feasible inter-process heat integration alternatives using our multiagent system.

Abstract

The aim of this contribution is to address design, synthesis and scheduling simultaneously with the consideration of economic savings in utility requirements. The recent design and synthesis model by Seid and Majozi (2013) is extended to incorporate the design of the associated utility facility, since it is proven to result in better design objective and computational efficiencies. Additional feature of the proposed model is the determination of optimal pipe connection between processing equipment. The model is implemented in a case study in order to demonstrate its application. From the case study, the profit is increased by 20% and the total utility requirement is reduced by 41.1% for the design and synthesis of energy integrated batch plant compared to the basic design.

Keywords: Design; synthesis; multipurpose batch plant; energy integration; optimization; scheduling.

1. Introduction

There is a great deal of interest in the manufacture of fine chemicals, pharmaceutical products, polymers, food and beverages using batch operations because of their suitability for producing low-volume, high value products, their flexibility to adopt complex operations due to fast market change and their capability to manufacture different products using the same facility. In these batch facilities the different products compete for the available resources, (equipment, utility, manpower and storage) which renders the design and operation of these plants a challenging task. Great effort has been made in the last two decades to develop efficient models for design and synthesis problems.

Papageorgaki and Reklaitis (1990) proposed a mixed integer linear programming (MILP) formulation which accommodated equipment used in and out of phase, units available with different sizes in a processing stage and tasks which can be processed in different equipment. Most of the previous published work were restricted by the following key assumptions: (a) there was a prespecified assignment of equipment items to product tasks, (b) parallel production was only allowed for products that had no common equipment requirements, (c) all units of a given type were identical and could be used in the out of phase mode, (d) all units of a given type were devoted to the production of only one product at a time. Xia and Macchietto (1997) presented a general formulation considering linear/nonlinear models for capital cost of processing units/storage vessels and processing task models with fixed, linear and nonlinear processing time in a general form. The formulation resulted in a mixed integer nonlinear

programming (MINLP) solved by a stochastic MINLP optimizer. A short term scheduling model was implemented based on discrete time representation that allowed multiple batches of a product to be processed in any sequence. This deviated from previous published literature that considered campaign mode of operation. Lin and Floudas (2001) presented a formulation based on the scheduling formulation of Ierapetritou and Floudas (1998) using a unit specific event point and continuous time representation. The formulation addressed a single campaign production approach where multiple batches of a product can be produced in the given time horizon. A comparison with earlier formulation was given. The increasing importance of utilities rationalization within the design of multipurpose batch plants was first addressed by Barbosa-Povoa et al. (2001) who presented a mathematical formulation for the detailed design of multipurpose batch process facilities. This work was later extended by Pinto et al. (2003) where economic savings in utility requirements were obtained while also considering the cost of the auxiliary structures, i.e. heat-exchanger transfer area, and the design of the utility circuits and associated piping costs. Pinto et al. (2008) presented a review on the design of batch plants where both the grassroots and the retrofit design problems are analysed. Two types of plants are considered, the multi-product and the multipurpose plants. They also discussed the limitations and gaps in the published methods in literature.

2. Mathematical model

The mathematical model comprises the following sets, variables, parameters and constraints:

Sets

$J = \{ j \mid j$ is an equipment including heat exchanger$\}$, $P = \{ p \mid p$ is a time point$\}$, $S = \{ s \mid s$ is any state$\}$, $I_c = \{ i_c \mid i_c$ is a task that requires heating$\}$, $I_h = \{ i_h \mid i_h$ is a task that requires cooling$\}$, $I_{rm} = \{ i_{rm} \mid i_{rm}$ is a task that requires raw material$\}$

Continuous variables

$cw(i_h, p)$ = external cooling required by task i_h at time point p, $st(i_c, p)$= external heating required by task i_c at time point p, $w(i_h, i_c, p)$= amount of heat exchanged between the cold and hot task, $tp(i, p)$ = time at which a task finish, $tu(i, p)$ = time at which a task start, A = optimal heat exchanger area required, $mu(i_h, p)$ = amount of material processed by the hot task, $mu(i_c, p)$ = amount of material processed by the cold task, $q(s^p, p)$= amount of product delivered

Binary variables

$x(i_h, i_c, p)$ = 1 if hot task i_h is integrated with the cold task i_c at time point p; 0 otherwise, $y(i, p)$= 1 if task i is active at time point p; 0 otherwise, $e(j)$= 1 if unit j is selected; 0 otherwise

Parameters

C_p = specific heat capacity of fluid, $E(i)$= constant coefficient of amount of heat required or removed corresponding to task i, $\xi(i)$= variable coefficient of amount of heat required or removed corresponding to task i, M= any large number $T(i)$= operating temperature for a task i, $\Delta T^{\min}$ = minimum allowable thermal driving force, C_c = cost unit for cooling, C_h = cost unit for steam, U = overall heat transfer coefficient, $price(s^p)$=selling price for a product, AWH = annual working hour, H = time horizon of interest, FOC = fixed operating cost for a task, VOQ = variable operating cost for a task, FEC = fixed capital cost of equipment, VEQ = variable capital cost of equipment, RCS = raw material cost

Constraints

The recent robust design and synthesis formulation for multipurpose batch plants by Seid and Majozi (2013) is used as a platform. In addition to the design and synthesis model of Seid and Majozi (2013) the following energy integration constraints are used.

Constraints (1) and (2) are active simultaneously and ensure that one hot unit will be integrated with one cold unit when direct heat integration takes place.

$$\sum_{i_c} x(i_h, i_c, p) \le y(i_h, p), \forall\ p \in P,\quad i_h \in I_h \tag{1}$$

$$\sum_{i_h} x(i_h, i_c, p) \le y(i_c, p), \forall\ p \in P,\ i_c \in I_c \tag{2}$$

Constraint (3) ensures that minimum thermal driving forces are obeyed.

$$T(i_h) - T(i_c) \ge \Delta T^{\min} - M(1 - x(i_h, i_c, p)), \forall\ p \in P,\ i_c, i_h \in I \tag{3}$$

Constraint (4) states that the cooling of a heat source will be satisfied by direct heat integration as well as external utility if required.

$$(E(i_h) y(i_h, p) + \xi(i_h)\, mu(i_h, p))(tp(i_h, p) - tu(i_h, p)) = cw(i_h, p) + \sum_{i_c} w(i_h, i_c, p), \forall\ p \in P,\quad i_h \in I_h \tag{4}$$

Constraint (5) ensures that the heating of a heat sink will be satisfied by direct heat integration as well as external utility if required.

$$(E(i_c) y(i_c, p) + \xi(i_c))(tp(i_c, p) - tu(i_c, p)) = st(i_c, p) + \sum_{i_h} w(i_h, i_c, p), \forall\ p \in P,\quad i_c \in I_c \tag{5}$$

Constraint (6) states that the amount of heat exchanged between the hot and cold unit is limited by the total duration of the cold unit.

$$w(i_h, i_c, p) \le (E(i_h) y(i_h, p) + \xi(i_h)\, mu(i_h, p))(tp(i_c, p) - tu(i_c, p)), \forall\quad p \in P,\ i_c \in I_c,\ i_h \in I_h \tag{6}$$

Constraint (7) ensures that the amount of heat transferred from the hot unit to the cold unit is limited by the duration of the hot unit.

$$w(i_h, i_c, p) \le (E(i_c) y(i_c, p) + \xi(i_c)\, mu(i_c, p))(tp(i_h, p) - tu(i_h, p)), \forall\ p \in P,\quad i_c \in I_c,\ i_h \in I_h \tag{7}$$

Constraint (8) states that the amount of heat exchanged between the hot and cold unit cannot exceed a predetermined maximum value *M*.

$$w(i_h, i_c, p) \le M x(i_h, i_c, p), \forall\ p \in P,\quad i_c \in, I_c,\ i_h \in I_h \tag{8}$$

Constraints (9) and (10) are used to determine the heat exchanger area required.

$$UA(T(i_h) - T(i_c))(tp(i_h, p) - tu(i_h, p)) \ge w(i_h, i_c, p), \forall i_h \in I_h, i_c \in I_c, p \in P \tag{9}$$

$$UA(T(i_h) - T(i_c))(tp(i_c, p) - tu(i_c, p)) \ge w(i_h, i_c, p), \forall\ i_h \in I_h, i_c \in I_c, p \in P \tag{10}$$

Constraints (11) and (12) are used to synchronize units when heat integration takes place.

$$tp(i_h, p) \ge tp(i_c, p) - M(1 - x(i_h, i_c, p)), \forall\ p \in P,\quad i_c \in I_c,\ i_h \in I_h \tag{11}$$

$$tp(i_h, p) \le tp(i_c, p) + M(1 - x(i_h, i_c, p)), \forall\ p \in P,\quad i_c \in I_c,\ i_h \in I_h \tag{12}$$

Constraint (13) and (14) are used to cater for external utilities.

$$u_c = \sum_p \sum_{i_c} cw(i_c, p), \forall p \in P\ , i_c \in I_c \tag{13}$$

$$u_h = \sum_p \sum_{i_h} st(i_h, p), \forall p \in P\ ,\ i_h \in I_h \tag{14}$$

Constraint (15) is the objective function expressed as maximization of profit.

$$\text{maximize} \left(\begin{array}{l} \sum_{s^p} price(s^p)\, q(s^p, p) - \sum_p \sum_{i \in I_{rm}} RCS * mu(i, p) - \\ \sum_p \sum_{i \in I} FOC * y(i, p) + VOC * mu(i, p) \\ - C_c u_c - C_h u_h \end{array} \right) * (\text{AWH/H}) - \sum_{j \in J} FEC * e(j) + VEQ * ss(j) \tag{15}$$

3. Case study

This example, which was first examined by Sundaramoorthy and Karimi (2005), is studied extensively in literature. It is a relatively complex problem and is often used in literature to check the efficiency of models in terms of optimal objective value and CPU time required. The plant has many attributes of a multipurpose batch plant, with the following features: units performing multiple tasks, multiple units suitable for a task, states shared by multiple tasks and different products produced following different production paths. The state task network representation (STN) for this case study is depicted in Figure 1. The scheduling and design data are presented in Table 1. The raw material costs for state A, B and C are 1, 0.5 and 0.2 cost units (c.u/kg) respectively. The selling price for product 1 and 2 are 4 and 7 c.u/kg. respectively. Reaction 1 operates at 200 ^{o}C and it is exothermic which requires 0.167 kw/kg of cooling load. Reaction 2 operates at 70 ^{o}C and it is endothermic which requires 0.222 kw/kg of heating load. Reaction 3 operates at 160 ^{o}C and it is exothermic which requires 0.194 kw/kg of cooling load. Steam cost and cooling water cost are 0.7 and 0.15 c.u/MJ respectively. The plant operates 300 days/year.

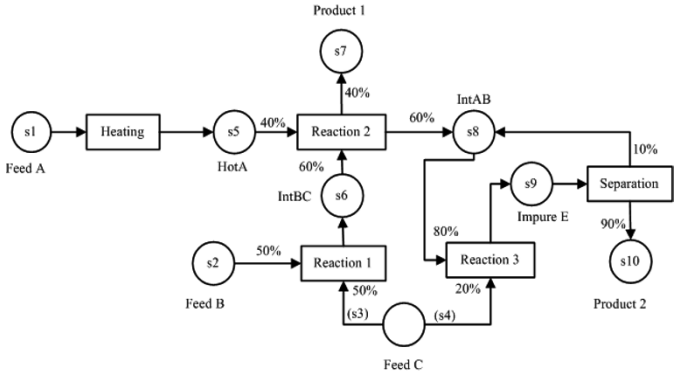

Figure 1. STN representaion for the case study.

Table 1. Equipment and scheduling data for the case study.

Unit	Capacity (ton/m^2)	Suitability	Processing time	Cost model (k c.u.)

Vessel 7	5.0-50.0	(Impure E)		90.0+5*s*
Heat exchanger 1	0.0-200.0	RX1-RX2		60+5s
Heat exchanger 2	0.0-200.0	RX2-Rx3		60+5s

Results and discussion

The computational results found are depicted in Table 2 and Table 3. An overall profit of 2.6x10^8 c.u. was obtained using the model that catered for energy integration which is much better than the objective value of 2.08x10^8 c.u. obtained by the model without considering energy integration. Consequently, a 20% increase in profit was achieved by

allowing heat integration between the hot and cold tasks. From Table 3 a significant saving in hot utility can be attained by integrating the hot and cold tasks leading to supplanting most of the external utility requirement (160 GJ hot utility required by energy integrated batch plant vs. 271.9 GJ hot utility required by the basic design without energy integration). Consequently a saving of 41.1% in hot utility requirement is achieved. This indicates that solving a design and synthesis problem for batch plants by considering scheduling and heat integration results not only in efficient use of equipment resources for maximum production of products but also rational use of energy for sustainable operation. It is worth mentioning that this comprehensive model also determines the optimal heat exchanger area required in order to allow the heat transfer. An optimal area of 25.6 m^2 for heat exchanger 1 and 43.2 m^2 for heat exchanger 2 was obtained. Figure 2 details the possible amount of energy integration between the cold and hot units and the time intervals during which energy integration occurred. The energy requirements of reactor 1 and reactor 2 during the interval 4 h to 6 h is highlighted to elaborate on the application of the proposed model. The cooling load of reactor 2 between 5 h and 6 h was 25 GJ. This cooling requirement is fully satisfied through energy integration with reactor 1 in the same time interval, resulting in supplanting an external cooling requirement if it operated in standalone mode. At the beginning of the operation of reactor 1 from 4 h to 5 h, the heating requirement was 25.8 GJ. This value was obtained using the time average model by multiplying the duration (5 – 4 h) and the energy demand per hour (51.6 GJ/2 h (total duration of the task) = 25.8 GJ) where the heating requirement is fully satisfied by external heating. For the rest of its operation between 5 h to 6 h, the heating requirement was 25.8 GJ, satisfied partly with energy integration (25 GJ) and the difference by external heating with energy requirement of 0.8 GJ. The amount of material each unit is processing, the type of task each unit is conducting at a specific time point and the starting and finishing times for each task is also presented in Figure 2.

Table 2. Equipment design capacity for the case study.

Unit	Equipment capacity range	Design capacity with consideration of energy integration	Design capacity without consideration of energy integration
Heater	5-30	19	13.3
Reactor 1	5-50	47.7	20
Reactor 2	5-50	50	20
Still	5-20	20	33.3
Vessel 4	5-50	19	13.3
Vessel 5	5-50	30.6	28.7
Vessel 6	5-50	32.1	14
Vessel 7	5-50	33.3	0
Heat exchanger 1	0-200	25.6	-
Heat exchanger 2	0-200	43.2	-

Method	Time point	Objective value	Binary variables	Continous variables	Constraints	CPU time (s)	Cold utility	Hot utility
Design without energy integration	11	$2.08*10^8$	176	793	2079	19	220.4 GJ	271.9 GJ
Design with energy integration	11	$2.6*10^8$	222	887	2367	198	34.4 GJ	160 GJ

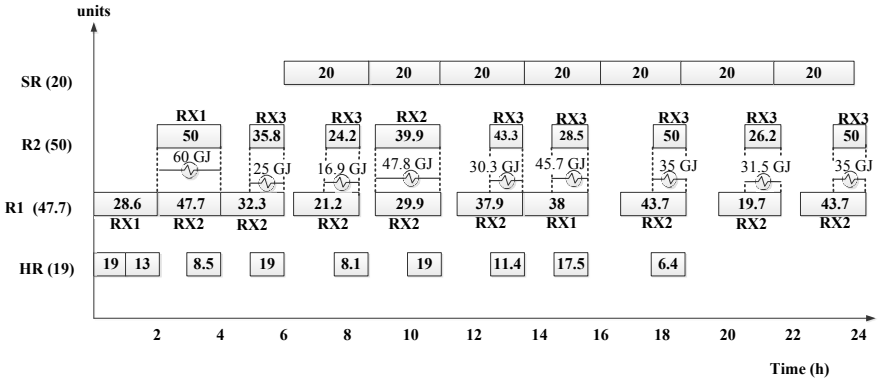

Figure 2. Gantt chart for the case study.

4. Conclusions

An efficient method for the design and synthesis of batch plants that incorporates energy integration was presented. The developed model simultaneously solved scheduling and energy integration within the same design framework leading to optimal design of equipment and rational use of energy. From the case study, the profit maximization was increased by 20% in the energy integrated batch plant compared to the basic design where utilities were the only option to satisfy the heating and cooling load requirements demanded by the tasks. The total hot utility requirement was reduced by 41.1% for the energy integrated batch plant compared to the basic design. From this it can be concluded that for efficient design of batch plants, energy integration must be incorporated in the design problem.

Abstract

In this paper we propose a novel mathematical framework for the study of biorefinery networks. The framework is based on a natural decomposition of the biorefinery network in two sub-problems: a supply of intermediates and a demand of intermediates. The two sub-problems can be optimized independently of each other and their solutions are later coordinated to yield the optimal feasible biorefinery complex. Based on this separability, a computer aided computational environment that emulates the proposed framework is presented.

Keywords: Biorefinery, multi-objective optimization, computer aided collaborative environment

1. Introduction

Advances in technologies for processing biomass feedstocks have resulted in the development of a large number of potential processing schemes for the production of biomass-based fuels, chemicals and materials. To address questions such as which is the most attractive set of products that can be produced from a particular feedstock, which are the best processing pathways, and which are the costs and environmental benefits associated with these conversions, detailed techno-economic analysis of particular combinations of feedstock-technology-products have been performed (Torres et al., 2010; Sen et al., 2012), and more recently, frameworks to systematize the analysis and evaluation of multiple-feedstock multiple-product integrated biorefineries have been proposed (Kim et al., 2013; Murillo-Alvarado et al., 2013).

These frameworks are based on constructing the superstructure of all potential technologies that link biomass feedstocks to the desired products and then the most promising pathways and combination of processes are found through mathematical programming, where the degrees of freedom for optimization involve the type of technologies to be used, and the optimal values of the process design parameters. A common feature of these approaches is that the whole conversion process, *i.e.* from biomass feedstocks to products, is assumed to take place in the same facility, a single actor biorefinery. Moreover, an a-priori fixed, and limited in size, set of target products is considered in all case studies.

In this paper, we propose an alternative framework for the design and optimization of biorefineries in which we aim to introduce the flexibility required for the simultaneous and independent assessment of processes for the production of new bio-based compounds that are being developed

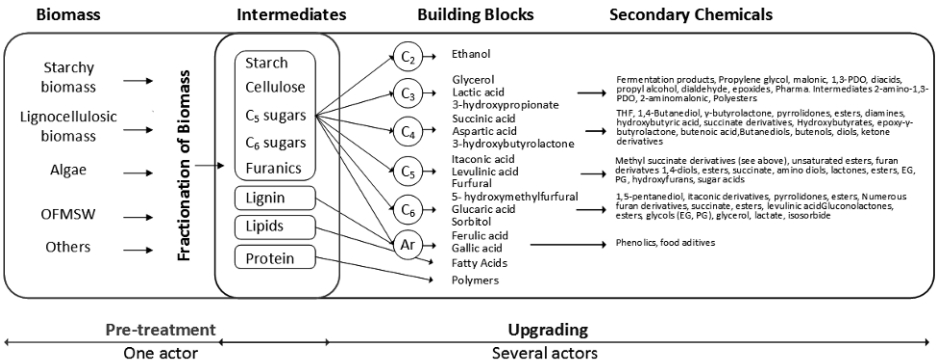

Figure 1: Schematic of a biorefinery complex. Adapted from Werpy and Petersen (2004).

by multiple actors. Within this framework, at the final stage of the design problem, the optimal profitability of the biorefinery complex as a whole will also be guaranteed.

We propose to do so by establishing a natural decomposition of the biorefinery network in a supply and a demand sub-problems which are linked through a set of intermediates. Through the formulation of a multi-actor multi-objective optimization problem, and using a two level Lagrangian approach, in Section 2 we will show that the proposed biorefinery network is separable and that each actor can separately optimize its own process. Furthermore, in Section 3 we will outline the structure of a computer-aided collaborative design environment which was designed to emulate the proposed mathematical framework.

2. Framework for the design of biorefineries

2.1. Problem Statement

Figure 1 shows a schematic of a general biorefinery complex. It comprises several biomass feedstocks that upon fractionation produce a number of "intermediate compounds". These intermediates can in turn serve as feedstocks for different thermochemical or biochemical processes, and be converted into a large variety of chemicals, such as those reported in Werpy and Petersen (2004).

All types of biomass can be seen as composed of a complex mixture of the same major compounds namely carbohydrates (poly and monosaccharides), lignin, lipids and proteins, where differences in their relative amounts and inter and intramolecular chemical bonds give rise to differences in physical structure and reactivity. Processes such as solvent extraction, hydrothermal or organosolv pre-treatment and enzymatic hydrolysis, among others, aim to separate and break down these compounds. Therefore, upon fractionation any type of biomass subject to an appropriate sequence of pre-treatment processes will result in different streams containing the above mentioned major compounds, mixtures of them (in polymeric and monomeric form) and in some cases products of their decomposition. As a first approximation, we will define these streams as our intermediates. Then, downstream processes can use them as feedstocks provided that their quality (highly dependent on the choice of pre-treatment method) and cost are acceptable for their own technologies.

A set of intermediates defined in this way naturally divides the biorefinery complex in two: a supply of intermediates problem and a demand of intermediates problem. The supply of intermediates problem entails finding the set and sequence of pre-treatment technologies to optimally produce the different intermediates; the demand of intermediates problem entails finding an appropriate intermediate and set of technologies to optimally produce a desired product. Then, once the cus-

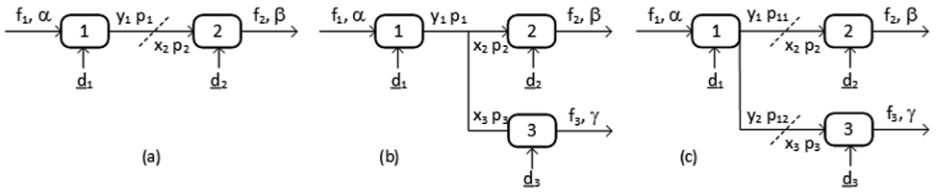

Figure 2: Prototypical network for the biorefinery complex. (a) two actor biorefinery: one supplier one consumer one intermediate; (b) three actor biorefinery: one supplier two consumers competing for the same intermediate (c) three actor biorefinery: one supplier, two consumers of different intermediates.

tomers on the demand side have selected the set of intermediates that are technologically feasible, as the starting points of their processes, the optimal biorefinery complex is completed by defining the optimal flowrates and transfer prices for these intermediates.

2.2. Separability of the biorefinery complex

Based on the division of the biorefinery complex discussed before, we have identified three prototypical networks that describe it: (a) one supplier and one consumer linked to one intermediate, (b) one supplier and two consumers competing for the same intermediate and (c) one supplier producing two intermediates for two different consumers (see Figure 2). Then other configurations of the biorefinery can be expressed by combining these three.

In what follows, we will assume that the inlet flowrate of the biomass feedstock (f_1), the outlet flowrate of products (f_2, f_3) and their corresponding prices (α, β, γ) are known, and our goal is to find the optimal set of design variables for each actor ($\underline{d_I}$) and the optimal transfer flowrates (x_j, y_i) and prices (p_i) . We will consider the profit, defined as the difference between the revenues obtained from selling the product and the feedstock and operational costs, as the function to be maximized by each independent actor.

2.2.1. Two actor biorefinery

For the simplest case (Fig. 2a), the profits of each actor can be expressed as: $P_1 = p_1 y_1(f_1, \underline{d_1}) - c_1(f_1, \underline{d_1}) - \alpha f_1$ and $P_2 = \beta f_2(x_2, \underline{d_2}) - c_2(x_2, \underline{d_2}) - p_2 x_2$. Clearly $y_1 = x_2 = x_I$ and $p_1 = p_2 = p_I$. Therefore maximizing both profits at the same time is not possible as an increase in the term $p_I x_I$ results in an increase of P_1 and a decrease in P_2. Then, the multiobjective optimization problem (MOP) in Eq.1 is formulated to find the solution that maximizes the composite profit.

$$\begin{aligned} Max \quad & P_1 + sP_2 \qquad (1) \\ s.t. \quad & y_1 = x_2 \\ & p_1 = p_2 \\ & P_1 \geq 0 \\ & P_2 \geq 0 \\ & \underline{d_i} \in \mathscr{D}_i \quad \text{i=1,2} \end{aligned} \qquad s = 1 \implies \qquad \begin{aligned} min \quad & c_2(f_1, \underline{d_1}) + c_2(x_2, \underline{d_2}) \qquad (2) \\ s.t. \quad & y_1 = x_2 \\ & -p_1 y_1(f_1, \underline{d_1}) + c_1(f_1, \underline{d_1}) + \alpha f_1 \leq 0 \\ & -\beta f_2(x_2, \underline{d_2}) + c_2(x_2, \underline{d_2}) + p_2 x_2 \leq 0 \\ & \underline{d_i} \in \mathscr{D}_i \quad \text{i=1,2} \end{aligned}$$

By using the Karush-Khun-Tucker conditions it can be proven that the only solution that results in positive profit for both parties is when the value of s, the trade-off between P_1 and P_2, equals 1, and any other value for s leads to a solution where one of the actors has no profit.

Then, by substituting $s = 1$ in Eq.1 it can be shown that the MOP simplifies significantly resulting in the minimization of the summation of the *operational costs* of both units subject to the mass

balance constraint at the connection point, as shown in Eq.2.

The Lagrangian of this optimization problem (Eq.2) can be rearranged in a sum of two terms one depends only on variables from unit 1 and the second depends only on variables from unit 2, where the only common variable among these two parts is the Lagrange multiplier (λ) corresponding to the satisfaction of the mass balance at the connection point.

The solution of the optimization problem in Eq.2 can be found through a two-level Lagrangian approach in which, first, for different values of the Lagrange multiplier, each actor separately minimizes its own *operational burden* defined as $\ell_1(\lambda, f_1, \underline{d}_1) = c_1(f_1, \underline{d}_1) - \lambda\, y_1(f_1, \underline{d}_1)$ for actor 1, and $\ell_2(\lambda, x_2, \underline{d}_2) = c_2(x_2, \underline{d}_2) + \lambda\, x_2$ for actor 2; and second the dual function $\mathscr{D}(\lambda) = \min\ell_1(\lambda) + \min\ell_2(\lambda)$, is maximized with respect to λ to find the optimal values for the design variables $\underline{d}_1^*$, $\underline{d}_2^*$ and transfer flowrate $y_1^* = x_2^* = x_I^*$.

It can be seen that the optimal price for the intermediate p_I^* is not defined by the solution of the previous problem and that, given $\underline{d}_1^*$, $\underline{d}_2^*$ and x_I^*, any price that satisfies the non-negative profit constraint for both units is equally optimal for the overall network, although not for the individual actors. The prices at which these inequality constraints become equality constraints (*i.e.* one of the profits is zero) provide the bounds for the price of this intermediate, which should be compared against the market price of similar intermediates.

However, by examining the units of the terms for the operational burdens (see above) it can be seen that the Lagrange multiplier, λ, has units of \$/(unit of mass of the intermediate), and thus can be interpreted as the price to be paid for the intermediate, and λ^*, the value at the optimal and feasible solution as the price of the intermediate that offers the optimal balance between the *operational burdens* of both units, *i.e.* $\lambda^* = p_I^*$. A detailed discussion on the mathematical approach can be found in Torres and Stephanopoulos (2014).

2.2.2. Extension to multiple-actors biorefinery network

The procedure outlined above for a two-actor biorefinery, can be easily extended to the other two prototypical networks of Fig. 2: two consumers that compete for the same intermediate (Fig. 2b) and one supplier that produces two intermediates for two different consumers (Fig. 2c).

In both cases, a MOP analogous to the one in Eq.1 was proposed to maximize a composite function of the three profits subject to the mass and cash balance constraints for each intermediate. With similar arguments as before, it can be shown that:

1. only when the trade-offs $s_i = 1$ all actors have positive profits
2. the problem is separable and the two-level Lagrangian approach can be used to solve it, where for the general case of one supplier providing multiple intermediates for j different consumers the operational burdens to be minimized by each actor are as follows:
   - operational burden for the supplier s
     $\ell_s(\underline{\lambda}, f_s, \underline{d}_s) = c_s(f_s, \underline{d}_s) - \sum_{i=1}^{\#\text{ of intermediates}} \lambda_i\, y_i(f_s, \underline{d}_s)$
   - operational burden for the consumer j
     $\ell_j(\lambda_j, f_j, \underline{d}_j) = c_j(f_j, \underline{d}_j) + \lambda_j x_j$
3. the Lagrange multipliers that maximize the dual function can be interpreted as the transfer price for the intermediates produced by the supplier.

3. Computer Aided Collaborative Environment

Based on the separability of the biorefinery, we have designed a computer aided collaborative environment to emulate the proposed framework. This environment is implemented in the commercial software Aspen Plus, and a screenshot of it is presented in Fig. 3, where the division in a supply side, a line of intermediates and a demand side with several consumers is clearly identified.

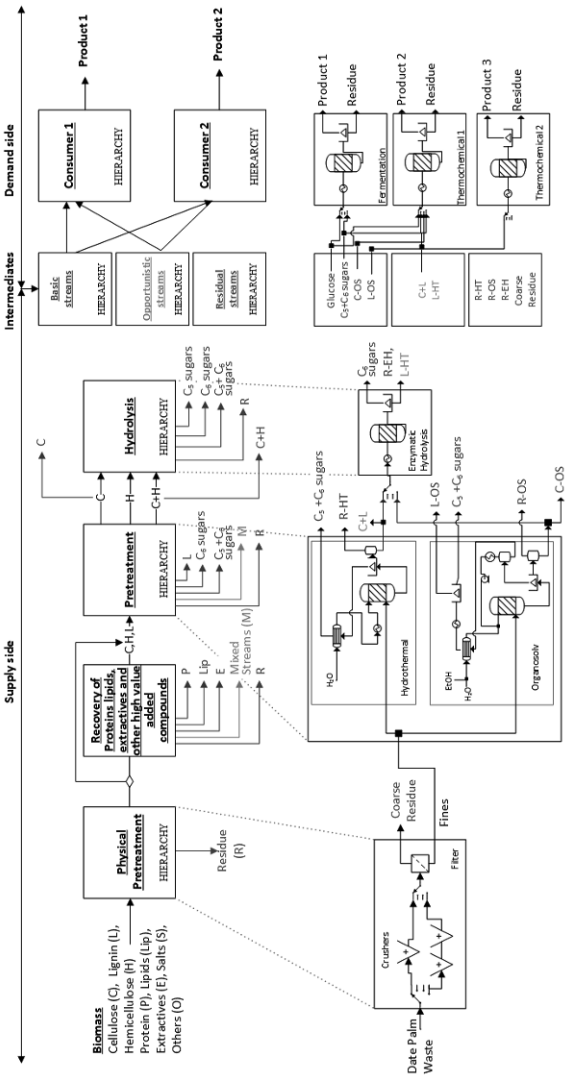

Figure 3: Computer Aided Collaborative Environment: main flowsheet and example of accesible processing options

The supply side of the problem coincides with the pretreatment of biomass and we have identified four main blocks that need to be applied in sequence in order to systematically fractionate the biomass. These blocks are (1) a "physical pretreatment" block which includes oopertions that reduce the size of biomass and remove debris, water and salt; (2) a "recovery of high value added compounds" block which includes operations for the separation of sensitive intermediates (e.g. proteins) which will be destroyed by subsequent processing are recovered, (3) a "traditional" pretreatment block that targets the separation of cellulose, lignin and hemicellulose using for example hydrothermal, steam explosion or organosolv processes, and (4) a "hydrolysis" block that breaks down polymeric compounds, present in the streams that exit the previous blocks, into monomeric ones.

As shown in Fig. 3 for the processing of date palm waste (a lignocellulosic type of biomass) each of these blocks contains flowsheets for several alternative processes. By combining or by-passing them, different fractionation sequences that result in streams that differ in their quality (composition of major and minor compounds) and production cost are obtained. The choice of processes, their operating conditions, as well as whether a stream exiting each of the supply side blocks is considered to be an intermediate or connected to the next block in the sequence for further processing, represent the decision variables for this part of the problem.

We have included three blocks for intermediates streams and hierarchically classified them as follows: Basic streams: those streams that are expected to serve as a starting point for a large number of consumers, such as cellulose, lignin and glucose rich streams, basically those that align with the intermediates proposed in Fig:1; Opportunistic streams: streams containing by-products, or partially fractionated biomass, that have not yet been considered in the literature as feedstocks for bio-based chemicals, but whose characteristics indicate that might be used as a much cheaper source, and streams that target a very specific set of specialty products; Residual streams: streams that can clearly not be used for the production of specialty biomass based compounds as for example solid residues, but would need to be treated for disposal.

Within this computer-aided collaborative environment, we aim to provide actors working on the demand and supply sides, the design capabilities for independent and parallel assessment of processing options. In such setting, realistic estimates of flows and compositions of the intermediate streams, along with economic and environmental assessment is provided. Thus, customers, researchers working on the upgrade of the intermediates, can, independently of each other, test and optimize their processes for different intermediates, be aware of the presence of minor compounds that might be detrimental for their own technologies, have the option of considering less processed but less expensive streams, and propose new technologies to process intermediate streams that they might not currently be aware of.

Finally, it should be mentioned that the assignment of streams as intermediates as well as the definition of the supply-demand side boundary is expected to evolve as more knowledge on the consumer side is acquired. As an example, processes that convert some of the current intermediates (for example, glucose rich streams) into a particular building block (for example a C_3 building block) could be also included in the supply side (and offered as an intermediate) if it proves to dominate the pathway to feasible consumer side processes.

4. Conclusions

A multiactor biorefinery network composed by one supplier and several consumers has been proposed as the natural framework for designing biorefineries. A multi-objective optimization problem that aims to find the solution that maximizes the overall profit of the network has been proposed for its analysis. It was found that the proposed MOP is separable and that by using a two-level Lagrangian approach the optimal design variables for each actor as well as the optimal flowrates and prices for the transfer of intermediates could be computed. A computer aided environment which emulates the proposed framework and allows actors on the supply and demand side to work independently on their processes is presented.

Integrated Design and Control of Semicontinuous Processes Using Mixed Integer Nonlinear Dynamic Optimization

Vida Meidanshahi, Thomas A. Adams II*

Department of Chemical Engineering, McMaster University, 1280 Main St. West, Hamilton, Ontario, Canada, L8S 4L8

Abstract

Semicontinuous separation is a distillation based process intensification technique devised for the purification of ternary mixtures to desired purities. It is particularly promising for small scale production processes where the semicontinuous system has a lower total annualized cost relative to the conventional continuous process, thus it can be a suitable option for the purification of biofuels. Semicontinuous systems are dynamic, control driven processes that work in a stable limit cycle with several modes of operations. Therefore, designing the system and its controllers is a challenging task which has not been thoroughly considered in the literature. In this work, for the first time, a methodology is presented to simultaneously obtain the optimum design parameters of the semicontinuous system such as the number of column stages, feed and side stream locations, as well as the optimum tuning parameters for the PI control structure. To design the semicontinuous process, it is formulated as a mixed integer nonlinear dynamic optimization problem using the equation oriented gPROMS software which has built-in deterministic optimization packages. The benzene, toluene and *o*-xylene mixture is chosen as a case study to demonstrate the methodology. The optimization took 1.03 CPU hours and the optimum design parameters are obtained. The results show that the total annualized cost of the designed semicontinuous system is lower than the respective conventional continuous process.

Keywords: Semicontinuous Separation; Integrated Design and Control; Mixed Integer Nonlinear Dynamic Optimization; gPROMS

1. Introduction

The goal of process intensification is to reduce equipment sizes, improve the efficiency of processes and increase profitability. Semicontinuous separation is a process intensification technology which is capable of reducing the capital cost, and potentially the total annualized cost (TAC) of distillation processes. Semicontinuous separation utilizes a storage tank integrated with a distillation column to achieve ternary purification, whereas two distillation columns are typically required in a conventional system (Phimister and Seider, 2000). In a semicontinuous setup, the side stream of the distillation column is constantly recycled back to the storage tank (which is called middle vessel), and after first charging it with the feed to be separated, the contents of the tank are continuously fed to the column. The light and the heavy boiling point components are continuously removed in the distillate and bottom streams of the distillation column, respectively, resulting in the concentration of the intermediate

boiling point component in the middle vessel. Upon the achievement of the desired purity for the intermediate component, the content of the middle vessel is discharged and it is subsequently charged with fresh feed. However, the column works continuously with no start-ups and shut-downs. Due to the cyclic behaviour of the system the composition and the flow rate of the feed to the distillation column changes over the cycle time of the process. Furthermore, the system is control driven, working in three distinct modes of operation: charging, processing and discharging.

Semicontinuous separation is particularly interesting for biofuel production processes, as small scale distributed plants with low capital costs are typically desired. Pascall and Adams (2013) used a semicontinuous system for purification of bio-DME and achieveda remarkable reduction in the cost of producing bio-DME for small-scale distributed networks. Also, Niesbach et al. (2013) studied separation of butyl acrylate from a mixture of several impurities by utilizing the semicontinuous separation technique. Changes in the bio-resource feedstock in the production of butyl acrylate introduce different impurities in the product. However, the semicontinuous system is flexible in terms of impurities and without changing operating conditions of the system, the desired product purities are obtained.

To design the semicontinuous system for any arbitrary ternary mixture, appropriate design parameters such as number of stages, feed and side draw locations, column diameter, middle vessel volume and controller settings must be determined. These design parameters are crucial to guarantee best performance of the system as well as the lowest TAC of the system. This results in a mixed integer nonlinear dynamic optimization (MINLDO) which is one of the most challenging classes of optimization problems, but is the proper framework to simultaneously design the system and its control structure. However, in the case of highly complex semicontinuous systems (hybrid nature, high number of integer variables and expensive computational times) previous attempts at dynamic optimization were limited to stochastic methods such as particle swarm optimization (PSO) and a subset of decision variables.

Adams and Seider (2008) proposed a bi-level optimization algorithm for high dimensional hybrid systems. In this method the decision variables are divided into global and local variables. However, the authors considered only the continuous design variables and control parameters without any integer variables as decision variables. In 2013, Pascal and Adams optimized a semicontinuous system for bio-DME production. They linked Aspen Dynamics software with Excel Visual Basic for Applications (VBA) and used a PSO technique to optimize only the controller tuning parameters of the system. In each of these cases, the required computation time was over a CPU-month and was effective only for smaller subsets of the decision variables of interest.

In this work, a methodology for the synthesis of semicontinuous systems is presented using a deterministic mixed integer nonlinear dynamic optimization algorithm. The separation of benzene, toluene and o-xylene (BTX) is selected as a case study and the system is modelled in gPROMS v4. The resulting MINLDO is solved with a gradient based method. An economic evaluation is performed to compare the conventional distillation system and the optimally designed semicontinuous system.

2. Process Modelling

The optimum conventional continuous configuration for separation of an equimolar mixture of benzene, toluene, and *o*-xylene (BTX) to products with 99 mole% purity consists of two distillation columns with 30 and 28 stages, respectively, as shown in Figure 1(a) (Ling and Luyben, 2009). The semicontinuous counterpart of this system is shown in Figure 1(b). Meidanshahi and Adams (2014) presented a detailed procedure for designing the semicontinuous system for the BTX mixture. Their simulations were performed in Aspen Plus Dynamics V8 which provides a rigorous distillation column model (RadFrac). For the semicontinuous system the optimum number of stages is between a minimum of 28 to a maximum of 58 (summation of stages in the conventional continuous configuration). As the number of stages decreases, the total direct cost of the system decreases but the operation cost increases. On the other hand, the tuning parameters for the PI controllers (which are the main drivers of the process) affect the cycle time, the production rate and the operating costs of the process. Therefore, to have the lowest TAC, the optimum number of stages, optimum locations for feed and side draw and optimum tuning parameters are needed.In this work,a MINLDO is proposed to design an optimum semicontinuous configuration. Although, Aspen Dynamics provides a good rigorous model for simulation purposes,the built-in dynamic optimization solver are not suitable for MINLDO purposes. Therefore, the process is simulated in gPROMS V4 using its process model library (PML).

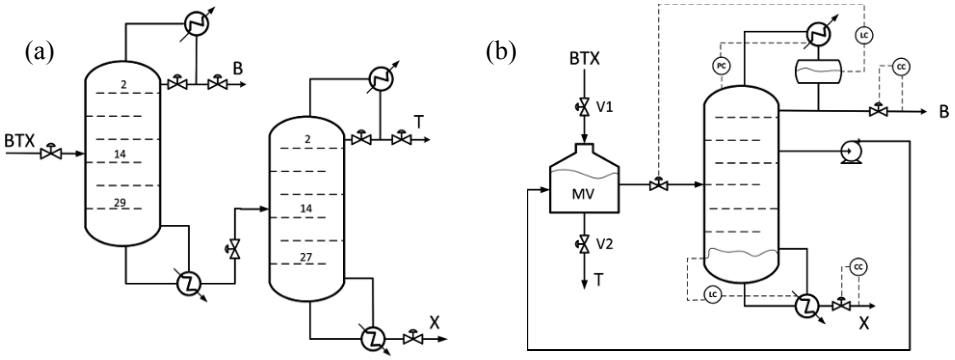

Figure 1- Schematic of the (a) conventional continuous and (b) semicontinuous configuration for BTX separation system.

3. Optimization

The semicontinuous separation is a hybrid process with three modes of operation: charging, processing and discharging. However, the processing mode constitutes the main fraction of the cycle time thus this work focuses only on the optimization of the processing mode. The problem of dynamically optimizing all modes of operation is the focus of future work. To synthesize the optimum process, some design parameters such as column diameter (1.2 m) and the control structure are fixed while other design parameters such as number of column stages, location of feed and side streams and middle vessel height (integer variables) as well as gains and reset times of all five PI controllers (continuous variables) are optimized. The superstructure considered for the distillation column is shown in Figure 2. It has 50 stages with the feed introduced at stage 30 and the side stream withdrawn at stage 20. For detailed information on the value of design parameters and initial conditions, refer to Meidanshahi and Adams (2014).

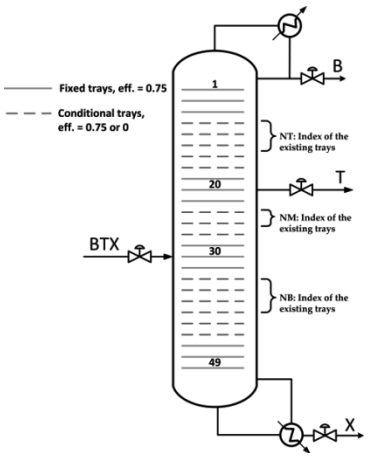

Figure 2- Superstructure for optimization of the column in the semicontinuous system.

To optimize the design parameters of the distillation column, the method proposed by Javaloyes-Antón et al. (2013) is employed.The superstructure of the distillation column consists of four sets of permanent and three sets of conditional trays. Also included in the structure are the feed location, location of side draw, condenser and reboiler. The permanent trays have a defined Murphree efficiency (0.75 in this work) while the Murphree efficiency of the conditional trays are either 0.75 or zero depending on their existence (active) or non-existence (inactive).

The total number of stages as well as the location of feed and side streams is determined by the total number of active and fixed trays. In order to avoid problems associated with non-unique solutions (which would happen if a set of conditional trays were permitted to alternate between active and inactive trays, for example), an integer variable is defined for each set of conditional trays which represents the number of active trays in that set. Consequently, all model equations associated with the conditional trays are structured such that all conditional trays within a set at or below this integer value are active, and all conditional trays above this integer value are inactive. Thus only one possible permutation of inactive/active trays exists for each value of the integer variable. The objective of the dynamic optimization is to minimize the TAC of the system per annual processed feed, as shown in Eq. (1). The optimization problem is subjected to some constraints as shown in Eqs. (2)-(6).

$$\text{Min:} \quad \left(\frac{\textit{Total Direct Cost}}{\textit{Payback Period}} + \textit{Annual Operating Cost}\right)/\textit{Processed Feed} \tag{1}$$

$$0.1 \leq \text{Condenser liquid level fraction} \leq 0.9 \tag{2}$$

$$0.3 \leq \text{Reboiler liquid level fraction} \leq 0.9 \tag{3}$$

$$\text{Average distillate purity} \geq 99 \text{ mole\%} \tag{4}$$

Average bottom purity ≥ 99 mole% (5)

Purity of toluene in the middle vessel by the end of cycle ≥ 99 mole% (6)

The operating costs were calculated considering only the utility costs of steam and cooling water according to the method discussed in Towler and Sinnott (2012).The cost of the distillation column is calculated using the equations reported in Bansal et al. (2002). The MINLDO is solved using the gPROMS optimization toolbox. To solve the MINLDO, gPROMS uses control vector parameterization with the single shooting sequential method and solves the resulting mixed integer nonlinear problem (MINLP) by employing the outer approximation with equality relaxation and augmented penalty method (OAERAP) (Viswanathan and Grossmann, 1990).

4. Results

Due to the nonconvexities of the problem, the OAERAP method only guarantees the local optimality of the solution but not its global optimality. However, the computational time of this deterministic method linked with equation oriented solver is promising compared to heuristic optimization methods. Where 40 CPU days were required to optimize only the tuning parameters of the semicontinuous system using Aspen and PSO (Pascal and Adams, 2013), the MINLDO proposed in this work, took 1.03 CPU hours to solve the problem and obtain a locally optimum solution for both integer and continuous decision variables. Table 1 shows the optimum values of the design parameters for semicontinuous system while Table 2 shows the optimum values of the tuning parameters.

Table 1- Semicontinuous design parameters.

	No. of stages	Feed stage	Side stage	Middle vessel height (m)
Base-case design	50	30	20	6
Optimum design	37	22	13	4

Table 2- Gains (k) and reset times (τ) of distillate composition controller (1), bottoms composition controller (2), reflux drum liquid level controller (3), sump level controller (4) and column pressure controller (5).

	k_1	τ_1	k_2	τ_2	k_3	τ_3	k_4	τ_4	k_5	τ_5
Base-case design	1	100	1	100	0.5	100	0.5	100	0.5	100
Optimum design	0.1	88	5	328	2.2	81.3	0.72	94.2	0.55	102

Table 3- Economic evaluation.

	Operating cost ($/y)	Direct cost ($)	Total annualized cost ($/y)	Cycle time (h)	Feed processed (Mkg/y)	Objective function ($/Mkg)
Semicontinuous base-case design	67,533	216,186	139,595	3.48	33.7	4,137
Semicontinuous optimum design	71,271	158,193	124,002	0.74	46.7	2,655
Conventional continuous	45,276	275,004	136,944	—	46.5	—

The optimum semicontinuous design has fewer stages and consequently has lower direct costs relative to the original base-case semicontinuous design created using standard heuristic methods, and the conventional continuous system (Table 3). However, having fewer stages, the operating costs of the optimum semicontinuous system is higher than the other considered systems. A payback period of 3 years is considered for calculation of TACs. Most notably, the optimum semicontinuous system has the lowest TAC. The cycle time of the semicontinuous system was a decision variable in the optimization problem. The optimum values of the tuning parameters have resulted in lower cycle time for the optimum configuration.

5. Conclusions

A successful method for the determination of an optimal integrated design and control problem with integer variables for semicontinuous systems has been demonstrated for the first time in this work. Most prior studies on semicontinuous systems over the last decade were focused on the feasibility and the applicability of the process. Most prior studies acknowledged the importance of optimization of this cyclic process. However, huge computation times, complex system dynamics, and an inability to handle complex design decisions requiring integer variables were hindering factors to achieve this goal. In this work, the problem was addressed by a mixed integer nonlinear dynamic optimization framework to optimize both integer and continuous design parameters of the system. gPROMS, was used to simulate the system and its deterministic optimization toolbox is employed to solve the optimization problem. The computational time was 1.03 CPU hours and the results show significant promise that the methodology can be rapidly applied to all semicontinuous systems studied to date. For future work, more operational details of the cycle will be considered, such as charge and discharge modes. Then, future studies will consider a superstructure that can choose the best control structure, or potentially more complex controllers such as model predictive controllers instead of PI controllers.

Abstract

A computational platform for the simulation, design and analysis of the Polylactic (PLA) acid production process using different lignocellulosic raw materials has been developed. The computational platform considers three main reactive-separation processes: 1) the bio-conversion process, where an hydrolysis-saccharification-culture process to produce the inoculated hydrolysate is coupled with a fermentation-separation process producing the broth with crude lactic acid; 2) the purification process, where a sequence of conventional and reactive distillation columns to perform the esterification and hydrolysis reactions, respectively, are used to produce a polymer grade lactic acid; and 3) the polymerization process, where a ring-opening polymerization reaction scheme to produce high molecular weight PLA is carried out. The platform was constructed on the Aspen Plus Environment. The implementation of the platform in a systematic manner allowed the evaluation of various mono and disaccharide materials to produce PLA. The results show that with a higher concentration of glucose the molecular weight of the PLA produced increased. However, the operation of the purification section, that is, the reactive distillation columns should be carried out carefully in order to obtain a purified lactic acid near to 88% mass fraction.

Keywords: Polylactic acid, computational platform, reactive-separation process

1. Introduction

Polylactic acid (PLA), a biodegradable poly hydroxy alkanoate (PHA), it is a promising replacement for synthetic polymers. The advantages of Polylactic acid are its high tensile strength, high modulus, thermoplastic property, biodegradability and bioenvironmental compatibility/absorbability. It is used in making of biodegradable sutures, clamps, bone plates and biologically active controlled release devices (Jamshidian *et al*., 2010).

The production of PLA can be divided into two main steps: production of lactic acid and its polymerization to PLA. The production of lactic acid follows a fermentation process to produce a broth containing crude lactic acid and a downstream processing of the fermentation broth to obtain polymer grade lactic acid. Most frequently used procedures for lactic acid production are batch, repeated batch and continuous fermentation. For the separation and purification different procedure are used for example: electrodialysis, liquid extraction and reactive distillation. Various mono and disaccharide materials are generally used for its production i.e., glucose (dextrose) and glucose syrup as end product of starch conversion; maltose as a product from barley malt or other source; sucrose as end product of beet and cane sugar production. The amount of these cheap raw materials in México is significant all along the country. Therefore, the requirement of a computational tool to evaluate the economical and environmental feasibility of a PLA production plant is highly required. The present work proposes a computational platform based on three different reaction-separation sections: 1) Bio-conversion process: a hydrolysis-saccharification-culture process to produce the inoculated hydrolysate is coupled with a fermentation-separation process producing the broth with crude lactic acid; 2) Purification process: a sequence of conventional and reactive distillation columns to perform the esterification and hydrolysis reactions, respectively, are used to produce a polymer grade lactic acid, and 3) Polymerization process: a ring-opening process to produce high molecular weight PLA. The platform was constructed on the Aspen Plus Environment. Figure 1 shows a simplified flowsheet of the computational platform to produce PLA.

2. The Bio-conversion Process

For the bioconversion different carbohydrate transformation processes on the basis of experimental and literature data were used (Ali *et al.*, 2013).A pretreated lignocellulosic material was used as feedstock for this purpose (45 % cellulose, 20 % hemicelluloses, 30 % lignin, 5 % acetate groups, in weight). Lignin, cellulose and hemicelluloses were defined by their chemical structure and physical properties, which were obtained from the National Renewable Energy Laboratory (NREL) database (Wooley and Putsche, 1996), whereas other conventional components were selected from the ASPEN PLUS data bank. The proposed lactic acid production process started with a fermentator, where glucose and xylose are transformed into lactic acid. The formed lactic acid is precipitated from the fermentation liquid as calcium lactate, $Ca(OH)_2$ is added in aqueous form (in a ratio lime-water of 15:85 wt/wt). The produced lactic acid is then separated by filtration and subsequently washed in a two-steps operation. A design specification is defined to control the amount of water necessary to achieve a solid content less than 1% wt/wt in the liquid part. In the dissolution reactor, the acidification of this slurry is carried out in order to obtain lactic acid in solution and to remove the calcium salt. For this purpose, an aqueous H_2SO_4 stream (15:85 wt/wt sulphuric acid-water) is added. The calcium sulphate formed is separated by filtration and the liquid mixture containing lactic acid is submitted to the evaporation equipment. Table 1 shows the simulation results of the bioconversion section for selected streams of the reference study case.

3. The Purification Process

Many methods for purification of lactic acid have been proposed, including ultrafiltration, reverse osmosis, adsorption, and reactive extraction. However, these methods all have disadvantages. For example, ultrafiltration and osmosis are impractical

for large raw material capacity. Adsorption and reactive extraction have particle selectivity, capacity, and regeneration problems. Most importantly, all of these methods suffer from low lactic acid recovery.

In view of these limitations, the most attractive method for purification of lactic acid from fermentation broth is a two-step reactive-distillation process in which the acid is first reacted with an alcohol to form a more volatile ester which can be purified by distillation. Then, pure lactic acid is recovered by hydrolysis of the ester. This purification method not only can handle large raw material capacity but also can achieve high lactic acid recovery. In the present work, the vapor−liquid and vapor−liquid−liquid equilibria were estimated for each process using NRTL activity model for the liquid phase and Hayden-O´Conell second virial coefficient model for the nonideality of the vapor phase. The alcohol considered for the esterification reaction is methanol and the corresponding ester is methyl lactate (METHY-01). Also, solid-catalyzed reaction kinetics are used for each reaction and the reactive zones can be located in different sections of the reactive distillation columns. Kinetic data on solid-catalyzed lactic acid esterification and hydrolysis reactions have been reported by Su *et al.* (2013). Table 2 shows the simulation results of the purification section for selected streams of the reference study case.

4. The Polymerization Process

Once the upstream from the fermentation and purification sections where lactic acid is generated and concentrated upto 88 wt% in aqueous solution (LA-FEED), the solution is fed to the oligomerization reactor, which further concentrates the lactic acid solution by removing water. The resulting product contains a mixture of lactic acid and predominately linear oligomers in an aqueous solution. A column is used to separate vaporized lactic acid, which is returned to the process. A catalyst (SnO) is added to the oligomer from the first reactor through a static mixer. The liquid is fed to a continuous wiped film evaporator/reactor, where the oligomers decompose to form lactide rings. The first column (C200) removes residual water from the mixture. The second column (C300) removes residual lactic acid from the lactide stream. Lactide from the first section of the plant is mixed with an appropriate polymerization catalyst and a phosphite stabilizer in a polymerization reactor. The lactide polymerizes back to polylactide, approaching very close to the ring/chain equilibrium point. The resulting mixture is passed on to a neutralizing vessel where the catalyst is neutralized. This residual lactide is removed in another wiped-film evaporator (WFE) and recycled as vapor and the final PLA polymer is produced. The process described above is a modified version of the proposed by Savey and Liu (2008). Table 3 shows the simulation results of the polymerization section for selected streams of the reference study case.

5. Study Case and Results

To implement the computational platform a reference study case was used. This is, a hypothetical mixture with 75 % of glucose and 8 % of xylose producing a broth of lactic acid from the fermentation process of 0.59 mole fraction of lactic acid and 0.41 of water. This broth if fed to the purification section and a mixture of polymer grade lactic acid and water of 88% and 12 % mass fraction respectively is produced. The above mixture is driven to the lactide generation and to the opening ring polymerization reactors and a PLA with a molecular weight of 62362 units is produced. Further, four scenarios of composition in glucose and xylose were stated to test the computational platform: a) sugar cane residuals were used as raw material with glucose-xylose content of 39 and 23% respectively, that is, a residual lower in glucose concentration than the reference case;

b) beets with 18 and 53%; c) pineapple with 19.4 and 22.4 % and d) banana with 9.6 and 9.4%. Table 4 shows the different composition scenarios of the lignocellulosic raw materials, the lactic acid broth composition produced and the lactic acid polymer grade purified. Also, it can be noted the final PLA flow produced and its molecular weight respectively. It can be observed from the results that the reduction in the lactic acid composition in the broth from the fermentation step affects significatively the purified polymer grade lactic acid flow. However, it has small influence on the flow of the PLA produced. Nevertheless, the molecular weight of the PLA, which is the key property indicating the biodegradability of the biopolymer, is strongly affected. It should be pointed out that these differences in the PLA weights are a consequence that the lactic acid exit purity required of the purification section is not achieved (88% mass fraction).

Table 4. Composition scenarios of *lignocellulosic* raw materials

RAW MATERIAL	COMPOSITION % (dry)		LACTIC ACID BROTH (mole fraction)	POLYMER GRADE LACTIC ACID FLOW (Kg/hr)	POLYLACTIC ACID PRODUCED (Kg/h)	PLA MOLECULAR WEIGHT
Reference	Glucose 75 Xylose 08		0.59	11335.2	8778.1	62,362
Sugar Cane	Glucose 39 Xylose 23		0.40	7525.7	8778.1	44,387
Beets	Glucose 18 Xylose 53		0.38	7203.7	9199.6	35,432

Abstract

Northern Chile is characterized by significant mineral resources, particularly copper, nitrate, lithium, molybdenum, rhenium, among others. Moreover, these resources are located in the Atacama Desert, the driest in the world. Water resources are exhausted, but Chile has an extensive coast from where to get water. Then, any new operation or expansion of a current operation must use seawater. The distance from the coast to mining operations ranging from a few kilometers to about 300 kilometers, but even more significant, these operations can be found from 600 to 4,000 meters above sea level. Then, the cost of transporting desalinated water can be greater than the cost of desalination.

This paper presents a methodology to design the system of desalination plant and desalinated water transport. The objective is to determine the location and size of desalination plants and the water distribution system that minimizes capital and operational costs. The methodology uses a superstructure that represents the set of alternatives on which the optimal solution is found. A mathematical model is generated to represent the desalination plant and water distribution system. The end model corresponds to a MINLP problem which is solved in two steps using commercial software. A case study is used to demonstrate the applicability of the methodology developed.

Keywords: process design, desalination, distribution network, mining, seawater.

1. Introduction

The Atacama Desert is commonly known as the driest place in the world, especially in Antofagasta Region (Chile). The average rainfall in the Chilean region of Antofagasta is just 1 millimeter (0.04 in) per year. On the other hand, Antofagasta has represented one of main point of investment for Chile due to the extraordinary mineral wealth of its soils. The region has contributed with 7% of Chilean GDP over the last decade and 60% of the regional GDP is contributed by the mining industry. Chile produces around 35% of world copper production and more than half of that is extracted from Antofagasta Region. Antofagasta also produces gold, silver, molybdenum, potassium nitrate, iodine (50% of the world supply) and lithium carbonate (world's largest producer). Furthermore, mining investment in Chile for the next nine years exceeded 105 billion dollars, being the Antofagasta region the zone of greater investment. The especial

weather conditions and the economic development have increased water and energy demands.

Water scarcity is one of the main problems for the mining industry whether for mine expansion, exploitation of existing mines or development of new mines. The mines are typically located at elevations between 600 and 4,000 m above the sea level, where the main local water supply is from groundwater sources. The increase in the demand of water has been the main cause that regional basins are now depleted and practically all the existing areas with sub-aquifers have been declared under official protection in order to safeguard the fertile plains and wetlands they nourish.

Given this lack of water, the use of seawater has become the most appropriate one. Then, several desalination plants by reverse osmosis (RO) have been installed to provide drinking water. Also, most of the new mining projects have considered, and continue including, the use of seawater or desalinated water to supply their operations. However, the implementation of large systems of seawater desalination and water transport face other issues such as local geography, community relations, environmental impacts, corrosion, adaptation of mineral processes, and energy requirements.

Considerable efforts have been made for the research of the optimum design of RO system and water supply systems. For example, El-Halwagi (1992) investigated the synthesis of RO networks which involve multiple feed streams using a mixed integer nonlinear programming (MINLP) model. Malek et al. (1996) provided an economic model that relates the various operational and capital cost elements to the RO design variable values. Then, Maskan and Wiley (2000) used a directed graph and connectivity matrix to represent the RO networks superstructure. Lu et al. (2012) considered a RO-based desalination process for the production of fresh water from three raw feeds (seawater, brackish and regenerated water). A systematic methodology was presented for the optimal design of RO desalination system that processes multiple feed streams simultaneously, and at the same time, supplies various water streams of different quality. Alnouri and Linke (2013) presented a methodology for optimal design of seawater RO desalination system that addresses the issue of boron removal. The development of water supply systems without the use of optimization provides non-optimal structures. For this reason, several methodologies have been presented for the optimal design of water supply systems. These methodologies usually result in MINLP models. A good review on these issues is given by Coelho and Andrade-Campos (2014).

Despite the advances described above, few studies have considered the simultaneous design of desalination plants and water supply network. Atilhan et al. (2012) introduced an optimization-based approach for the integrated design and operation of macroscopic water networks. A structural representation approach was developed to embed all potential configurations of interest. This representation accounts for water resources, desalination plants, water users, wastewater treatment facilities, and storage. However, the water supply system and the cost of water transportation were not included in the methodology. Also, Atilhan et al. (2011) introduced an approach to the design and decision making of desalination and distribution networks for water supply in regions; however a linear model was considered for the cost of water piping and pumping, without considering aspects such as geometric height differences between source and destination and the pipe design.

In this work, a methodology to design the system of desalination plant and desalinated water transport is presented. The objective is to determine the location and size of desalination plants and the water distribution system that minimizes capital and operational costs.

2. Methodology

2.1 Description of the problem

The problem can be defined as: given the requirements of desalinated water from mining companies, the potential locations of pumping stations, and potential locations of desalination plants; identify the location of the desalination plants and pumping stations; the size of desalination plants, pumping stations and pipe diameter; and operational conditions of pumping stations and water distribution network, which pose a minimal cost.

To find this optimal a superstructure containing a set of feasible water desalination plants and transport system is used, as shown in Figure 1. This superstructure is defined in So_n potential RO plants with known location and maximum production capacity, in N_n potential pumping stations with known location and elevation, and in Si_n mining industries with known demand for desalinated water, location, and elevation.

2.2 Mathematical model

In the mathematical representation of this superstructure four main sets are used: the set of RO plants, SO = {so | so is a RO plant}, the set of pumping stations N = {n | n is a pumping station}, the set of mining plant SI = {si| si is a mining plant}, and the set of pipe diameters D = {d | d is a pipe diameter}. In addition, possible connections between sites within the network were established, being defined distance and geometric height difference between each of them.

Part of the mathematical model describing the superstructure is presented below, and in it appropriate relationships and constraints between variables representing the entire system are defined. These relationships are the equations of continuity in each of the sites, Eqs. (1) - (3),

$$Q_{so}^{*} = \sum_{n \in N} Q_{so,n} \qquad \forall so \in SO \tag{1}$$

$$\sum_{i \in input} Q_{i,n} = \sum_{j \in output} Q_{n,j} \qquad \forall n \in N \tag{2}$$

$$Q_{si}^{*} = \sum_{n \in N} Q_{n,si} \qquad \forall si \in SI \tag{3}$$

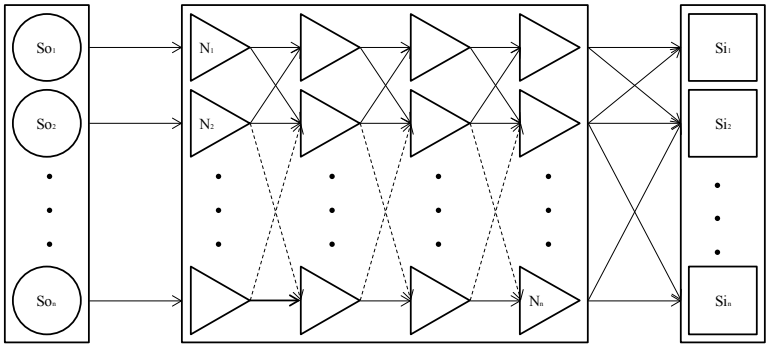

Figure 1. Superstructure of feasible water desalination and transport system

where $Q_{i,j}$ is the volumetric flow rate pumped from site *i* to *j*. The constraints associated with the maximum production capacity, C_{so}, of RO plants, ($Q_{so}^{*} \leq C_{so}$), and desalinated water demands, R_{si}, set by the mining industries ($Q_{si}^{*} \geq R_{si}$) are also included.

For the selection of the pipe diameter between *i* and *j*, a disjunction is used (Eq. 4), which is expressed using the convex hull method.

$$\bigvee_{d \in D} \begin{bmatrix} y_{i,j,d} \\ D_{i,j} = D_d \\ f_{i,j} = f_d \end{bmatrix} \qquad \forall\ (i,j) \in FIJ \tag{4}$$

where FIJ is the set of streams allowed between all the sites *i*, *j*; and *i* & *j* are elements of the set $SI \cup SO \cup N$. In Eq. (4) the friction factor ($f_{i,j}$) is assumed a function of the pipe diameter (and roughness), this is the Reynold number is big enough to not consider its contribution to the friction factor (see Swamee and Jain, 1976).

2.3 Objective function

The objective function minimizes the total annualized cost of all desalination plants, pipelines, and pumping stations required to meet water demands defined by mining industries plants, namely:

$$TC = \sum_{so \in SO} TC_{so} + \sum_{i,j \in FIJ} TC_{i,j} + \sum_{n \in N} TC_n \tag{5}$$

The cost of producing desalinated water is highly variable and dependents on several factors such as energy, chemicals, and labor, among others (Karagiannis and Soldatos, 2008). In this work, the cost function associated with RO plants was extracted from the database of costs raised by Wittholz (2008), and introduced here as a disjunction,

$$\bigvee_{c \in C} \begin{bmatrix} y_{so,c} \\ TC_{so} = PA \cdot UPC_{so,c} \cdot Q_{so}^{*} \\ Q_c^{LO} \leq Q_{so}^{*} \leq Q_c^{UP} \end{bmatrix} \qquad \forall\ so \in SO \tag{6}$$

where $UPC_{so,c}$ is unit cost of producing desalinated water ($/m^3) if $Q_c^{LO} \leq Q_{so}^* \leq Q_c^{UP}$, including capital and operational costs.

As proposed by Swamee (2001), the cost function of water transport network is composed by the annualized capital cost of the pipeline Eq. (7) and operational cost of pumping stations Eq. (8),

$$TC_{i,j} = \frac{k_P \left(1 + \frac{H_{i,j}}{H_b}\right) L_{i,j} {D_{i,j}}^m}{PL} \qquad \forall\, (i,j) \in FIJ \tag{7}$$

$$TC_n = \left(\frac{k_N (1 + s_b)\rho g}{\eta PL} + \frac{8.76 F_D F_A E_c \rho g}{\eta}\right) \cdot \sum_{j \in output} Q_{n,j} \cdot H_{n,j} \qquad \forall\, n \in N \tag{8}$$

In calculating the necessary pumping head, $H_{n,j}$, the Darcy-Weisbach equation was used to calculate the friction losses in the system, so $H_{n,j}$ is established in the follows:

$$H_{n,j} = \Delta Z_{n,j} + H_0 + \frac{8 f_{n,j} L_{n,j} {Q_{n,j}}^2}{\pi^2 g {D_{n,j}}^5} \tag{9}$$

where $\Delta Z_{n,j}$ is the elevation difference from site *n* to *j*, $L_{n,j}$ is the length of pipe from site *n* to *j*, and H_0 is the terminal head.

3. Case study

The case study considers the supply of water for three mining plants located at 1,500, 2,500 and 3,000 m above sea level, and with desalinized water demand of 5,400, 1,800 and 7,200 m^3/h respectively. If the current strategy of mining companies is used, then three RO plants must be built, each one to satisfy a mining plant. Thus three RO plants, each with a capacity sufficient to meet all mining plants water demand was considered. The pumping system is constituted by eleven pumping stations.

The problem was resolved using BARON under GAMS environment and not solution was found after 7,200 s. Then, the problem was resolved in two steps: first for each diameter the optimal solution was found; then the water network was fixed and the pipe diameters were calculated to find the optimal solution. Table 1 shows the results, where the alternative 3 is the best solution. The other two alternatives, local optimum, are included for discussion. Alternative 1 is the strategy currently used by mining companies.

Table 1. Local solutions for the case study. Cost in million $ per year

Alternative	Number of RO plant	RO cost	Number of pumping stations	Pumping cost	Total length of pipes	Piping cost	Total cost
1	3	78	9	126	690 km	55	259
2	1	61	6	125	527 km	46	232
3	1	61	4	125	357 km	36	222

Based on the results of Table 1, desalination costs are between 27 and 30 % of total costs, pumping costs between 48 and 56% of the total, and the costs of pipelines between 16 and 21 % of total cost. The best solution has the lowest cost of pumping, pipelines and desalination. Based on others results observed, there is a tradeoff between the three aforementioned costs to obtain the best solution. Therefore, the simultaneous design of desalination plants, pipelines and pumping system is desirable.

4. Conclusions

The problem of supplying desalinated water to mining plants that are between 600 and 4000 m above sea level was addressed. The proposed methodology considers the design of the desalination plant together the distribution system of desalinated water. A case study was included to illustrate and validate the methodology. The results indicate that the methodology is an appropriate tool to analyze these problems and their application to similar problems is easily adaptable. Also, there is a tradeoff between costs of desalination plant, pumping system, and pipeline system.

Abstract
Polymerase chain reaction (PCR) is routinely used for analysis of genes from targeted cells leading to an understanding of the fundamental molecular biology involved in cellular events and for detecting abnormal pathways involved in disease development. In a previous paper we argued that the three commonly known strategies to alleviate the impact of cell pretreatment on PCR had serious shortcomings. Furthermore microfluidic strategies that permit simple operation, simple device design and are compatible with Taq polymerase are highly in demand. In this paper, we discuss optimization of microfluidic platform designs, which may be more efficient than the current one we have developed. The microfluidic reactor modelled in this paper relies on the diffusion of molecules from the loading chambers into a small reaction chamber. This results show that diffusion into the reaction chamber can be modified using different loading chamber geometries. Based on the results we have began to develop a mixed integer optimization model to automatically design the geometry to meet the desired transport rates of species in PCR.

Keywords: PCR, microfluidics, optimization, diffusion

1. Introduction
Polymerase chain reaction (PCR) is routinely used for analysis of genes from targeted cells leading to an understanding of the fundamental molecular biology involved in cellular events and for detecting abnormal pathways involved in disease development. Microfluidic devices allow genetic analysis using only tiny amounts of cell samples with high sensitivity and high degree of integration (Ottensen et al., 2006; Marcus et al., 2006; Easley, et al., 2006; Muddu et al., 2011; Agrawal et al., 2007; Bailey et al., 2007; Qavi et al., 2010). The first step in genetic analysis of cells is the lysis of cells leading to a release of genes. Subsequently the genes are isolated, purified, amplified and analysed using PCR (Kim et al., 2009; Chen et al., 2007). The integration of these steps on a microfluidic platform is complicated and needs careful design. The entire process involves various chemical and biological reagents; unfortunately this leads to some reagents interfering with the functions of others. For example chemical reagents used for cell lysis (such as sodium dodecyl sulphate and Triton X-100) may inhibit PCR by reducing polymerase activity (Wilson, 1997; Radstrom et al., 2004; Erlich, 1989). In addition intracellular molecules such as proteins (Hall et al., 2013), polysaccharides (Monteiro et al., 1997), and ions (Al-Soud and Radstrom, 2001) (including Ca^{2+}, Fe^{3+}

and EDTA) in the cell lysate may interact with a polymerase leading to reduced PCR amplification. There are three main strategies for mitigating the impact of cell pretreatment on PCR as follows: (i) Institute an isolation step to remove the lysis reagent and undesired intracellular molecules while preserving nucleic acids. This is typically done by adsorption of nucleic acids on solid surfaces (for example beads or matrices) while replacing the solution (Marcus et al., 2006; Easley et al., 2006; Legendre et al., 2006; Hong et al., 2004). These adsorption and desorption processes increase the complexity of the procedure. Additional chambers and structures may also be needed on the chip to accommodate the procedure. (ii) Use lysis methods that interfere with PCR to a less degree than surfactants, typically in combination with dilution. Freeze-thaw (Toriello et al., 2008) or heating (White et al., 2011; Lien et al., 2007) has been applied to cell lysis in the context of genetic analysis. These methods are less efficient than surfactant-based lysis (Gilbert et al., 2006). In Toriello (Toriello et al., 2008), lysis and PCR were conducted in connected chambers of different sizes so that the lysis reagent was diluted 100-fold when PCR was carried out. Such dilution compromises the limit of detection and requires complex device structure and operational procedure. (iii) Use Direct PCR kit based on Phusion polymerase that is tolerant to surfactant-based lysis reagents (Manage et al., 2011). However, Phusion polymerase can be inhibited by SYBR green and other dyes (Mao et al., 2007) and lacks 5' to 3' exonuclease activity (Wang et al., 2004). Thus commonly used fluorescence-based quantification is impossible with the Phusion polymerase system. Overall microfluidic strategies that permit simple operation, simple device design and are compatible with Taq polymerase are in very high demand. Such strategies will be particularly beneficial for precise and demanding operations such as genetic analysis based on single cells (Novak et al., 2011; Liu et al., 2011; Leung et al., 2012). Our research seeks to address this need.

2. Methodology

In our paper (Ma et al., 2014) and as discussed in the introduction, we argued that the three commonly known strategies to alleviate the impact of cell pretreatment on PCR had serious shortcomings. Furthermore microfluidic strategies that permit simple operation and device design and are compatible with Taq polymerase are highly in demand. To this end we have developed a microfluidic device that permits "one-pot" strategy for multi-step PCR analysis starting from cells (i.e. using one reactor for successive reactions without separation and purification, Ma et al., 2014). The strategy exploits diffusivity differences, effectively replacing the smaller reagent/intracellular molecules in the reaction chamber by diffusion while retaining the larger DNA molecules inside. This simple scheme effectively removes reagents from the previous step to avoid interference and thus *permits multi-step processing in the same reaction chamber*. Our approach shows high efficiency for PCR and potential for a wide range of genetic analysis including assays based on single cells.

Our microfluidic device includes a reaction chamber connected with two loading chambers on both sides. Closing two-layer valves could cut off the connections between the reaction chamber and the two loading chambers. The lysis buffer and the PCR mix are introduced into the chamber by concentration-gradient-driven diffusion. During such diffusion, the new solution replaces the solution and molecules from the previous step without removing the slow-diffusing genomic DNA. The single chamber ("one-pot") design drastically minimizes the complexity of the microfluidic device. We envision

that this may be a general approach for on-chip multi-step assays on genomic DNAs. In this paper we discuss some optimization of microfluidic platform designs, which may be more efficient than the current one we have developed. We are beginning to build these devices to efficiently carry out PCR; the data collected would also be employed to validate our modeling effort. Using the PDE toolbox (pdetool) in MATLAB as a basis, we developed additional code to model diffusion through the reactor. We considered the following components: Primers, Taq Polymerase (Tag), dNTP, small ions, intracellular proteins and Triton X-100. Figures 1 through 5 show different reactor geometries with mesh points. We calculated the average relative concentration in the reaction chamber at each time point.

3. Results

The main focus of this modeling effort is on the diffusion from the loading chamber into the PCR reactor. In Figure 6, *for a given species* we have plotted the results for the different geometries. In contrast in Figure 7, *for a given geometry*, we have plotted the results for the different species. The first three geometries in Figure 6 (Geo 1, 2 3) show essentially no differences in diffusion rates; note that time is in minutes and "concentration" is percent of starting concentration. This is likely due to similar geometry closer to the reaction chamber. Since the reaction chamber is significantly smaller than the loading chamber, the diffusion rates will not change so long as there is a large volume of solution in direct contact with the reaction chamber. Only when this volume is restricted, do changes in diffusion rates appear.

Geo 4 and 5 in Figure 6 show significant changes in the results. The diffusion rate for Geo 4 is slower. The most notable difference is in the small ions. Geo 4 has a 16% lower concentration of small ions than that of Geo 1 at the end of one hour. Geo 5, on the other hand, has some more interesting results. For small ions and dNTP the results for Geo 5 look nearly identical to Geo 4. However for Taq Polymerase and primers the diffusion rates for these two components are highest in Geo 5.

4. Conclusions

Polymerase chain reaction is routinely used for analysis of genes from targeted cells leading to an understanding of the fundamental molecular biology involved in cellular events and for detecting abnormal pathways involved in disease development. In this paper, we have discussed optimization of microfluidic platform designs, which may be more efficient (experimentally) than the current one we have developed. The results show that diffusion into the reaction chamber can be modified using different loading chamber geometries. The geometries in Figure 4 and Figure 5 display this idea with their slowed diffusion in most components. The study also showed that smaller changes in the geometry do not affect diffusion rates in any significant way. If the bulk geometry in direct contact with the diffusion chamber is unchanged, the diffusion rates will remain unchanged. We also realize that in the near future we need to add advection to the PDE model in order to improve the transport through advection-diffusion. Based on the current results we have begun to develop a mixed integer optimization model to automatically design the geometry to meet the desired transport rates of species in PCR. The automatic generation of the geometry would employ Bezier curves often used in computer graphics; Sharifi and Achenie (2007) employed a similar concept. After experimental validation, the results will be reported in a paper.

Abstract

An integrated biorefinery is a processing facility that integrates multiple biomass conversion pathways to produce value-added products. To date, various biomass conversion pathways are available to convert biomass into a wide range of products. Hence, there is a need for a methodology capable of evaluating the integrated processes in order to identify the optimal products possible to be produced from biomass and the optimal conversion pathway in producing them. In many cases where the desired properties cannot be met by a single molecule, an optimal mixture of chemicals would be required. In this respect, product and process design decisions would be a challenging task for an integrated biorefinery. In this work, a two-stage optimisation approach is developed to identify the optimal conversion pathways in an integrated biorefinery which convert biomass into an optimal mixture with desired properties. In the first stage, the optimal mixture is designed via computer aided molecular/mixture design (CAMD) tools. Once the optimal mixture is established, the second stage determines the optimal conversion pathway via superstructural mathematical optimisation approach. With such approach, the optimal conversion pathway can be determined based on different optimisation objectives. To illustrate the proposed methodology, a case study on the design of fuel additives as a mixture of different molecules from palm-based biomass is presented.

Keywords: product design, mixture design, integrated biorefinery, integrated product and process design, inverse design techniques.

1. Introduction

Fossil fuels have been widely utilised as the main source of energy for heat and power production. Besides, fossil fuel has also been an important feedstock for various commodity and specialty chemical productions. However, vast consumption of fossil fuels also contributed to significant environmental issue such as the increased level of greenhouse gases in the atmosphere (Panwar et al., 2011). With the increasing awareness toward clean and sustainable development, biomass has been identified as one of the most promising sources of renewable energy. To convert biomass into energy and value-added products, an integrated processing facility known as an integrated biorefinery is needed. An integrated biorefinery is a processing facility that integrates multiple chemical reaction pathways to convert biomass into value-added products along with heat and power (Fernando et al., 2006). To date, there are a large number of established biomass conversion pathways available for implementation in an integrated

biorefinery to convert biomass into a wide spectrum of products. As such, there is a need to screen all potential pathways systematically and determine the optimum pathway that produces the desired products. Various approaches have been developed for process synthesis and screening of potential conversion pathways for integrated biorefineries.

It can be seen that most of the current works in this area are focused on identifying and designing the optimal processing routes that leads to the product without considering the requirement of product needs. To address this issue, the product design aspects have to be taken into consideration to design integrated biorefinery. This can be achieved by integrating the chemical product design steps during the synthesis and design of integrated biorefinery. According to Cussler and Moggridge (2001), chemical product design is a process of choosing the optimal product to be made for a specific application. Most of the time, functionality of a product are defined in terms of physical properties rather than chemical structure of the product. Hence, chemical product design can be considered as an inverse property prediction problem where the preferred attributes of the product are represented in terms of physical properties (Gani and O'Connell, 2001). As product specifications are often extracted from customer needs, it is required to translate qualitative attributes into quantitative parameters in order to design a product (Achenie et al., 2003). The process of representing product attributes by using measurable parameters is often done by CAMD techniques. CAMD techniques are important for product design because they are able to predict and design molecules with a given set of properties. CAMD techniques have been extensively applied in designing different chemical products over the recent decades. Hechinger et al. (2010) presented a work for the design of biofuels from biomass by integrating product and process design. The work identifies the molecular structures of the biofuels by using CAMD techniques while searching the alternative production pathways by utilising reaction network flux analysis. Chemmangattuvalappil et al. (2010) developed a general framework for the integration of process and molecular design problem for the design of industrial solvent. Roughton et al. (2011) proposed a methodology for the simultaneous design of ionic liquids and azeotropic separation processes. Recently, Mattei et al. (2014) presented a virtual product-process design laboratory for the design and analysis of blended liquid products and emulsion-based products. Despite the usefulness of the aforementioned works, it is found that the development on simultaneous process and product design of integrated biorefinery is still in its early stages. In cases where a single component/molecule is insufficient to meet desired properties, it is an opportunity to explore the potential of designing an optimal mixture from an integrated biorefinery. Therefore, this remains as the scope of this work.

2. Methodology: Two stage optimisation approach

This work presents a systematic methodology for simultaneous process and product design for an integrated biorefinery. A two-stage optimisation approach is utilised to identify the optimal product in terms of mixture of several individual components as well as the optimal conversion pathway for the mixture.

2.1. Mixture design

In this stage, the optimal mixture is designed by utilising signature based molecular design techniques (Chemmangattuvalappil et al. 2010). The main component of the mixture is first identified from the available products or designed based on the target

properties. The additive components required for the mixture are then designed such that when mixed together with the main component, the properties of the mixture will fall within the target property ranges as shown in Eq.1.

$$v_{mp}^{\mathrm{L}} \le \sum_i x_{ip} V_{ip} \le v_{mp}^{\mathrm{U}} \qquad p = 1, 2, \ldots P \tag{1}$$

where x_{ip} is the fraction of chemical component i for target property p, V_{ip} is the value of target property p for chemical component i, v^{L}_{mp} and v^{U}_{mp} are the lower and upper limits of mixture m for target property p respectively. According to Churi and Achenie (1997), the main purpose in designing mixtures is that mixtures have the potential for giving a good mix of target properties which are unattainable by individual chemical components. For example, for refrigerant design, although difluoromethane (CH_2F_2) is a better refrigerant in terms of low compressor displacement and zero ozone depletion, its vapor pressure it too high for an efficient refrigerant. This can be overcome by mixing chloromethane (CH_3Cl) and CH_2F_2 (Duvedi and Achenie, 1997). Hence, mixtures offer greater flexibility in matching multiple target properties. To design an optimal mixture in terms product properties by mixing different chemical components, multiple mixture target properties are needed to be considered and optimised simultaneously. This can be solved as multi-objective optimisation problem where multiple target properties are optimised during the design of the mixture. Fuzzy optimisation approach is applied in this work to trade off different target properties simultaneously. The application of fuzzy set theory in optimal decision-making is introduced by Bellman and Zadeh (1970). Zimmermann (1978) later extended the approach to address mathematical programming problems which involve multiple objectives by integrating multiple objectives into a single objective. An optimised trade-off solution can be obtained by solving the overall objective based on the predefined fuzzy limits. To maximise the mixture property, trade-off between properties to be optimised is done by introducing a degree of satisfaction, λ which is bounded within the interval of 0 and 1.

$$\lambda_p = \frac{v_{mp}^{\mathrm{U}} - V_{mp}}{v_{mp}^{\mathrm{U}} - v_{mp}^{\mathrm{L}}}, \quad \lambda_p = \frac{V_{mp} - v_{mp}^{\mathrm{L}}}{v_{mp}^{\mathrm{U}} - v_{mp}^{\mathrm{L}}} \tag{2}$$

where λ_p is the degree of satisfaction for property p. The first equation in Eq.(2) is used for properties to be maximised while the second equation in Eq.(2) is utilised for properties to be minimised. To obtain the optimal solution, max-min aggregation is applied (Zimmermann, 1978), where the least satisfied degree of satisfaction of these properties is maximised.

2.2. Integrated biorefinery design

In the second stage, an integrated biorefinery is synthesised based on the components designed for the optimal mixture in the first stage. This is done by utilising superstructural mathematical optimisation approach. A superstructure which includes all the possible conversion pathways and technologies that process the biomass into the intermediate, and convert the intermediates into the final products is constructed as the representation of an integrated biorefinery. As such, the optimal conversion pathway based on different optimisation objectives that leads to the desired optimal mixture can be determined in this stage. For cases where the conversion pathway leads to the formation of products as a mixture of several components, separation processes are included.

3. Case study: Production of biofuel additives from palm-based biomass

In this case study, a mixture design problem of bio-based fuel additives with a specified set of properties is produced from palm-based biomass. The optimal mixture is designed such that it possesses target properties which fall within the specified target property ranges. These target properties include higher heating value (*HHV*) which is estimated by group contribution (GC) model developed by Yunus (2014), lethal concentration ($\log LC_{50}$) estimated by connectivity index from Koch (1982), viscosity (η) estimated by GC model from Conte et al. (2008), heat of vaporisation (H_v) estimated by GC model from Marrero and Gani (2001) and oxygen content (*OC*). The target property range for *HHV* is within 3500 and 5500 kJ/mol, *OC* within 2.00 and 6.70 wt %, $\log LC_{50}$ within 2.40 and 3.60, H_v within 30 and 50 kJ/mol and η within 0.30 and 0.90 cP. The main component (MC) of the fuel is predetermined by using a pseudo-component consists of different types of hydrocarbons. The objective of the mixture design is to improve *HHV* and *OC* of the main component by designing additive component made from alkane and alcohol for the fuel. In this work, linear mixing rule is applied to estimate *HHV*, $\log LC_{50}$, *OC* and H_v of the mixture. For η, a mixing rule developed based on property integration as proposed by Qin et al. (2004) is utilised. In order to target the multiple objectives, fuzzy optimisation approach has been applied along with CAMD techniques. Following the proposed approach, the best five solutions for the design of additives made from both alkane (Alk) and alcohol (Alc) are obtained and summarised in Table 1.

Table 1. Possible designs of additives made from alkane and alcohol

Sol.	Properties				
	HHV (kJ/mol)	*OC* (wt %)	log LC_{50}	H_v (kJ/mol)	η (cP)
Alk. A	6767	0.00	1.08	44.32	0.89
Alk. B	6765	0.00	0.86	46.24	0.69
Alk. C	6751	0.00	0.90	44.60	0.60
Alk. D	6126	0.00	1.16	42.97	0.64
Alk. E	6112	0.00	1.25	41.33	0.56
Alc. A	2683	21.62	3.05	50.90	2.50
Alc. B	2669	21.62	3.11	49.25	2.18
Alc. C	3335	18.18	2.60	55.80	3.09
Alc. D	3321	18.18	2.63	54.16	2.70
Alc. E	3307	18.18	2.78	52.52	2.36

By mixing the MC with the identified additive components, the best five mixtures identified together with the mixing ratio of main and additive components are shown in Table 2. Mixture A possesses *HHV* of 4626 kJ/mol, *OC* of 4.34 wt %, $\log LC_{50}$ of 2.97, H_v of 40.22 kJ/mol and η of 0.83 cP.

Table 2. Possible designs of mixture

Mixture	MC (wt %)	Alk (wt %)	Alc (wt %)
A.	52.30	Alk. A (23.85)	Alc. C (23.85)
B.	53.30	Alk. D (23.44)	Alc. D (23.26)
C.	53.74	Alk. A (26.90)	Alc. A (19.36)
D.	53.71	Alk. C (26.99)	Alc. B (19.30)
E.	52.30	Alk. B (23.85)	Alc. C (23.85)

Once the optimal mixture is identified in stage one, the optimal conversion pathways that convert palm-based biomass into the identified additive components is determined in stage two. The superstructure model of this case study is shown in Figure 1.

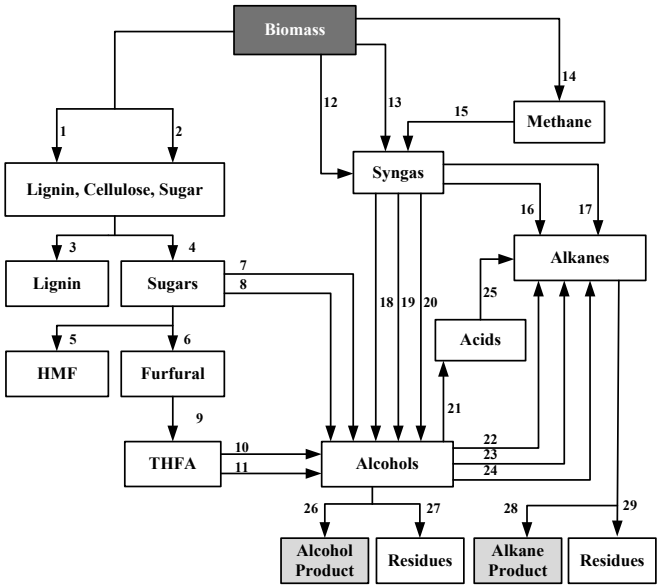

Figure 1. Superstructure of conversion pathways to produce additive components

The numbers in Figure 1 represent different conversion pathways and technologies that process the biomass into the intermediates, and convert the intermediates into the final product. In this case study, the optimisation objective of the integrated biorefinery is to identify the conversion pathways with maximum product yield (Scenario 1) and maximum economic potential (Scenario 2). From the optimal mixture generated in the first stage of the methodology, it is identified the mixing ratio of additives alkane (Alk. A) and alcohol (Alc. C) for mixture A is 1:1. Thus, the production ratio of alkane and alcohol in the integrated biorefinery is fixed as 1:1. With a feed of 50,000 tonnes per year of palm-based biomass, superstructural optimisation model is formulated and solved. The results are shown in Table 3.

Table 3. Comparison of results for Scenario 1 and 2.

Scenario	1	2
Conversion pathways	1,3,4,6,9,11,12,16, 23,26,27,28,29	1,3,4,6,9,10,12,17, 23,26,27,28,29
GP^{Total} (U.S $/y)	5.43×10^6	19.71×10^6
Alkane production rate (t/y)	1169.38	406.33
Alcohol production rate (t/y)	1169.38	406.33
Alkane by-product production rate (t/y)	10303.30	10831.65
Alcohol by-product production rate (t/y)	2710.84	9650.45

In scenario 1, Alc.C is produced from biomass in the sequence of ammonia explosion, Organosolv separation, dehydration of sugars, hydrogenation of furfural, hydrogenation of THFA 2 and fractional of distillation of alcohols. Meanwhile, Alk. A is produced from fractional distillation of alkanes, which are produced from pyrolysis of biomass followed by Fischer-Tropsch process 1 together with dehydration of alcohols 2. In scenario 2, most of the conversion pathways of scenario 2 are similar to those of scenario 1. However, hydrogenation of THFA 1 is chosen instead of hydrogenation of THFA 2 and Fischer-Tropsch process 2 is selected over Fischer-Tropsch process 1 in order to produce the additives while generating maximum profit.

4. Conclusions

This paper introduces a systematic two-stage optimisation approach for optimal mixture design in an integrated biorefinery by integrating product and process design. In the first stage, mixture design is done by CAMD technique. Main component of the mixture is first identified from the target properties. This is followed by the identification of additive components to form the mixture with the main component. Hence, the optimal mixture that possesses optimal product properties can be designed by mixing the identified main component and additive components together. In the second stage, the optimal conversion pathway is determined via superstructural mathematical optimisation approach. Future efforts will be focused on improving the completeness of the methodology. Product stability analysis and verification can be investigated to improve the accuracy of the mixture design methodology.

Abstract

Ionic liquids (ILs) have been introduced as potential replacement of conventional CO_2 capturing solvents, for their negligible vapour pressure and high thermal stability. Besides, through matching cations and anions, ILs provide a flexibility to tune their properties. However, due to vast number of potential ILs, time and expense required determine suitable ILs for CO_2 capture is unaffordable. In this work, a systematic visual approach to design IL as CO_2 solvent, via property clustering technique and group contribution method has been developed. This approach allows visualisation of high-dimensional problem into two or three dimensions. A case study has been presented to elaborate application of the developed approach.

Keywords: Ionic liquid design, property clustering, group contribution.

1. Introduction

Carbon dioxide (CO_2) emission is now a major issue faced by society, which is closely related to the global energy demand and supply. Fossil fuel remains dominant and supply up to 80 % of global energy consumption, and thus accounts for two-thirds of global CO_2 emissions (IEA, 2013). Carbon capture and storage (CCS) is a possible solution to this, by separating CO_2 from emission sources and storing it in secure geological storage. Ionic liquids (ILs) have recently emerged as green solvents and suggested as possible CO_2 capturing solvents. ILs have very unique combination of properties, including large liquid phase range, negligible vapour pressure, and high thermal stability (Plechkova and Seddon, 2008). They are also called "designer" solvents, for their thermophysical properties can be tuned by switching cations and anions, and thus can be designed for specific application. However, it was reported that there are 10^6 unique combinations of cations and anions (Plechkova and Seddon, 2008). It is a challenging task to find potential ILs for specific task and fulfil certain properties, by trial-and-error approach.

To address this problem, works have recently been done to synthesise novel ILs structure through systematic approach. Roughton et al. (2011) presented simultaneous process and ILs design for azeotropic separation process, by using a newly developed UNIFAC model. Hada et al. (2013) proposed a methodology combining group

contribution (GC) method, chemometric and property clustering technique to design IL. Chong et al. (2014) presented a mixed-integer nonlinear programming formulation to design optimal ILs to capture CO_2. The aforementioned works are based on mathematical optimisation techniques, which is preferable when solving relatively complex problem. However, these techniques do not provide insights of the problem, which might be useful for people without mathematical optimisation background. In addition, nonlinear property prediction models used in previous works increase the complexity of the approach that can lead to sub-optimal solutions. This work introduces a property based visual representation of IL design problem, by using property clustering technique and GC method.

2. Property Clustering

Property clustering is a tool developed by Shelley and El-Halwagi (2000) to represent and track properties in a process streams following a conserved manner. This technique allows for representation of process from a properties perspective and visualisation of process design problems (Eljack and Eden, 2008). Eljack et al. (2006) extended this technique and introduced molecular property operators that can solve molecular design problems. This technique allows for simple linear additive rules of the groups, as described in Eq. (1).

$$\psi_j\left(P_{ji}\right) = \sum_{g=1}^{N_g} n_g\left(P_{jg}\right) \tag{1}$$

In Eq. (1), $\psi_j(P_{ji})$ is the molecular property operator of the j^{th} property of component i, n_g is the number of group g, and N_g is the total number of molecular groups. This equation shows that the property operator will follow simple linear mixing rules, regardless of the linearity of the raw property. Through the following steps shown in Eq. (2), property clusters can be obtained from property operators (Eden et al., 2004). In Eq. (2), Ω_{jg} is normalised property operator for property j, $\psi_j(P_{jg})$ is reference operator of j^{th} property, AUP_g is augmented property index of group g, and C_{jg} is property cluster for property j of group g.

$$\Omega_{jg} = \frac{\psi_j\left(P_{jg}\right)}{\psi_j^{ref}\left(P_j\right)}, \qquad AUP_g = \sum_{j=1}^{NP} \Omega_{jg}, \qquad C_{jg} = \frac{\Omega_{jg}}{AUP_g} \tag{2}$$

3. Visualisation of the Problem

Using property clustering technique, the IL design problem can now be visualised in a ternary diagram. In the ternary diagram, each vertex represents a pure property cluster. It should be noted that the number of clusters is limited to three for visualisation purpose, but this does not indicate that the number of properties considered in IL design is also limited to three. Besides, properties with no available GC prediction models can also be included as addition considerations, as long as there are appropriate prediction models for these properties. All considered properties of designed IL should be within the property constraints. For properties included in ternary diagram, El-Halwagi et al. (2004) showed that the constraints can be represented as a feasibility region defined by six unique points. To ensure the designed ILs are valid solutions, following design and optimisation rules have also been developed, based on rules previously developed by Eden et al. (2004) and Eljack and Eden (2008).

Rule 1: When two groups, G_1 and G_2, are added linearly on the diagram, the AUP values and distance between them provide information of G_1-G_2 structure.
Rule 2: More groups can be added if the free bond number, *FBN* of the structure is not zero
Rule 3: The final IL molecular structure must not have any free bond, to ensure the structure is complete and feasible (i.e. $FBN = 0$).
Rule 4: Location of the final formulation is independent of the order of group addition.
Rule 5: In pure IL design, only one cation core and one anion group can be chosen.
Rule 6: The cluster value of the designed IL must be located within the feasibility region on the ternary diagram.
Rule 7: The AUP value of the designed IL must be within the range of target AUP. If the AUP value is outside the range of target AUP, the IL is not a feasible solution.

In the case where properties with no GC prediction models are considered, these properties must be calculated for the designed IL using appropriate prediction models. The calculated property values must be within the range of target properties for the designed IL to be a valid solution. It is common that there is negative GC data, and this will lead to negative property operator and cluster value. In this situation, the group will reside outside the ternary diagram, and using this group will violate Rule 1. Solvason et al. (2009) has discussed about this limitation and another rule is developed to overcome this. Without Rule 8, a negative AUP is mathematically possible, but it gives an infeasible solution. This can be avoided by adjusting reference values of the properties.

Rule 8: All AUP values of the groups must be positive.

4. Case Study

An illustrative case study is included to demonstrate the proposed approach. As shown in Table 1, three cation cores, two anions and three organic functional groups are considered in this design problem. The main objective is to determine a list of potential ILs for carbon capture purpose. In this IL design formulation, the three properties considered for visualisation purpose are density (ρ), heat of vaporisation (ΔH_{vap}), and specific heat capacity (c_p), which are denoted as C_1, C_2, and C_3 respectively. In addition to these, viscosity (μ) and solubility of CO_2 (x_{CO2}) are included for screening purpose. The GC prediction models for density (Qiao et al., 2010), heat of vaporisation (Verevkin, 2008), and specific heat capacity (Gardas and Coutinho, 2008) are shown in Eq. (3).

$$\rho = \rho_0 + \sum_g n_g \rho_g, \qquad \Delta H_{\text{vap}} = \sum_g n_g \Delta H_{vap,g}, \qquad c_p = R\left(\sum_g n_g c_{p,g}\right) \tag{3}$$

Table 1: Organic function groups, cation cores, and anions considered

Type	k	Groups	Type	k	Groups
Organic groups	1	CH_3	Cation cores	6	$[MIm]^+$
	2	CH_2		7	$[Py]^+$
	3	OH		8	$[MPyr]^+$
Anions	4	$[BF_4]^-$			
	5	$[Tf_2N]^-$			

where ρ_0 is the adjustable parameter for density and R is gas constant. From Eq. (3), the property operators can be identified and property clusters are then determined using Eq. (2). Group contribution model for density is possible in pure component design because it is not estimation of mixture density. The viscosity of IL is determined using Eqs. (4) and (5).

$$\ln \frac{1{,}000\mu}{\rho M} = A + \frac{B}{T} \tag{4}$$

$$A = \sum_g n_g A_{g,\mu}, \qquad B = \sum_g n_g B_{g,\mu} \tag{5}$$

where M is IL molecular weight, T is the system temperature in K, $A_{g,\mu}$ and $B_{g,\mu}$ are contributions of group g to parameters A and B respectively. The solubility of CO_2 is determined through equilibrium relationships as shown in Eq. (6). The nonideality of liquid phase, due to presence of ionic and organic compounds, is modelled through activity coefficient γ_i. Activity coefficient is estimated using UNIFAC model for systems containing ILs (Lei et al., 2013).

$$y_i P \varphi_i(T, P, y_i) = x_i \gamma_i P_i^s \tag{6}$$

where x_i and y_i are the mole fractions of component i in liquid and gas phases respectively, P is the system pressure in MPa, P_i^S is the saturated vapour pressure of component i, and $\varphi_i(T,P,y_i)$ is the gas-phase fugacity coefficient. The target property ranges are shown in Table 2. Designed ILs should possess similar properties as current CO_2 solvents, i.e. ethanolamines (The Dow Chemical Company, 2003). Low viscosity of IL is desired to minimise pumping power required to circulate IL solvent within the system. Therefore, the target viscosity is set between 0 to 0.1 Pa.s. Solubility of CO_2 is measured in terms of CO_2 mole fraction in liquid phase at equilibrium. Using the proposed approach, the problem is visualised and shown in Figure 1. The dotted line represents the feasibility region based on the target property ranges in Table 2. The maximum and minimum AUP is determined to be 2.703 and 11.502 from this boundary. Note that, G_1 and G_2 locate out of ternary diagram because they have negative property cluster values.

Eight candidates ILs are formulated, as shown in Figure 2, as potential CO_2 solvents reside within feasibility region. The AUP values of these candidates are determined, as shown in Table 3, and they are all within the range of AUP of feasibility region determined from the six point bounding. Lastly, the properties of all ILs, including the screening properties, are back calculated, and included in Table 3. These designed ILs fulfill all the property constraints set in Table 2.

Table 2: Target property ranges to design IL for carbon capture purpose

Property	Lower Bound	Upper Bound
ρ (g/cm^3)	1	2
ΔH_{vap} (kJ/kmol)	40,000	200,000
c_p (kJ/kmol.K)	100	600
μ (Pa.s)	0	0.1
x_{CO2}	0	1

5. Conclusions

A systematic visual approach to design IL as CO_2 capturing solvent is presented in this work. This approach utilises property clustering technique, and group contribution methods to estimate properties of ILs. The proposed approach provides insight to the user when designing ILs as CO_2 capturing solvents.

Abstract

C5 fraction, which accounts for 15-25% in naphtha, consists of molecules such as isoprene (IP), pentadiene (PD), cyclopentene(CP), and cyclopentadiene (CPD) can be used to manufacture petroleum resin and other high value-added products. Yet it is often burned as fuel and not fully utilized because separation of these products with close boiling points is difficult. One common process is to react CPD itself to form di-cyclopentadiene (DCPD) so that it can be separated from the other C5 molecules. Extractive distillation was also used to recover alkynes from light ends. Such a process involves use of multiple separation columns and reactors. Furthermore, it was found that the reactor is highly coupled with one of the separation columns by a recycle stream, leading to snowball effect and difficulty in control. Hence a wide range of opportunities for process intensification and integration was available. It was found that the entire separation process can be substantially simplified by reducing number of reaction zones from 2 to 1 and number of columns from 8 to 6. Such a simplification increases product concentration of DCPD from a range between 85wt% and 92wt% to 99wt%, while maintains the high purity (>99.75wt%) for the IP stream and specified purity (>89.90wt%) for the PD plus CP stream. This process can be further simplified by using thermal coupling and external heat integration. Such simplifications and intensified techniques lead to substantial reduction in capital costs, energy costs as well as process operability.

Keywords: Intensification, steady-state simulation, plant-wide process, heat integration, thermal coupling.

1. Introduction

Diolefins, including CPD, IP, CP, and PD in C5 fraction, are the byproduct of ethylene industry. They were obtained from naphtha cracking process by conventional distillation and extractive distillation. The rise of the shale gas industry, where light oil can be used for the ethylene synthesis enabled ethylene to be obtained easily, lowering its production cost. Therefore, the current processes in the naphtha industry need to be improved in order to increase their competitive strength.

Various strategies were provided for treating hydrocarbon streams comprising CPD and other dienes. The multiple dimerization and depolymerization method was embodied by Owen et al. (2001), Liu et al. (2012), and etc. They have showed that it is capable of achieving high concentration of DCPD by the use of multiple reactors combined with

recovery processes of other materials.
IP is the main component and is mixed with close boiling-point components in C5 crude. Some azeotropes can be found between them. Extractive distillation is commonly used in the industry to separate these azeotropes. Three solvents can be used in the extraction distillation for the purification of IP. They are acetonitrile (ACN), dimethylformamide (DMF), and n-methyl-2-pyrrolidone (NMP). (Shu et al., 2009; Liu et al., 2014)

The separation processes are normally complicated involving multiple reactors and distillation units. The aforementioned literature suggested varies of improving the process. However, to our best knowledge, an unified benchmark of various processes and a systematic approach to improving the process have not been found in open literature. The objective of this study is therefore to develop an ASPEN Plus steady state model and use it to investigate how such a process can be simplified using process intensification and integration techniques.

2. Conventional process

The main purpose for the separation process of crude C5 elements is to recover high value-added components, such as CPD, IP, and PD/CP. In this study, a conventional plant-wide process of the crude C5 was simulated and shown in Figure 1 on the basis of the US patent 20032100809A1 (Tian et al., 2003) and the CN patent 102951989 A (Sun et al., 2003). In this conventional process, the target specifications commonly used in the industry are given in Table1. Using the simulation model we developed, the product purities and recovery was also listed. In addition, for a 75,000 Ton per annum plant, the total reboiler duty required was found to be 34.5 MJ. With an 8-year payback period, the amortized capital expenditure (ACAPEX) was found to be 2,316,000 USD/yr. The annual operating cost (AOC) was found to be 2,856,000 USD/yr and the total annual cost (TAC) equals 5,172,000 USD/yr. The above costs were estimated using the method described in Douglas (1988).

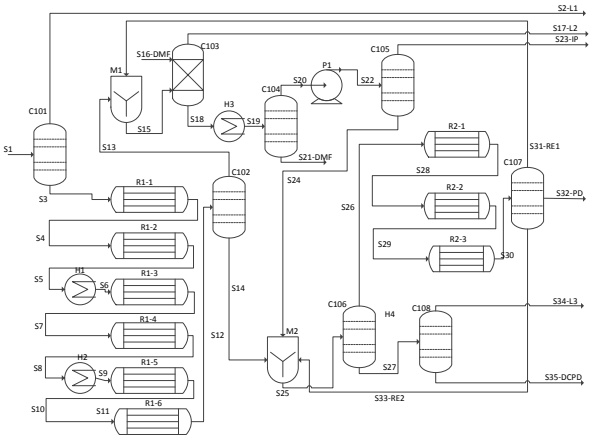

Figure 1 Conventional process flowsheet (CP).

In general, the conventional process CP can provide an effective way to recover the valuable materials in crude C5. However, the main issue of the complexity in the design and control remains unsolved. First, the bottom recycle stream from column 107 is the

key factor to affect the reaction conversion and may cause the snow-ball effects in the second reaction zone and product PD/CP: the rest CPD in the second zone is mostly reacted into DCPD, resulting in the PD/CP stream concentrated without CPD. However, the different CPD concentration and conversion would be found in different recycled rates. Then the snow-ball effect would happen with inadequate CPD conversion and cause the faulty concentration of PD/CP. Second, the whole process containing at least 8 columns and reactors with the length of 98 meters needs high capital costs. In the following, the problems mentioned above are solved by simplifying the conventional process.

Table 1 Targets specifications and simulated performance.

	Target	Conventional process
IP product concentration (wt%)	99.75	99.82
IP product recovery (%)	>90	90.52
PD+CP product concentration (wt%)	89.81	90.79
PD+CP product recovery (%)	-	92.84
DCPD product concentration (wt%)	83.27	86.73
DCPD total recovery (%)	-	89.30
Process duty (MW)	-	34.50
Operating Cost ($1000/y)	-	2,856
Capital Cost ($1000/y)	-	2,316
TAC ($1000/y)	-	5,172

3. Simplified process

In the study, a simplified process (SP) shown in the Figure 2 is presented by deleting the first reaction zone, columns 106 and 108, and two recycle streams from column 107. The first reaction zone is deleted because the presence of IP can increase the concentration of by-products that will decrease the purity of DCPD. With IP removed, the second reaction zone is sufficient to maintain the high conversion of CPD without the use of the first reaction zone. In IP extraction zone, IP can be separated and recovered properly by adjusting temperature and pressure conditions. The stream S31, riches in IP and CPD, can then be deleted by ignoring the tiny impurity of the product PD/CP. This simplification might cause little loss of IP. However, higher recovery can be achieved by reducing the side reactions involved IP. The omission of the columns 106 and 108 in the conventional process can avoid the use of the recycle stream S33, because column 6 in the simplified process is sufficient to directly separate the heavy components (L3) and DCPD.

Table 1 also contained the target specifications of product recovery and product concentrations to be achieved in the simplified process. From the proposed simplified process, high purity products were obtained along with highly improved recovery ratios. The resulting DCPD product stream with 98.84wt% DCPD makes this production process more competitive. In addition, the recovery of the IP product can be increased by 7.1%, the recovery of the PD/CP product can be improved by 1.2%, and the recovery of the main product, DCPD is raised by 4.9%. Overall, the total reboiler duty required for the simplified process can be reduced by 8.1% due to non-recycle of the two streams from column 107 in the conventional process.

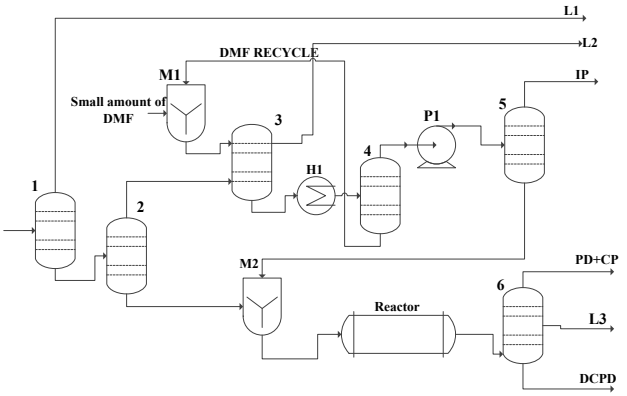

Figure 2 A simplified process flowsheet (SP).

4. Intensified process

The simplified process given in Figure 2 still consists of 6 distillation columns in IP removal and C5 recovery units. They can be intensified by using thermal coupling and heat integration. However, column 3 is operated at high pressures than the other columns. Hence a logical choice would be to combine columns 4 and 5 and columns 1 and 2 as the divided-wall column (DWC) first.

In Figure 3, the intensified process was shown. Columns 4 and 5 were integrated into a DWC 4&5 by sharing a condenser. The bottom product containing enriched DMF of 99.98wt% is recycled to mixer 1 while other containing mixed C5s is sent to mixer 2. The distillate product of the DWC is high purity of IP above 99.75wt%, the same product specification as in the simplified process, showed in Figure 2. The DWC configuration can reduce 30% of the total reboiler duty in columns 4 and 5.

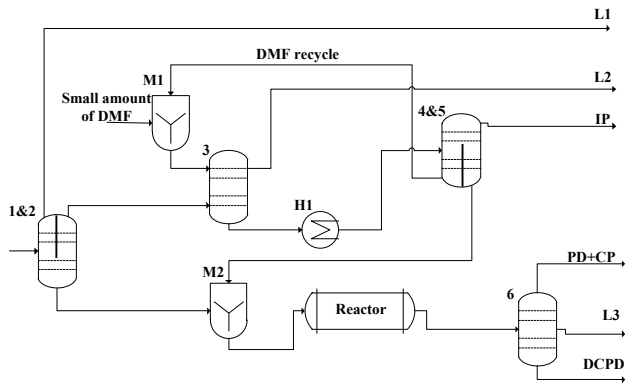

Figure 3 2DWC: Intensification process with DWCs 1&2 and 4&5.

Figure 3 also illustrated the process in which columns 1 and 2 are further integrated into a DWC 1&2 by sharing a reboiler. The DWC configuration can reduce 13% of the total reboiler duty in columns 1 and 2.

In addition to implementing thermal coupling between two columns to reduce reboiler

duty, more heat duty can be recovered from the bottom stream of column 3. To effectively extract IP, column 3 is operated at high pressure, resulting in high temperature of 220 ºC at the column bottom. The bottom stream of column 3 must be cooled to 50 ºC before it was sent into column 4 for further separation as the energy source of external heat integration (EHI). Figure 4 shows the process of 2DWC+EHI. The bottom stream in column 3 can be used to heat the bottom streams in column 6, DWC 4&5, and DWC 1&2, and it can also pre-heat H2. The reboiler duty needed in column 6 can be completely deleted by the heat integration in heat exchanger E1 given in Figure 4. The reboiler duties of the DWC 4&5 and DWC 1&2 are partially supplied by heat integration in heat exchangers E2 and E4 and E5. In addition, the inlet stream of the adiabatic reactor is pre-heated by heat integration in heat exchanger E3. The reaction temperature is then raised from 70 to 135 ºC, and results in faster reaction rate. At the same time, the reactor length can be reduced from 30 meters to 15 meters under the same reaction situation.

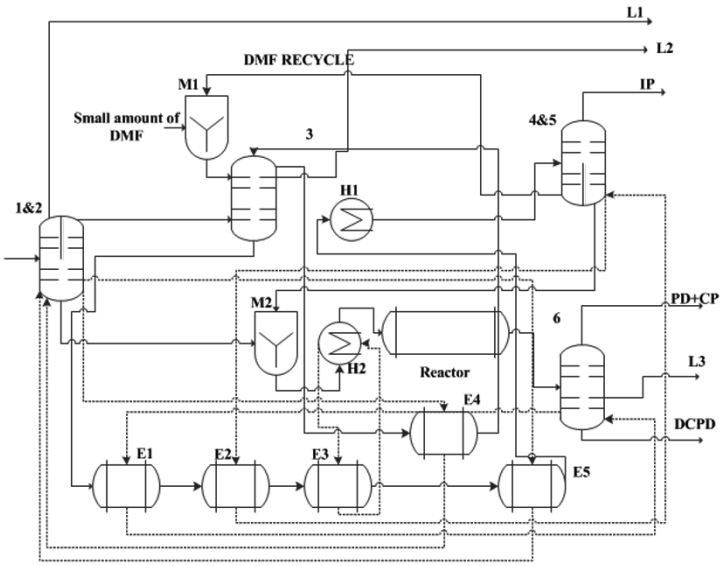

Figure 4: 2DWC+EHI: intensified process with two DWCs and external heat integration.

The reboiler duty can be decreased by 43% with contributions in the order of external heat integration (20%), integration of DMF recovery (10%) and elimination of the first reactor section (8%), and integration of light recovery and IP separation columns (5%). Figure 5 illustrates the reduction of ACPAEX, AOC, and TAC, for different process configurations. The simplified process deleted many columns and reactors, resulting in sharp decrease of the ACAPEX about 35%. With further integration using DWC and EHI, the total reduction in process ACAPEX was found to be about 41%. The total reduction in annual operating cost can be reduced by 29%, and hence the TAC can be reduced by 34%.

5. Conclusions

In the study, the conventional process of the crude C5 for the separation of IP, PD/CP, and DCPD can be substantially simplified by (1) separating IP first before CPD

dimerization, (2) using a side-draw column in the final separation, (3) using divided wall columns and (4) external integration. The needs 60% of the original capital cost under the same product purity requirements. The intensification process designed by the use of thermal coupling and heat integration technologies can further reduce heat duty 38% and operating cost 29% of the simplified process. The recovery and purity of the main product, DCPD, can be increased by reducing the numbers of reaction zones and changing the position of the reaction zones. Simulation results demonstrate that the economic benefit of the crude C5 conventional process can be enhanced by the intensification technologies of thermal coupling and heat integration.

Abstract

CO_2 removal from flue gas emitted by coal fired power plants is an important objective for process sustainability. However, solvent regeneration in state-of-the-art absorption processes results in power plant efficiency losses of 7 to 15 % (Neveux et al., 2013). Process intensification, combining different and innovative technologies for gas separation, can result in highly efficient processes capable of reducing the energy penalty caused by CO_2 capture. Current approaches for conceptual process design (CPD) however rarely consider emerging technologies like membrane contactors or hybrid process configurations. We present a multi-stage approach to overcome this drawback, which bases on process decomposition in different levels, combined with an efficient screening of promising materials and process design variants by means of shortcut methods. The approach follows the idea of an iterative refinement, in which the modeling accuracy increases while the number of process variants decreases.

Keywords: Process intensification, design approach, carbon dioxide capture, hybrid processes, membrane technologies.

1. Introduction

Since CO_2 is considered as a major greenhouse gas, its emissions have to be reduced significantly. Current state-of-the-art for CO_2 removal is the reactive absorption using aqueous amine solutions (e.g. MEA). Due to the loss in process efficiency, caused by the high energy demand for the solvent regeneration, CO_2 removal is practically not used at large scale industrial application. In the last decades a lot of research effort was directed towards the investigation of alternative solvents to reduce the energy requirements of ab/desorption processes (see recent review of Le Moullec et al. (2014)). Gas membranes (GM) (Merkel et al., 2010) and membrane contactors (MC) (Favre and Svendsen, 2012) are potential alternatives to absorption columns to increase energy efficiency of CO_2 capture. MC provide a constant volume-specific interfacial area which can be orders of magnitude higher than for conventional equipment (Li et al., 2013). Moreover, GM and MC can be combined with ab/desorption processes to hybrid process configurations. Such hybrid processes can create synergies which potentially compensate for the drawbacks of the involved technologies, compared to stand-alone processes. Only few articles have recently considered the design of such hybrid process configurations (e.g. Bock et al., 2014). Even less research covers systematic CPD methodologies for hybrid processes related to gas separation (e.g. Hasan et al., 2014).

Hence, a systematic approach allowing for Process Intensification from the beginning of a CPD is essential. An approach towards such a holistic CPD is introduced in the subsequent sections and illustrated for CO_2 capture from a coal fired power plant.

2. Approach for CPD of post-combustion CO_2 capture process

2.1. Problem statement

The separation process design is decomposed in four subordinated levels which are arranged in a hierarchical order as illustrated in Figure 1. The decomposition provides a universal perspective on general separation processes.

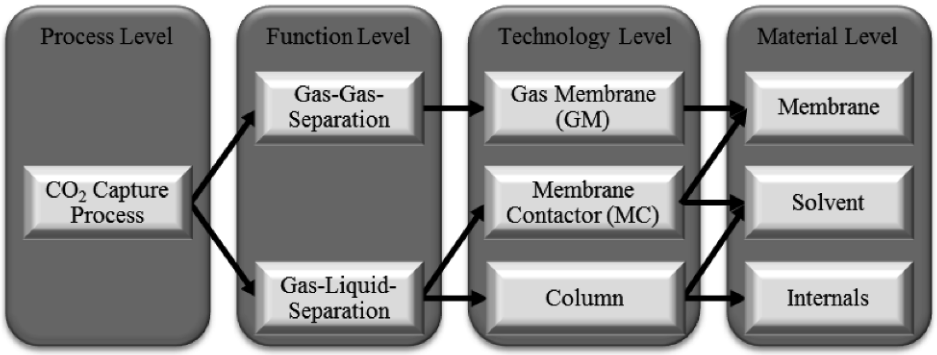

Figure 1: Illustration of process decomposition in subordinated levels

The applied decomposition is illustrated for CO_2 capture process. In order to solve the separation problem, different functions from the "function level" can be utilized and potentially combined. For CO_2 capture two feasible functions are considered, which are gas-gas and gas-liquid-separation. Since gas-liquid-separation necessitates a solvent, a second gas-liquid-separation for solvent recovery is also required, resulting in an ab/desorption process. The considered functions can be achieved by different technologies, applying several materials.

2.1.1. Technology level

Each technology can be operated within its specific operating window. The operation of columns is mainly limited by critical L/G ratios which can result in flooding, foaming or loading (Kenig and Górak, 2005). While such limitations do neither exist for MC nor for GM, there are certain limitations for the applicable operating temperature and pressure. Exceeding these boundaries can lead to membrane deformation due to the polymeric nature of the membrane (Merkel et al., 2010). The pressure difference for MC can not exceed a certain limit to avoid breakthrough of either the liquid or the gas phase. The performance and limitations of the different technologies also depend on the specific materials. Therefore, the available technologies can only be fully characterized in combination with the specific materials, which are defined in the "material level".

2.1.2. Material level

While GM performance depends strongly on operating conditions and the membrane material, MC performance is by definition not determined by the membrane material. However, selection of thermally and chemically stable material is important, but can only be determined experimentally. Hence, a membrane material selection for MC is not further considered, since the separation performance of MC is determined by the selected solvent. This also applies to columns such as the limitation by the gas-liquid

equilibrium, specified by the selected solvent as well. An additional material that needs to be selected for columns represents the type of internals.

2.1.3. Process variants

Regarding all presented technologies and corresponding materials as potential variants for the given separation process, this results in a tremendously complex CPD task. The complexity increases even more if the combination of technologies to hybrid process configurations is taken into account, as illustrated in Figure 2.

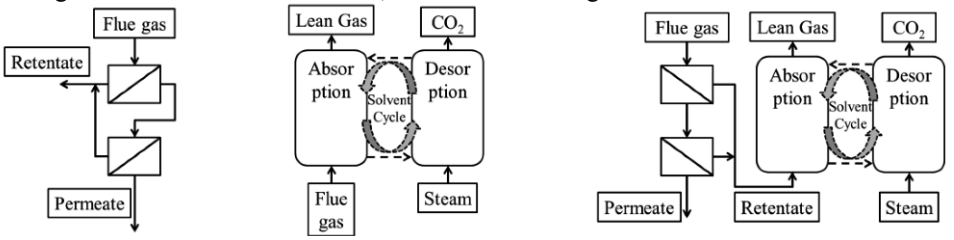

Figure 2: Schematic illustration of GM (left), ab/desorption (middle) and hybrid processes (right)

For the current study 14 different GM materials taken from Merkel et al. (2010) can be installed in two different configurations. While a single-stage configuration purifies the gas stream once, a two-stage configuration further processes the permeate of the first stage in a subsequent stage. Each stage can be operated in either counter-current or cross-flow mode. This results in 56 GM variants as standalone solution. For gas-liquid separation 7 solvents from Schäffer (2013) are considered, which already present a pre-selection based on economic and environmental considerations. Taking into account three different column internals (trays, random and structured packing) results in 21 combinations of solvents and internals for the absorption column. In combination with the MC, there are 28 potential variants only for the absorption. As the solvent is fixed by the absorption, only 4 different variants for desorption are feasible, resulting in 112 possible ab/desorption processes. Taking into account hybrid process configurations, in which gas-gas-separation is performed as pre-treatment step upstream of a gas-liquid-separation, adds additional $112 \cdot 56 = 6272$ potential hybrid processes to a total 6440 potential process variants. Additional structural combinations further increase this number, which already emphasizes the need for a systematic approach to handle this complex CPD problem.

2.2. Methods

In order to solve the complex CPD problem a multistage approach, based on an iterative refinement and successive reduction of the number of process variants, is applied in this work. Similar to the idea of the process synthesis framework of Franke et al. (2004) or Marquardt et al. (2008), the tremendous number of process variants is first screened by means of simple shortcut methods. The simplifying assumptions of the shortcut methods are discarded in the subsequent steps, in which more detailed models are used to determine more accurate performance estimates for a steadily decreasing number of considered process variants. The focus of this work is on the first shortcut-screening step. As it is applied in an early phase of CPD, they need to operate with little information and allow for a qualitatively accurate evaluation in order to reduce the large number of potential process variants. A first material screening is therefore performed based on key performance indicators of the different technologies. For the evaluation of GM materials a shortcut-model, similar to that proposed by Scholz et al. (2015), is utilized. The required membrane area is calculated based on literature data for permeabilities and selectivities. Beside the membrane properties, the operating mode

(cross-flow and counter-current) and the operating conditions ($p_{Feed}/p_{Permeate}$) are taken into account. The final performance is evaluated based on cost calculations for capital investment and operation. Since 70-80% of the separation costs for gas-liquid-separations are caused by solvent regeneration (Notz et al., 2011), the minimal energy requirement (MER) for solvent regeneration is used for a first evaluation of the potential solvents, which can be investigated without fixing the technology, as MER is the same for MC and columns. The MER depends on the gas-liquid equilibrium, accounting for the chemical reaction in the liquid phase, as well as the loading of the solvent after ab- and desorption. To account for these factors the modified Kremser-method, as presented by Notz et al. (2011), is utilized and the liquid to gas ratio (L/G) ratio is optimized. Besides the screening of different solvents for MER, the method further allows for the determination of an optimal L/G and number of theoretical stages, in terms of cost estimates, such that the different technologies can be compared on a common basis. Based on the shortcut screening a selection of promising process variants will be taken to the next evaluation level, for which simplifying assumptions, like isothermal and isobaric operation and constant inert gas and liquid streams, as assumed for the Kremser method, will be subsequently removed. MESH models can be applied in order to consider heat effects for the columns, while a final design will be determined by detailed rate-based models, accounting for heat and mass transfer as well as the hydrodynamics of the process. This iterative refinement is crucial to reconsider the selection, depending on the change in performance estimate due to the increased accuracy. In the current paper, only the best process determined in the shortcut screening is evaluated by means of a detailed rate-based design, to illustrate the projected approach.

3. Case Study

CO_2 capture from a coal fired power plant is chosen as a case study. The corresponding separation task is characterized by a typical CO_2-content in the flue gas of 13.73 Vol.-%, a total flue gas stream of 673.5 kg/s and a capture rate of 90% is targeted.

3.1. Material screening

Assuming comparable membrane material cost, a first material screening is performed based on the minimum area required in a two-stage configuration and constant high driving force (cf. Figure 3 (left)). Due to the large differences, from the set of 14 membranes only the two membranes with the lowest required membrane area are further investigated. The results of a first solvent screening for ab/desorption processes by means of the MER are also illustrated in Figure 3 (right). As MER for most of the investigated solvents are in a similar range, only AP is discarded. This material screening already reduces the number of potential process variants from 6440 to 872.

3.2. Process evaluation

For GM two-stage configurations operated in cross-flow (CF) or counter-current (CC) mode are considered. The operating conditions ($p_{Feed}/p_{Permeate}$) are optimized for total annualized cost (TAC), based on cost correlations taken from Woods (2010). Assuming a constant price of 50 € m^{-2} for all investigated membranes, the economic performance strongly correlates with the membrane area. Here, CC was determined as best operation mode such that only results for CC of both promising membranes (No. 1 and 14 in Figure 3) are illustrated in Figure 4. For each of the remaining six solvents gas-liquid-separation is evaluated in columns and MC. Internals for columns are selected based on the optimized L/G ratio, resulting in random packed columns. A HETP value of 0.9 m was considered for column sizing and cost calculations (Woods, 2010), for which an

adapted L/G ratio was determined by means of the extended Kremser method assuming 10 theoretical stages for absorption and 15 for desorption, similar to Notz et al. (2011).

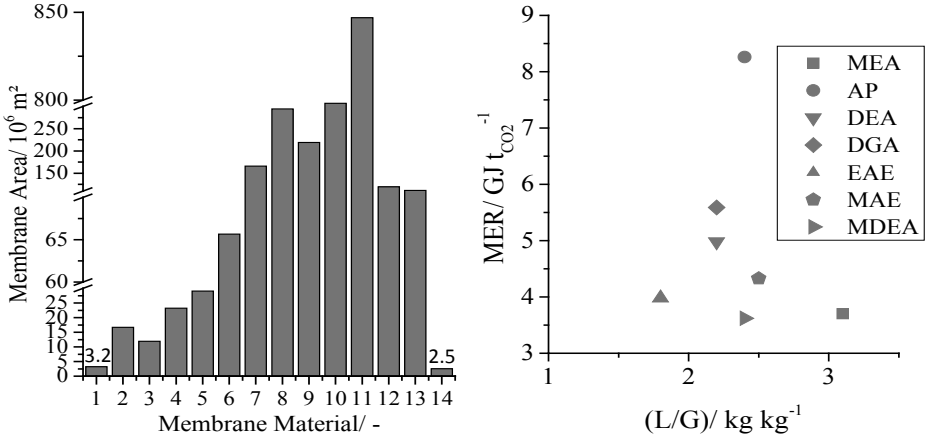

Figure 3: Material screening for (left) GM membranes and (right) solvents

The determination of the required membrane area for the MC process is performed in accordance to Li et al. (2013). Here, similar to the constant HETP value of the column, an average value of 0.4 kg_{CO2} m^{-2} h^{-1} for the trans-membrane flux of CO_2 in the MC is assumed. The price per m² is assumed with 50 €. Due to the fact that gas-liquid equilibrium data for desorption is restricted to temperatures of 120 °C, MC cannot be considered for desorption. Hence, columns are used as desorption technology for MC processes, presenting already a combination of different technologies. Finally, hybrid GM and ab/desorption processes are taken into account.

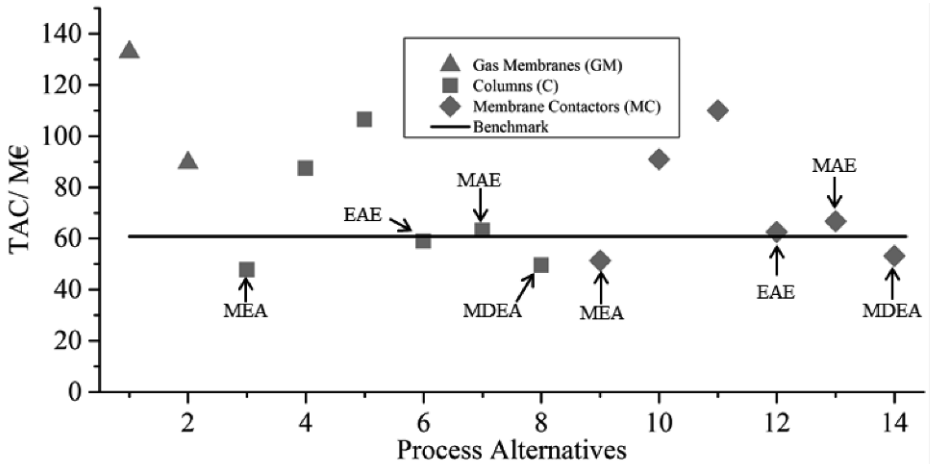

Figure 4: Results of process evaluation

Here, the best performing GM process (No. 2 in Figure 4) is combined with the best performing column and MC process (No. 3 and 9 in Figure 4) respectively. However, the hybrid processes do not make use of the GM, resulting in the simple MEA-based column process as best solution. The results of the short-cut-based economic evaluation of the remaining 16 variants are illustrated in Figure 4. MEA-based ab /desorption in columns, which is currently the state-of-the-art process, is also identified as most

promising process by means of the shortcut-screening. Since the results of a detailed rate-based design calculation, illustrated by the black line in Figure 4, provide a difference between short-cut and detailed calculation of about 21 %, which is in a proper range for shortcut estimations, it indicates the potential of all processes in below that line to be competitive. Thus, based on the utilized available data, stand-alone GM and the considered hybrid processes seem to be less promising. Nevertheless, research on more efficient membrane materials continue, to develop GM into a valuable technology for future processes (Sandru et al., 2013). Based on the current calculations either the GM performance has to be increased or the membrane price has to be reduced by 70% in order to be competitive.

4. Conclusions and Outlook

A systematic multi-stage approach for Process-Intensification-focused CPD of gas separation processes is developed and successfully applied to CO_2 capture from flue gas as a case study. The most promising process alternatives are identified and evaluated by shortcut methods and compared against the rate-based modelled MEA-process as benchmark. Hereby, the MEA and MDEA process are found as most promising and have to be investigated in more detail.
Intermediate evaluation steps are required in order to reduce the experimental effort before starting a final detailed rate-based optimization. In addition the “technology & material level” will be extended to include additional intensified gas separation technologies, like rotating-packed-beds, or enzyme-activated solvents.

Natural Gas to Liquid Transportation Fuels and Olefins (GTL+C2_C4)

Onur Onel,[a] Alexander M. Niziolek,[a] Christodoulos A. Floudas[a*]

[a]*Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ 08544, USA*
floudas@titan.princeton.edu

Abstract

Co-production of liquid transportation fuels and olefins from a natural gas feedstock is investigated. A superstructure of alternatives is presented with multiple natural gas conversion routes, hydrocarbon production and upgrading methods, and olefins purification options. The superstructure, which is modeled as a mixed integer nonlinear optimization problem (MINLP), is solved to global optimality using a rigorous branch-and-bound framework. The co-production of fuels and olefins from natural gas is found to be profitable,and the net present value increases at higher olefins production levels.

Keywords: Liquid fuels, olefins, natural gas, global optimization.

1. Introduction

The United States produced about 7.45 million barrels of petroleum per day in 2013, while consuming 18.95 million barrels per day (EIA, 2014). High crude oil prices, volatility of the global oil market, and political instabilities in petroleum supplying countries pose serious challenges for crude oil imports.Advances in the shale gas production that provide inexpensive and abundant natural gas to the market, combined with commercially existing natural gas reforming technologies, make natural gas an attractive alternative for liquid fuels production.

Previous studies have shown the viability of liquid transportation fuels production from single and hybrid feedstock systems (Baliban et al., 2010, 2012b, 2013). C_2 to C_4 olefins (ethylene, propylene, butenes, and butadiene) are high value petrochemicals that are mid-products of petroleum refining and are used in subsequent industries (Onel et al., 2014). Therefore, an alternative process towards the production of liquid fuels should also consider the production of these high value petrochemicals. In this study, co-production of liquid fuels and olefins is investigated from a natural gas feedstock. The existing superstructure (Baliban et al., 2010, 2012b, 2013) is enhanced to allow for the production and purification of the olefins. A global optimization-based process synthesis framework with simultaneous heat, power, and water integration is applied to investigate the refinery across different case studies.

2. GTL+C2_C4 Superstructure and Mathematical Modeling

A process superstructure that converts natural gas to liquid transportation fuels was previously developed (Baliban et al., 2013). Additionally, process alternatives for the production of C_2 to C_4 olefins and liquid fuels were investigated for a refinery that uses biomass and natural gas as feedstocks (Onel et al., 2014). The following subsections will describe the key sections of the GTL+C2_C4 refinery.

2.1. Natural Gas Conversion

The natural gas can be directed to six different processes in the refinery: auto thermal reforming, steam reforming, oxidative coupling, partial oxidation, heat generation via fuel combustion, and electricity generation via a gas turbine. The reformers can be utilized to produce the syngas intermediate, whereas oxidative coupling produces olefins and partial oxidation produces methanol for further upgrading. The auto thermal reformer requires high purity oxygen to allow for the partial combustion of natural gas that will provide heat for the endothermic steam reforming reactions. The steam reformer requires an external heat supply to provide required heat for the same endothermic reactions. The reformers can operate at three discrete temperatures (ATR: 900 °C, 950 °C, or 1000 °C, SMR: 800 °C, 850 °C, or 900 °C). The syngas produced is sent to the syngas treatment section, and the raw hydrocarbons produced in the oxidative coupling and partial oxidation processes are sent to the hydrocarbon upgrading section.

2.2. Syngas Treatment

The raw syngas can be sent to a dedicated reverse-water-gas-shift (rWGS) reactor to adjust the H_2/CO ratio.If the H_2/CO ratio of the raw syngas is above the favorable ratio required by the hydrocarbon production processes, CO_2 in the process can be recycled to the rWGS to enhance the overall carbon conversion. The syngas can also bypass the rWGS and be sent directly to the scrubbing system after being cooled down to 185 °C.

The syngas can then be directed to the Rectisol process to remove CO_2 if CO_2-lean syngas is required by the hydrocarbon production alternatives. The recovered CO_2 is either vented, sequestered, or recycled back to the refinery, while the syngas is sent to the hydrocarbon production section.

2.3. Hydrocarbon Production and Upgrading

The clean syngas can be converted to raw hydrocarbons using a methanol synthesis reactor or one of six Fischer-Tropsch (FT) reactors (two cobalt-based and four iron-based). The cobalt based reactors can achieve 60% per-pass CO conversion, whereas the iron-based reactors can facilitate the WGS reaction to convert recycled CO_2. The FT effluent contains a liquid waxy phase and an effluent containing raw hydrocarbons. The waxy liquid phase is sent to a wax hydrocracker to produce distillate range products (Bechtel, 1998). The raw hydrocarbons can be either separated via standard upgrading by a system of hydrocarbon recovery column, reformers, a C_5/C_6 isomerizer, a $C_3/C_4/C_5$ alkylation reactor, and a saturated gas plant (Bechtel, 1998) or passed through a ZSM-5 based catalytic process to be upgraded into gasoline and distillate (Mobil, 1983).

The clean syngas can be directed to a methanol synthesis reactor. The methanol synthesis reaction (Eqn. 1) and WGS reaction (Eqn. 2) reach equilibrium in the effluent:

$$CO + 2H_2 \leftrightarrow CH_3OH \quad (1)$$

$$CO + H_2O \leftrightarrow CO_2 + H_2 \quad (2)$$

The raw methanol is flashed and degassed to remove the unreacted gases. The unreacted gases are recycled back to enhance the overall conversion, whereas the methanol is sent to either methanol-to-gasoline (MTG) or methanol to olefins (MTO) processes. The MTG reactor is a ZSM-5 based reactor that converts methanol into gasoline range hydrocarbons, which are subsequently upgraded in a series of processes (NREL, 2011). The MTO is a SAPO-34 based reactor that is used to convert methanol to olefins at high selectivity (95 wt%). The effluent is fractionated to separate light gases and gasoline range hydrocarbons. The olefins are sent to either a ZSM-5 based MOGD unit to be converted into fuels (Tabak and Yurchak, 1990) or to the olefins purification section.

2.4. Olefins Purification Section

In this section, the olefins produced throughout the refinery are purified. Light gases and C_3-C_5 gases from FT upgrading, and olefins from the MTO process are fed into this section. The CO_2 is removed from light gases which is followed by a demethanizer that separates light gases from olefins. The demethanizer effluent is combined with mixed olefins from the MTO process and directed to a deethanizer column. The distillate is directed to a series of selective hydrogenation and distillation columns to separate ethylene from ethane. Ethylene is sold as a product, whereas ethane is recycled back.

The C_3-C_5 hydrocarbons are sent to a distillation column to separate out C_5 content, and then mixed with the deethanizer bottom which also contains C_3-C_4 hydrocarbons. These hydrocarbons are seperated via a depropanizer. The distillate that essentially contains propane and propylene is distilled one more time to produce propylene. The propane is either recycled back or mixed with the LPG outlet (Onel et al., 2014).

The C_4 hydrocarbons (butanes and butenes) are separated from each other by means of extractive distillation that uses a polar solvent,dimethyl formamide (DMF), because the boiling points of butanes and butenes prevent them from being separated via simple distillation. The butane mixture can be recycled back or mixed with the LPG outlet, whereas the crude butenes can be (1) sold as a mixture, (2) separated to 1-butene and 2-butene to be sold, or (3) converted to butadiene via an Oxo-dehydrogenation process (Onel et al., 2014). The Oxo-D process converts 100% of 1-butenes and 92.7% of 2-butenes with a selectivity of 95% towards butadiene.

2.5. Light Gas Handling

The main sources of light gases in the refinery are (1) unreacted syngas from the hydrocarbon production units, (2) light gases produced in the hydrocarbon upgrading section, and (3) light gases separated in the olefins purification section. An internal gas loop configuration is designed to recycle light gases back to the reformers, FT or methanol synthesis reactors to increase the overall carbon conversion. An external gas loop configuration is also designed to avoid accumulation of inert species in the refinery. The external loop utilizes a fuel combustor to provide high-temperature heat and a gas turbine to provide electricity for the process.

2.6. Hydrogen and Oxygen Production

Hydrogen and oxygen are produced within the refinery by pressure-swing adsorption (only H_2), air separation unit (only O_2), and electrolysis (both H_2 and O_2) processes.

2.7. Waste Water Network

The waste water treatment network incorporates a biological digestor and a sour stripper to remove sulfur species, NH_3, and oxygenates. The effluent water can be discharged, utilized for steam production, or sent to the electrolyzers.

2.8. Heat and Power Integration

An optimization based heat-integration approach is adapted for simultaneous heat integration (Papoulias and Grossmann, 1983; Duran and Grossmann, 1986; Floudas et al., 1986). A series of heat engines are included to convert excess heat into electricity (Elia et al., 2010) for simultaneous power integration.

2.9. Unit costs

Different literature sources and the Aspen PEA is used to assign a base cost function to each unit in the refinery (Baliban et al., 2012b, Onel et al., 2014). The balance of plant (*BOP = 0.32*) and indirect costs (*IC = 0.20*) are also included to calculate the Total Plant Cost (TPC) of a unit, shown in Eqn. 3:

$$TPC = (1 + IC).(1 + BOP).Co.\left(\frac{Sr}{So}\right)^{sf} \quad (3)$$

The $C_o.(S_r/S_o)^{sf}$ stands for the base cost function that is obtained from the literature or Aspen PEA. The total overnight capital of the refinery is converted to an annualized capital charge(15.41%/yr) using the methodology in Kreutz et al. (2008).

2.10. Objective Function

The profit is maximized (or –profit is minimized) in this large scale nonconvex MINLP with the objective function shown in Eqn. 4:

$$MIN \sum_{F \square Feed} Cost^{F} + Cost^{El} + Cost^{Seq} + \sum_{u \square U_{inv}} Cost_{u}^{U} - \sum_{P \square Products} Cost^{P} \quad (4)$$

All of the terms in the objective function are levelized with the energy output of the refinery to obtain the total cost in \$/GJ. $Cost^{F}$ includes the contributions from the feedstocks, $Cost^{El}$ is the electricity cost, $Cost^{Seq}$ is the CO_2 sequestration cost, $Cost_u^{U}$ is the investment cost of unit u, and $Cost^{p}$ is the sales revenues from the products.

The overall model has 13849 continuous variables, 34 binary variables, 16304 constraints, and 735 nonconvex terms. A branch and bound algorithm is used to solve this MINLP to global optimality. At every node, piecewise linear underestimators are used to relax the problem into a mixed integer linear (MILP) problem. The MILP is solved with CPLEX to provide a lower bound to the real problem. At each node the optimal set of binary variables from CPLEX are fixed to convert MINLP to an NLP. NLP is solved to local optimality using CONOPT to provide an upper bound solution (Baliban et al., 2012a, 2012b)The optimality gap is tightened by finding better upper and lower bounds within the branch and bound algorithm. A more detailed explanation of the algorithm can be found in the textbooks of Floudas (1995, 2000).

2.11. Net Present Value Analysis

Net present value analysis is performed to evaluate process economics in a more comprehensive manner. The operating days are assumed to be 330 days. The discount rate is taken to be 10 % and the total tax rate (including federal and state) is taken to be 40 %. 10 year MACRS depreciation scheme is used and the investment period is taken to be 3 years with 30 years plant lifetime (Onel et al., 2014). Net present value is calculated using Eqn. 5:

$$\sum_{i=-2}^{30} (Inv_i + W_i + NAE_i + D_i)(1 + Discount\ Rate)^{0-i} \quad (5)$$

where Inv_i is the investment in year i, W_i is the working capital in year i, NAE_i is the net annual earnings in year i, and D_i is the depreciation credit gained in year i.

3. Computational Studies

The process synthesis model is solved to global optimality within a branch-and-bound framework to determine the optimal process topology that produces liquid fuels and olefins at the maximum profit. Six (6) distinct case studies are examined that investigate the effect of refinery scale and olefins production levels on the overall profit of the GTL+C2_C4 plant. Two refinery scales are investigated: 10 thousand and 50 thousand barrels per day of liquid fuels. No restriction is placed on the type of liquid fuels products nor the composition of olefins output from the refinery. The olefins produced are dependent on the refinery scale and are investigated parametrically. For the 10 kBD refineries, the amount of olefins produced daily will be 100, 500, or 1000 metric tons. Likewise, for the 50 kBD refineries, the amount of olefins produced daily will be 500,

2500, or 5000 metric tons. The case studies are denoted as $N - C - O$, where N represents the fuel compositions (U for unrestricted), C represents the refinery capacity, and O represents the amount of olefins produced daily. Additionally, the process synthesis model includes an environmental constraint that precludes the GTL+C2_C4 refineries from having higher life-cycle GHG emissions than current petroleum-based processes. The cost parameters used in the model are illustrated in Table 1:

Table 1.Cost Parameters Used in the GTL+C2_C4 process

Item	Cost	Item	Cost	Item	Cost
Natural Gas	$5.00/TSCF	Butanes	$1.84/gallon	Electricity	$0.07kWh
Freshwater	$0.50/MT	LPG	$1.40/gallon	CO_2TS&M	$5/MT
Gasoline	$2.86/gallon	Diesel	$3.04/gallon	Kerosene	$2.96/gallon
Ethylene	$1.38/kg	Propylene	$1.34/kg	Mixed	$0.35/kg
Budadiene	$1.87/kg	1-Butene	$2.05/kg	Butenes	

The overall profit breakdown, as well as the net present value, is shown Table 2:

Table 2. Overall Profit Breakdown of the GTL+C2_C4 refineries.

$/GJ of products	U-10-100	U-10-500	U-10-1000	U-50-500	U-50-2500	U-50-5000
Natural Gas	7.99	7.84	7.65	8.12	7.87	7.72
CO_2 Seq.	0.00	0.00	0.00	0.00	0.00	0.00
Investment	4.64	4.15	3.73	3.50	3.19	2.93
O&M	1.22	1.09	0.98	0.92	0.84	0.77
Electricity	0.25	0.31	0.45	0.12	0.29	0.37
Gasoline	-19.56	-14.84	-11.40	-19.56	-14.84	-11.40
LPG	-1.85	-1.45	-1.15	-1.85	-1.45	-1.15
Ethylene	-0.81	-3.08	-4.74	-0.81	-3.08	-4.74
Propylene	-1.15	-4.36	-6.70	-1.15	-4.36	-6.70
1-Butene	-0.48	-1.82	-2.80	-0.48	-1.82	-2.80
2-Butene	-0.07	-0.27	-0.42	-0.07	-0.27	-0.42
Butadiene	0.00	0.00	0.00	0.00	0.00	0.00
Mixed Butenes	0.00	0.00	0.00	0.00	0.00	0.00
Total ($/GJ)	-9.82	-12.43	-14.41	-11.27	-13.65	-15.41
NPV (MM$)	509	1055	1754	3756	6597	10180

Each of the case studies utilized an auto thermal reformer operating at 1000 °C as the natural gas conversion technology. Synthesis gas is converted to methanol, and then the methanol is split between the MTG and MTO reactors to produce the liquid fuels and olefins, respectively. In the optimal topology, gasoline and LPG are the liquid fuels that are produced, whereas the mixed butenes are separated to 1-butene and 2-butene for olefins production. The total figure, "Total ($/GJ)", shown in Table 2 is the difference between the costs associated with the production of olefins and liquid fuels and the total revenue obtained from selling these products. A more negative value corresponds to a more profitable GTL+C2_C4 refinery. The overall profit of the refineries increases as the amount of olefins produced increases and economies of scale are evident as the refinery capacity increases. The most profitable GTL+C2_C4 plant, U-50-5000, has an overall profit of $15.41/GJ and a net present value of 10180 MM$.

4. Conclusions

A superstructure is introduced that allows for the co-production of liquid fuels and olefins from natural gas. The optimal solution and topology is obtained using a global

optimization framework across different case studies. Two different plant scales are investigated to show the effects of economies of scale. The olefins production is varied parametrically to observe the effect it has on the plant profitability. The profit and the net present value are observed to increase as the olefins production increases. All the case studies provided highly profitable refineries that suggest that co-production of liquid fuels and olefins from natural gas is an economically viable alternative.

Abstract

To minimize environmental impacts, coupling integrated product and process design with life-cycle assessment (LCA) is a powerful yet challenging approach. A challenge in LCA is the proper accounting for all co-products occurring along the entire supply chain, known as allocation problem. In this paper, we provide a systematic analysis for LCA-based product and process design including alternative allocation methods. We apply the approach to polyol production from CO_2. Here, alternative allocation methods lead to very different polyol products and processes. Finally, we derive general principles regarding co-product allocation in LCA-based product and process design.

Keywords: Life-cycle assessment, product-process design, CO_2 utilization, polymers.

1. Introduction

Today, most polymers are synthesized from fossil-based feedstocks. As alternative and renewable carbon feedstock, carbon dioxide (CO_2) has recently been successfully utilized as building block for polyols, a direct precursor of polyurethanes (Langanke et al., 2014). In addition to the direct utilization of CO_2 as feedstock for polyols, CO_2 can also be used indirectly to produce further chemicals in the polyol supply chain.

Both direct and indirect utilization of CO_2 provide novel degrees of freedom to design the polyol supply chain. These degrees of freedom can be exploited to minimize environmental impacts in the design of a polyol polymer with desired properties and the associated processes in the supply chain. For this purpose, we conduct an integrated design of both product and processes coupled with life-cycle assessment (LCA).

Integrated product and process design is a challenging problem by itself (Gani, 2004; Adjiman et al., 2014). Coupling the integrated design problem with LCA introduces further challenges; in particular the evaluation of co-products has to be addressed since many products are co-produced in the chemical industry, e.g., in (bio-) refineries, steam crackers and also for CO_2 capture from CO_2 point sources (von der Assen et al., 2013). In this case, the environmental impacts have to be allocated to the individual co-products. A set of allocation methods exists in LCA. The choice of the allocation method is known to often lead to strongly varying product footprints (Curran, 2007).

The goal of this work is to analyse the effect of alternative allocation methods in LCA-based product and process design of polyols. The design approach consists of the integrated optimization of the polyol supply chain and the polyol product with respect to minimal environmental impacts (Section 2). As representative environmental impact, the carbon footprint is chosen as single LCA metric to avoid further complexity by multiple environmental objectives. The polyol product has to meet target properties such as the molar mass, OH number, and glass transition temperature. The polyol supply chain includes all processes for production of feedstocks and energy from cradle to gate. We illustrate how

alternative allocation methods change both the optimal monomer composition and the supply chain of the polyol (Section 3). We finally derive general principles regarding allocation approaches in LCA-based product and process design (Section 4).

2. Formulation of Optimization Problem

The aim of LCA-based product and process design is to identify a product and its supply chain with minimal environmental impact. The design problem can be generally formulated as the following non-linear program (NLP):

$$\begin{aligned} \min_{s,\nu} \quad & h = C^T \cdot s && \text{minimal environmental impacts} \\ \text{s.t.} \quad & g(\nu, s) \leq 0 && \text{Constraints from supply chain processes} \\ & l \leq D \cdot \nu \leq u && \text{product design constraints} \\ & s \in \mathbb{R}^k && \text{n process variables} \\ & \nu \in \mathbb{R}^l && \text{m product variables} \end{aligned} \tag{1}$$

The following sections specify the details of problem (1) for CO_2-based polyols.

3. Synthesis and Properties of Polyols

3.1. Polyol Supply Chain Superstructure

Polyether polyols are the most common type of polyols. They can be synthesized from the reaction of a multi-functional alcohol starter (glycerol in this work) with epoxides such as propylene oxide (PO). PO can partly be substituted by CO_2 making the overall reaction more energy efficient since the production of PO is energy intensive (von der Assen and Bardow, 2014). Each molecule of CO_2 reacts with one molecule of PO forming a poly-carbonate (PC) unit in the polymer chains. In addition to PC units and the conventional poly-ether (PE) units from PO, poly-oxy-methylene (POM) units from complete polymerization of formaldehyde can also be incorporated into the polyol. The overall reaction for a hypothetical statistical polyol from the considered feedstocks is:

$$\nu_1\,\mathrm{PO} + \nu_2\,(\mathrm{PO}{+}\mathrm{CO_2}) + \nu_3\,\mathrm{FA} + \mathrm{Starter} \rightarrow \mathrm{HO}\text{-}\{(\mathrm{PE})_{\nu 1}\,(\mathrm{PC})_{\nu 2}\,(\mathrm{POM})_{\nu 3}\}\text{-}\mathrm{OH} \tag{2}$$

Figure 1 shows the considered cradle-to-gate supply chain superstructure for production of polyols. The supply chain illustrates that CO_2 can be incorporated into the polyol both directly and indirectly through methanol and/or formaldehyde.

3.2. Estimation of Polyol Properties

Reaction (2) is thermodynamically feasible for all combinations of ν_i, i.e., $\Delta g^R \leq 0$. However, the product composition ν_i alters the polyol properties. The considered polyol properties in this work are the molar mass M, the OH number, and the glass transition temperature T_g. The properties are estimated from the polyol structure via group contribution methods (van Krevelen and te Nijenhuis, 2009):

$$M = \sum\nolimits_i \nu_i M_i + M_S \;; \qquad OH = \frac{1000\; M_{KOH} F}{M} \;; \qquad T_g = \frac{\sum_i \nu_i Y_{g,i} + Y_{g,S}}{M} \tag{3}$$

The molar mass M of the polyol can be computed from the molar masses M_i of the monomer units PE, PC and POM, and the molar mass M_S=92 g/mol of glycerol as starter. The OH number is a common metric for polyols and can be determined via M and the number F of hydroxyl groups in the starter. Since we fix F=3 for glycerol and M_{KOH}=56 g/mol, bounds for OH are equivalent to further bounds on M. The glass

transition temperature T_g is obtained from the corresponding group contributions $Y_{g,i}$ and $Y_{g,S}$ of the monomers and starter, respectively. Although T_g is non-linear in ν_i, the product design constraints in Eq. (1) can be formulated in a linear way:

$$\sum_i \left(T_{g,min}\, M_i - Y_{g,i}\right) \nu_i \leq Y_S - T_{g,min} M_S \tag{4}$$

$$\sum_i \left(Y_{g,i} - T_{g,max}\, M_i\right) \nu_i \leq T_{g,max} M_S - Y_S \tag{5}$$

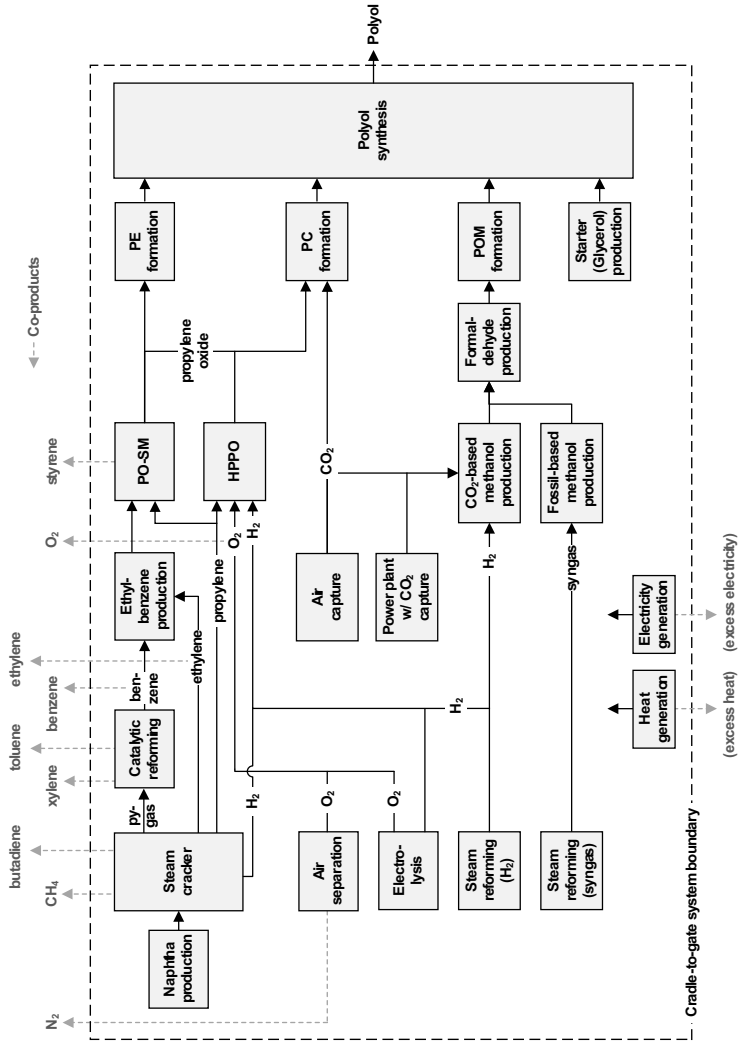

Figure 1. The supply chain superstructure for polyol production illustrating the major feedstocks propylene oxide, CO_2, and formaldehyde as well as glycerol as starter. Co-products in the upstream processes (grey, dashed arrows) leave the cradle-to-gate system boundaries. Energy flows as heat and electricity are also considered (omitted in figure for better visualization).

4. Evaluation of Co-Products in Life-Cycle Assessment

In LCA, process systems are typically modelled as set of linear equations. The product under study is specified in the functional unit as vector $f \in \mathbb{R}^m$. LCA process data is given as technology matrix A and intervention matrix B. Each entry $a_{i,j}$ of A quantifies the flow of product i to process j. To supply only the product flow in f, matrix A is scaled with a scaling vector s (Heijungs and Suh, 2002):

$$A(v) \cdot s = f. \tag{6}$$

For the process of polyol synthesis modelled by Eq. (2), the corresponding entries in A contain the product variables ν. Thus, the mass balances for PE, PC and POM in equations in (6) are non-linear with respect to the design variables s and ν. The environmental impacts h associated with production of the product flow in f are

$$h = (Q \cdot B) \cdot s, \tag{7}$$

where matrix B contains the emissions and resources (rows in B) exchanged between processes (columns in B) and the environment. Matrix Q contains characterization factors to aggregate emissions and resources into environmental impact indicators.
The process superstructure in Figure 1 shows that many upstream processes of polyol production generate co-products. Due to these co-products, the set of equations (6) is over-determined and, in general, no scaling vector s exists to supply only the polyol without any co-products. To still obtain specific environmental impacts for polyol production, three approaches exist in LCA: system expansion, avoided burden and allocation.

4.1. System expansion

System expansion includes all co-products in an expanded functional unit $f_{exp} = f + \tilde{f}$, where f contains only the original product, here the polyol, and $\tilde{f}$ contains the unknown quantities of the co-products. Thereby, the environmental impacts are determined for a basket of products. For system expansion, the first two equations of NLP (1) can be re-formulated as follows:

$$\min_{s,\tilde{f},\nu} \quad h = (Q \cdot B) \cdot s \tag{8}$$

$$\text{s.t.} \quad (A(\nu) \quad -I) \cdot \begin{pmatrix} s \\ \tilde{f} \end{pmatrix} = f \tag{9}$$

4.2. Avoided burden

The co-products of the polyol supply chain can be considered to avoid the production of these products by alternative processes. The alternative processes cause environmental burdens. These burdens can thus be avoided by co-production. The co-products are therefore credited with an ‘avoided burden’. Process data of the alternative, ‘avoided burden’ processes are contained in matrices A_{avo} and B_{avo}. For the avoided burden approach, the first two equations of NLP (1) can be re-formulated as follows:

$$\min_{s,s_{avo},\nu} \; h = Q \cdot (B \quad -B_{avo}) \cdot \begin{pmatrix} s \\ s_{avo} \end{pmatrix} \tag{10}$$

$$\text{s.t.} \quad (A(\nu) \quad -A_{avo}) \cdot \begin{pmatrix} s \\ s_{avo} \end{pmatrix} = f \tag{11}$$

4.3. Allocation

Allocation splits a process with *n* co-products into *n* processes with only one product each. The inputs in A and emissions in B are allocated to the single-product processes according to the co-products' share in mass, energy content or economic value. The allocation criteria can be cast into a matrix C (Jung et al., 2014). With matrices T_1, T_0 and U that handle the process splitting, the first two equations of NLP (1) can be re-formulated for allocation as follows (Jung et al., 2014):

$$\min_{\tilde{s},\nu} \quad h = Q \cdot (B \cdot T_0) \cdot C \cdot \tilde{s} \tag{12}$$

$$\text{s.t.} \quad [U \circ (A(\nu) \cdot T_1)] \cdot C \cdot \tilde{s} = f \tag{13}$$

Since the process splitting increases the number of processes, the dimension of $\tilde{s}$ in Eqs. (11+12) is also increased compared to s in Eqs. (6+7).

5. Results and Discussion

5.1. System expansion

If there are no constraints on the expanded functional unit, all products can be added to $\tilde{f}$ in Eq. (9). In this case, the optimal expanded functional unit includes the polyol and an infinite amount of CO_2 from air capture. The air-capture process provides a net GHG sink for the cradle-to-gate scope. The optimal polyol contains only glycerol and CO_2-based POM units, which are produced without any co-products. However, this solution is degenerate in the context of polyol design since the mono functional process air capture is employed beyond the amounts actually needed for polyol production. To avoid these solutions, the expanded functional unit $\tilde{f}$ should contain only those co-products that leave the system boundaries in Figure 1; for other co-products i we set $\tilde{f}_i = 0$. In this case, the optimal expanded functional unit contains 1,000 kg polyol, 145 kg styrene, 101 kg N_2, 63 kg CH_4, 51 kg butadiene, 26 kg toluene, 19 kg ethylene, and 3 kg xylene. Not all potential co-products, i.e., benzene, O_2, heat and electricity, are included in $\tilde{f}$. Still, the interpretation of such largely expanded functional unit might be difficult. The optimal polyol composition in this case is shown in Figure 2.

5.2. Avoided burden

The superstructure is expanded by avoided burden processes for co-products leaving the system boundaries. For production of 1,000 kg polyol, this approach leads to assigning credits for co-production of 661 kg styrene, 460 kg N_2, 285 kg CH_4, 232 kg butadiene, 118 kg toluene, 85 kg ethylene and 13 kg xylene; in total 1,854 kg co-products. Hence, the avoided burden approach favours co-production compared to system expansion where no credits are assigned to co-products. The polyol consists of mostly PC units which are always produced together with various co-products (Figure 2).

5.3. Allocation

We applied allocation based on mass, energy and price to processes for co-products leaving the system boundaries. The optimal polyols consist of glycerol, POM and PC units. PC content is highest for mass allocation due to low footprints of PO from PO-SM where most emissions are allocated to styrene. For price allocation, the allocation factor for PO from PO-SM is highest and thus, PC content is lowest.

For all considered allocation methods (5.1-5.3), the molar mass M equals the upper bound M_{max}. Methanol required for POM is produced exclusively by the CO_2/H_2 process. In almost all cases, CO_2 is captured from the power plant. H_2 is always produced in the fossil-fuelled processes steam cracker and steam reforming.

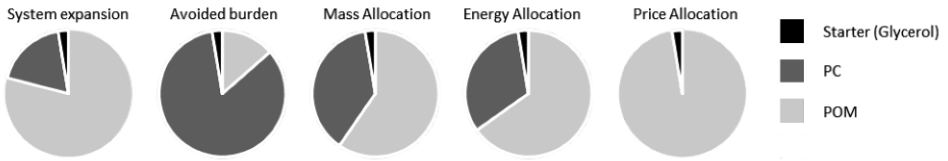

Figure 2. Environmentally optimal polyol compositions (wt %) for alternative allocation methods.

6. Conclusions

In this work, we have presented an approach for coupling an integrated product and process design problem of polyols with LCA. In particular, we systematically integrated allocation methods from LCA to account for co-products in the supply chain. The influence of allocations methods on LCA results has received much attention in the LCA literature. This experience from LCA can be used for in product and process design for co-product evaluation. In the presented example of CO_2-based polyols, we found that alternative allocation methods lead to very different products and processes. Furthermore, general principles for allocation methods in an LCA-based product and process design can be derived: System expansion is always applicable since no additional data are required. Since system expansion does not assign credits to co-products, a supply chain with no or few co-products is favoured. Including all co-products in the functional unit, however, might create too big a basket of goods where interpretation might be difficult. For avoided burden, LCA process data for alternative production technologies without co-products are required. In practice, such data are not always available. As expected, application of the avoided burden approach in the design problem favours co-production across the supply chain. For allocation, results depend strongly on the allocation criterion.

Abstract

Existing wastewater treatment plants (WWTP) need retrofitting in order to better handle changes in the wastewater flow and composition, reduce operational costs as well as meet newer and stricter regulatory standards on the effluent discharge limits. In this study, we use an optimization based framework to manage the multi-criteria WWTP design/retrofit problem for domestic wastewater treatment. The design space (i.e. alternative treatment technologies) is represented in a superstructure, which is coupled with a database containing data for both performance and economics of the novel alternative technologies. The superstructure optimization problem is formulated as a Mixed Integer (non)Linear Programming problem and solved for different scenarios - represented by different objective functions and constraint definitions. A full-scale domestic wastewater treatment plant (265,000 PE) is used as a case study in order to highlight the use of the framework for generating optimal retrofitting solutions.

Keywords: cold anammox, retrofit, optimization, wastewater treatment, Sharon

1. Introduction

Wastewater treatment process synthesis can be defined as the step in the design of a WWTP where the design engineer selects unit processes from a number of alternatives and interconnects them to create the process flow diagram (i.e. WWTP network). Process synthesis is also performed during retrofitting studies in the sense that a new task can be added to the existing treatment line or one or several processes can be changed as a result of emerging needs. For instance, increased nitrogen limitation in the regulations for the WWTP effluents (Water Framework Directive, 2000/60/EC) gave rise to development of innovative nitrogen removal technologies mostly used for water streams resulting from sludge treatment (Lackner et al., 2014). Similarly, recovery possibilities for clean water, energy and materials shifted the perception about wastewater towards being a valuable resource rather than being a waste. While the regulations change to impose stricter effluent limit values for the contaminants, the increasing population and the size of the cities makes the expansion of the existing WWTPs harder. In this study, we use our previously developed framework using superstructure based optimization in order to perform a retrofitting study focusing on improving the performance of a full-scale WWTP – in particular the Avedøre WWTP treating municipal wastewater and located in Copenhagen, Denmark. The objective is to find novel solutions in terms of enhancing the nitrogen removal capacity and reducing utility consumption needs.

2. The Framework

The superstructure optimization based framework, illustrated in Figure 1, is previously developed for chemical process synthesis (Quaglia et al., 2012) and then modified and adapted for the WWTP design/retrofitting cases. The steps of the framework are recalled briefly in this section, while the details including the mathematical formulation and database generation for alternative treatment technologies can be found elsewhere (Bozkurt et al., 2014). After defining the wastewater characterization, sink limitations and objective function in the first step, the superstructure is generated consisting of the base case of the existing WWTP (i.e. the existing treatment units, only in the retrofitting studies) and other alternative treatment technologies under the existing or new treatment tasks. The formulation of the superstructure is then finalized by defining the feasible connection streams between the treatment tasks. Each treatment unit in the superstructure is defined using a generic model based on mass input-output. The parameters of the generic model are maintained in a database, e.g. process performances (yields, stoichiometry etc.), utility consumptions, volumes and sludge production. The optimal wastewater network problem is then formulated as a mixed integer (non)linear programming (MI(N)LP) problem and solved for deterministic conditions and under uncertainty by defining several scenarios.

3. Case study

3.1. Problem definition

Avedøre WWTP is located west of Copenhagen (Denmark) and receives wastewater from 10 suburban municipalities with a population of approximately 265,000 people. Annually, around 25-30 million m^3 of wastewater is treated in the plant by physical, biological and chemical means. The wastewater treatment line consists of solids separation by means of sedimentation in the primary treatment and removal of organics and nutrients together with solids in the secondary treatment prior to the discharge of the treated water into Køge bay. Organics, nitrogen and partly also phosphorus are removed by the activities of a mixed culture of organisms in activated sludge (AS) reactors operated under alternating oxic/anoxic conditions (Tchobanoglous, 2003). The remaining phosphorus (from biological removal) is precipitated chemically by iron chloride addition. The resulting sludge, on the other hand, is stabilized in an anaerobic digester prior to be incinerated to produce heat and electricity. Table 1 illustrates the influent wastewater characterization and effluent water quality, given as a yearly average of 2012 data.

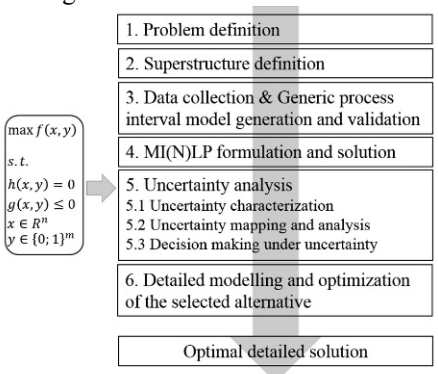

Figure 1. The superstructure based optimization methodology

Table 1. Influent and effluent composition for Avedøre WWTP (yearly average, 2012)

Parameter	Unit	Influent	Effluent
COD	g / m^3	476	23
BOD	g / m^3	180	2
NH_4-N	g / m^3	33	1.2
NO_X-N	g / m^3	-	3.0
Total-N	g / m^3	43	4.8
Total-P	g / m^3	6.5	0.6
SS	g / m^3	209	4.6
Flow rate	m^3 / d	72,000	

The retrofitting problem is defined so that the feasibility of extending the existing treatment line will be analysed in two ways: (1) addition of a new task and alternative technologies in the sludge reject water line; and (2) evaluating an innovative nitrogen removal technology in the main wastewater treatment line. The objective function is defined such that it covers the annual operational and capital cost (only for the new treatment units), which is to be minimized.

3.2. Superstructure definition

The superstructure developed for the case study is illustrated in Figure 2. The process intervals shown in gray are the existing units (i.e. PC – primary clarifier, AS – activated sludge type biological treatment unit, Thick – sludge thickener, AD – anaerobic digester and Dewat – dewatering unit) and the wastewater source and sinks are illustrated in the first and last columns of the superstructure. On the other hand, nitrogen removal alternatives are added in the reject water line, which comprises 5 – 20 % of the total nitrogen load into the system. Furthermore, as an alternative to the AS unit, a combination of a high rate oxic system and an anammox reactor is considered.

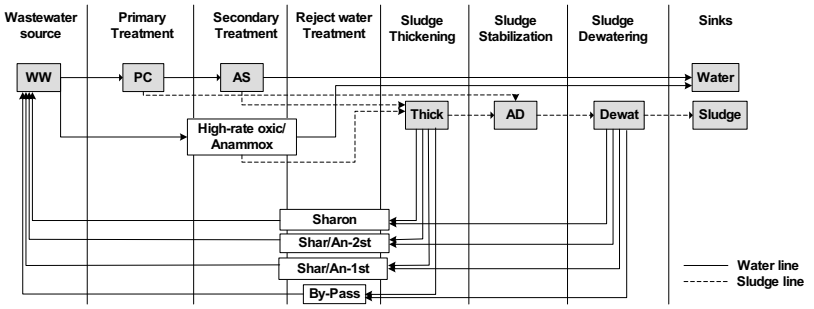

Figure 2. Avedøre WWTP retrofitting case study superstructure

3.3. Data collection & generic process interval model generation

In order to design the individual treatment technologies, the systematic data collection and design procedure, which is developed in the context of the superstructure based optimization methodology, has been used (Bozkurt et al., 2014). Accordingly, the base case of Avedøre WWTP is designed based on the design data obtained from the treatment plant by following the design methodology.

3.3.1. Main stream treatment alternatives

- The high-rate oxic system is characterized by its short solids retention time (SRT) and hydraulic retention time (HRT), as well as its effectiveness in terms of COD removal at low energy cost. It is preferred also because it diverts high organic loads to sludge treatment, which further contributes to biogas production. In this study, it is designed such that it is working with 0.5 days of SRT and 2 hours of HRT resulting in approximately 60% reduction in the biodegradable organic matter. Since the SRT is short, hardly any nitrifiers grow in the medium; therefore, there is no nitrogen removal in this reactor (Versprille et al., 1984). However, it is coupled with a novel technology (i.e. anammox), which is proven to effectively treat nitrogen rich streams at high temperatures (e.g. sludge reject water stream); recent studies showed, however, the effectiveness of the annamox technology in cold and dilute municipal wastewater streams (Winkler et al., 2011; Wett et al., 2013). In this particular case study, the anammox reactor is designed so that there is heterotrophic activity (i.e. denitrification) and ammonium oxidizing bacteria (AOB) and anammox activity (i.e. two step reaction summarized in Eq. 3 and 4) in the medium. Accordingly: (1) The heterotrophic SRT is

selected as 10 days resulting in 80% biodegradable COD removal, (2) As a result of AOB and anammox activity, 88% NH_4-N and 76% total-N is removed and (3) The sizing of the reactor is done based on volumetric nitrogen loading rate, which is selected as 0.2 kg N /m^3 d (Wett et al., 2013).

3.3.2. Side stream treatment alternatives

Three different nitrogen removal alternatives with different mechanisms and reactor configurations are placed in the superstructure under the reject water treatment task. The Sharon reactor operates with the nitritation/denitritation mechanism (as shown in Eq.1 and Eq.2, respectively) in a single CSTR type of reactor. The system can be operated without any sludge retention, and therefore its SRT is equal to its HRT and the sizing of the reactor is done accordingly. The second reaction completes the nitrogen cycle by converting the nitrogen compounds into nitrogen gas and also produces alkalinity which helps maintain the system pH, which otherwise decreases as a result of proton production in the first reaction. This mechanism needs oxygen for nitritation and carbon addition for denitritation. Since the COD in the reject water stream is usually low, carbon is added as methanol. This route reduces the aeration and carbon addition requirements by almost 25 and 40%, respectively, as compared to the conventional nitrification/denitrification route. The other two technologies (i.e. Sharon/Anamox-2stage and Sharon/Anamox-1stage) are operated with the partial nitritation/anammox mechanism as illustrated in Eq.3 and Eq.4, respectively. The difference is, in the Sharon/Anammox-2stage technology, partial nitritation and anammox occur in physically separated reactors, whereas Sharon/Anammox-1stage is a single reactor in which two different microorganism types (i.e. Ammonium oxidizing bacteria for partial nitritation and anaerobic ammonium oxidizers for anammox) are present in granular form or on a support medium. Different performance evaluations have been reported for different reactor configurations, and therefore both are included in the superstructure.

$$NH_4^+ + 1.5O_2 \rightarrow NO_2^- + H_2O + 2H^+ \quad (1)$$

$$NO_2^- + 0.5CH_3OH + 0.5CO_2 \rightarrow 0.5N_2 + HCO_3^- + 0.5H_2O \quad (2)$$

$$NH_4^+ + HCO_3^- + 0.75O_2 \rightarrow 0.5NH_4^+ 0.5NO_2^- CO_2 + 1.5H_2O \quad (3)$$

$$NH_4^+ + 1.124NO_2^- + 0.014HCO_3^- + 0.121H_2CO_3 \rightarrow 0.987N_2 + 0.138NO_3^- + 0.27C_5H_8N_{0.5}O_2 + 2.185H_2O \quad (4)$$

4. Results and Discussion

The deterministic superstructure optimization problem is formulated as a Mixed Integer Linear Programming (MILP) problem and solved under two scenarios.

4.1. Scenario 1

In the first scenario, the base line for wastewater and sludge treatment is maintained and the effect of side stream treatment alternatives on the system performance (i.e. operational cost and nitrogen removal performance) is investigated. When the optimization problem is solved, the Shar/An-1st technology is selected among the side stream treatment alternatives, in addition to the base case; Table 3 summarizes the results comparing the base case with the selected alternative. In the current formulation of the base case, the reject water stream contributes to the total nitrogen load (which is mostly in the form of NH_4-N) by 7%. When a simple mass balance calculation is done around nitrogen and the associated oxygen consumption in the entire treatment plant, it can be seen that around 5.5% of the NH_4-N load (134 kg N/d) is removed in the side stream unit. This means that less NH_4-N needs to be nitrified in the AS unit. It is known from stoichiometry that conventional nitrification/denitrification in the main AS unit consumes around 60% more oxygen as compared to the partial nitritation/anammox route (for the first route it is 4.57 kg O_2/kg NH_4-N whereas this value is 1.71 kg O_2/kg NH_4-N for the latter case). The nitrogen mass removed in the side stream accounts for a daily reduction of the oxygen consumption with 395 kg. Reduction in oxygen demand means a reduction in the operational cost needed to supply the air, hence explaining the improvement obtained in the utility consumption (2,920 unit cost annually) in Table 3. Another point to note with respect to the performance of the system is that the base case (with respect to yearly average values) already performs well in terms of nitrogen removal. Despite that, a slight improvement is observed with the addition of Shar/An-1st reactor into the plant layout. The fact that the improvement is not too significant is mostly related to the nitrogen load of the reject water stream, which is very low (i.e. 7% of the total-N load into the treatment plant and is known to increase up to 20-30% in practice) in this yearly averaged case. Future work will consider evaluation of daily and weekly peak load to the plant as alternative scenario to compare the performance of the side stream technologies with the base case plant operation.

Table 3. Scenario 1 cost breakdown: the analysis is carried out at average influent load

	Utility cost (unit cost)	**Landfill cost (unit cost)**	**Capital cost (unit cost)**	**OBJ (unit cost)**	**Eff. Total N (g N/m^3)**
Base case	201,115	565,385	-	67,478	7.8
Shar/An-1st	198,195	565,020	3,342	67,217	7.5

4.2. Scenario 2

In the second scenario, together with the alternatives of the reject water stream, an alternative treatment technology in the main wastewater treatment line is also considered as shown in Figure 2. The deterministic solution of the network selection problem, which is formulated as a MILP problem with an objective function definition of minimizing the capital and operational cost of the WWTP, resulted in the selection of the base case together with the Shar/An-1st technology. In Table 4, a comparative analysis of the system performance is shown for the selected network and a simulation made by fixing the High-rate oxic/Anammox process interval. Consequently, when the operational costs are compared, it is seen that the high-rate oxic/anammox system is favored as compared to the current AS system (i.e. low aeration requirement, low sludge production and high biogas production associated with higher organic content entering the anaerobic digester). However, when capital cost requirement is considered as well,

the high-rate oxic/anammox technology is not found optimal. It should be noted here that this system has almost 50 % less footprint than the AS system which has traditionally very large reactor volumes (e.g. 5,000–10,000 m^3). Therefore, the potential savings made in land requirement (as well as reduced size for reactor construction) are likely to favor the cold anammox technology for greenfield projects.

Table 4. Comparative system performance analysis for scenario 2

	Network	Utility cost	Landfill cost	Biogas price	Capital cost	OBJ	Eff.TotN (g N/m^3)
Selected	**PC-AS**-Thick-AD-Dewat-Shar/An-1st	198,195	565,020	699,340	3,342	67,217	7.5
Simulated	**High-rate oxic/Anammox**-Thick-AD-Dewat-Shar/An-1st	176,295	555,530	1,151,940	595,392	175,277	6.6

5. Conclusions

An optimization based framework is successfully used to evaluate novel retrofitting solutions for a full scale municipal WWTP. The decision on which technology to employ is rendered on quantitative metrics which complements the experience based approach predominantly used today. Among retrofitting alternatives, the so-called anammox technology is found promising candidate for greenfield project applications where savings in land requirement is factored in to the decision making. Overall the tool is expected to support and facilitate generation and evaluation of ideas for identifying optimal solutions to design and retrofit WWTPs.

Abstract

The current work addresses the assessment of alternative solvent/process flowsheet combinations in amine based CO_2 capture plants based on economic and static controllability criteria. Various amine solvent blends are employed within an integrated framework that supports optimal design while also considering process performance under multiple variations in process parameters and disturbances. Process operability is explored through the implementation of a multi-variable control scheme that prioritizes control objectives and resource utilization. The steady-state process behavior is investigated through nonlinear sensitivity analysis and quantified in terms of an overall operability index that encompasses the steady-state effort required by the control system to compensate for the effects of exogenous disturbances on the control objectives. Aqueous mono-ethanol-amine (MEA) and 3-amino-1-propanol (MPA) solutions employed in different flowsheet structure configurations enabling material and energy distribution options are evaluated in terms of economic and operability performance.

Keywords: CO_2 capture, optimal design, static controllability, amine solvents.

1. Introduction

CO_2 capture plants are generally required to operate under variable process conditions due to either variations in production levels dictated by both the preceding CO_2 generation plant and the capture plant operating strategy or the influence of unexpected exogenous disturbances. In order to ensure optimal performance and the satisfaction of the operating and economic specifications for such plants, reliable and efficient control systems are designed so that the effects of disturbances on the control objectives can be successfully alleviated. An integrated approach in the process and the control system design requires the investigation, assessment, and rank-ordering of a set of candidate flowsheet and control structure configurations under the presence of multiple and large in magnitude disturbances representing real-time operating scenarios.

The analysis is performed by a disturbance nonlinear sensitivity technique and reveals an inherent property of the process/control system (Seferlis and Grievink, 2001). Disturbance sensitivity analysis have been combined with process optimization by selecting suitable pairings among controlled and manipulated variables with the help of steady state gain matrices (McAvoy, 1999) and frequency domain calculations (Lewin, 1996). Ricardez-Sandoval et al. (2011) studied worst case scenarios during the integration of design and control for large-scale processes. Papadopoulos and Seferlis

(2009) have proposed a generic framework for integrated solvent selection, process design and controllability assessment using a sensitivity analysis approach.
Control strategies for CO_2 capture plants have been investigated by Panahi and Skogestad (2011, 2012) by implementing a self-optimizing control scheme that enables the tracking of the economically optimal process trajectory. Nittaya et al. (2014) have proposed plant-wide control structures based on relative gain array considerations, Léonard et al. (2013) explored the dynamics and control, and McDowell and Shah (2014) studied the dynamic behavior of complex capture configurations. The current work investigates the interactions among solvents for different flowsheet configurations and control structures under multiple disturbance variation through a systematic nonlinear sensitivity analysis.

2. Methodology

The employed approach involves a rigorous, effective, and systematic two-stage screening and evaluation method of CO_2 capture flowsheets and solvents, based on economic and controllability performance. Flowsheet configurations are initially selected based on an economic criterion through a design optimization stage (stage 1). The design optimization stage calculates the optimal flowsheet configuration utilizing a superstructure representation of the plant with flexible process models and operating conditions. A specific flowsheet is derived for each employed solvent in the capture plant. Obviously, all flowsheets are optimized subject to the same process targets and constraints.
However, CO_2 capture processes operate under essentially dynamic environments susceptible to variations in operating parameters and exogenous disturbances. Based on the overall operating policy the capture plant may function at variable capacity whereas disturbances may affect flue gas volumetric flow rate, composition and CO_2 concentration. The steady-state response of the capture process under the effect of simultaneous multiple disturbances of finite magnitude is assessed in a disturbance sensitivity stage (stage 2). For each combination of solvent/flowsheet the control objectives are defined. Such objectives may include the amount of captured CO_2, the purity of the CO_2 stream, the energetic penalty for the separation, and the replenishment of the solvent. These objectives are directly or indirectly linked with variables associated with the process itself. Following Seferlis and Grievink (2004) the disturbance sensitivity problem is formulated as:

$$\begin{aligned} &\underset{\mathbf{y},\mathbf{u}}{\text{Min}} \quad f = \left(\mathbf{y}-\mathbf{y}_{sp}\right)^{\mathbf{T}}\mathbf{W}_y\left(\mathbf{y}-\mathbf{y}_{sp}\right)+\left(\mathbf{u}-\mathbf{u}_{ss}\right)^{\mathbf{T}}\mathbf{W}_u\left(\mathbf{u}-\mathbf{u}_{ss}\right) \\ &\text{s.t.} \quad \mathbf{h}\left(\mathbf{x},\mathbf{y},\mathbf{u},\mathbf{p}\right)=\mathbf{0} \quad \mathbf{g}\left(\mathbf{x},\mathbf{y},\mathbf{u},\mathbf{p}\right)\le\mathbf{0} \\ &\qquad \mathbf{y}^{lb}\le\mathbf{y}\le\mathbf{y}^{ub}, \quad \mathbf{u}^{lb}\le\mathbf{u}\le\mathbf{u}^{ub} \end{aligned} \tag{1}$$

where $\mathbf{W}_y$ represents weights that are used to penalize the deviation of each controlled variable, $\mathbf{y}$, from their desired level value ($\mathbf{y}_{sp}$), whereas $\mathbf{W}_u$ represents the weights that penalize the deviations of manipulated variables, $\mathbf{u}$, from an optimal operating point ($\mathbf{u}_{ss}$). In addition, $\mathbf{x}$ denotes the state variable vector and $\mathbf{p}$ the vector of model parameters and exogenous disturbances. Problem (1) is solved for different values of the parameters vector by pathfollowing the parameterized Karush-Kuhn-Tucker optimality conditions of (1). The aggregate disturbance variation is represented by a single scalar variable, ζ, that acts as the coordinate in the disturbance space. A static controllability performance index constitutes the tool for the assessment and ranking of the alternative solvent/flowsheet/control structure combinations. The static controllability index Ω_{SC}

expresses the deviations of the controlled variables from target values in a least squares sense along the disturbance magnitude coordinate, ζ, and is defined as follows:

$$\Omega_{SC}(\zeta) = \sum_i w_{u,i}(\zeta) \left\| \frac{u_i^*(\zeta) - u_i^*(0)}{u_i^*(0)} \right\|^2 + \sum_i w_{y,i}(\zeta) \left\| \frac{y_i^*(\zeta) - y_i^*(0)}{y_i^*(0)} \right\|^2 \quad (2)$$

The weighting terms, w, in Equation 2 determine the significance of each calculated segment along the perturbation direction and set the hierarchy in achieving the set targets. Generally, from Equation 2, a large value for Ω_{SC} would imply large errors in the controlled variables during the dynamic transition from one steady state operating point to another. A predictor-corrector type of continuation method as implemented in PITCON (Rheinboldt, 1986) is used with ζ acting as the independent continuation parameter for the calculation of the optimal solution trajectory.

3. Controllability case study

Two different flowsheet structures and two amine solvents are evaluated using disturbance sensitivity analysis (Figure 1). The conventional flowsheet (CF) consists of the basic absorption-stripping loop. An alternative flowsheet with a double section stripper and an intercooled absorber (DSS-ICA) flowsheet combines the beneficial effect of material redistribution in the stripper with temperature control in the absorber (Damartzis et al., 2014).

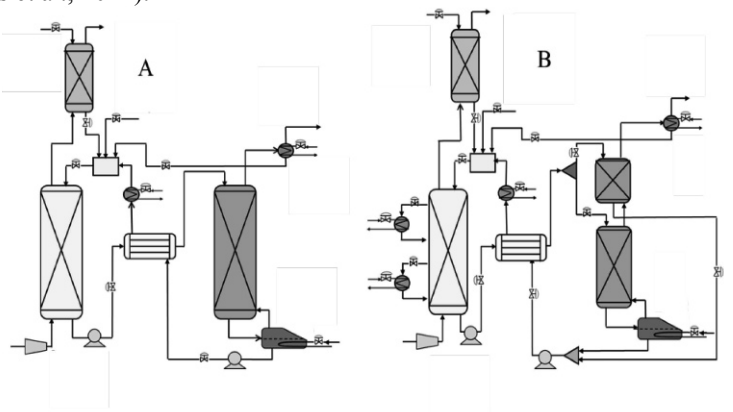

Figure 1. CF (A) and DSS-ICA (B) flowsheet configurations

A flue gas stream typical in quicklime production units is treated by aqueous solutions of monoethanolamine (MEA) 30 % wt and 3-amino-1-propanol (MPA) 30 % wt in the presented CO_2 capture flowsheets. In both cases the controlled variables constituting the process targets include: (a) the CO_2 capture efficiency (% CO_2 captured), (b) the lean stream temperature, and (c) the lean stream loading. Manipulated variables that are used in order to achieve the process targets include: (a) the reboiler duty, (b) the cooler duty, (c) the water and amine make-up flows and in the case of the DSS-ICA flowsheet (d) the intercooler duties and (e) the split ratio of the stream splitter. Manipulated variable upper bounds of 20% the nominal values calculated in the optimization stage are imposed except the reboiler duty where only a 5% upper bound is imposed. The tight bound in the reboiler duty simulates a constrained situation, which aims to examine the behavior of the process/control system under a severe lack of resources The examined

disturbance scenario involves a total increase in the flue gas stream flow rate by 20%, with a simultaneous increase of 10% in the flue gas inlet temperature (Figure 2). Emphasis is given in the achievement of a 90% CO_2 capture level enforced by applying a large weight in the respective entries of $\mathbf{W}y$ in Equation 1.

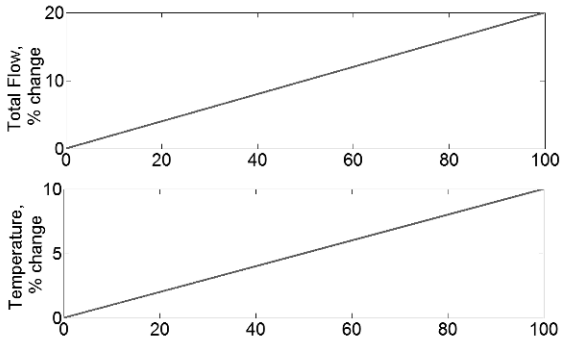

Figure 2. Change in flue gas stream properties in the disturbance scenario. The abscissa represents the independent continuation ζ variable.

4. Results and discussion

The reboiler duty response is shown in Figure 3 with the strict bound imposed being clearly visible. The MPA/DSS-ICA combination seems to handle the disturbance slightly better than the other tested combinations as it exhibits a smaller initial slope during the increment of the reboiler duty. This is attributed to the additional resources available in the DSS-ICA flowsheet (e.g., use of intercoolers) to compensate for the increased flue gas temperature. MPA also seems to be able to handle the disturbance in a more efficient way than MEA, in terms of reboiler duty use, for both flowsheet configurations as indicated by the static behavior in Figures 3-8.

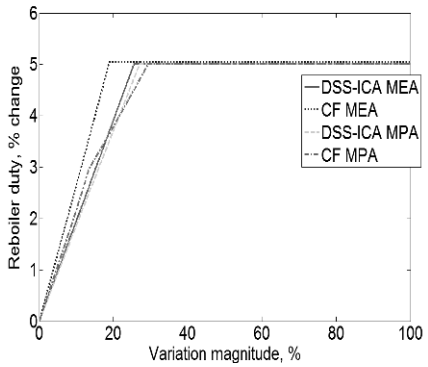

Figure 3. Reboiler duty variation.

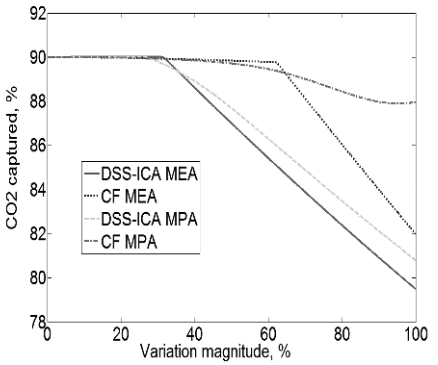

Figure 4. CO_2 capture variation.

The CO_2 capture efficiency as presented in Figure 4 strongly favors the MPA/CF combination. Sharp slope changes in Figure 4 can be explained by considering the responses in the rest of the process resources. Indeed, these changes in the slope occur when some other degree of freedom (manipulated variable) are lost due to saturation. Specifically, for the MEA/CF case, this corresponds to the upper bound of the cooler duty (Figure 5), whilst for both DSS-ICA cases, the CO_2 capture efficiency starts to

drop as soon as both intercoolers reach their upper bound (Figure 6). A diversification is also observed between the two solvents in terms of intercooler usage. It is observed that the MEA plant preferentially utilized both intercoolers in an effort to maintain the captured CO_2 close to the set point; however the result was worse than in the case of the MPA plant by almost 2%.

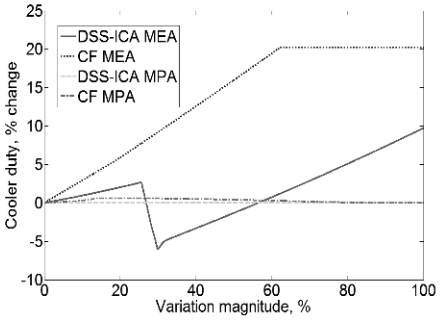

Figure 5. Cooler duty variation

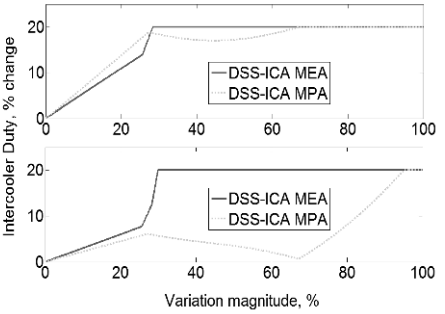

Figure 6. Intercooler duty variation

A key parameter in the operation of the capture plant is the amount of make-up solvent needed to compensate for the lost amine in the vapor phase (Figure 7). Amine make-up is a decisive factor that strongly affects the total operating process cost together with the reboiler duty. It is therefore imperative to maintain low flow rates in the make-up streams in the process to keep the cost at acceptable levels. It is observed that the combination of MPA/DSS-ICA flowsheet achieves low amine make-up flowrates and hence records a superior economic performance over the other combinations.

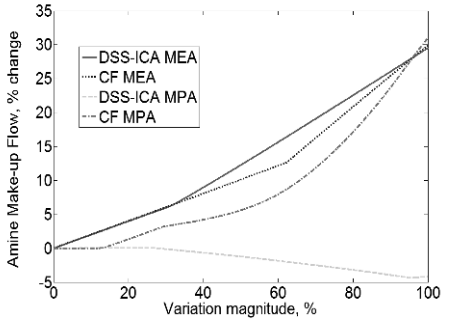

Figure 7. Amine make-up flow variation

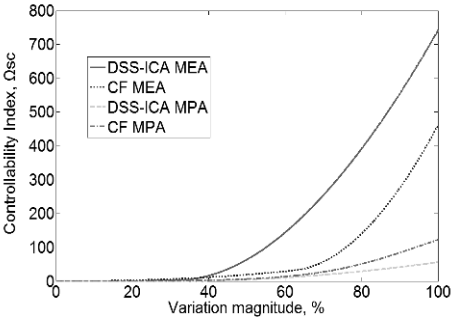

Figure 8. Controllability index variation

Overall, the superiority of the MPA/DSS-ICA pair in terms of disturbance handling is clearly visible in Figure 8, which shows the response of the operability index Ω_{SC} over the extent of the disturbance magnitude variation. Not only the MPA/DSS-ICA combination results to small Ω_{SC} throughout the disturbance span leading to a better disturbance handling, but also both MPA cases show decreased values compared to the cases where the MEA solvent is used. The reason of the superior performance the MPA plant has over the MEA plant can be attributed to the low sensitivity the CO_2 loading behavior shows as conditions such as temperature and CO_2 partial pressure change.

5. Conclusions

A systematic, rigorous, and efficient procedure for the evaluation, rank ordering, and screening of alternative combinations of solvents, process flowsheet, and control structure configurations of CO_2 capture plants has been presented. The ability of the solvent-flowsheet-control structure configurations to compensate for the effects of frequently occurring disturbances due to variable operating conditions is investigated thoroughly with an example testing the integrity of the control system to simultaneous exogenous disturbances. The MPA/DSS-ICA flowsheet exhibited the best performance among the explored plants. The controllability study acts complementary to the solvent selection and the design optimization steps and adds another dimension in which the plant performance must be evaluated and analyzed.

Abstract

In this work, we propose the use of the product-driven process synthesis (PDPS) methodology for the product and process design stage in biorefinery. The aim of the biorefinery is to optimize the total use of the whole feedstock – with focus being on various products simultaneously – rather than to maximize the extraction yield of one single product. The challenge is therefore two-fold; first to identify the main compounds of interest, i.e. the products of the biorefinery, and second to design a process scheme that will allow for an optimal quantity and quality of the identified compounds. To illustrate how PDPS can be used in biorefinery a case study based on sugar beet leaves is described. The identification of the main compounds of interest is based on the functionalities that they can deliver in the final applications, rather than on their quantities in the feedstock. To design the process scheme for the extraction of the selected compounds, task networks, currently used for the extraction of the individual compounds of interest, are used after adaptations. These adaptations are done on the basis of the qualitative and/or quantitative changes that certain tasks – used for the extraction of one compound – may cause on another compound of interest. By using the sugar beet leaves biorefinery case, we show that the PDPS methodology can be a useful tool for structured decision making during the product and process design stage in biorefinery.

Keywords: biorefinery, sugarbeet-leaves, functionalities, product-driven-process-synthesis.

1. Introduction

In the last fifteen years the biorefining industry has gained great momentum. The biorefinery concept describes the process for an integrated extraction of various compounds from one feedstock. The aim of the process is to optimize the total use of the whole feedstock (focus on various products) rather than to maximize the extraction yield of one single product. As such, the volume of the waste is decreased and the economic potential of the process increases, given that the value of the separated compounds is significantly higher than the value of the feedstock.

The challenge is then to design a process scheme that will allow optimization of the different process parameters to yield an optimal quantity as well as quality of the different compounds. The first step in this process is to define which products should be obtained. For instance, sugarbeet leaves contain different types of proteins, carbohydrates, lipids, minerals, phenolics and other minor compounds that can be used in various applications (e.g. pastry products, mayonaise) and in different fields (e.g. food, feed, non-food). The second step is to identify which process steps can lead to obtaining these products. Thus, the main difference in biorefinery compared to traditional approaches is that the sequence of activities in the value chain needs to be inverted. This change in approach has been already acknowledged by other researchers, but has not been studied in details (Marquardt *et al*., 2010).

The product driven process synthesis (PDPS) methodology was introduced to describe the production of a set of (structured) products starting from several raw materials (Bongers and Almeida-Rivera, 2012). This methodology combines the conceptual process synthesis methodology with the product design. It consists of a number of hierarchical levels, where decisions related to the framing level of the design until the design of the task networks and the equipment needed are made (Bongers and Almeida-Rivera, 2012). The aim of this work is to demonstrate how PDPS could be used in the field of biorefinery. Given the fact that PDPS has been originally designed for the production of a set of products from a set of raw materials, it is conceivable that there are some limitations in its application in biorefinery. Therefore, we also propose some adaptations that allow for a successful application of the PDPS in biorefinery. In the following part, we present a case of a sugar beet leaves biorefinery as an example to demonstrate the main steps and adaptations in this approach. As an illustration, only the first four levels of PDPS are discussed (Bongers and Almeida-Rivera, 2012). Depending on interest and the starting material, different choices can be made. Notice that, for this case study, in each step choices have been made that in other cases can be made in a different way leading to different results.

2. PDPS application in sugar beet leaves biorefinery

2.1. Framing level

Sugar beet leaves are currently not used in the industry. After the sugar beets are harvested, the sugar beet leaves are embed in the soil. In this way, a plethora of compounds, such as proteins, carbohydrates, phenolic compounds, lipids, minerals that are present in the sugar beet leaves are left unexploited. These compounds, once extracted from the leaves could be used in various applications, and thus increase the value of the feedstock. Taking into account, for instance, that in the Netherlands the sugar beets cultivation covers an area of 73,200 Ha, it becomes clear that the economic output that could be potentially derived from the exploitation of the sugar beet leaves is significant (FAOSTAT, 2014).

The challenge is then to identify the main compounds of interest; i.e. the output/products of the biorefinery. To facilitate this process of identifying the compounds of interest, we propose the addition of a set of hierarchical steps, as part of this PDPS level, that can lead to a pre-selection of the main compounds of interest in a structured way. The first step in this process is the decomposition of the sugar beet leaves in major and minor compound classes (e.g. proteins, minerals), as shown in Table 1. Based on the compounds identified in sugar beet leaves, a list with commercially available products containing the same or similar compounds is composed. The functionality of each of these compounds in the final product is

identified and added to this list. The functionalities as described and presented in this list refer both to the health-related functionalities (e.g. lowering the glycemic index) and to the techno-functional properties (e.g. emulsifying capacity) of the compounds. It is important to note that the same functionality can be derived from more than one compounds. In principle, the different functionalities can be further assigned to different sales prices. The selection of the compounds of interest is then based on both the quantity of the compounds present in sugar beet leaves and on their potential price. In this respect, both compounds present in sugar beet leaves in high quantities that could potentially yield a low price and compounds present in low quantities that could potentially yield high prices are selected. We here identify three main compounds of interest, namely proteins, carbohydrates and phenolic compounds.

Table 1. Chemical composition of sugar beet leaves (% w/w in dry matter basis)

Protein	Neutral carbohydrates	Uronic acids	Lipids	Chlorophyll	Lignin	Ash	Phenolics	***Total***
33.1 (±0.4)	19.5 (±0.6)	7.7 (±1.4)	8.0 (±1.0)	0.5 (±0.2)	10.1 (±0.6)	15.2 (±0.5)	4.8 (±0.1)	98.9

	...	...	...

2.2. Consumer preferences and product ideas

The output of the sugar beet leaves biorefinery are products that are used in industry as ingredients for other products, and they can thus be used as alternatives for existing ingredients (food, feed, non-food). Hence, a list of product ideas can be extracted from

analysis of the currently available industrial preparations (e.g. starches, protein isolates etc.) that are presented in Table 2. Using this list, we define the final products of the sugar beet leaves biorefinery as following:

a) Proteins for food applications
b) Carbohydrates for non-food applications
c) Phenolic compounds for non-food applications

The consumer preferences can also be derived from the analysis of the currently available industrial preparations ("applications" as shown in Table 2). For instance, a coffee creamer (based on whey protein) is a white powder, that dissolves easily in water and does not aggregate upon heating. Based on these characteristics we could extrapolate what the consumer preferences were, and thus define the consumer preferences for the proteins derived from the sugar beet leaves. The next step is to link the consumer preferences to product specifications that can be controlled and objectively measured. To form this link typically a house-of quality is used (Benner *et al.*, 2003). In Table 3, the characteristics (product specifications) of the three products of the sugar beet leaves biorefinery are summarized.

Table 3. Example of typical product characteristics given a specific field of application.

Proteins (food applications)	**Carbohydrates (non-food applications)**	**Phenolics (non-food applications)**
Free of color	Type/modifications	Purity
No off-taste	Solubility	
Solubility	Color	
Nutritional quality (amino acid balance)	Water binding capacity	
Digestibility	Purity	

2.3. Input-Output level

The input of the process refers to the sugar beet leaves. The specifications of the input are thus described by the chemical composition of the sugar beet leaves, as shown in Table 1. The output of the process refers to the three products (proteins, carbohydrates, phenolics) and their characteristics, as they have been defined in the previous levels.

Task networks

Since the most commonly used plant protein source is soy, we based the task networks for the extraction of proteins from sugar beet leaves on the typical task networks used for the extraction of proteins from soy (Figure 2a) (Kuipers *et al.*, 2005). The extraction of carbohydrates and phenolics presented here are based on protocols currently used for the extraction of these compounds from stover and tea leaves, respectively (Figure 2b, 2c) (van Dongen *et al.*, 2011, Lin *et al.*, 1996).

Table 4. Example of fundamental steps during the extraction of proteins, carbohydrates and phenolics from sugar beet leaves and their expected effects.

Compounds	**Fundamental steps**	**Effect**
Proteins	Heating	Denaturation (loss of solubility)
Carbohydrates	Heating pH>10	Depolymerization (low water binding capacity)
Phenolics	Heating pH>10	Oxidation Polymerization

The next step is to integrate the three task networks used for the extraction of individual compounds to one integrated task network that describes the simultaneous or sequential extraction of the three compounds from the sugar beet leaves. This integration is rather complex due to the different characteristics of the final products For instance, a task network designed to yield the maximum quantity and/or quality of one output might hinder the quantity and/or quality of another output. In the same line, the loss of quality or quantity of one product may be compensated by the increase in quality or quantity of another product. To tackle this challenge, we propose an extra step before the final design of an integrated task network, which is the identification of the critical tasks during the extraction of the individual outputs. In Table 4 the fundamental tasks that could affect the characteristics of the individual compounds are identified (Table 4).
Using these fundamental tasks as a guideline as well as some heuristics and domain knowledge, one integrated task network is designed (Figure 3). It is conceivable that in practice more than one integrated task networks can be designed based on different fundamental tasks. The next levels of the PDPS can be further used for the selection and optimization of one final integrated task network, based also on experimental data. In addition, the equipment needed for the process can be also selected and designed.

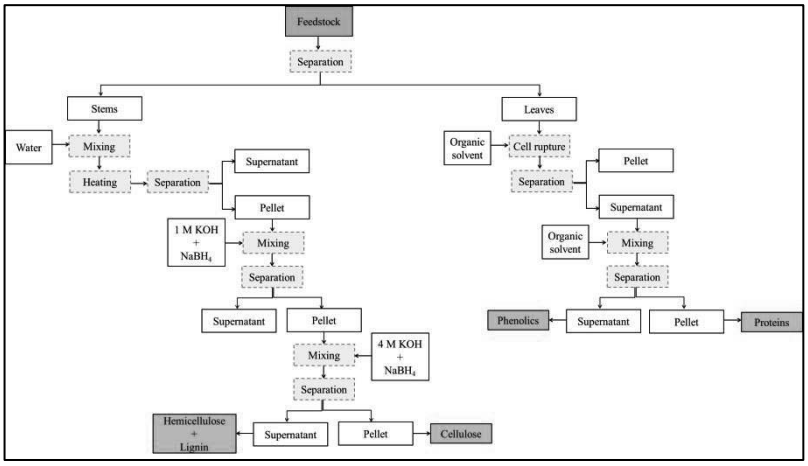

Figure 3. Example of an integrated task network for extraction of proteins, carbohydrates and phenolics from sugar beet leaves.

3. Conclusions

The challenge in designing a biorefinery is related to the various outputs, differing in their physical characteristics, deriving from one initial input (feedstock). To tackle this challenge, the first step is to invert the sequence of activities in the value chain by using the adapted version of PDPS that is described in this manuscript. The adaptations refer both to the identification of the main compounds of interest, i.e. the outputs of the biorefinery and the design of an integrated task network for the different products. To facilitate this process of identifying the main compounds of interest, we propose to link the compounds present in the feedstock to functionalities that are typically ascribed to them in different industrial applications. The benefit of this process is that the selection of the major compounds of interest is not merely based on their quantity but also on their potential sales price, which is different for different functionalities. The task networks developed and optimized for the extraction of independent compounds, do not yield the same results when used as parts of an integrated task network. The identification of the fundamental tasks before the task network integration is thus an extra fundamental step added in the traditional PDPS that can facilitate the selection of one integrated task network. In conclusion, the PDPS methodology can be a useful tool for structured decision making during the product and process design stage in biorefinery.

Integrating expanders into sub-ambient heat exchanger networks

Chao Fu, Truls Gundersen

Department of Energy and Process Engineering, Norwegian University of Science and Technology,Kolbjoern Hejes vei 1.A, NO-7491 Trondheim, Norway

Abstract

The Appropriate Placement of expanders in heat exchanger networks is complex, since both heat and work are involved. In addition, the role of streams (as hot or cold) may temporarily change. This paper proposes four theorems for the integration of expanders into sub-ambient heat exchanger networks with a target of minimizing exergy consumption. A systematic methodology for heat exchanger network design including expanders is developed on the basis of traditional Grand Composite Curves (GCCs). It is concluded that in order to achieve a design with minimum exergy consumption, expansion should preferably be done at pinch temperatures, and/or ambient temperature.

Keywords: Appropriate Placement; Pinch Analysis; Pinch Expansion; Exergy.

1. Introduction

The concept of Appropriate Placement is fundamental in Pinch Analysis and addresses how different pieces of equipment should be integrated with heat recovery processes, also referred to as Correct Integration (Linnhoff and Vredeveld, 1984; Linnhoff and Parker, 1984). The placement of expanders refers to the inlet temperature of expansion processes. The appropriate placement of expanders has been discussed by Aspelund *et al.* (2007) and Gundersen *et al.* (2009), and formulated as the following heuristic rule: expansion provides cooling to the system and should thus preferably start at pinch temperature. However, such observations are not based on strict mathematical or thermodynamic analysis. When designing a heat exchanger network (HEN) including expanders, the application of the rule is not straightforward.

A systematic methodology for in the integration of expanders into sub-ambient HENs is developed in this paper. Since both heat and power are involved, the objective of this work has been to minimize exergy consumption for the integrated processes. A set of theorems has been proposed for sub-ambient processes, indicating that Pinch Expansion (expander inlet is at pinch temperature T_{PI}) is the preferred scheme with respect to exergy consumption. A graphical design procedure is developed, based on the Grand Composite Curve (GCC).

2. Theorems

The following four theorems are proposed for the integration of expanders into sub-ambient HENs (the proof is not included due to space limitation):

(1) A HEN design with Pinch Expansion consumes the smallest amount of exergy if the following conditions are satisfied: (i) the outlet temperature of Ambient Expansion (expansion starts at ambient temperature T_0), $T_{exp,0}$, is higher than cold utility temperature (T_{CU}), and (ii) Pinch Expansion does not introduce a new pinch point.

(2) After the cooling demand has been satisfied by Pinch Expansion, the remaining expansion should be done at T_0 if $T_{exp,0} \geq T_{PI}$.

(3) The cooling by Ambient Expansion should be utilized before using Pinch Expansion, if new pinch points are introduced by Pinch Expansion and $T_{exp,0} < T_{PI}$.

(4) Ambient Expansion should be used if $T_{exp,0} < T_{CU}$.

3. Design procedure

Theorem 1 indicates that new pinches may be introduced when Pinch Expansion is used. The maximum fraction of the stream that can be expanded at the pinch, $(mc_p)_{exp,PI,\max}$, is thus limited. Figure 1 shows the GCC for Pinch Expansion without pressure manipulation. Modified temperatures (T') are used, which means that for cold streams $T' = T + 0.5\Delta T_{\min}$, and for hot streams $T' = T - 0.5\Delta T_{\min}$, where $\Delta T_{\min}$ is given as the minimum temperature difference for heat transfer. The outlet temperature of Pinch Expansion is $T'_{exp,PI}$. A temperature is defined as a Potential Pinch Point if it may create a new pinch after a portion of the cooling effect caused by Pinch Expansion is included. The following temperatures are Potential Pinch Points: (i) the convex kink points on the GCC in the region between $T = T'_{PI}$ and $T = T'_{exp,PI}$ (such as points *b* and *c*); (ii) the point $T = T'_{exp,PI}$ on the GCC (point *e*) or the point with the lowest temperature on the GCC (point *f*) if $T'_{exp,PI}$ is lower than this temperature; (iii) the intersection point between the constant temperature line $T = T'_{exp,PI}$ and a pocket (point *g*) in the GCC.

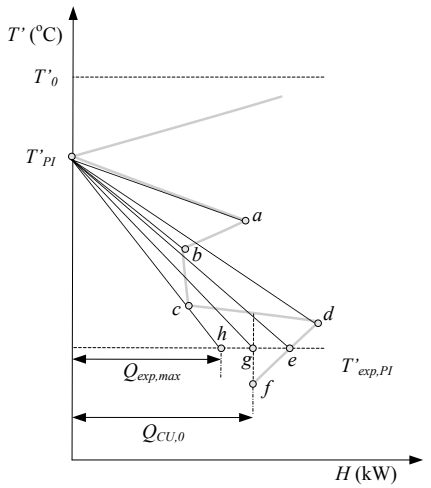

Figure 1. GCC without pressure manipulation

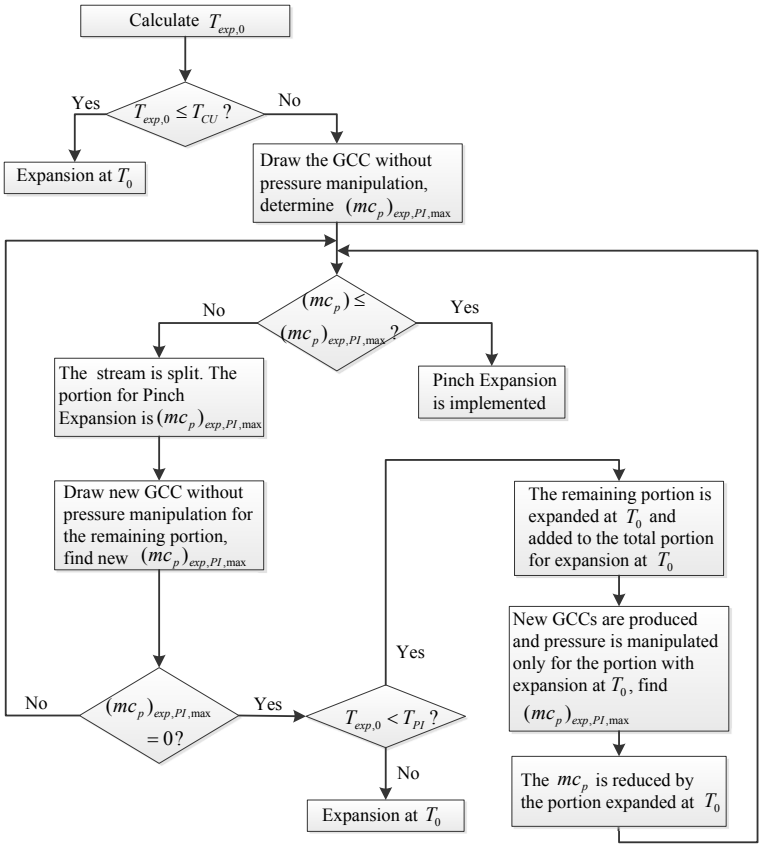

Figure 2. Design procedure for integrating expanders into sub-ambient HENs

The maximum fraction of the stream that can be expanded at the pinch, $(mc_p)_{exp,PI,\max}$, is determined by the following steps: (1) starting at the pinch point (T'_{PI}), draw lines between the pinch point and Potential Pinch Points and extend the line with the largest negative slope until it intersects with the constant temperature line ($T = T'_{exp,PI}$). The corresponding cooling demand $Q_{exp,\max}$ at the intersection (point *h* in Figure 1) is then determined; (2) this cooling demand is equal to the maximum work resulting from Pinch Expansion, and $(mc_p)_{exp,PI,\max}$ can thus be determined as $Q_{exp,\max}/(T'_{PI} - T'_{exp,PI})$. If the mc_p of the stream to be expanded is larger than $(mc_p)_{exp,PI,\max}$, a new pinch point will be created. Stream splitting is required and the fraction of the stream using Pinch Expansion is $(mc_p)_{exp,PI,\max}$.

On the basis of the four theorems, a design procedure has been developed and is illustrated in Figure 2. The first step is to calculate $T_{exp,0}$ and compare it with T_{CU}. According to Theorems 1 and 4, expansion should start at T_0 if $T_{exp,0} < T_{CU}$ and at T_{PI} if $T_{exp,0} \ge T_{CU}$. When Pinch Expansion is used, the maximum portion that can be

expanded, $(mc_p)_{exp,PI,\max}$, is limited by the cooling demand below pinch. Using the concept of Potential Pinch Points, $(mc_p)_{exp,PI,\max}$ can be determined. According to Theorem 1, the entire stream is expanded at T_{PI} if its heat capacity is smaller than $(mc_p)_{exp,PI,\max}$. Otherwise, the stream is split and Pinch Expansion is used for the portion $(mc_p)_{exp,PI,\max}$. A new GCC is then produced, where the pressure manipulation of the portion with Pinch Expansion, i.e. the heating or cooling of the portion from T_s to T_{PI} before expansion and from $T_{exp,PI}$ to T_t after expansion are included. The pressure manipulation of the remaining portion should not be included. The portion available for expansion at new pinch temperatures can then be determined. The procedure is repeated until either the entire stream has been expanded or the cooling demand has been completely satisfied (i.e. the pinch problem has become a threshold problem, $(mc_p)_{exp,PI,\max}=0$). In the latter case, according to Theorem 2, the remaining portion of the stream is expanded at T_0 if $T_{exp,0} \geq T_{PI}$. Otherwise, and according to Theorem 3, the portion for expansion at the original T_{PI} should be reduced and an iteration procedure is required: A new GCC is produced by including pressure manipulation only for the portion of the stream with expansion at T_0 (the other portion of the stream is included in the GCC without pressure manipulation), and the procedure for implementing Pinch Expansion is repeated. The procedure stops if the entire stream has been expanded, otherwise the portion for expansion at T_0 increases until $T_{exp,0}$ is higher than the new pinch temperatures (which means that the pinches above $T_{exp,0}$ have been removed). When the cooling demand has been completely satisfied by expansion at the new pinch point(s) below $T_{exp,0}$, the remaining portion of the stream should be expanded at T_0.

According to the design procedure, it can be observed that in order to achieve a design with minimum exergy consumption, expansion of streams should preferably be implemented at pinch temperatures and/or ambient temperature.

4. Example

The stream data is shown in Table 1, indicating that a hot stream (H1) is expanded. The following assumptions are made: (1) expander polytropic efficiency=1, (2) $\Delta T_{\min}=4$ K, (3) T_0=288 K, and (4) the fluid to be expanded is ideal gas with constant specific heat ratio κ=1.4. $T_{exp,0}$ is calculated to be 210.4 K> T_{CU}=120 K, thus Pinch Expansion should be used. A first case (O) without pressure manipulation is studied to find T_{PI}= 242 K (for hot streams) and $(mc_p)_{exp,PI,\max}$. The GCCs for Case O and the following cases are not presented due to space limitation.

The following cases are compared: Case A - Ambient Expansion is used and $T_A = T_s = T_0$ (288 K); Case B - Pinch Expansion is used for the entire stream; Case C - stream splitting is used: the portion for Pinch Expansion is $(mc_p)_{exp,PI,\max}$ and the remaining portion is expanded at T_0 (expansion at the new pinch is thus not applied); Case D - stream splitting is used: expansion at the original and new pinches are applied

Table 1. Stream data

Stream	T_s, K	T_t, K	mc_p, kW/K	ΔH, kW	p_s, bar	p_t, bar
H1	288	124	4	656	3	1
H2	242	148	9	846	-	-
C1	120	208	7	616	-	-
C2	168	284	8	928	-	-
Heat source	288	288	-	-	-	-
Cooling source	120	120	-	-	-	-

until the cooling demand has been satisfied, and the remaining portion is expanded at T_0 (thus Ambient Expansion as mentioned in Theorem 3 is not utilized); Case E - the proposed procedure is used, i.e. the cooling resulting from Ambient Expansion is utilized before Pinch Expansion is used. Stream H1 becomes different new streams in each case, as shown in Table 2. For example, H1 is split into three portions in Case D: the portion α=1.07 kW/K is expanded after being cooled from T_s to T_{PI}, and then cooled from $T_{exp,PI}$=176.8 K to T_t; the second portion β=1.56 kW/K is expanded after being cooled from T_s to the new pinch $T_{PI,new}$=172 K, and then cooled from the outlet temperature of this expansion $T_{exp,PI,new}$=125.7 K to T_t; the remaining portion γ=1.37 kW/K is expanded at T_0 (= T_s) and then cooled from $T_{exp,0}$=210.4 K to T_t.

Table 2. Stream data for H1

Cases	T_s, K	T_t, K	mc_p, kW/K	ΔH, kW	p_s, bar	p_t, bar
Case A						
H1	210.4	124	4	345.6	1	1
Case B						
H1_1	288	242	4	184	3	3
H1_2	176.8	124	4	211.2	1	1
Case C						
H1_α1	288	242	1.07	49.2	3	3
H1_α2	176.8	124	1.07	56.5	1	1
H1_β	210.4	124	2.93	253.2	1	1
Case D						
H1_α1	288	242	1.07	49.2	3	3
H1_α2	176.8	124	1.07	56.5	1	1
H1_β1	288	172	1.56	181.0	3	3
H1_β2	125.7	124	1.56	2.7	1	1
H1_γ	210.4	124	1.37	118.4	1	1
Case E						
H1_β1	288	172	1.56	181.0	3	3
H1_β2	125.7	124	1.56	2.7	1	1
H1_γ	210.4	124	2.44	210.8	1	1

Table 3. Performance comparison

Cases	O	A	B	C	D	E
Hot utility demand, kW	184	424.4	374.8	411.1	290.3	303.6
Cold utility demand, kW	142	72	72	72	0	0
Pinch temperature, K	240	170	170	170	122	122
Expansion work, kW	-	310.4	260.8	297.2	248.1	261.3
Exergy consumption, kW	-	-209.6	-160.0	-196.4	-248.1	-261.3

The performance comparison is shown in Table 3. The exergy consumption in all cases is negative, indicating that exergy is produced. Case A (Ambient Expansion) is used as the basis for comparison. Direct Pinch Expansion for the entire stream (Case B) reduces the exergy production by 23.7%. When the cooling demand has been completely satisfied by Pinch Expansion (Case D), the exergy production increases by 18.4%. Maximum exergy production (a 24.7% increase) is achieved in Case E. Although less work is produced by expansion, the cooling demand has been completely satisfied by Pinch Expansion in both Cases D and E. As a result, the exergy consumption is smaller (or the exergy production is larger) compared to Case A.

5. Conclusions

A systematic methodology for the integration of expanders into sub-ambient heat exchanger networks has been developed. The objective has been to minimize exergy consumption (or maximize exergy production). Four theorems are proposed and used as the basis for the design. A straightforward graphical design procedure based on the Grand Composite Curve is presented. It is concluded that in order to achieve a HEN design with minimum exergy consumption, expansion should preferably be done at pinch temperatures and/or ambient temperature.

Abstract

Coal to Liquid (CTL) processes have received renewed attention in recent years. However, these processes face significance challenges in terms of the very high water consumption, and high CO_2 emissions if Carbon Capture and Sequestration is not applied. Although the water consumption of a CTL process can be reduced when a closed cooling water system is applied and air cooling is used instead of cooling water, the overall mass balance for a CTL process still requires water as a feedstock(, to provide the hydrogen needed in the process. Our previous analysis shows that 1.3 tons of water is needed as feedstock to produce one ton of CH_2 assuming coal as pure carbon. On the other hand, when biomass is used in the XTL (X= Coal, Biomass, Natural Gas, Waste etc.) process, there is a potential that water is actually produced from the process. As the composition of biomass is close to a very low quality coal, it raises questions that for some low quality coal, it is possible that extra water is not really needed for the overall mass balance.

In this contribution, basic process synthesis tools including mass and energy balances are applied to investigate the possibility of a water free XTL process. It is found that as long as there is hydrogen in the feedstock, a water free XTL process is possible at the cost of a lower carbon efficiency as the result of imbalance of the hydrogen / carbon ratio in the feed. The region where a water free XTL process can be achieved with reasonable carbon efficiency is investigated. Addition of water in the feed can improve the carbon efficiency of the process, therefore a balance between the water requirements and carbon dioxide produced needs to be considered.

Keywords: XTL processes, - water consumption, process synthesis, carbon efficiency.

1. Introduction

Coal to liquid (CTL) process has received renewed attention in recent years. However, these processes face significant challenges in terms of the very high water consumption, and high carbon dioxide emissions, if Carbon Capture and Sequestration is not applied. Water shortages can be an issue when planning a new CTL plant especially since many undeveloped coal resources lie in areas with limited water supply.

It is interesting to note that although there have been some recent publications by King et.al. (2008), Mielke et. al. (2010), US DoE (2006) providing the water consumption figures of a CTL plant, all of them refer to a report prepared for the US Department of Energy (DoE) by Marano et al (2001), which refers to the water consumption data from an earlier study by

DoE (1998), where the overall plant design was considered but raw water consumption wasn't really been optimized. There was also an earlier study by Choi (1997)which provides the water consumption for a natural gas to liquid (GTL) plant even though water consumption was not the focus of the study. Thus the water consumption figures in the literature, especially in terms of coal-to-liquid (CTL) and biomass-to-liquid (BTL) are limited. The actual water consumption of a plant depends strongly on the process chosen and the feedstock composition. For example, Shell (2014) claims on its website that its mega size Pearl GTL plant, which is the world biggest commercial GTL plant, "run the plant without drawing on Qatar's scarce natural fresh water resources or on seawater". In other words, this GTL process is actually 'water free'. Gabriel (2014) et al. has also shown that water can be produced in a well-designed GTL process. There is no reason to doubt that the water consumption of a CTL process can also be reduced if needed.

The fresh water consumption of a XTL (X=Coal, natural Gas, Biomass, Waste, etc.) composes of two parts; firstly as feed in the process, and secondly in the utility section, especially as cooling water. Cooling water is used to remove heat from the process. The return water can be either discharged into the environment or be cooled and recycled. Modern chemical plants prefers to use evaporation tower to cool down the cooling water before it is recycled, the water loss in the evaporation tower normally mainly contributes to the water loss of the process. If an evaporation tower is not used, the cooling water is a closed-loop and other techniques such as air cooling or refrigeration are used to cool down the cooling water, in order to reduce the water consumption. Shell's Pearl GTL plant has demonstrated that this is feasible. In the case of CTL processes, the overall mass balance for a CTL process doesn't really favours a 'water free' process as there isn't enough hydrogen in the coal and extra hydrogen is needed in the process, and this is normally provided by water. The hydrogen to carbon monoxide ratio in the synthesis gas fed to the Fischer Tropsch section also has to be corrected by the water gas shift (WGS) reaction, where further water is also required.

Patel et. al. (2007a) has calculated that a minimum of 1.3 tons of water is needed as feedstock to produce one ton of $-CH_2-$, assuming coal as pure carbon. Metzger et. al. (2013) showed that when biomass is used in an XTL process, there is potential that water is actually produced from the process. As the composition of biomass is close to a very low quality coal, it raises the question that, for some low quality coal, as to whether the extra water is really needed for the overall mass balance.

2. Methodology

Patel et al. (2007b) stated that chemical processes are limited by certain fundamental constraints, such as: (1) Mass balance constraints, where all atoms of material entering as feed must leave in a product stream; (2) Energy balance constraints, where all energy entering the system that is not used in chemical transformation must be rejected. This means that the change in enthalpy between the products and the feed material must be less than zero ($\Delta H_{process} \leq 0$). When $\Delta H_{process} > 0$, energy must be provided by burning some fuel, and the products of this burning then need to be accounted for as part of the products.

In this study, process mass balance and energy balance are applied to the XTL process to determine how much water is really needed in the process and what the cost of the water-free process is.

The feedstock utilized in XTL processes can be very complex, ranging from natural gas, liquid fuels, coal, coke, biomass and waste etc. The formula of the feedstock used in a XTL process can be simplified as CH_xO_y, where x is the atomic ratio of hydrogen and carbon in the feedstock, and y is the atomic ratio of oxygen and carbon. In most cases other than methane, x is not greater than 2.2 and y is not greater than 1. There are normally other elements in the feedstock, such as sulphur and nitrogen. These are ignored in this calculation. The higher heating value of the feedstock is estimated by using the formula developed by Channiwala et al. (2002), based on over 50 fuels covering gas, liquid, coal, biomass and waste. The equation is as follows:

$$HHV = 0.3491\ C + 1.1783\ H + 0.1005\ S - 0.1034\ O - 0.0151\ N - 0.0211\ A \quad (1)$$

$0\% \le C \le 92.25\%$, $0.43\% \le H \le 25.15\%$, $0\% \le O \le 50\%$, $0\% \le N \le 5.6\%$, $0\% \le S \le 94.08\%$, $0\% \le A \le 71.4\%$, $4.745\ MJ/kg \le HHV \le 55.345\ MJ/kg$, where C, H, O, N, S and A represents carbon, hydrogen, oxygen, nitrogen, sulphur and ash contents of material, respectively, expressed in mass percentage on a dry basis. This formula gives an average absolute error of 1.45% to the measured values of HHV, as claimed by Channiwala et al. (2002). This formula was chosen in this study as it covers a wide range of all different kinds of fuel, and has an acceptable error.As nitrogen, sulphur and ash are not consider in this calculation, Eq. (1) is simplified as

$$HHV = 0.3491\ C + 1.1783\ H - 0.1034 \quad (2)$$

Eq. (2) is employed in this study.

3. Calculations and Discussion

3.1. Overall reactions without adding water

If no water is used in the feed, the overall reactions of a XTL process can be written as

$$CH_xO_y \rightarrow aCH_2 + bCO_2 \quad (3)$$

CH_2 is used here to represent the hydrocarbons formed in the XTL process. All produced hydrocarbon is considered as a product, to simplify the calculation. A basis of 1 mol of CH_xO_y is considered. Furthermore, a and b represent the quantity (in moles) of CH_2 and CO_2 produced respectively.

Eq. 3 only holds in cases where $x + y = 2$. As an indication, the value of x + y for bituminous coal is around 0.8, approximately 0.3 for anthracite and 2.5 for cellulose. In cases where $x + y \neq 2$, either oxygen is needed as feed to provide necessary oxygen, or water is to be produced as a product, as shown in Eq. (4) and (5) respectively:

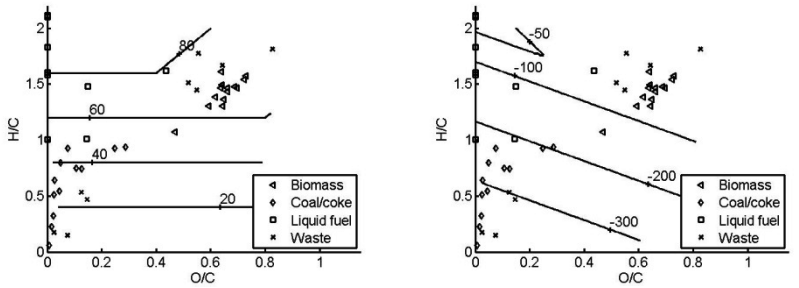
$$CH_xO_y + dO_2 \rightarrow aCH_2 + bCO_2 \quad (4)$$

or

$$CH_xO_y \rightarrow aCH_2 + b\,CO_2 + eH_2O \quad (5)$$

where for reaction (4), the sum of x and y need to be not greater than 2, and for reaction (5), the sum of x and y need to be not less than 2.

Carbon efficiency is used to measure how efficient the process is. Carbon efficiency is defined as the molar ratio between the carbon in the product, in this case, the CH_2, and the carbon in the feedstock, i.e. CH_xO_y. It is easy to calculate the carbon efficiency when only the mass balance is considered. For Eq. (4), where all the hydrogen in the feed only ends up in the product, the carbon efficiency is x/2, while for Eq. (5), the carbon efficiency is less than x/2, depending on the amount of water produced. The calculated carbon efficiency, as a function of the values of x and y is shown in Figure 1(a). Figure 1(b) shows the enthalpy change of the process $\Delta H_{process}$. For easy interpretation, fuel compositions used in Channiwala (2002)'s calculation are also listed, categorized in groups of biomass, coal/coke, liquid fuel and waste.



(a) (b)

Figure 1 (a) carbon efficiency of XTL overall process (%); (b) Heat of XTL overall process (kJ/mol)

It can be seen that for the range of feedstock studied, the ΔH of processes are all negative, indicating these processes are all feasible when energy balances are also considered i.e. there is no need for any further external energy supply. This means that as long as there is hydrogen in the feedstock, the water free XTL processes are possible, when both mass and energy balances are considered.

It should also be noted that this water free XTL process comes at the cost of carbon efficiency. For feedstock with excess hydrogen, such as biomass, the carbon efficiencies are at an acceptable range of about 50-80%, where for certain biomass water is actually rejected from the system, in agreement with our previous calculation. For feedstock with insufficient hydrogen, especially in the case of high quality coal, the carbon efficiencies of water free XTL processes are very low.

This is obvious because if no water is added in the process, all the hydrogen which ends up in the products must come from feedstock, and the balance of the carbon has to be ejected as carbon dioxide. The more hydrogen in the feedstock, the more hydrocarbons can be formed as products, thus the higher the carbon efficiency. This also indicates that adding water into the system can improve the carbon efficiency. Thus there is an intricate balance between the carbon efficiency and the water requirements of an XTL process

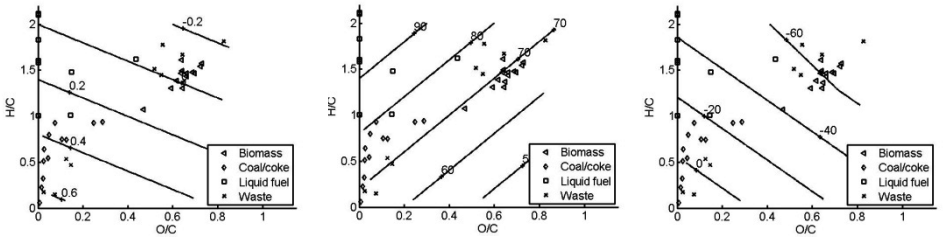
3.2. Overall mass balance with water in the feedstock

If water is allowed in the feed, the XTL process can be written as

$$CH_xO_y + dO_2 + eH_2O \rightarrow aCH_2 + bCO_2 \quad (6)$$

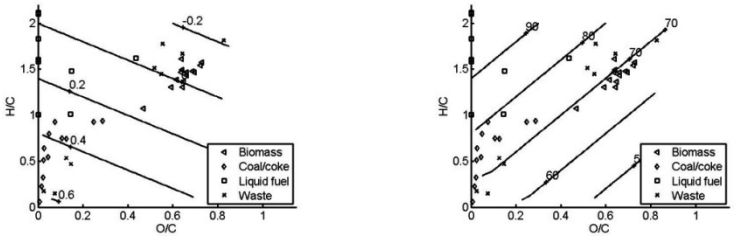
When $x + y > 2$, it is actually the same mass balance as Eq. (5) where water is produced and oxygen is not needed in the feed. When $x + y \leq 2$, water is needed in the feed and oxygen might be needed to balance the oxygen.

Eq. (6) can be balanced with multiple solutions, but the maximum amount of water needed can be found, as shown in Figure 2a, where the negative amount of water means water is produced as a product. The carbon efficiency and $\Delta H_{process}$ are also shown in Figure 2b.



(a) (b) (c)

Figure 2, (a) maximum amount of water needed for XTL process, shown as molar ratio of water and carbon in the feed. (b) Carbon efficiency of XTL processes where maximum amount of water is used in the feed. (c) $\Delta H_{process}$ of XTL processes with maximum amount of water is fed, in kJ/ mol(Carbon in feed)



(a) (b)

Figure 3, (a) maximum amount of water allowed to keep a negative $\Delta H_{process}$ (b) carbon efficiency of XTL processes with the water added as shown in figure 3(a).

The calculation shows that for most of the region covering biomass and low quality coal, the $\Delta H_{process}$ is still negative when maximum amount of water is fed as feed in the XTL processes. Carbon efficiencies of the XTL processes improve dramatically when water is added, especially for a feedstock with limited hydrogen. For example in the case of high quality coal carbon efficiency improves from about 20% to about 70% when water is added at a water carbon molar ratio of about 0.6. But the $\Delta H_{process}$ turns positive in the case of high quality coal, indicating further energy is needed in this process. We can provide the energy needed by burning the feedstock, which lowers the carbon efficiency but also consume less water. The maximum amount of water needed and their carbon efficiencies to maintain a negative $\Delta H_{process}$ is shown in Figure 3.

It is worth noting that there is normally water in the feedstock, especially the case of low quality coal and biomass. 20% moisture in a feedstock with about 50% mass percentage of carbon gives a water carbon molar ration of about 0.26. When we check the region where maximum amount of water needed over carbon is less than 0.26, we find that it covers the whole biomass region and is very close to the region of low quality coal. This indicates that extra water is not necessarily required when using biomass or low quality coal as the feedstock in a XTL process.

4. Conclusion

We can conclude that for overall XTL processes where hydrocarbon is produced from a carbon resources,

1. Water free XTL processes are possible, at the cost of lower carbon efficiency;
2. Carbon efficiency can be improved by adding water in the feed, where only a limited amount of water is actually needed;
3. For biomass and low quality coal, when the water content in the feed is normally high, no fresh water is actually needed in the XTL processes, thus a water free XTL process is possible.

Abstract

Synthesis gas (syngas), mainly constituted by carbon monoxide (CO) and hydrogen gas (H_2), is produced mostly through biomass gasification and methane reforming. In the last decade, the thermochemical route to produce ethanol and higher alcohols from syngas has been gaining space as a possible route to produce synthetic fuels and additives. This kind of process presents a series of advantages as: short-time reaction, abundant and lower-price feedstocks, the use of lignin and the almost complete conversion of syngas, having the potential to exceed ethanol production by fermentative route. Aiming to produce ethanol through thermochemical route, a singular process (a small-scale plant with capacity to process 100 kmol/h of syngas) was proposed for a first evaluation using the commercial simulator ASPEN Plus v7.3. Four different Rh-based catalysts were tested in the process (RhFe, RhLa, RhLaV, and RhLaFeV), trying to take advantage of the characteristics of Rh-based catalysts as high ethanol selectivity and hydrocarbons production. The process design took into account the reactor selectivity and conversion. Through sensitivity analysis, the downstream process were configured searching for the best possible design of separation steps, making possible to obtain ethanol (>99 % wt.), methanol (>90 % wt.), Liquified Petroleum Gas (LPG, mixture of C_2H_6, C_3H_8 and C_4H_{10}, > 99 % wt.) and pentane (>95% wt.).

Keywords: syngas, ethanol, hydrocarbons, simulation.

1. Introduction

Analysing the world's energy scenario it is possible to observe the continuous rise of petroleum prices, the constant growth of world's population and the consequent increase of energy demand, making attractive the development of renewable, alternative and sustainable energy sources derived from biomass or industrial co-products. Due to the present demands, the interest on the thermochemical route, that converts synthesis gas (syngas) to alcohols, has been renewed and now this route is seen as a possible alternative to supply the fuels market in the near future.

Biomass and coal gasification generates the syngas, a mixture of mostly CO and H_2 known by its use in the production processes of ammonia (Harber-Bosch) and hydrocarbons (Fischer-Tropsch). However, the catalytic conversion of syngas to alcohols, studied during the last 90 years has been gaining space in the last few years as a possible route to produce synthetic fuels and additives (Subramani and Gangwal, 2008; Christensen, 2011). In this route, the initial feedstock is gasified to syngas and

then reformed, cleaned, compressed and catalycally converted into a mixture of high-weight alcohols. This process has also advantages as: short-time reaction, abundant and cheap feedstocks, use of lignin and almost complete conversion of syngas.
Among several catalysts, Rhodium (Rh) is known for its position in the periodic table, between those metal that dissociate CO, forming long-chain hydrocarbons (Fe, Co), and those that do not dissociate CO and produce methanol (Pd, Pt, Ir). Thus, the Rh-based catalysts can form long-chain oxygenate compounds from CO hydrogenation (Spivey and Egbebi, 2007). However, one of the drawbacks of Rh-based catalysts is the high selectivity to hydrocarbons production, generally varying in their chain size from C_1-C_5.
In this work, using the commercial simulator ASPEN Plus v7.3, it was possible to propose a first process design that uses Rh-based catalysts with different promoters (RhFe, RhLa, RhLaV, RhFeLaV), find its best operational settings based on the demands required by each catalyst taking advantage of their characteristics, analyse it regarding energy consumption and production, and finally, point out possible solutions and future developments.

2. Process Design

2.1. Reaction kinetics

The reaction kinetics was obtained from Gao et al. (2011). In their studies, the authors considered the formation of hydrocarbons (CH_4, C_2H_n, C_3H_n) and ethanol, obtaining the kinetic parameters for the Arrhenius model. To obtain a more extended model, considering the formation of alcohols (oxygenates portion) and hydrocarbons (C_{2+} portion) until C_5, we used the Anderson-Schulz-Flory (ASF) distribution (Gunturu et al.,1998). The use of ASF distribution is only reflected in the pre-exponential factors of the reaction kinetics, which were recalculated and properly introduced in the simulator.

2.2. Process Layout

The process layout, shown in Figure 1, was heuristically defined for the four different catalysts. Starting from the products obtained in the reactor, a mixture of alcohols, hydrocarbons, water and non-reacted syngas, the downstream operations were chosen in a way to obtain the desired products for the following steps. After choose a unit operation, according to the stream demands, it was improved using sensitivity analysis.

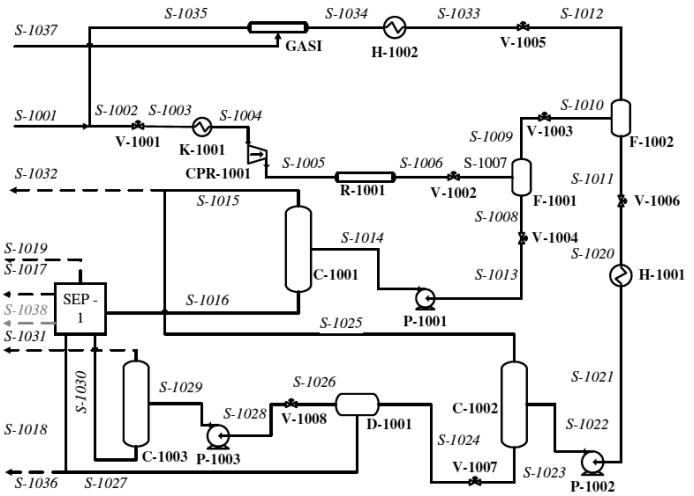

Figure 1. Process flowchart

The syngas enters in the process through S-1001 stream, which is mixed with the recycle stream S-1035, and the resulting stream (S-1002) is then heated, compressed and introduced in the reactor. From the reactor (R-1001) a mixture of alcohols, hydrocarbons, water and non-reacted syngas (S-1006) is obtained, which goes to the first flash drum (F-1001) for a gross separation of water and alcohols (S-1008). The flash's top stream (S-1009), which contains most of hydrocarbons and non-reacted syngas, is directed to the second flash (F-1002) which operates at moderate pressure and very low temperature. The top stream of F-1002, containing the major part of non-reacted syngas and methane, goes to the GASI reactor, which emulates the total conversion of this stream to pure syngas, when this stream reacts with oxygen (S-1031). As seen from the flowchart in Figure 1, the recycle generated by the GASI reactor can be "turned on" and "off" by just disconnecting S-1035, then S-1001 is automatically adjusted to supply the syngas demanded by the process. The goal of the recycle section is to calculate the amount of syngas that can be recovered from the process, admitting total use of the effluent stream (S-1012).

The bottom stream of F-1001 (S-1008) is directed to the distillation column C-1001, in which the rest of hydrocarbons (S-1015) are separated from the water/alcohols mixture (S-1016). The stream S-1011, originated from F-1002, goes to the distillation column C-1002, which operates at moderate pressure. Two streams are generated in this column, the top stream (S-1025), which is rich in C_2-C_4 hydrocarbons (LPG), while the bottom stream (S-1023) is composed by pentane and a small fraction of water and alcohols. S-1023 is sent to the decanter (D-1001), in which the aqueous phase (S-1027) and the pentane-rich phase (S-1026) are split. This stream is directed to the distillation column C-1003, where pentane is obtained in the top stream (S-1031) and a mixture of alcohols and water in the bottom stream (S-1030).

The design used in SEP-1 (Figure 2) is already known from the first generation ethanol production (Dias et al., 1009). It consists of a set of four distillation columns. The first distillation column (C-101) receives a mixture of two streams (S-1009 and S-1031) containing water, alcohols, and traces of hydrocarbons.

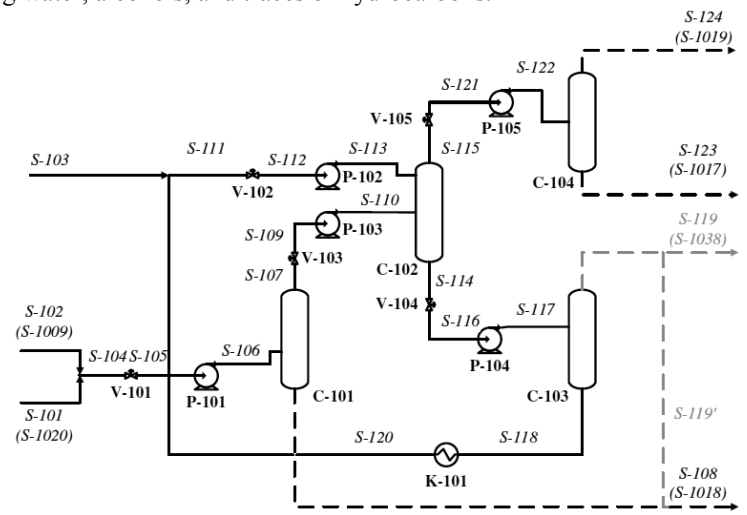

Figure 2. SEP-1 flowchart

In its top stream, C-101 has a concentrated alcohols/water mixture, while in its bottom a water stream (>99 % wt.). In the second column (C-102) is promoted an extractive

distillation (with ethylene glycol), where the mixture entering the column is dehydrated. In its top stream (S-115), C-102 has the mixture methanol/ethanol, which is directed to C-104, where the two alcohols are obtained separately. In the distillation column C-103, the solvent is recovered (S-118) being reintroduced to the system through S-111. The water-rich stream (S-119), highlighted in gray, depending on its composition, can be mixed with S-108 resulting in a stream with >99 % wt. water or, when it has a fraction of higher alcohols, stored to be separated by other unit.

3. Results and Discussion

Four simulations were carried out using the commercial simulator ASPEN Plus v7.3. Based on the properties of the components generated in the reactor and the operating conditions, two thermodynamic packages were chosen. Thus, for the operations containing polar compounds at pressures below 10 bar, the UNIQUAC thermodynamic package was used, and, for operations involving hydrocarbons at pressures above 10 bar, the PENG-ROBINSON thermodynamic package was used.

3.1. Products

The reactor is continuously fed with 100 kmol/h of syngas at a mole ratio of 1:2 ($CO:H_2$). This value was found by sensitivity analysis to result in the best relation between carbon monoxide conversion and ethanol selectivity for the four simulations.
Temperature and pressure were maintained respectively at 270 °C and 1.8 bar, while the catalyst load, obtained through sensitivity analysis, varied between catalysts (17500 kg of $RhFe/SiO_2$, 15000 kg of $RhLa/SiO_2$, 8500 kg $RhLaFeV/SiO_2$ and 8500 kg $RhLaV/SiO_2$). The reactor's conversion was limited by the H_2 supply. In the sensitivity analysis, when the conversion suffered no significant increase (1% from the last point), the catalyst load stop increasing, obtaining the results for conversion (CO mass basis) of: 73.21 % ($RhFe/SiO_2$), 78.73 % ($RhLa/SiO_2$), 86.23 % ($RhLaFeV/SiO_2$) and 85.47 % ($RhLaV/SiO_2$).

In the process, four products are generated, ethanol (the desired oxygenated product), methanol, pentane and LPG (liquefied petroleum gas, a mixture of C_2-C_4 hydrocarbons). As seen from Figure 3, the catalysts generate different amounts of each product. The most prominent product is the LPG, generally followed by ethanol, except in the RhLaFe catalyst, where pentane is the secondary product.

All the product streams were obtained at or above 99 % wt. purity except stream S-1031 (pentane) for the catalyst $RhFe/SiO_2$. Due the low pentane mass flow, this stream attained only 95 % wt. of pentane, which is contaminated with methanol.
The process generates, besides the product streams, three other streams. S-1018 containing most of the water generated in the reactor, while S-1035 recycles the syngas and S-1038 carries water and a small amount of alcohols (C_{3+}). Using the catalyst $RhFe/SiO_2$, the recycle stream attains 624.9 kg/h of syngas with a mole ratio of 1:1.29 ($CO:H_2$), the water stream 385.9 kg/h (99.4 % wt.) carries all the water, being other stream not necessary. In turn, using the catalysts RhLa, RhLaFeV and RhLaV, the process produces respectively water: 435.9 kg/h (99.7 % wt.), 441.4 kg/h (99.8% wt.) and 390.3 kg/h (99.7 % wt.) and syngas: 404.4 kg/h (1:1.3), 230.6 kg/h (1:0.78) and 230.57 kg/h (1:0.86). The mass flows of the stream containing higher alcohols residues in the three cases were respectively: 23.6 kg/h (96.4 % wt. water, 0.8 % wt. propanol, 1.0 % wt. butanol and 1.1 % wt. pentanol), 54.3 kg/h (66.8 % wt. water, 0.6 % wt. ethanol, 9.2 % wt. propanol, 11.0 % wt. butanol and 12.2 % wt. pentanol) and 103.4

kg/h (64.0% wt. water, 0.1 % ethanol, 10.6 % wt. propanol, 12.1 % wt. butanol and 13.0 % wt. pentanol).

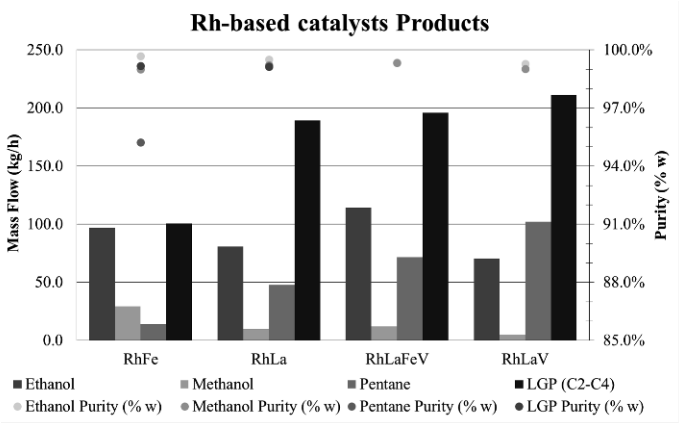

Figure 3. Mass Flow and Purity of Products

3.2. Energy Consumption

The unit operations were set based on sensitivity analysis. For the two flash drums, temperature and pressure were varied in order to obtain in F-1001 the best ratio between alcohols and water (S-1008) and syngas and hydrocarbons (S-1009) recoveries and in F-1002 the recovery of 99.9 % wt. of syngas and methane of the feed stream. The three distillation columns were configured regarding the energy spent in the reboiler. C-1001 had the alcohols and water recovery 99.9 % wt. from the inlet flow established as the goal for its operation, varying the number of stages (N_{STAGE}), feed stage (F_{STAGE}) and the mass reflux ratio (M_{RR}). In C-1002, using the same variables of the prior case, the analysis had as restrictions: the recovery of 99.9 % wt. of the LPG from inlet stream above 99 % wt. purity. Fixing pentane recovery (95 % and 99 % wt.) in C-1003, and varying N_{STAGE}, F_{STAGE} and M_{RR} its final design was obtained.

In SEP-1 the same analysis procedure was followed, the columns were set varying $N_{STAGE,}$ F_{STAGE} (in the case of C-102 both feed stages were varied) and M_{RR}. In the first distillation column of this set (C-101) the main obstacles for its best operation were the azeotropes ethanol/water, propanol/water and butanol/water. Thus, knowing that a reasonable quantity of water would be carried to the second column (C-102), it was possible to best configure the column related to two variables: the recovery of ethanol in the top stream and water purity in its bottom stream. In C-102 the top stream purity was prioritized, in order to have a mixture of at least 99 % wt. of ethanol and methanol with a recovery of both from the feed stream of 99.9 % wt., ethylene glycol at a mass ratio of 1:1 (solvent: feed stream) was introduced in the column. About 99.9% of this solvent is recovered by the distillation column C-103, which produces also a water-rich mixture in its top. The alcohols streams are obtained in column C-104, in which ethanol and methanol are obtained at minimum 99 %wt. purity.

The analysis were carried out in order to achieve the minimum energy required to obtain the desired products with the restrictions described above. In this way, Figure 4 shows the contribution in energy consumption of each unit of the process. Due the exothermic nature of the reactions, the net energy consumption is positive. The reactor appears as the main contributor for cooled units followed by F-1001, which receives all the mass flow coming from the reactor and needs to cool it down to send streams pure enough to

C-1001 and F-1002. SEP-1 is represented as one whole block and has a contribution in both, heated and cooled units. As can be seen, among the cooled units, SEP-1 is the third biggest energy consumer, while among the heated units, the first. Its energy consumption is directly related to the data observed in Figure 3. When the catalyst produces more alcohols, the energy is proportional in SEP-1, in both ways, heating and cooling. The same behavior can be seen in the distillation columns C-1002 and C-1003 but this time related to LPG and pentane production.

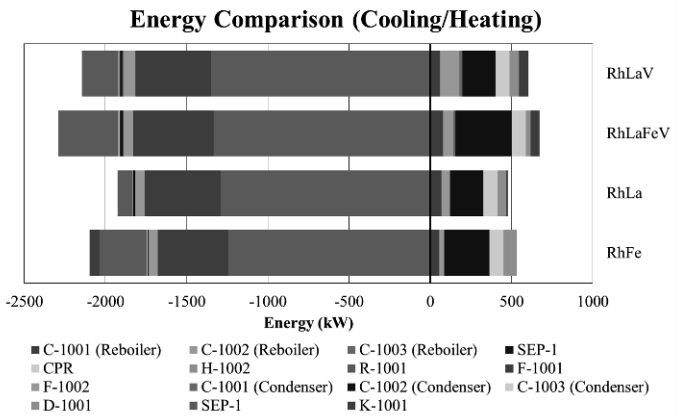

Figure 4. Energy Consumption Comparison

4. Conclusion

Regarding energy aspects, the process showed itself viable due the exceeding energy generated by the reactor that, through energy integration, can be used in the process or in cogeneration. Considering the ratio(catalyst load)/(products mass) the process using RhLaV and RhLaFeV are more favourable, however with different focus, hydrocarbons and ethanol production, respectively. Three further steps can be taken from the results obtained here; the energy integration with other biofuels production processes, the scale-up considering the recovery of the higher alcohols and the catalyst improvement.

Kathrin.Werth@bci.tu-dortmund.de

Abstract

To enable the use of alternative cheap feedstock in the production of biodiesel, such as waste cooking oils, the contained free fatty acids have to be separated from the triglycerides. For that purpose an integrated process incorporating reactive distillation and organic solvent nanofiltration is proposed. To determine the potential of the integrated process a detailed model was developed for computer-aided process analysis. Necessary parameters such as permeabilities and kinetics were estimated based on experimental investigations. Process analysis revealed that reactive distillation is a suitable process for the pre-treatment of waste cooking oil and that the application of organic solvent nanofiltration could enhance profitability of the process.

Keywords: Process intensification, rate-based model, esterification, free fatty acids.

1. Introduction

Biodiesel based on renewable resources shows a great potential as alternative future fuel. Until now no economic production of biodiesel is possible because of the high raw material costs of virgin vegetable oil that account for three-fourth of the total production costs (Lim and Teong, 2010). A promising and cheap alternative feedstock are waste cooking oils, which reduce the raw material cost by a factor of three (Yaakob et al., 2013) and upgrade the produced biodiesel to a second generation biofuel. The main drawback of these low-quality oils is the high amount of free fatty acids (FFA) which tend to hydrolyse under the alkaline conditions in the transesterification reaction of biodiesel. Therefore, the amount of FFA in the waste cooking oil has to be minimised in a pre-treatment step to avoid this undesired side reaction in the transesterification.

One possibility to reduce the amount of FFA is the esterification of the acids with an alcohol in a pre-treatment step. Since this reaction is equilibrium limited the application of reactive distillation (RD) is favourable. However, as indicated by Marchetti and Errazu (2008), the low concentration of FFA in the column due to the high amount of non-reacting triglycerides (TG) in the waste cooking oil might result in a reduced reaction rate and conversion. To overcome these challenges, which might restrict the operation window of RD, an integrated process combining RD with organic solvent nanofiltration (OSN) is proposed. Thereby, OSN facilitates an energy efficient separation of FFA and TG due to its mild operation conditions.

In order to prove the feasibility of this concept a systematic experimental and theoretical investigation is performed. As model system the esterification of oleic acid and ethanol

in presence of vegetable oil is chosen. A rigorous model for the integrated process incorporating RD and OSN is developed for the purpose of process analysis and design. To determine missing parameters for reaction kinetics and permeabilities, the esterification of FFA as well as OSN and RD are investigated experimentally. The model is validated based on the experimental results and used for a process analysis of RD and OSN in order to determine suitable operation windows for a further integration and later process design.

2. Modelling of integrated process

In order to provide a rigorous model for the integrated process, comprehensive models for the RD column and an OSN cascade are developed in Aspen Custom Modeler® (ACM). Thermodynamic and physical properties are calculated using Aspen Properties®.

2.1 Reactive distillation

For modelling of RD a rate-based model incorporating heat and mass transfer equations as well as correlations describing the fluid dynamics is used. A detailed description of the RD model is given by Keller and Górak (2013). To adapt the model to the integrated biodiesel process, suitable kinetics for the esterification of FFA with ethanol are necessary. The temperature dependence of the reaction rate is taken into account according to the Arrhenius approach which describes the reaction rate constant as a function of pre-exponential factor k_0 and activation energy E_A. Both parameters have to be estimated based on experimental results.

2.2 Organic solvent nanofiltration

The OSN cascade comprises of various membrane modules which can be connected in parallel or series and can be operated at different temperature and pressure. The optimal configuration for the OSN cascade can be determined based on a superstructure model approach (cf. Micovic et al., 2014). Mass transfer through the membrane is described by the solution-diffusion model (Wijmans and Baker, 1995), in which the flux J of component i represents the product of permeability P_i and driving force ΔDF_i (see Eq. (1)).

$$J_i = P_i \cdot \Delta DF_i \tag{1}$$

The driving force is determined by the difference in chemical potential across the membrane, calculated based on the operating conditions and concentration in feed and permeate. The permeability accounts for the complex interactions between membrane, solvent and solute and is influenced by concentration, temperature and pressure. Till now no accurate prediction of separation performance in OSN is possible because it depends on various factors (e.g. molecular size of components, solubility parameters, solvent interactions, membrane material etc.). Therefore, permeabilities have to be determined experimentally.

3. Experimental investigation and parameter estimation

Since few data is available experimental investigations were performed for the esterification of oleic acid with ethanol and the membrane separation of waste cooking oils to determine the missing parameters.

3.1. Kinetics of esterification of free fatty acids

Experiments of the esterification of oleic acid and ethanol to produce ethyl oleate and water were performed in a batch reactor at different temperatures. To achieve high conversion of oleic acid an excess of ethanol of 6:1 was applied. This ratio was chosen according to preliminary tests and to ensure feasible and stable conditions in the RD experiments. First, a screening of homogeneous and heterogeneous catalysts was performed. For the tested heterogeneous catalysts, Amberlyst^{TM}-15 very low conversion of FFA was observed and thus no application in RD is possible because of the short residence time in the column. The homogeneous catalyst sulphuric acid was identified as a suitable catalyst which leads to high conversion of FFA ($X_{FFA} \sim 80\,\%$) in reasonable reaction times.

Subsequently, the impact of TG from which a high amount is present in waste cooking oils on the conversion of FFA was investigated. As expected the experimental results show that the initial reaction rate is reduced (see Figure 1) since the concentrations of reactants and products are decreased by the present TG. The parameters for the reaction kinetics were determined from the experimental reaction data. The simulated conversions of FFA are in satisfying accuracy with the experimental results for a first process analysis (see Figure 1).

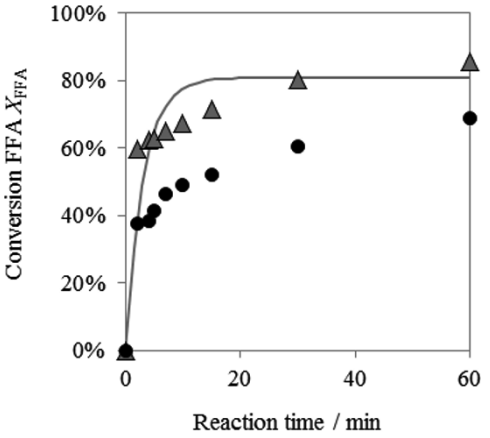

Figure 1: Conversion of oleic acid without triglyceride in the reaction mixture (grey) and in presence of triglyceride (black) at a temperature of 71 °C. Symbols represent experimental data and the solid line represents the simulated data in the absence of triglyceride.

3.2. Membrane permeabilities

A screening of the commercial available membranes GMT-ONF^{TM} 1, GMT-NC^{TM} 1 (both PDMS) and PuraMem^{TM} 280 (polyimide), which differ in polymer material and molar weight cut-off, was performed to determine the potential of this separation step. Furthermore, the influence of different solvents (n-hexane and ethanol) on the selectivity of the separation of oleic acid from TG was investigated, because it is known that solvents can significantly influence the separation behaviour (Schmidt et al., 2013).

Permeabilities of each component are estimated based on the partial permeate fluxes. As exemplarily shown for the investigated membrane GMT-ONF^{TM} 1 (see Figure 2) the

permeate fluxes calculated by the solution-diffusion model are in good agreement with the measured fluxes. For this membrane the flux of n-hexane is considerably higher than for ethanol which also results in higher selectivities for n-hexane. However, for the dense membrane PuraMem^{TM} 280 an appropriate permeability of FFA is found while TG is fully rejected if ethanol is used as solvent instead of n-hexane. For the overall process the application of ethanol as solvent is favourable because it is used as reactant in the following esterification step. Since the membrane PuraMem^{TM} 280 shows high ethanol flux and full rejection of FFA, only this membrane type is considered in the subsequent process analysis.

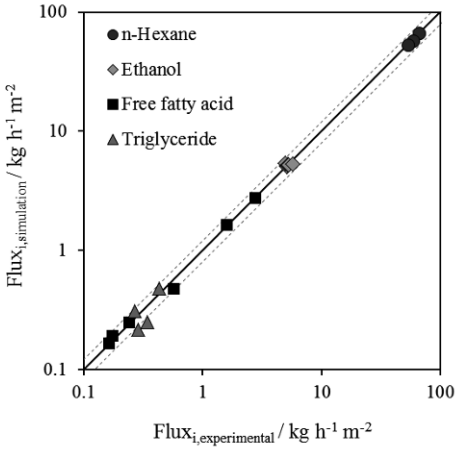

Figure 2: Measured and calculated partial permeate fluxes for the membrane GMT-ONF^{TM} 1.

4. Process analysis

Within process analysis, the influence of various parameters on the process performance of RD and OSN was investigated to determine suitable operation windows for both unit operations. A feed of 1400 kg/h waste cooking oil with a FFA content of 30 wt% was assumed.

In the process analysis of RD the influence of reflux ratio, distillate-to-feed (DF) ratio as well as packing height on the conversion of FFA was investigated (see Figure 3). For the esterification of pure FFA a required packing height of 2.4 m were determined to achieve full conversion of FFA whereby no rectifying section is necessary. If waste cooking oil is applied as feedstock, the energy demand is drastically increased compared. But it is found that the reduced reaction rate due to the presence of TG only slightly affects the conversion of FFA in RD and thus the performance of RD.

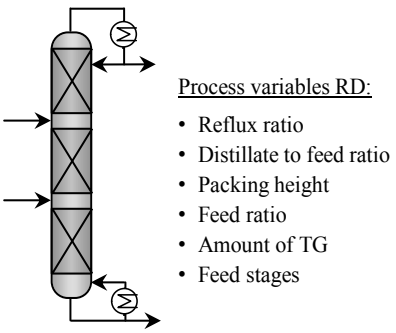

Figure 3: Model setup for RD column (process variables considered in analysis indicated).

A sensitivity analysis was performed in order to identify the influence of different process and design variables and to determine the feasible operation regions of RD for further process optimization. Figure 4 illustrates the results of the sensitivity analysis for a fixed column set-up and indicates that a low reflux ratio and thus a low amount of the by-product water in the column are favourable to achieve full conversion of FFA. Additionally higher DF ratios result in increased conversion but are directly linked with increasing reboiler duty. This trade-off between high conversions and operational costs (in this case reboiler duty) has to be addressed by further process optimization, which will be part of future work.

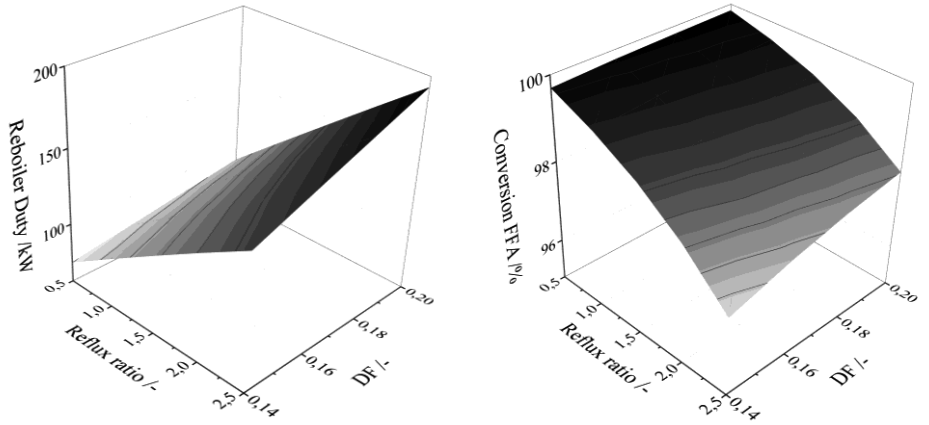

Figure 4: Dependency of reboiler duty (left) and conversion of FFA (right) on reflux ratio (RR) and distillate to feed ratio (DF) for the esterification of pure FFA. Packing height, feed ratio and position of the feed stages are kept constant.

The process analysis of the OSN cascade was performed by means of an evolutionary multi-objective algorithm (Micovic et al., 2014) which allows to analyse the influence of contradicting objectives. Here, membrane area minimization and the maximization of the retentate mass fraction of TG was accomplished by manipulating the different design degrees of freedom and operating conditions of the OSN cascade (see Figure 5).

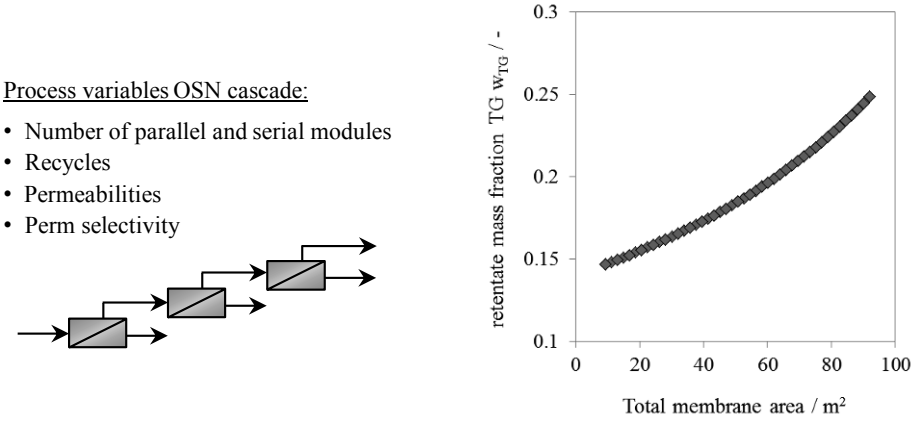

Figure 5: Model setup for OSN cascade with considered process variable in analysis indicated (left). Mass fraction of triglyceride in the retentate in dependence of total membrane area for a three stage OSN cascade equipped with the PuraMem^{TM} 280 membrane (right).

Since only the PuraMem^{TM} 280 membrane was considered (cf. Section 3.2), the permeability and the perm selectivity were kept constant, while the number of parallel and serial modules, the recycle flow rates and the operating pressure of the three-stage OSN network, for which the retentate of the previous stage is processed in the subsequent stage, were optimized. The results of the optimization are illustrated on the right side of Figure 5. These results indicate that for the maximum considered membrane area of 92 m^2 the maximal separation of FFA is achieved. In the retentate an amount of 24.8 wt% TG and 6.4 wt% FFA is obtained, while the permeate contains only FFA and ethanol. This allows processing the FFA to more valuable products (e.g. nitriles, amines), which would lead to enhance the profitability of the overall process. Additionally, it has been shown recently that a separation of saturated and unsaturated FFA via OSN might be possible (Bowden, 2014) and thus new building blocks for chemical production can be generated.

5. Conclusion and future work

Comprehensive models for RD and OSN were developed in order to investigate an integrated biodiesel process. The necessary parameters such as kinetics and permeabilities were estimated based on experimental results. The models were subsequently used for a detailed process analysis in order to determine suitable process configurations and favourable operating conditions. It was found that performance of RD is only slightly affected when TG is present in the reaction mixture. However, by incorporating OSN the profitability of the process might be increased. Based on the current results a detailed process design will be performed considering energy efficiency as well as production costs to determine the most promising process configuration. Furthermore, the developed models facilitate the investigation of the influence of fluctuating feedstock composition, which will also be done in future work.

patelb@unisa.ac.za

Abstract

One of the major challenges of achieving a sustainable integrated biorefinery lies in the systematic synthesis and design of such systems. There is a need to develop quick and efficient methods to screen the various product options in order to determine which products best utilise the feedstock.

This contribution develops upfront conceptual-level design targets for the production of fuels and chemicals from biomass. These targets aim to provide insight into the design of sustainable biorefineries, prior to the detailed design, with an aim of maximising feedstock utilisation thereby increasing the process efficiency and reducing the emissions from such processes. The targets for these different products are compared using sustainability metrics such as Atom Economy and E-factor. Products which maximise the Atom Economy are determined. This work further identifies integration opportunities and assesses whether combining the production of fuels and chemicals can achieve higher process efficiencies.

Keywords: Biorefineries, design targets, Van Krevelen diagram, process synthesis.

1. Introduction

One of the major challenges of achieving a sustainable bio-refinery lies in the systematic synthesis and design of an integrated biorefinery (Kokossis and Yang, 2010). The key aim is to improve the efficiency, economics and reduce the environmental impact of such processes. In addition, there are many possible products that can be produced, ranging from low-value bulk products (such as fuels) to high-value specialty chemicals (Fernando et al., 2006). Quantitative accounts of the highest efficiency, minimum amount of energy or lowest amount of carbon dioxide that is emitted i.e. design performance targets, can provide essential insight into efficient material and energy utilization. Yuan et al (2013) provides a comprehensive review of various process synthesis methodologies and tools for the optimal synthesis of biorefineries. These methods include classical process synthesis methodologies including hierarchical decomposition, mathematical programming and graphical insight.

This study aims to develop systematic process synthesis tools for the conceptual design of a biorefinery based on the work of Patel et al. (2007, 2010). The study will develop targets for a biorefinery by determining the optimal overall process mass balance by investigating the choice of end-product on the efficient utilisation of the feed-material.

2. Approach

There are three fundamental properties that are utilised on a macroscopic level to determine overall targets for biomass conversion processes, i.e. mass, energy and entropy (or exergy).

In terms of mass, an atomic species balance as a process synthesis tool provides significant insight into the efficient utilization of raw materials. It is important to note here that the overall process mass balance can be determined before any detailed simulation of the process. Here it is proposed that the designer should dictate the overall process mass balance, instead of allowing the process to dictate the mass balance. A graphical approach will be employed to determine the overall mass balances as will be explained in section 3. The energy balance can also be applied to a process without taking the details of the flowsheet or units into consideration. The energy balance gives an indication of the quantity of energy flowing into or out of the process, thus providing a target for the minimum amount of energy required or produced by the overall process. Furthermore, the second law of thermodynamics (entropy/exergy analysis) can also be employed to provide a target for processes as the second law provides a limit to the amount of work required or produced by a process. The maximum theoretical work produced (or minimum work required) from a process is related to the change in the Gibbs energy of the process.

Process design targets will be assessed and compared using three sustainability metrics: carbon efficiency, Atom Economy and E-factor (Sheldon, 2011; Constable et al., 2002). The exergetic efficiency is also used to compare various targets. All three metrics are easily calculated once the overall process mass balance is known. The definitions of the metrics are as follows:

$$Atom\ Economy = \frac{Mass\ of\ desired\ product}{Total\ mass\ of\ feed} \quad (1)$$

$$Carbon\ Efficiency = \frac{Moles\ of\ C\ in\ desired\ product}{Moles\ of\ C\ in\ feed} \quad (2)$$

$$E - factor = \frac{Mass\ of\ waste\ produced}{Mass\ of\ desired\ product} \quad (3)$$

$$Exergetic\ Efficiency = \frac{Chemical\ exergy\ of\ desired\ product}{Chemical\ exergy\ of\ feed} \quad (4)$$

Eqs.(1) to (3) provide a useful indication of raw material utilization and waste generation. Eq.(4) provides an indication of the thermodynamic efficiency of the process. The exergetic efficiency provides a target in terms of the work losses associated with a process.

3. Targets for Biorefineries

3.1. Case Study: BTL

Consider converting biomass with a chemical formula of $CH_{1.5}\ O_{0.7}$ (representing biomass with an ultimate analysis of 48 % C, 45 % O and 6 % H, which is typical for wood) into hydrocarbons (i.e. single feedstock, single product process) i.e. Biomass-to-

liquids (BTL). Hydrocarbons will be denoted as $-CH_2-$.The higher heating value (HHV) of the specified biomass is taken to be 20 MJ/kg.

The overall process mass balance can be determined for this process and as is as follows (Metzger et al., 2013):

$$1.463CH_{1.5}O_{0.7} \xrightarrow[Mass\ Balance]{} -CH_2- + 0.098H_2O + 0.463CO_2 \quad (5)$$

It is clear from Eq. (5) that for every mol of $-CH_2-$ produced, almost half a mol of carbon dioxide is produced. The carbon efficiency of the overall process can be calculated to be 68%. Since the desired product consists only of C and H atoms, the oxygen atoms in the biomass end up as carbon dioxide. Note that according to Eq. (5), BTL processes have the potential of producing water. The Atom Economy and E-factor for the overall BTL process was determined to be 39% and 1.6 respectively, suggesting that the raw material is not being used efficiently.

Therefore by deoxygenating biomass to produce liquid fuel (hydrocarbons), we end up losing 32% of the carbon resource. Furthermore, addition of further oxygen into the system will reduce the carbon efficiency. For example, adding 0.3 mol of oxygen reduces the carbon efficiency to 49%.

The process energy and work requirements can also be determined. For the mass balance given by Eq. (5), the change in enthalpy and Gibbs energy were found to be negative (ΔH = -74 kJ/mol, ΔG = -104 kJ/mol), suggesting that no external heat or work is required. In principal, energy could be produced from the process.

3.2. Van Krevelen Diagram

A graphical representation known as the Van Krevelen diagram (Prins et al., 2007) can be utilised to synthesise the overall mass balances for various biomass conversion processes. The diagram plots the atomic ratios H/C and O/C. The diagram is a useful synthesis tool as the composition of various biomass as well as other compounds containing C, H and O can be represented on the diagram. However, the limitation of the diagram is that compounds such as H_2O, O_2 and H_2 cannot be explicitly represented.

As an example, consider using a biomass with a known composition ($CH_{1.5}O_{0.7}$) to produce liquid fuels ($-CH_2-$) as discussed in section 3.1. The other components involved are H_2O and CO_2. These components are identified on the Van Krevelen diagram, except for water. Water addition or removal can be represented by a straight line with a slope of 45°. In order to move from biomass to $-CH_2-$, one would need to add hydrogen and remove oxygen. In this case, this occurs by converting the biomass into CO_2 and point A (a combination of $-CH_2-$ and H_2O). The quantities of each component can be determined from the lever rule. This mass balance corresponds exactly to the mass balance as given by Eq. 5.

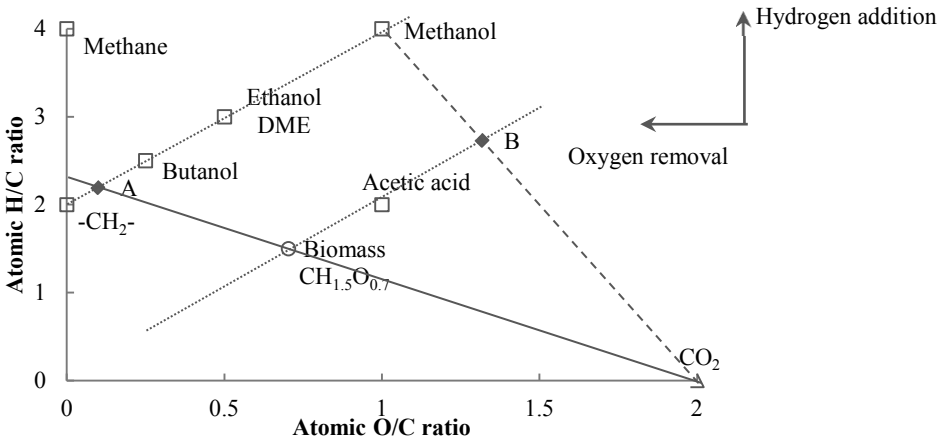

Figure 1. Van Krevelen diagram for the synthesis of biomass conversion processes

Consider a second example, producing methanol from biomass (again considering CO_2 and water as components as well). In this case, both hydrogen and oxygen addition is necessary (which suggests water addition). Point B, the point of intersection between the 45° line passing through the biomass point (the line that represents water addition) and the line between methanol and CO_2 represents the intersection point of feed materials and products. Once again, the quantities of each component can be determined from the lever rule.

3.3. Comparison of performance targets (overall mass balances) for fuel production from biomass

The overall mass balances for various fuels (methanol and hydrocarbons) produced from biomass can be evaluated either from the Van Krevelen diagram. The change in enthalpy and Gibbs energy of each mass balance can also be calculated. The metrics for each mass balance can be determined. All these parameters are summarized in Table 1.

For the case of methanol, the overall mass balance requires water as a feedstock. As previously mentioned, the BTL process could potentially produce water. It is also interesting to note that both processes have exactly the same carbon efficiency of 68%. In terms of Atom Economy and E-factor, the methanol-based process has the highest Atom Economy and the lowest E-factor (even when compared to ethanol or butanol).

This suggests that producing methanol from biomass utilises the feed material more efficiently and generates the least amount of waste (on a mass basis). From an energy and work perspective, it is clear that both processes have a negative change in enthalpy and Gibbs energy (except for the methanol process, which has a slightly positive ΔH). This implies that all processes should potentially be feasible from a heat and work perspective and the processes do not require external heat or work supply. The exergetic efficiency for all the processes are quite high, with the methanol process having the highest efficiency.

Table 1. Comparison of overall mass balances for various fuels produced from biomass.

Product	Overall Mass Balance	ΔH (kJ/mol)	ΔG (kJ/mol)	Carbon Efficiency (%)	Atom Economy (%)	E-Factor	Exergetic Efficiency (%)
Hydro-carbons (-CH_2-)	1.463 $CH_{1.5}O_{0.7}$ ⇒ 0.098 H_2O + -CH_2- + 0.463 CO_2	-73.7	-100.4	68	39	1.6	85
Methanol	1.463 $CH_{1.5}O_{0.7}$ + 0.902 H_2O ⇒ CH_3OH + 0.463 CO_2	3.6	-34.6	68	61	0.64	94

3.4. Performance targets (overall mas balances) for production of chemicals from biomass

Performance targets for the production of chemicals such as acetic acid from biomass are shown in Table 2.

Table 2. Comparison of overall mass balances for chemical produced from biomass.

Product	Overall Mass Balance	ΔH (kJ/mol)	ΔG (kJ/mol)	Carbon Efficiency (%)	Atom Economy (%)	E - Factor	Exergetic Efficiency (%)
Acetic Acid	1.951 $CH_{1.5}O_{0.7}$ + 0.537 H_2O + 0.049 CO_2 ⇒ $C_2H_4O_2$	-89.7	-109.6	100	100	0	89

In order to produce acetic acid from the specified biomass, both hydrogen and oxygen addition is necessary. However, the hydrogen addition is far less than that required for methanol, whereas the oxygen addition for both processes is equal. The consequence of this provides an overall mass balance for acetic acid production which has a carbon efficiency and Atom Economy of 100% i.e. such a process could potentially produce no waste. In fact, as can be seen from the mass balance, a small amount of carbon dioxide is required as feed material.

3.5. Targets for the co-production of fuel and chemicals

Considering the high carbon and atom economy of the acetic acid process, there may be significant advantages in co-producing acetic acid and a fuel. Consider, as an example, co-producing acetic acid and hydrocarbons (-CH_2-). The overall mass balance for such a process could be determined using the Van Krevelen diagram and by determining the limiting variable (either ΔH or ΔG). The overall mass balance is shown in Table 3.

The finding summarized in Table 3 shows that it is possible to co-produce hydrocarbon and acetic acid in a ratio of 1:0.9 with a carbon efficiency and Atom Economy of 87% and 79% respectively.

Table 3. Overall mass balance for the co-production of fuel and chemicals from biomass

Product	Overall Mass Balance	ΔH (kJ/mol)	ΔG (kJ/mol)	Carbon Efficiency (%)	Atom Economy (%)	E - Factor	Exergetic Efficiency (%)
Hydrocarbons ($-CH_2-$) and Acetic acid	$3.246\ CH_{1.5}O_{0.7} + 0.393\ H_2O \Rightarrow -CH_2- + 0.913C_2H_4O_2 + 0.419\ CO_2$	-155.9	0	87	79	0.27	87

This is a substantial increase from simply producing fuel ($-CH_2-$), where the Atom Economy was 39%. It can also be noticed that the water requirement has also decreased from the case where only acetic acid was produced. Note that the process was found to be limited by ΔG and that the process has a high exergetic efficiency.

4. Conclusions

This study introduces a graphical approach for the conceptual design of biorefineries using the Van Krevelen diagram. The approach provides a quick method of screening, evaluating and comparing various biomass conversion processes. The study establishes the overall process mass balance target for the production of various fuels as well as chemicals from biomass. The study also incorporates sustainability metrics such as carbon efficiency, Atom Economy and E-factors to assess these overall mass balance targets. The exergetic efficiency of the various overall mass balances are also determined and compared. These targets, combined with the metrics, provide meaningful insight into maximising feedstock utilisation and process efficiency. Opportunities for co-producing fuels and chemicals can also be assessed.

Abstract

Within the agro-food industry, agro-materials are converted into a range of valuable semi-finished and finished products. To reach a sustainable, resource efficient food system, the optimal process pathways converting the agro-material into these products have to be identified. To identify these pathways, a systematic Process Synthesis (PS) method is needed for the agro-food industry. This sustainability driven PS method should enable the synthesis of the optimal process pathways, converting an agro-material into a range of valuable products, producing minimal waste or low-value by-products. In this paper, the elements required for such a method are proposed. The relevance of these elements is illustrated with a simple illustrative case for the processing of tropical fruit. The proposed approach uses Multi-Objective Optimisation methods, to provide decision support for PS to decision makers in the agro-food industry. This leads to new insights in optimal pathways for processing agro-materials for the agro-food industry.

Keywords: Process Synthesis, Agro-Food Industry, Multi-Objective Optimisation, Decision Support.

1. Introduction

In a sustainable, resource efficient food system, agro-materials have to be converted into a range of valuable products. To find the process pathways that enable this optimal conversion, a systematic approach to process (re-)design is necessary.

The design of most food manufacturing processes is historically grown. In a stepwise manner, new technologies were included and processes were reshaped to meet new requirements (legislations, consumer demands, competition). At the start of the 20th century, the agro-food industry generally extracted one product from an agro-material, for example starch from potatoes and sugar from sugar beet. Environmental concerns and decreasing margins forced the industry to valorise and reduce waste streams, extracting for instance whey proteins from whey and using sugar beet pulp for yeast production (van der Padt 2014). In this approach to process design, or Process Synthesis (PS), process pathways are designed sequentially. This evolutionary approach is illustrated in the left side of Figure 1.

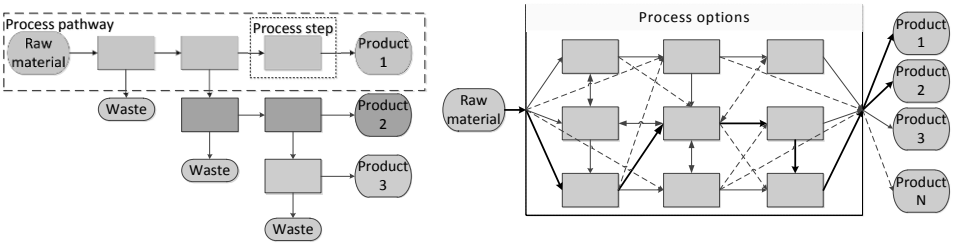

Figure 1: Evolutionary process design (left) and integral process design (right)

A more integral approach to the (re-)design of food manufacturing processes is needed to valorise the full potential of agro-materials (right side of Figure 1).

Recently, Bongers and Almeida-Rivera (2009) showed that PS methods developed for the chemical industry do not suffice in the food assembly industry. Unlike basic chemical products, the functionality and quality of food products is often dependent on their internal structure. They introduce a Product Driven Process Synthesis (PDPS) methodology, taking into account the specific nature of food products and production processes. This methodology maps and optimises a process pathway while considering consumer needs and raw material sourcing (Bongers et al. 2012).

Similar to the chemical industry, the raw materials used by the food assembly industry (such as sucrose and cream) are standardised commodities that can be purchased at the global market. The agro-food industry however, relies on agro-materials for raw materials. Renewable materials, such as agro-materials, vary more in quality than raw materials used by the chemical industry, are subject to seasonality and are only produced in certain areas (Halasz et al. 2005). Additionally, agro-materials contain many components, which in turn have functionalities like foaming capacity or emulsifying capacity. For example, a sugar beet contains sucrose, but also other sugars, proteins, cellulose, lignin and salts (Kuhnel et al. 2011). The choice to primarily extract sucrose from the sugar beet greatly influences the potential use of the other components, as, for example, the proteins and their functionality are lost during the current extraction process of sucrose. The focus on a single end product in a product oriented method like PDPS, although applicable for food products, is not effective to ensure full valorisation of an agro-material. Instead, similar to for instance (Simasatitkul et al. 2012), multiple products should be considered. This is necessary to arrive at a sustainable food production system. To find the process pathways that optimally convert an agro-material into valuable finished and semi-finished products, a range of products and alternative process pathways have to be considered. In this paper the elements relevant for such a sustainability driven PS method for the agro-food industry are proposed (section 2) and illustrated with a small illustrative case (section 3). Conclusions and ideas for future research are presented in section 4.

2. Sustainability driven PS for agro-food industry

A product portfolio has to be defined to find those process pathways that convert the agro-material into a range of valuable products. The availability and structure of the agro-material and its functionalities and a database of food and non-food products and usage are used to develop a perceived product portfolio.

Next the process pathways necessary to convert the agro-material into these products are synthesised. To manage and evaluate the number of alternatives, and choose among the better ones, decision support is needed. Meeuse (2007) states that optimisation

based mathematical programming has limited applicability for structured food products, due to the absence of rigorous models describing the relevant physical and chemical phenomena. However, to determine the boundary conditions within which a certain process pathway is preferable, only a limited level of detail is needed. Abstract representations of separation, structuring, transformation and stabilisation processes are used to build a type of superstructure. Because any process design problem has multiple objectives (Westerberg 2004), Multi-Objective Optimisation (MOO) methods are needed to find the better designs among the many alternatives and support decision making. The sustainability driven PS method we propose, consists of the following steps:

1. Develop a product portfolio based on agro-material composition and functionalities.
2. Synthesise process pathways, using abstract representations of processes, to create a superstructure.
3. Use MOO methods to find the better designs among the alternatives and support decision making.

The method should explicitly consider structure, functionalities, seasonality and regional aspects like transportation. In the following section we illustrate this method with an illustrative case for a tropical fruit process.

3. Illustrative case

Tropical fruits are harvested and can generally be directly send for export as whole fruits, or further processed into many food (e.g. snacks, drinks, ingredients) and non-food (e.g. peels as cattle-feed, seeds for landfill) products.

3.1. Product portfolio development

In this illustrative case, a limited product portfolio is considered, as it is sufficient to illustrate the proposed elements of the PS method without adding too much detail. The first step is therefore bypassed by choosing a basic product portfolio, consisting of whole fruits, fresh cut fruit and dried fruits for the local market and whole and dried fruits for the global market. Additional products like peels and seeds are considered to be waste (see Figure 2).

3.2. Synthesise process pathways

When the processor á priori decides to export whole fruits (pathway 1), he may want to stabilise ripening processes in the fruits to extend their shelf life, increase the time available for sorting and making a larger part of the fruits suitable for long distance transport. A mild heat treatment can be used for this purpose (Tharanathan et al. 2006). However, quality development in these fruits is related to the ripening processes (Tharanathan et al. 2006). Therefore, stabilising the ripening process will negatively affect the potential of the fruits that cannot be sent for export. When considering the full product portfolio instead, the ‘ripening functionality’ of the whole fruits can be maintained by omitting the stabilising step. This reduces the amount of fruit suitable for export, but increases the quality and value of the remaining product portfolio. In the illustrative case, the other options are producing fresh cut fruits (pathway 2) and dried fruits (pathway 3). An overview of the process pathways is given in Figure 2.

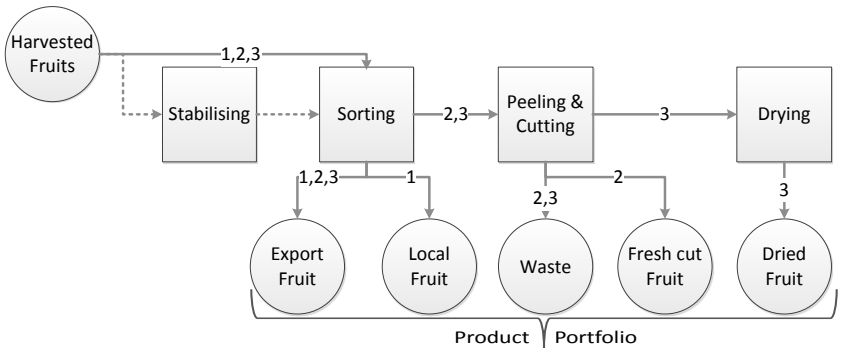

Figure 2: Product portfolio and three process pathways (indicated 1, 2, 3) of the illustrative case

3.3. Decision support

Fresh cut fruits can only be sold locally due to shelf life limitations. They will fetch a lower price than exporting whole fruits or sales of dried fruit, because they can only be sold during the fruit its season, in which the fruits are abundant and prices generally drop. Although sales of dried fruits drop when the fresh fruits are available, dried fruits can be sold outside of the season, due to their extended shelf life, and will therefore fetch a higher price. These issues are examples of seasonal and regional aspects relevant for the agro-food industry. The revenue for each product, energy input for each process step and conversion rates assumed, are shown in Table 1.

The processor has to decide which process pathway and product portfolio has his preference, based on his objectives. To enable easy graphical representation, two objectives are considered in this example. We assume the processor wants to maximise revenue and minimise energy consumption.

In Figure 3 the Pareto optimal (or efficient) solutions for the showcase are presented, and example product portfolios are shown. These solutions are the solutions that cannot be improved respective to one objective, without compromising at least one of the other objectives (Mavrotas 2009).

Table 1: Assumed revenue and energy input values and conversion rates

Revenue (€ / kg)				Energy input (kJ / kg)		
Export Fruit	Local Fruit	Fresh Cut	Dried Fruit	Sorting	Peeling	Drying
0.80	0.25	0.70	9.00	2.16	4.32	2500

Suitable for export	Obtained fresh cut after peeling	Drying ratio
30%	65%	1:10

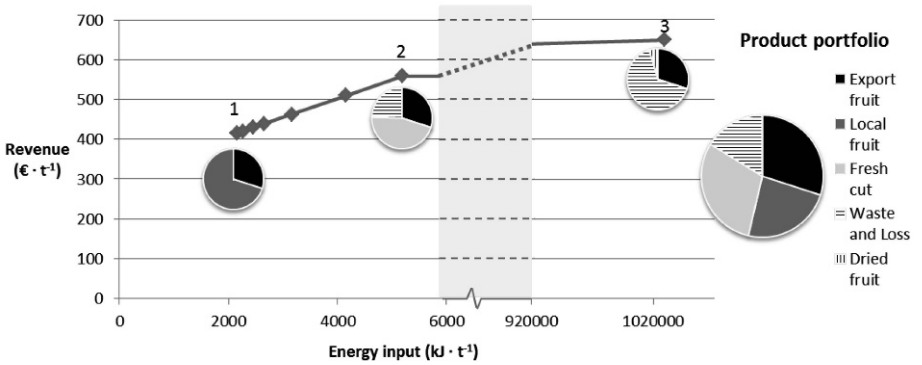

Figure 3: Pareto optimal solutions of the illustrative case, process pathways 1, 2 and 3 are indicated accordingly

Several MOO methods exist that can identify the Pareto optimal solutions. For a priori methods, the decision maker specifies his preferences before finding solutions to the problem (e.g. by assigning weights or target values to the objectives). A posteriori methods first generate the set of Pareto optimal solutions, after which the decision maker chooses from among the options. In a linear problem like this illustrative case, the weighting method will only provide extreme solutions (Mavrotas 2009). To generate a set of Pareto optimal solutions that includes non-extreme Pareto optimal solutions, the augmented ε-constraint method as described by Mavrotas (2009)Mavrotas (2009) is used. The product portfolios resulting from pathway 1, 2 and 3 are indicated in Figure 3. These are the extreme Pareto optimal solutions. The other points shown are examples of non-extreme Pareto optimal solutions.

The Pareto curve and related product portfolios provide insight in the relation between the performance of a process pathway and the resulting product portfolio. It is clear that a lot of energy is needed to produce dried fruits. On the other hand, the shelf life of dried fruits is much longer than the shelf life of fresh cut fruits, and they can be stored at ambient conditions, while fresh cut fruits require chilled storage and transportation. In this example, product portfolios with dried fruits require much more energy than product portfolios with only whole fruits or fresh cut fruits. However, if the scope is extended to include transportation, the energy requirement of portfolios containing fresh cut fruits will increase compared to the portfolios containing dried fruits. This shows the importance of considering regional aspects like transportation in PS for the agro-food industry, to prevent obtaining a sub-optimal Food Supply Chain (FSC) by optimising only the agro-food industry part of the chain.

The processor can use the Pareto-curve obtained through MOO, to determine the desired combination of process pathway and product portfolio. Decision making is influenced by the relative importance of the objectives, and preferences for a certain product portfolio. The preferred solution is influenced by external factors, such as changes in energy price and demand. An (expected) increase in energy price can cause the preferred product portfolio to shift to a portfolio with less energy consumption. These uncertainties are not yet taken into account, but should be considered, to obtain robust results with the proposed PS method, and determine the boundary conditions

within which a process pathway is preferred. This will provide new insights into optimal process pathways for the agro-food industry, and helps to identify potential for process development.

4. Conclusions and future research

A PS method for systematic design of process pathways for Agro-Food industry is proposed. Starting point for the method is the potential of the agro-material, related to its structure and functionalities. MOO methods are used to find Pareto optimal solutions to the problem and enable evaluation of the alternative process pathways to support decision making. This sustainability driven PS method should explicitly consider structure, functionalities, seasonality and regional aspects like transportation, as is illustrated by the case. Sensitivity analysis is needed to determine the boundaries within which a certain process pathway is attractive. The decision support provided by this abstract representation leads to identifying opportunities for process development. This link between decision support and process engineering provides a novel way of PS.
The potential of the proposed method needs to be explored by application to real life industrial cases, using different agro-materials. The elements relevant for the agro-food industry should be taken into account. Additionally, the agro-food industry is only one part of a FSC. Extending the method, considering the entire FSC, will prevent finding optimal solutions for the agro-food industry leading to sub-optimal FSCs.

Abstract

In this study, an integrated process of dimethyl carbonate (DMC) and ethylene glycol (EG) production from biomass was proposed. The process was started from biomass gasification, CO_2 separation and CO_2 conversion to ethylene carbonate. DMC and EG were produced via transesterification using reactive distillation and extractive reaction. A variety of key parameters of each part was examined to optimize operating condition, which is focused on heat consumption. DMC and EG can achieve 99.5 % mole of purity. The overall production can sustain itself without any external heat sources by using biomass combustion, and all performance indicators were considered under the energy self-sufficient conditions. The ratio of biomass fed to the gasifier and the combustor was found to be 0.34:0.66 (under energy self-sufficient conditions) where the C, H and O atom efficiencies of the process achieved were 32.87, 48.96 and 37.72%, respectively. Since all energy was supplied by biomass itself, the process was considered as carbon neutral with a fraction of carbon dioxide fixation from biomass into chemicals of 0.24.

Keywords: Aspen Plus; Biomass gasification; Process design; Process simulation

1. Introduction

Over several decades, greenhouse gases such as carbon dioxide (CO_2) and methane (CH_4) have been concerned as a crucial problem because it causes global warming and climate change (Song, 2006, Xu et al., 2010). Many attempts have been paid to search for new processes to utilize CO_2 (Aresta et al., 2007). Recent researches have shown that utilization of CO_2 as a chemical feedstock can produce a variety of chemical products via chemical and electrochemical processes (Olah et al., 2009). The products are for example dimethyl ether, formic acid, methane or DMC (Sakura et al., 2007).

DMC is one of significant chemical products as it can be used as methylating reagent, solvent, intermediate,or fuel additive etc. (Delledonne et al., 2001, Tundo et al., 2002). DMC can also be produced by various types of reaction pathways which have potential for utilizing the CO_2. One of those is the reaction between CO_2 and methanol. However, in this manner, it has to be operated at critical temperature and pressure (Guo et al.,

2008), leading to high energy consumption. Hence, other reaction pathways such as urea route, propylene carbonate route and ethylene carbonate route are currently explored.

The primary objective of this research is to develop a new DMC and ethylene glycol production from biomass via transesterification of ethylene carbonate and methanol. ASPEN Plus simulator was employed in order to optimize operating conditions in each main section, i.e. biomass gasification, methanol synthesis, CO_2 separation, ethylene carbonate synthesis, and DMC and EG synthesis, by focusing on heat consumption optimization. The atom efficiency and amount of CO_2 fixation into chemical is evaluated under energy self-sufficient condition where the process could sustain itself without any external heat source by partially utilizes biomass to generate heat.

2. Process Description

Figure 1 shows a simplified process flow diagram of DMC and EG production from biomass. Biomass was fed to the gasifier where autothermal reforming takes place. The product stream was further fed to CO_2 separation unit to produce a mixture of H_2 and CO before entering to the methanol production process. The separated CO_2 was utilized by reacting with ethylene oxide to produce ethylene carbonate. DMC and EG was produced via transesterification of methanol and ethylene carbonate in reactive distillation. In the purification process of DMC, an extractive distillation of DMC/methanol can be used to separate azeotropic mixture of DMC/methanol. For this work, aniline is used as entrainer in the extractive distillation as proposed by Hsu et al. (2010). In order to operate under energy self-sufficient condition, biomass was splitted and sent to a combustor for providing heat and electricity.

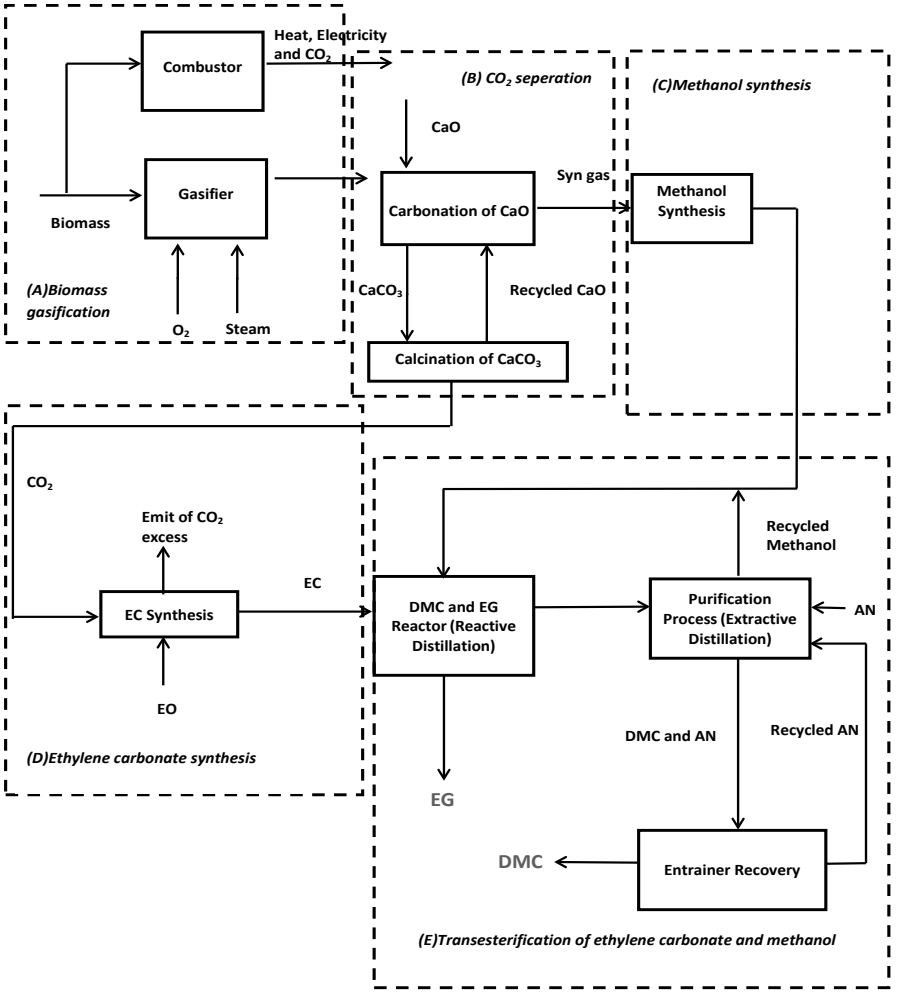

Figure 1 Diagram of integrated process of DMC and ethylene glycol production from biomass

3. Results and Discussion

3.1 Process design

Biomass gasification

The gasifier temperature of 900 °C was selected in this study following the previous report (Franco et al., 2013) which showed that this temperature favors energy and carbon conversions, as well as gas yield. The target of the gasifier in this study is to produce a mixture of H_2 and CO with H_2/CO of 2 for further methanol synthesis. The amounts of H_2O and external oxygen (represented by steam to biomass ratio (SBR) and equivalence ratio (ER), respectively) were adjusted to obtain H_2/CO ratio of 2 accompanying to balance endothermic and exothermic heat for the operation of energy self-sufficient gasification. The investigation to find suitable SBR and ER at the temperature of 900 °C found that SBR of 1.77 and ER of 0.718 could satisfy H_2/CO ratio of 2 and heat duty of 0.

Carbon dioxide separation
CaO was used as CO_2 sorbent. The $CaCO_3$ was regenerated in a calcination reactor. RGibbs model with the Peng-Robinson EOS property method was used to model both carbonation and calcination reactors w. The carbonation and calcination reactors were operated at a pressure of 1 bar with suitable operating temperatures of 600 and 860 °C, respectively.

Ethylene carbonate synthesis
The optimum operating condition for the ethylene carbonate reactor was found to be 30 °C and 25 bar in order to achieve high yield of ethylene carbonate.

Transesterification of methanol and ethylene carbonate for DMC and ethylene glycol production
The design flow sheet of this section integrated the reaction section and the separation section including reactive distillation reboiler, extractive distillation reboiler and entrainer recovery distillation reboiler by minimizing energy consumption.

- Design of reactive distillation column

For the given product specifications, the configuration of reactive distillation column reported by Hsu et al. (2010) was firstly adopted in our simulation. With respect to reactive distillation reboiler, recycled methanol flow rate seems to be the most important factor that affects the reboiler heat duty. The optimal design flowsheet of this column indicated that the output stream of EG could achieve mole fraction purity of 0.995 as the bottom product with an overall EG yield of 0.995. As the process was set up using optimal design specifications, the lower energy consumption in our proposed reactive distillation comparing to the previous study (Hsu et al., 2010) could be achieved.

- Design of extractive distillation and entrainer recovery column

Considering the top stream of reactive distillation column (63 °C, 1 bar, methanol mole fraction of 0.833), azeotropic composition of DMC and methanol could be found. Thus, the process was set up by using optimal design specifications of both columns, so the lower energy consumption in our proposed extractive and entrainer recovery comparing to the previous study (Hsu et al., 2010) could be obtained. Energy consumption was optimized by adjusting distillate rate of two distillation columns as process specifications were set up. According to extractive distillation, the following steps of calculation are applied to obtain a near optimal design: 1) Place the heavy-boiling entrainer ($N_{Aniline}$) and mixture of methanol and DMC feed location ($N_{methanol+DMC}$) on the top and the lowest of the extractive section, and 2) vary the number of stages in the rectifying, extractive and stripping section.

3.2 Overall integrated process of the optimal base case study
According to the suitable operating condition of each section including biomass gasification, CO_2 separation, methanol synthesis, ethylene carbonate synthesis, and DMC synthesis, the energy requirements of different units were calculated. Atom efficiency (or atom economy) was chosen as a criterion for considering reaction efficiency. For the base case study, it is found that the values of atom efficiency are C: 73.20, H: 92.95, O: 58.69. However, note that with this criterion definition, atom efficiency is not referring to energy efficiency for the overall chemical process.

3.3 Overall integrated process with an operation under energy self-sufficient condition

The operating condition and system performance of DMC production from biomass under energy self-sufficient condition is summarized in Table 1. The appropriate fraction of biomass fed to combustor and gasifier should be 0.66 and 0.34, respectively, in order to sustain the energy of overall process. However, the amount of CO_2 from CO_2 separation unit is more than that required for chemical production, an excess of CO_2 was purged from the chemical production process, therefore, a fraction of total CO_2 emission (combustion and purge) from biomass input is 0.76, while carbon dioxide fixation into chemicals is 0.24. Considering atom efficiency, it is found that the atom efficiencies under energy self-sufficient conditions are C: 32.87, H: 48.96, O: 37.72.

Table 1 Operating conditions and system performance of DMC production from biomass under energy self-sufficient condition

Operating conditions and performance indicators	
Overall biomass mass flow rate	1,100 (kg/h)
Biomass mass flow rate to the gasifier	376.68 (kg/h)
Biomass mass flow rate to the combustor	723.32 (kg/h)
Biomass fraction to the gasifier	0.34 (-)
Overall product yield	43.76 (wt.%)
Carbon atom efficiency	32.87 (%)
Hydrogen atom efficiency	48.96 (%)
Oxygen atom efficiency	37.72(%)
CO_2 fixation to chemicals	0.24 (-)

4. Conclusion

In this study, the simulation of overall process for DMC and ethylene glycol production from biomass was developed using the ASPEN Plus simulator. The process consists of five main sections i.e. biomass gasification, CO_2 separation, methanol synthesis, ethylene carbonate synthesis and DMC synthesis. The key performance indicators of biomass to chemical i.e. 1) atom efficiency under energy self-sufficient condition and 2) carbon dioxide fixation from biomass into chemicals under energy self-sufficient condition were defined. It is found that the atom efficiencies are C: 32.87, H: 48.96, O: 37.72 with carbon dioxide fixation from biomass into chemicals value of 0.24 could be achieved under energy self-sufficient conditions.

Abstract

Recently, carbon dioxide (CO_2) emissions to the atmosphere have become an issue for many industries, especially coal-fired power plants, due to their contribution to global warming. Many research projects were directed towards the development of effective solvents to combat these severe environmental problems. Aqueous ammonia is a solvent that has been proposed as a replacement to conventional aqueous monoethanolamine (MEA) in post-combustion CO_2 capture. In this study, an aqueous ammonia based CO_2 capture process was simulated by Aspen Plus simulator for capturing about 90 % by weight of CO_2 with a purity of 98 % by weight from a post-combustion flue gas based on a 180 MW_e coal-fired power plant. The simulation of this process was performed to meet the ammonia emission standard which allowed less than 2 kg/hr of ammonia emission. An ammonia-based simulation process consists of two parts: the CO_2 absorption process and the ammonia abatement process. To minimize the energy consumption of the process, heat integration was applied by adding a Heat Exchanger Network (HEN). HEN was designed by stage-wise model (Yee and Grossmann, 1990) and validated using the Aspen Plus simulator. Furthermore, capital investment and annual costs were investigated using Aspen Plus and some economic parameters to assess the feasibility of this process based on standard environmental regulations. The results showed that the performance of actual aqueous ammonia plants using process integration reduced the energy requirement from a "non-integrated process" by 58 % on the heaters, coolers and electrical units, resulting in a theoretical decrease of 47 % in the annual cost of utilities, compared to the cost without process heat integration.

Keywords: Post Combustion CO_2 Capture, MEA Scrubbing Process, Ammonia Scrubbing Process, Simulation Modelling, Heat Exchanger Network.

1. Introduction

Post-combustion capture (PCC) with chemical absorption has been considered as a feasible way for capturing huge amount of CO_2 emissions from coal-fired power plants. Commercially available chemical absorption technologies are mainly based on amines, especially monoethanolamine (MEA) due to the advantages of stable operation, high reactivity and high absorption capacity. However, the MEA process suffers from several critical disadvantages, such as high energy requirement for solvent regeneration and amine degradation as a result of high temperature in the regeneration section which is around 120 ºC. These facts cause the process to be unattractive for large scale operation. Compared to MEA, aqueous ammonia has advantages of high CO_2 loading capacity, no absorbent degradation and a low temperature in regeneration section (85-95 ºC) where

low-grade thermal energy can be used. Moreover, aqueous ammonia has the potential to capture CO_2, SO_2 and NO_x in the flue gas simultaneously. However, ammonia abatement is a necessary system for the aqueous ammonia process as ammonia can be volatile at operating conditions. In this study, an aqueous ammonia flow sheet for post-combustion CO_2 capture was simulated and optimized using a commercial simulation program (Aspen Plus). Then, a process heat integration by HEN using stage-wise model with General Algebraic Modelling System (GAMS) software was applied to optimize the energy requirement of heaters and coolers of the process. Finally, Aspen Plus was also used to calculate the investment cost to assess the feasibility of the aqueous ammonia based process for CO_2 capture.

2. Ammonia-based scrubbing system.

In this study, the Redlich–Kwong equation of state and the Electrolyte-NRTL model were used to compute the properties of the vapour phase and liquid phase, respectively. Flue gas from a 180 MW_e coal burning power plant with a flow rate 32 of ton/hr, and a gas composition of 84 % N_2, 12 % CO_2, and 4 % water vapour in standard volume (Khonkaen, 2014) was simulated in this study. The flow sheet development was divided into two parts including the CO_2 capture system and the ammonia abatement system.CO_2 capture system was designed to capture CO_2 about 90 % by weight from the flue gas. The flowsheet was optimized by varying the concentration of ammonia solution in a range between (2 and 8) wt. % and CO_2 lean loading of ammonia solution from 0.20 to 0.35 mole CO_2/mole NH_3. Then, 98 % by weight of CO_2 purity entering storage section was specified by varying the reflux ratio (mass), distillation rate and liquid holdup in the stripping section. The ammonia abatement system was used to recycle the volatized ammonia and also minimize ammonia vent to the atmosphere due to restriction of environmental standards. Vented ammonia flow rate was kept below 2 kg per hour based on ammonia emission standards. This limitation was set as the target of the absorber in the ammonia abatement system and achieved by varying aqueous ammonia concentration at the high loading. Obviously, a sequential optimization was observed (Zhang and Guo, 2013).

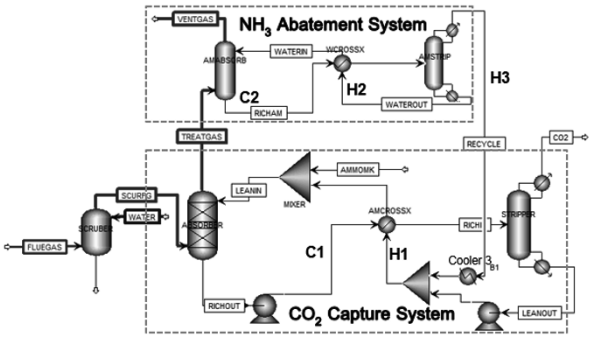

Figure 1. Simplified process flow diagram of aqueous ammonia-based scrubbing system.

2.1. Carbon-dioxide capture system

A simplified process flow diagram of CO_2 capture system was shown in Figure 1. At first, flue gas at high temperature from coal-fired power plant was cooled down to 46.1 ºC with a pressure near atmospheric pressure (115.1 kPa) in the scrubbing section by cooling water before entering to the absorber. Then, the flue gas with CO_2 contacted the

aqueous ammonia solution as counter-current flow to separate CO_2 from the flue gas stream. In the absorber column section, the equivalent equilibrium stages of the absorber were set at 20 stages. The packing type was chosen as DZ-II-750Y for economic evaluation, one of the CY structured packings, which has high mass transfer efficiency (Haroun et al., 2012; Zhao et al., 2011).

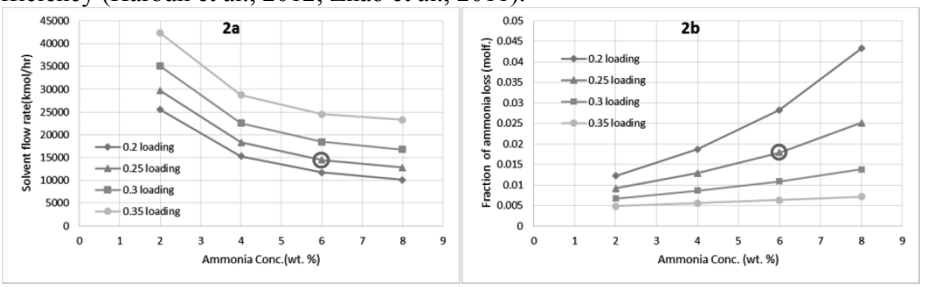

Figure 2a/2b.Optimization of ammonia solvent in the CO_2 capture system.

It is known that the annual cost is mainly due to the energy requirement from the regeneration of the solvent and utilities. Therefore, optimization of the solvent usage was adopted to find minimum-energy-usage condition for CO_2 capture process. Solvent circulation rate and fraction of ammonia loss (TREATGAS) were effectively related to the overall energy requirement of the system as shown in Figures 2a and 2b. Solvent flow rate and the fraction of ammonia loss were optimized by varying the ammonia concentration and CO_2 loading based on 90% CO_2 recovery. The result showed more ammonia concentration in the solvent flow caused more fraction of ammonia loss in TREATGAS stream resulting in more energy requirement in the ammonia abatement system. Increasing the ammonia concentration led to a decrease in the required solvent flow rate. The crucial parameter which affected the energy performance of ammonia-based system was the loading. Loading refers to the moles of CO_2 carrying species over the moles of NH_3 carrying species as specified in Equation 1.

$$\textbf{Loading} = \frac{[CO_2] + [HCO_3^-] + [CO_3^{2-}] + [NH_2COO^-]}{[NH_3] + [NH_4^+] + [NH_2COO^-]} \quad (1)$$

In case of increasing loading in the LEANIN stream, the fraction loss of ammonia decreased while the solvent flow rate deceased because of reduction in term of ammonia species and the availability to capture CO_2 from the flue gas. The optimal concentration of ammonia solution and CO_2 lean loading at 111 kPa and 25 ºC were 6 wt. % and 0.25 mole CO_2/mole NH_3, respectively. The optimal condition resulted in a solvent flow rate and ammonia loss equal to 14666 kmol/hr and 16.75 kmol/hr, respectively. Rich CO_2 ammonia solution had a loading of approximately 0.36 mole CO_2/mole NH_3 left from the bottom of the absorber to the stripping section for regeneration. The rich CO_2 ammonia solution was pumped and heated up at around 120 kPa and 60 ºC, respectively, before entering to the stripper. Heat from the reboiler was used to dissociate the chemical bonds of the formed carbamates and other compounds between ammonia and CO_2. Then, over 98 wt. % of CO_2 purity was stripped out at the top and the regenerated ammonia that exited from the bottom of the stripper. The condenser and reboiler temperatures were simulated in the ranges of (25 to 30) ºC and (85 to 95) ºC, respectively. Ammonia solution was mostly recycled back to the absorber section in order to minimize the ammonia usage. Ammonia solution and make-up water were used to maintain the concentration and CO_2 lean loading of the aqueous ammonia solution.

2.2. Ammonia abatement system

Process flow diagram of ammonia abatement system is shown in Figure 1. This system consists of an absorber to remove ammonia from the treated flue gas (TREATGAS stream) by using water, and a stripper to recover ammonia from the used absorbent (RICHAM stream). The TREATGAS stream is the flue gas with some ammonia contamination, leaves the absorber in CO_2 capture system and is then treated by counter-current flowing water stream with low-ammonia concentration and high CO_2 loading. The number of equivalent equilibrium stages of the absorber of this abatement system was set at 15 stages. The WATERIN stream at ambient condition with the flow rate, ammonia concentration and CO_2 loading of 832 kmol/hr, 9 ppm (by mass) and 1.2 mole CO_2/mole NH_3, respectively, were used to capture volatized ammonia in TREAT GAS stream from the CO_2 capture system. The flow rate of the treated flue gas (VENTGAS stream) in this abatement system was around 1.7 kg/hr which was acceptable for environmental emission standards. The used absorbent stream with rich ammonia (RICHAM stream) from the bottom of the absorber was regenerated in the stripping section. After regeneration, the stream with rich ammonia (RECYCLE stream) from the top of stripper of the abatement system was recycled to the absorber of CO_2 capture system to save ammonia usage in the overall process. The regenerated absorbent stream with lean ammonia (WATEROUT stream) from the stripper of the abatement system was regenerated and sent to the ammonia absorber to minimize water usage in ammonia abatement system. The most important operating conditions of the main streams are shown in Table 1.

Table 1. Optimal operating parameters of main streams in overall CO_2 capture process.

Streams	Optimal Operating Conditions
FLUEGAS	32 ton/hr, at 46.1ºC and 115.1 kPa
LEANIN	270 ton/hr, 6 wt. % NH_3 and 0.25 CO_2 loading at 25 ºC and 111kPa
TREATGAS	26 ton/hr, at 29 ºC and 101.325 kPa
VENTGAS	25.5 ton/hour at 32 ºC and 101.325 kPa
CO_2	6 ton/hr, 98 wt. % CO_2 at 25 ºC and 101.325 kPa

3. Process heat integration

Process heat integration is an important tool to reduce energy usage in the designed process by applying HEN. In the scratch process has three hot process streams from the scratch; H1, H2 and H3, and two cold process streams; C1 and C2, from the simplified CO_2 capture process, as shown in Figure 1, consumed heating and cooling duties of 24567 and 25284 kW, respectively. Heat integration was applied by GAMS program using the stage-wise model (Yee and Grossmann, 1990), as shown in Figure 4. The result from the GAMS model was the conceptual HEN design as shown in Figure 5a with two exchangers for H1-C1 and H2-C2 matches and heating and cooling duty savings of 9987 and 10705 kW, respectively. This conceptual process design with process heat integration, shown in Figure 5a, was validated by Aspen Plus (Figure 5b) simulator to ensure the feasibility of the process. The results showed that the relative error between the conceptual process and the validated process was very small.

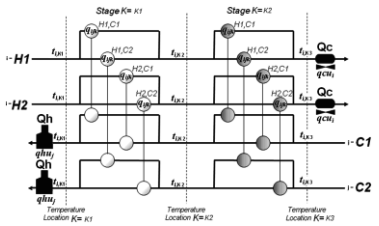

Figure 4.Stage-wise model for HEN (Yee and Grossmann, 1990)

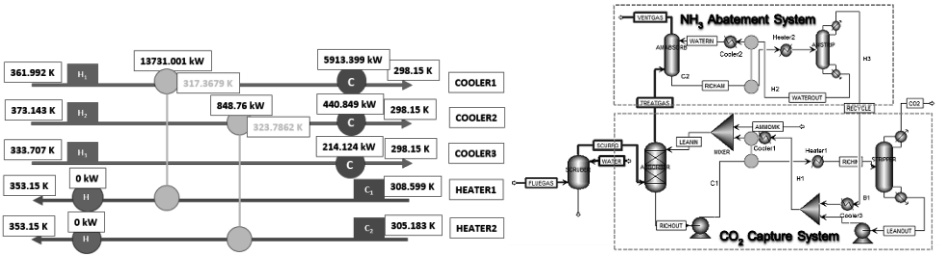

5a 5b

Figure 5a/b.Conceptual process integration from GAMS and validated process flow diagram of improved aqueous ammonia-based scrubbing system (Aspen Plus) with process heat integration.

The validated result showed that the energy requirement of the overall system was reduced by 58.1% compared to the ammonia-based process without process integration. The saving in hot and cold utilities were 59.3% and 57.7%, respectively as shown in Table 2. Furthermore, the overall energy used in regeneration of both CO_2 capture system and NH_3 abatement system was 8601 kJ/kg CO_2 which was a bit higher than the value reported as 8472 kJ/kg CO_2 by Zhangand Guo (2013) for a 550 MW plant size.

4. Economic evaluation

The economic evaluation of the process indicated the feasibility of the process design. In this study, the economics of the ammonia process was divided into two parts including the capital investment and the annual costs of the plant. The capital investment and annualized operating costs of the base-case process and the integrated process by process heat integration were shown in Tables 2 and 3. The purchased equipment cost was mainly performed on a commercial package in Aspen Plus v.8.6. The capital investment and operating costs were estimated using basic utility costs reported by Hassan et al. (2007). The result showed that the annual cost of the integrated process was reduced by 26.5% and resulted from savings in utility usage in the system of close to 58 %. The capital cost of integrated process increased by 39% compared to the process without heat integration. The overall results illustrated that the optimization of the based-case process and process integration application were beneficial in terms of savings in energy requirement and operating expenses of the process compared with basic process.

Table 2. Energy requirement in section for aqueous ammonia process

Parameters	Base Case	Integrated Case
Electricity (kW)	231	306
Hot Utility (kW)	24567	9987
Cold Utility (kW)	25283	10705
Overall Duty (kW)	50081	20998

Table 3. Economic evaluation of aqueous ammonia based processes

Parameters	Base Case	Integrated Case
Purchased Equipment Cost (MMUSD)	2.96	4.12
Capital Investment Cost (MMUSD)	21.51	29.95
Annual Cost (MMUSD/year)	6.72	4.94
Total Utilities Cost (MMUSD/year)	3.49	1.84

Table 4 Assumptions used for the economic estimation(Hassan et al., 2007)

Operating cost assumptions	Rate	Rate units
Electricity	0.06	USD/kWh
Industrial cooling water	0.015	USD/m^3
Steam at 100 Psi	9.18	USD/Ton

Conclusion

In CO_2 capture ammonia system, the optimal concentration and CO_2 lean loading of aqueous ammonia solution were found to be 6% by weight and 0.25 mole CO_2/mole NH_3. In the ammonia abatement system, the optimal concentration and CO_2 loading were 6 ppm by weight and 1.2 mole CO_2/ mole NH_3. These conditions led to the minimum energy consumption. The overall optimal energy used in the regeneration of both CO_2 capture system and NH_3 abatement system was 8601 kJ/kg CO_2. The study focused also on the comparison of energy requirement and capital investment cost of ammonia based process from post-combustion carbon dioxide capture process with and without heat integration based on the flue gas from a coal burning 180 MW_e power plant. The conceptual HEN design using the GAMS model and the validated one using the Aspen Plus simulator were in good agreement in terms of heat reduction. Energy requirement and utility costs savings of the integrated process compared to the basic process were about 58.1 % and 47.3 %, respectively. The total capital investment cost of the integrated process was 29.95 MM$ and the annualized operating costs were less than the ones from the base-case process by about 1.78 MM$/yr. Finally, the regeneration temperature was around 85 to 95 ºC where low-grade thermal energy could be utilized.

Abstract

The purification of bioethanol fuel requires an energy demanding separation process to concentrate the diluted streams obtained in the fermentation stage and to overcome the azeotropic behaviour of ethanol-water mixture. The classic separation sequence consists of three distillation columns that carry out several energy demanding tasks: pre-concentration of ethanol, extractive distillation and solvent recovery.

To solve this problem, we propose a novel heat pump assisted extractive distillation process taking place in a dividing-wall column (DWC). In this configuration, the ethanol top vapour stream of the extractive DWC is recompressed from atmospheric pressure to over 3.1 bar (thus to a higher temperature) and used to drive the side reboiler of the DWC, which is responsible for the water vaporization. The results show that the specific energy requirements drop from 2.07 kWh/kg (classic sequence) to only 1.24 kWh/kg ethanol (VRC assisted extractive DWC), thus energy savings of over 40 % and 24 % reduced total annual costs are possible, as compared to the conventional process.

Keywords: extractive distillation; dividing-wall column; heat pump; energy savings

1. Introduction

The industrial production of bioethanol relies on various routes: corn-to-ethanol, sugarcane-to-ethanol, basic and integrated lignocellulosic biomass-to-ethanol. In all cases, the raw materials undergo several pre-treatment steps before entering the fermentation stage where bioethanol is produced. A common feature is the production of diluted bioethanol (typically 5-12 %wt ethanol) that is further concentrated to reach the requirements of the international bioethanol standards (Vane, 2008). To reach the purity targets (max. 0.2 %vol water), an energy demanding separation is needed in practice, in order to overcome the presence of the binary azeotrope ethanol-water (95.63 %wt ethanol). The separation is typically carried out by distillation, the first step being a pre-concentration distillation column (PDC) that increases the ethanol content from 5-12 %wt up to 91-94 %wt (Frolkova and Raeva, 2010). The second step consists of the ethanol dehydration, up to concentrations exceeding the azeotropic composition. Quite a number of separation alternatives are available as described in the open literature: pervaporation, adsorption, pressure-swing distillation (PSD), extractive distillation

(ED), azeotropic distillation (AD), and hybrid methods combining these options (Vane, 2008; Frolkova and Raeva, 2010). Among them, extractive distillation (ED) is still the option of choice in case of large scale production of bioethanol fuel (Kiss and Ignat, 2012). Typically, ED is performed in a sequence of two columns, one being the extractive distillation column (EDC) which separates ethanol, while the other one is the solvent recovery column (SRC) that recovers the mass separating agent (MSA) which is recycled back in the process. Further improvements to the distillation process were proposed, with the aim to increase the energy efficiency of bioethanol purification: e.g. ED process optimization (Kiss and Ignat, 2013); thermally coupled distillation columns; azeotropic and extractive dividing-wall columns (Kiss, 2013).
This work proposes a novel heat pump assisted ED process that efficiently combines vapour recompression (VRC) heat pump with dividing-wall column technology, and allows a major reduction of the energy requirements. A 100 ktpy plant is considered, processing a feed with 10 %wt ethanol, by extractive distillation using ethylene glycol as solvent. Simulations were carried out in Aspen Plus, using NRTL model, and for a fair process comparison the same approach was used as in previous studies (Kiss, 2013).

2. Problem statement

For its use as biofuel or additive, bioethanol must have a purity of min. 99-99.8 %wt but this can be reached only by paying a large energy penalty. Although most of the water present in the diluted ethanol/water mixture (5-12 %wt) from the fermentation step can removed by ordinary distillation, the ethanol purity is limited to max. 95.6 %wt due to the presence of its binary azeotrope with water. Using process optimization and advanced distillation technologies, the energy requirements were reduced by 20 % from about 2.5 down to almost 2 kWh/kg bioethanol (Kiss, 2013). However, to put this into perspective, the energy needed for purification is still considerably high, especially when taking into account the energy content of the ethanol fuel (7.45 kWh/kg fuel).
To solve this issue we integrate VRC technology with an extractive dividing-wall column (E-DWC) capable of purifying bioethanol in a single distillation unit. As shown later, this integration unit allows significant energy savings, less CO_2 emissions and a reduced footprint, as compared to the conventional separation process.

3. Results and discussion

3.1. Classic extractive distillation process

Figure 1 presents the process flowsheet, including the mass and energy balance along with the key process parameters of the classic ethanol purification sequence based on extractive distillation (Kiss and Ignat, 2013).
The process consists of three distillation columns: pre-concentration distillation (PDC), extractive distillation (EDC) and solvent recovery (SRC). The PDC unit separates water as bottom stream and a near-azeotropic composition mixture as distillate (91%wt ethanol being the optimal value as reported by Kiss and Ignat, 2013). The second column (EDC) uses ethylene glycol as solvent that is added at a solvent-to-ethanol ratio of 1.25 mol/mol, on a stage above the feed stage of the near azeotropic ethanol-water mixture. The presence of the solvent changes the relative volatility of ethanol-water such that their separation becomes possible. High purity ethanol is collected as top distillate product of the EDC, while the bottom stream contains solvent and water. The third column (SRC) in the sequence separates the remaining water as distillate and completely recovers the solvent as bottom product, which is cooled in a feed-effluent heat exchanger (FEHE) and then recycled back to the extractive distillation column.

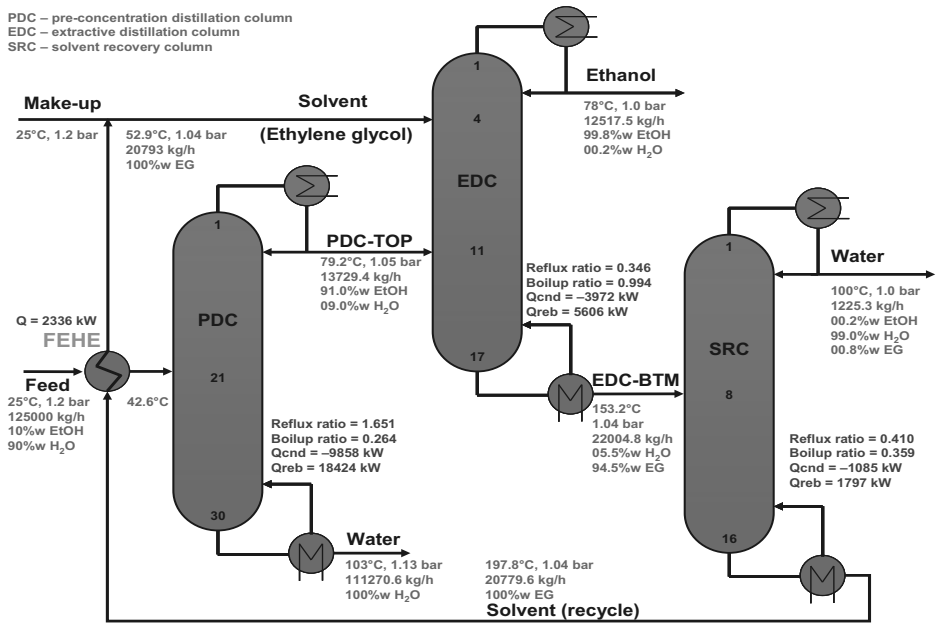

Figure 1. Flowsheet including key process parameters of the classic bioethanol separation by extractive distillation (the numbers on columns indicate the top, bottom and feed stage)

3.2. Vapour recompression assisted extractive DWC

Heat pump assisted distillation can be applied to classic columns (Kiss et al., 2012) but only to a lesser extent to dividing-wall columns (Chew et al., 2014) as the temperature span across the DWC is larger. Kiss et al. (2012) provided a useful scheme for the quick selection of appropriate heat pumps, while Plesu et al. (2014) introduced a criterion depending on the Carnot efficiency to decide whether a heat pump is worth considering:

$$Q / W = 1/\eta = T_c / (T_r - T_c) > 10 \quad (1)$$

where Q is the reboiler duty, W the work provided, while η is the Carnot efficiency, T_r the reboiler temperature and T_c the condenser temperature. When the Q/W ratio exceeds 10, then a heat pump should be considered, while when the ratio is lower than 5 then using a heat pump will not bring any benefits (Plesu et al., 2014). In case of the ethanol separation, the ratio Q/W is 16 (T_r=100 °C, T_c=78 °C) which is clearly favourable.

Notably, the use of a DWC was already explored as an attractive process alternative for bioethanol purification (Kiss and Ignat, 2012). Hereby we go further, by combining the E-DWC technology with vapour recompression (VRC) in order to increase more the energy efficiency. Figure 2 presents the flowsheet of the novel process based on VRC assisted extractive distillation in a DWC. For the reader's convenience, the mass and energy balance, as well as the key process parameters are also provided.

The feed side (prefractionator) acts as the PDC unit of the classic sequence. Water is removed as liquid side stream, but an additional side reboiler is needed in order to return the required amount of water vapours to the column. The liquid feed stream is fed on top of the prefractionator side, thus serving as a reflux to the PDC section. The vapour leaving the feed side of the E-DWC is enriched in ethanol. Solvent is added at the top of the E-DWC, this section acting in fact as the EDC unit of the conventional sequence.

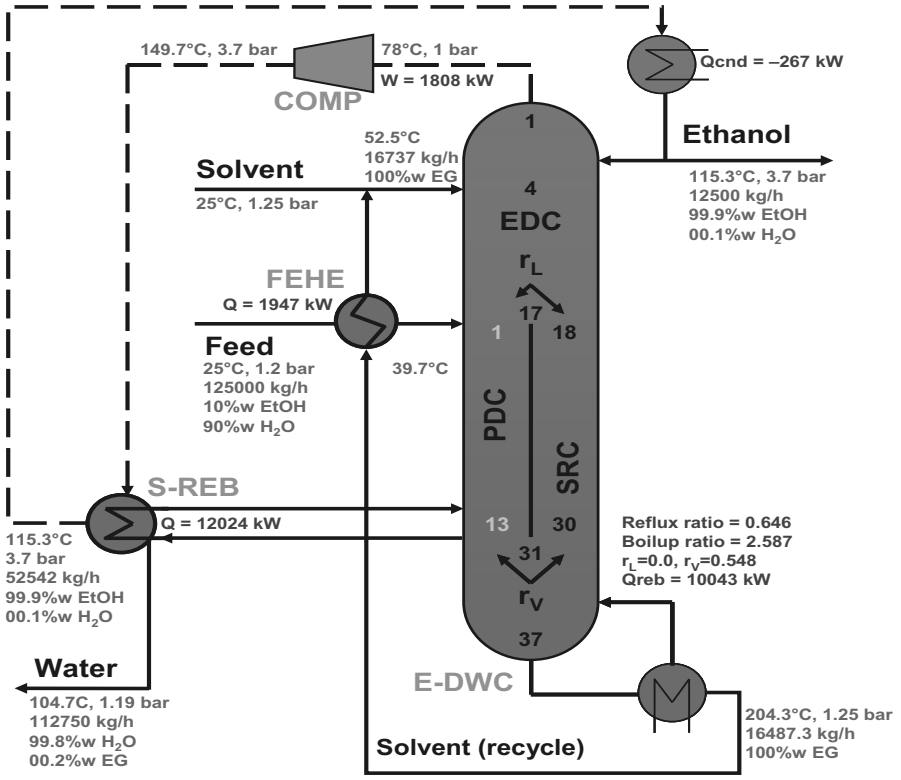

Figure 2. Flowsheet including the mass balance and key parameters of the novel process for bioethanol purification based on VRC assisted extractive distillation in a DWC.

Ethanol is separated here as high purity vapour distillate that is compressed to a higher pressure and temperature level, and then used to drive the side reboiler of the column and being eventually condensed and removed as main product. The liquid flowing down the top section (EDC) is collected and distributed only to the (SRC) side opposite to the feed side and further down the bottom of the E-DWC. This complete redistribution of the liquid flow is required in order to avoid the presence and loss of solvent on the feed side (PDC section). In the SRC section, the solvent is separated as bottom product then cooled in a heed-effluent heat exchanger (FEHE) and recycled to the E-DWC unit. The vapour from the bottom of the E-DWC to the lower part of the dividing-wall is not sufficient for the PDC section, thus the need for an additional side reboiler – which can be driven by a heat pump (VRC in this case). In spite of the high degree of integration of E-DWC, the controllability of such systems is satisfactory (Tututi-Avila et al., 2014).

3.3. Sensitivity analysis

Integrating a vapour recompression heat pump with an extractive DWC requires the setting of the appropriate discharge pressure from the compressor. Figure 3 shows the dependence of the compressor duty and the inverse of the log-mean temperature difference (LMTD) on the discharge pressure of the compressor involved by the VRC system. In terms of reducing the VRC costs, the compressor duty should be as low as possible (smaller and cheaper compressor), while the LMTD should be as high as possible (larger driving force and smaller heat exchanger).

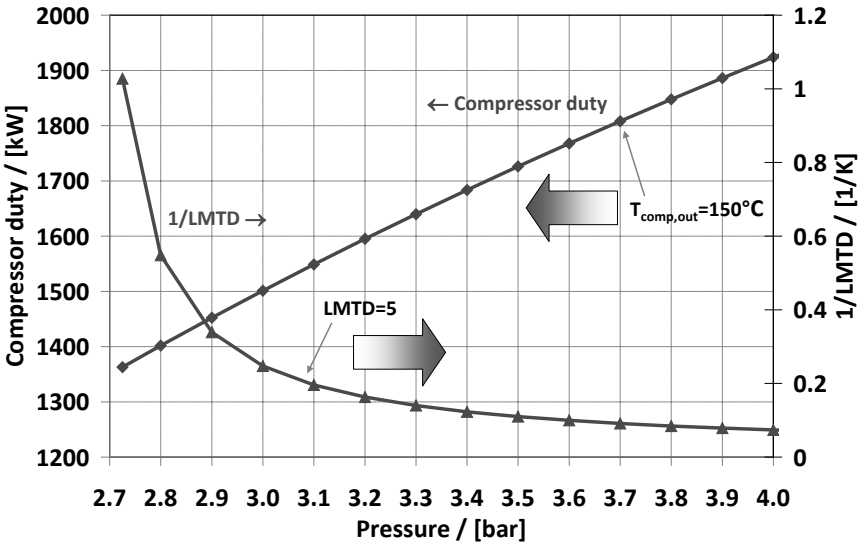

Figure 3. Dependence of compressor duty and the log-mean temperature difference (LMTD) in the side-reboiler, on the discharge pressure of the compressor (VRC system)

However, practical limitations are imposed and these reduce the available range for the discharge pressure to 3.1-3.7 bar. For the heat exchanger (side reboiler of E-DWC) which is part of the VRC loop, the LMTD must exceed 5 K to obtain a reasonable sized and inexpensive side-reboiler – as the heat exchange area (A) depends proportionally with the inverse of LMTD (e.g. $A = Q/U \times 1/LMTD$), when considering a constant heat duty (Q) and heat transfer coefficient (U). Similarly, the compressor is also limited not only by the compression ratio (typically up to 2.5-4.0), but mainly by the discharge temperature (DCT) which should not exceed 150°C for safety reasons – at higher temperatures the system may fail from worn rings, acid formations and oil breakdown.

4. Economic evaluation

The total investment costs (TIC), total operating costs (TOC) and total annual costs (TAC) were calculated according to the procedure described in our previous work (Kiss and Ignat, 2013). The equipment costs are estimated using correlations, based on the Marshall & Swift equipment cost index (M&S=1468.6 in 2012). A price of 600 US $\$/m^2$ was used for the sieve trays cost calculations. For the TAC calculations, a plant lifetime of 10 years was used. Furthermore, the following costs were considered for different types of utilities: 0.03 \$/t cooling water and 15, 17 and 20 \$/t steam of low, medium and high pressure, respectively.

Table 1 provides more details about the rest of key performance indicators. Due to the use of a compressor and a larger side-reboiler required by the VRC system, the total investment cost of the proposed VRC E-DWC process is about 29 % higher than for the classical process, but this is largely compensated by the significant energy savings, which exceed 60 % at a direct comparison. When taking into account the inefficiencies in power generation – e.g. by considering that the ratio of heat to electrical kW is about 3, then the equivalent energy requirements are $0.805 + 3 \times 0.145 = 1.24$ kWh/kg ethanol – the real savings in primary energy become 40 % which is still a remarkable figure.

Table 1. Process performance comparison (*E-DWC as reported in Kiss and Ignat, 2012)

Key performance indicator	Conventional	E-DWC*	VRC E-DWC
Total investment costs, TIC (k$)	3462	3626	4477
Total operating costs, TOC (k$/yr)	5784	5355	4221
Total annual costs, TAC (k$/yr)	6130	5718	4668
CO_2 emissions (kg CO_2 / ton product)	288.94	288.31	173.04
Thermal energy use (kWh / kg product)	2.07	2.07	0.80
Electrical energy use (kWh / kg product)	n/a	n/a	0.14
Equivalent energy requirements (kWh / kg)	2.07	2.07	1.24

Considering both the investment and operating costs, the total annual cost (TAC) is reduced by about 24 %, while the CO2 emissions – which are closely linked to the primary energy requirements – are reduced by 40 % (or even 60 % when the electricity for the compressor comes from renewable sources).

5. Conclusions

The novel heat pump assisted extractive distillation process proposed here is based on an efficient combination of vapour recompression (VRC) and DWC technology. In this configuration, the ethanol top vapour stream of the extractive DWC is recompressed from atmospheric pressure to 3.1-3.7 bar thus to a higher temperature, and used to drive the side reboiler responsible for water vaporization. The results show that the specific energy requirements drop from 2.07 kWh/kg (classic sequence) to only 1.24 kWh/kg ethanol (VRC assisted extractive DWC) hence energy savings of 40 % being possible. Considering the requirements for a compressor and use of electricity in case of the heat pump assisted alternative, about 24 % decrease of the total annual costs is possible for the novel process (in spite of the 29 % increase of total investment costs), as compared to the classic extractive distillation.

Abstract

Several alternative process pathways including biochemical and thermochemical conversions are available for the second generation biorefineries. In this view conceptual design of a superstructure and optimization methods for process synthesis are widely used in order to find the optimal process flowsheet (Stefanakis et al., 2014). In the present work the flowsheet resulting from the economic optimization of a multi-product lignocellulosic biorefinery superstructure was simulated by a process simulator (Aspen Plus). As a result, rigorous methods were used to calculate the stream thermodynamic properties and to model the process units. Economic analysis was applied to assess the economic feasibility of the process. Sensitivity analysis on the size of the plant, the product prices and the biomass price was carried out as well.

Keywords: biorefinery, process design, ethanol, succinic acid, levulinic acid.

1. Introduction

Second generation biorefineries are considered promising non-petroleum based processes for the production of fuels and chemicals with low greenhouse gas emissions. Process synthesis methods have been widely used in the conceptual design, optimization and simulation of sustainable and cost-effective biorefinery processes for the bioethanol production (Fumero et al., 2011). Lignocellulosic biomass can be converted not only to biofuels for transportation, but also to added-value chemicals (Werpy and Peterson, 2004). Several works aimed to determine which process is the best way to produce one or more products using lignocellulosic biomass. Stefanakis et al. (2014) considered eight possible products using sugars and lignin as chemical intermediates. Okoli and Adams (2014) evaluated the techno-economic feasibility of a lignocellulosic biorefinery producing biobutanol using thermochemical processes. A useful tool to evaluate rigorously the biorefinery performance is the process simulation software, as Aspen Plus. It has been widely used also to simulate biomass conversion plants exploiting combustion/gasification processes to produce electricity (Sofia et al., 2014) and also biorefining and fermentation processes (Humbird et al., 2011). Moreover, only few studies addressed the simulation and assessment of integrated biorefineries co-producing alcohols (ethanol or butanol), high-value chemicals (i.e. succinic acid) and electrical power.

In this paper a more rigorous simulation approach is presented and applied to assess the economic feasibility of an integrated multi-product biorefinery co-producing ethanol and two of the top value added chemicals (Werpy & Peterson, 2004), levulinic acid and succinic acid. The innovative features of this study are based on the algorithm proposed to reach the scope. In fact, first the optimal multi-product flowsheet was derived by applying mixed integer linear programming (MILP) methods to the initial

superstructure; then the obtained optimal flowsheet was simulated by the more rigorous process modelling software Aspen Plus. This procedure is the first step of an iterative algorithm using the results of the rigorous process simulation to recalculate the optimal flowsheet by the MILP method. This paper presents only the results of the first calculation sequence MILP – Aspen Plus. The economic results obtained by the two methods were compared to assess the influence of simplified process design equations and of the linear approximation on the overall process optimization. Sensitivity analysis on the size of the plant, the product prices, the biomass price was carried out as well.

2. Process optimization methodology of the lignocellulosic biorefinery

A previous work (Giuliano et al., 2014) addressed the construction of a superstructure for a multi-product lignocellulosic biorefinery producing levulinic acid, succinic acid and ethanol. The superstructure consisted in six alternative pretreatment processes. Furthermore, two types of acid for acid hydrolysis reactor, several enzymatic reactors and fermenters for hydrolysis and fermentation section were considered. At least two different process pathways for each purification section of each product were included. Finally, two alternative combustion processes were considered in the lignin valorisation section. All heat duties and all secondary streams (catalysts, reactants, solvents) were evaluated. Constraints about manufacturing and capital costs were also added. A mixed integer non-linear problem was obtained and, in order to solve it, the linear approximation and the discretization of the non-linear variables were used. Thus, mixed integer linear programming (MILP) was used to find the optimal solution in terms of process flowsheet and biomass allocation. The economic objective function was based on the net present value (NPV) of the biorefinery production. The objective function optimal value was affected by the approximations arising from the use of approximated methods for the sizing of the equipments and from the linearization of all nonlinear equations.

In the present work, the process simulation software Aspen Plus was used to simulate more rigorously the biorefinery and to optimize the operating conditions of each process unit of the flowsheet derived from the MILP solution. As a result, process simulations were expected to provide more precise values of the process yields and of the equipment size with respect to those obtained with the MILP analysis. Finally, economic analysis was applied to assess the economic feasibility of the process.

3. Process design of the lignocellulosic biorefinery

The flowsheet resulting from the process optimization of the lignocellulosic biorefinery consists in four sections. The first one is the biomass pretreatment. The second section consists in hydrolysis and fermentations. The third one is product purification. In the fourth one steam and electricity are generated (Figure 1). Three products are considered: levulinic acid, succinic acid and ethanol. The lignin stream is used in order to produce steam and electricity.

Biomass allocation coming from the optimization of the superstructure was used to split the pretreated biomass streams to the different process pathways of the flowsheet: 49.0 % of biomass fed to levulinic acid, 40.8 % to succinic acid, 10.2 % to ethanol. Lignocellulosic biomass is fed to pretreatments, where electricity request to mill biomass is required (Humbird et al., 2011).

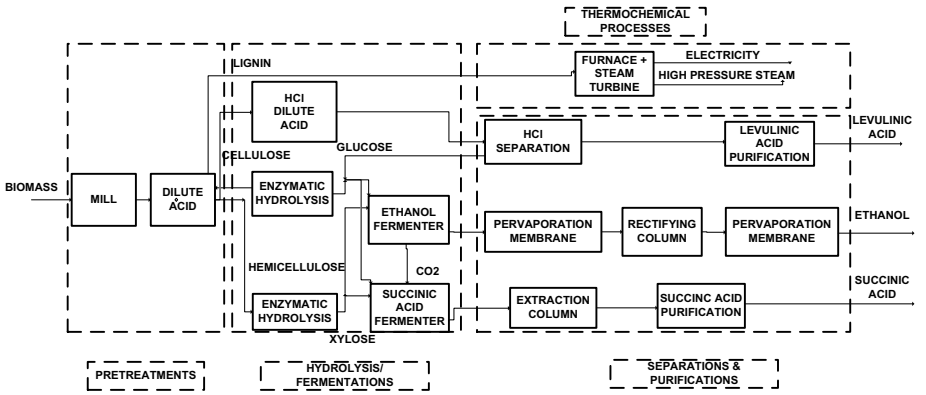

Figure 1. Flowsheet of the multi-product biorefinery.

Main design parameters are shown in Table 1. RSTOIC blocks (stoichiometric reactors) were used in pretreatment and hydrolysis and fermentation sections to set the conversions. Dilute acid pretreatment, using H_2SO_4, was necessary to separate cellulose and hemicellulose. A neutralization reactor was used to neutralize H_2SO_4 using NH_3. The solid fraction of cellulose and lignin essentially was sent to hydrolysis and fermentation section, while liquid fraction of hemicellulose, xylose and other soluble compounds were sent to enzymatic hydrolysis of hemicellulose. In the hydrolysis and fermentation section, part of the solid fraction (60 %) was sent to levulinic acid reactor, in which the glucose converts to levulinic acid and formic acid at 200 °C and 30 bar with HCl as catalyst. RSTOIC block was used in this stage and the conversions derived from Shen and Wyman (2012). Enzymatic hydrolysis was used to convert cellulose to glucose and to convert hemicellulose to xylose (Kadam et al., 2004). The glucose and xylose from hydrolysis reactors were mixed with the glucose rich stream from levulinic purification section. This mixed stream was separated in a stream sent to ethanol fermentation (20 %) and in a stream sent to succinic acid fermentation (80 %).

Ethanol fermenter performance was derived from Leksawasdi et al. (2001) and the beer stream was sent to a flash, at 32 °C and 1 bar, to separate the CO_2 gas. This CO_2 rich stream was sent to succinic acid fermentation section. Here glucose and xylose react with CO_2 to form succinic acid and oxygen. These reactions were simulated using a RSTOIC block assuming conversions derived from Song et al. (2008).

Table 1. Main design assumptions.

Unit	Parameters
Dilute acid pretreatment	T = 160 °C
Enzymatic hydrolysis	Cellulose conversion = 52 %
HCl hydrolysis and levulinic acid formation	T = 200 °C Cellulose conversion = 48 %
Ethanol fermentation	Glucose conversion = 92 % Xylose conversion = 93 %
Succinic acid fermentation	Glucose conversion to succinic acid = 53 %
Levulinic acid purification	Levulinic acid purity = 98.0 %wt
Ethanol purification	Ethanol purity = 99.5 %wt Membrane recovery = 90 %
Succinic acid purification	Succinic acid purity = 99.0 %wt
Heat integration	ΔT_{MIN} = 20 °C

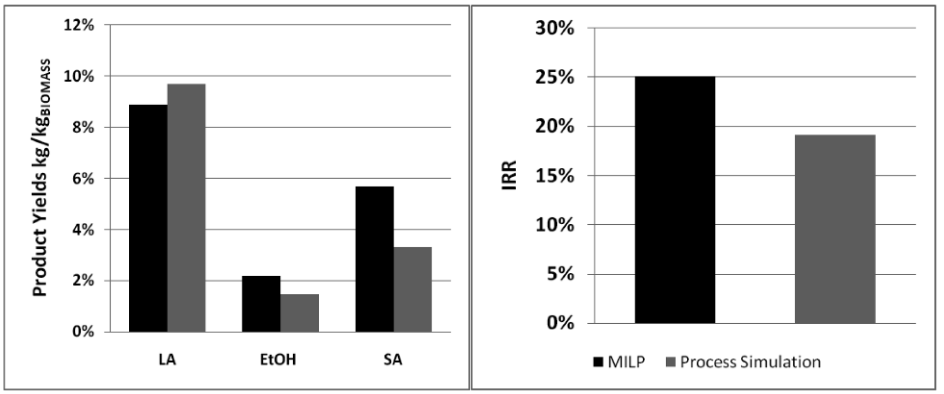

Figure 2. Product yields for the MILP model (dark bar) and for process simulation (light bar).

The purification section of the three products consists in several distillation and extraction columns. In this section the thermodynamic model used for the simulation was the NRTL. In the previous work (Giuliano et al., 2014) all separation yields of separation columns were assumed from data available in the literature. Instead, using the process simulator Aspen Plus it was possible to obtain more accurate separation yields for these equipment accounting for the system thermodynamics. Furthermore, it was also possible to optimize the operating conditions to minimize operating and capital costs using a rigorous multistage vapour-liquid equilibrium approach (RADFRAC block). Levulinic acid purification consisted in a flash in order to separate volatile HCl catalysts and in a distillation column to obtain levulinic acid 98.0 %wt from the bottom (Rackemann and Doherty, 2011). A sequence of three units were used to purify the ethanol. The first was a pervaporation membrane (O'Brien et al., 2000), the second a distillation column to reach to azeotropic composition and the third a pervaporation membrane in order to obtain ethanol 99.5 %wt (Alvarez et al., 2008). Succinic acid at 99.0 % was obtained by separating solids and then using a extraction column with octanol as solvent (Huh et al., 2006). This unit was necessary in order to remove other fermentation acids (formic acid, acetic acid, lactic acid). A vacuum distillation column was used to separate octanol from succinic acid. The last step was the crystallization of succinic acid. Process heat integration was performed by means of Aspen Energy Analyzer in order to obtain the required utilities and the size of the heat exchangers. Economic analysis of flowsheet was carried out as well. The capital expenditure was evaluated by scaling factors and cost index. The latter economic parameters relevant to biorefinery sections were taken from Hamelinck et al. (2005). Manufacturing costs, including reactants, catalysts and utilities, were assessed from data available in Humbird et al. (2011). The total investment cost (TIC) and the total annual costs (TAC) were derived. Finally, a profitability analysis based on the discounted cash flow method assuming a plant lifetime of 20 years was performed to derive the return on investment (ROI) and the internal rate of return (IRR).

4. Results of process design and sensitivities

The base case optimization problem was solved for a 50.0 t_{dry}/h biomass flowrate with a composition of 50.0 $\%_{wt}$ of cellulose, 16.0 $\%_{wt}$ of hemicellulose and 34.0 $\%_{wt}$ of lignin and ash. The base case values of the price of the three products are: 5.0 $/kg for levulinic acid, 7.5 $/kg for succinic acid and 0.75 $/kg for ethanol. The biomass price was assumed 40.0 $/t.

Table 2. Sensitivity analysis on plant size, biomass and product price.

Fed Biomass (t/h)	5	50	500
TIC (M$)	56.6	352.4	1,860.6
TAC (M$/y)	18.1	144.9	854.9
ROI (%)	4.6	20.9	60.0
IRR (%)	2.0	19.1	42.5
Levulinic Acid Price ($/kg)	2.50	5.00	7.50
Rev (M$/y)	180.2	267.6	354.9
ROI (%)	6.0	20.9	35.7
IRR (%)	4.2	19.1	29.2
Succinic Acid Price ($/kg)	3.75	7.50	11.25
Rev (M$/y)	237.9	267.6	312.1
ROI (%)	15.8	20.9	28.5
IRR (%)	14.9	19.1	24.5
Biomass Price ($/t)	20	40	60
TAC (M$/y)	137.7	144.9	152.1
ROI (%)	22.1	20.9	19.7
IRR (%)	20.0	19.1	18.1

The comparison between results of optimization using the mathematical programming (black bar) and results of process simulation (light bar) is reported in Figure 2. Products yields in terms of mass flow of products per unit mass flow of biomass do not vary significantly for levulinic acid and ethanol in both cases. The yield of succinic acid, instead, obtained from process simulation is 58.0 % of that calculated from the mathematical programming. This result is significantly affected by the simulation results of the extraction column of succinic acid using octanol as solvent. For this process unit A more accurate model accounting for complex thermodynamic interactions would be necessary for this process unit. The Internal Rate of Return (IRR) is equal to 25.1 % for the MILP and 19.1 % for the process simulation. This difference is mainly due to the lower revenues of the succinic acid for the second case. A sensitivity analysis was performed on the effect of the price of the products by varying the base case values by ± 50 %. Corresponding values are reported in the Table 2. Varying the biomass flow inlet the plant and, thus, the size of the biorefinery, the TIC and the TAC increase less than linearly with the size. The Internal Rate of Return increases much more from 2.0 % using 5 t/h to 42.5 % with 500 t/h because of economies of scales.

The levulinic acid price affects more significantly the revenues and the economic indexes. This is due to the higher production of levulinic acid (4.85 t/h) than the production of succinic acid (1.65 t/h). The effect of the biomass price on economic analysis is almost negligible: IRR varies from 18.1 % to 20.0 % and ROI from 19.7 % to 22.1 %. This can be explained considering that the feedstock cost covers only 10 % of total annual costs for the base case, 5 % for the lower price value and 14 % for the higher price value.

5. Conclusions

A more rigorous simulation approach affects the prediction of the product yields, in particular a lower value was obtained for the succinic acid. Furthermore, the IRR is lower for the process simulation of about 6 % with respect to evaluations derived from MILP. As expected, the plant profitability increases with the plant size due to the economies of scale. IRR and ROI are significantly influenced by the levulinic acid price while the biomass price has a negligible effect. Future work will consist in updating the

process conditions and yields and the unit size obtained by process simulations into the superstructure. An iterative procedure coupling MILP method and process simulation will be proposed.

Abstract

Water is the main resource for process industry both direct and indirect usages. The saving on water usage helps decrease the operating cost for process industry. This paper presents a method to design water/wastewater network with multiple contaminants to minimize amount of water used in the existing process. It includes two steps of calculations. The first step is initialization step with non-linear programming (NLP) to generate the topology of water network and the second step is optimizing step with mixed-integer non-linear programming (MINLP) to minimize amount of fresh water in the network. The main objective of this model is minimizing water usage and wastewater discharge in overall network. The result from this model is compared with one from the case study in the literatures of Koppol et al. (2003). All mathematical models of this work are solved by DICOPT solver in General Algebraic Modelling System (GAMS). The result shows that our model gives better total annual cost (TAC) than one from literatures.

Keywords: Water network, wastewater network, multiple contaminants, water treatment, mixed-integer non-linear programming (MINLP)

1. Introduction

Fresh water is one of the most important resources used in many industrial processes. One of many ways to reduce fresh water usage is to create the efficient flow network of water streams, called Water Network. Wastewater is generated from water-using processes and disposed to environment. Wastewater containing high concentration of contaminants is treated by treatment process before discharge. Treated wastewater can be re-used as fresh water for water-using process by the network. The problem of wastewater minimization in the industrial processes has been solved by mass exchange calculation unit by unit in a water network (Wang et al., 1994) under mass-balance constraint. The mathematical programming is another way to design the efficient water network. The linear optimization is used as initialization of non-linear optimization for calculating water network with fixed outlet concentration of contaminants (Doyle et al., 1997). The water utilization systems in process plants are divided into two parts; water-using processes and wastewater treating processes. The fresh water is reduced by the water network of the first part. The treatment cost is reduced by the wastewater network of the second part. Simultaneous design of these two networks reduces more fresh water usage by generating the water/wastewater network (Bagajewicz 2000). The mathematical programming is an approach to analyze the feasibility of zero liquid discharge by using different treatment technologies and economical feasibility (Koppol et al., 2003). Water allocation problems have more nonlinearity. The non-linear programming (NLP) is used by providing the lower bound of contaminant

concentration, resulting in reducing the gap between lower and upper bounds. And MINLP minimizes water usage by the water allocation (Faria et al., 2008). The grid diagram of water network model helps create the MINLP model to design the network with the good bounding point (Sarut et al., 2014). Our work proposes the easy way to find the initial point to solve the MINLP model for the optimal solution by comparison with the work from Koppol et al. (2003).

2. Problem Statement

Water/wastewater network model is stated as shown in Figure 1 with a set of water-using units with fixed load of contaminant, maximum allowable inlet and outlet concentration of each contaminant and a set of water treatment unit with outlet concentration of each contaminant. The fresh water without contaminants is water utility for the process. The main purpose of this paper is to use MINLP to generate the water network and water/wastewater network with minimum cost of fresh water usage and wastewater treatment. There are two design steps: the initialization step using NLP model and the final design step using MINLP model.

3. The NLP Model

The proposed NLP model initiates the topology of the Water Network by calculating the lower-bounds of water flowrate for each process ($Flowin_j$) which will be used in MINLP model of the second step as shown in Figure 2 for the final design of network. NLP model is written in terms of fixed contaminants load ($LoadA_{i,j}$) equations:

Step 1 NLP: minimize OFW = $\sum_j FW_j$

$$LoadA_{i,j} = Flowin_j \bullet (SA_i\text{-}DA_j) \qquad \forall i = j \qquad (1)$$

$$Flowin_j = \sum_i (FS_i \bullet x_{i,j}) + FW_j \qquad \forall j \qquad (2)$$

$$xF_{i,j} = FS_i \bullet x_{i,j} \qquad \forall i,j \qquad (3)$$

NLP model requires the maximum allowable fresh water flowrate (FW_j^{MAX}) as a starting point for Eq. (4). At first, it is assumed the process industrials use all freshwater without water network. It uses water flowrate as a FW_j^{MAX} calculated by Eq. (5). SA_i and DA_j must be lower than or equal maximum allowable concentration.

$$FS_i \geq FW_j^{MAX} \qquad \forall i = j \qquad (4)$$

$$LoadA_{i,j} = FW_j^{MAX} \bullet DA_j \qquad \forall i = j \qquad (5)$$

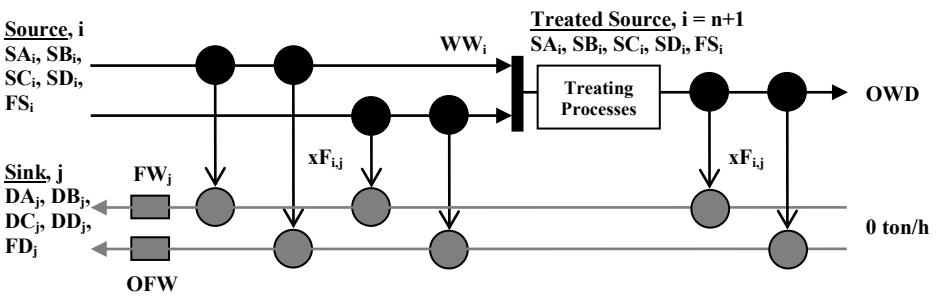

Figure 1. Grid Diagram of Water/wastewater network with four contaminants (A, B, C and D) and the end of pipe regeneration

4. The MINLP Model

After the water flowrates of processes ($Flowin_j$) are found, they are used as lower-bounds of flowrate of sources i (FS_i) in MINLP model under the objective of minimizing total annual cost (TAC) of Freshwater annual cost (FAC) and Treatment annual cost (TTC) in both Water Network and Water/wastewater Network. Additional equations are:

Step 2 MINLP: minimize TAC = Cost of freshwater+Cost of wastewater treatment

$$WW_i = (1-\sum_j x_{i,j}) \bullet FS_i \qquad i = 1 \text{ to } n \qquad (6)$$

$$FT = \sum_i WW_i \qquad i = 1 \text{ to } n \qquad (7)$$

$$OWD = FT - \sum_{i,j} xF_{i,j} \qquad i = n+1, \forall j \qquad (8)$$

$$TAC = (OFW \bullet CostFW \bullet HY) + (FT \bullet CostT \bullet HY) \qquad (9)$$

Where, n is number of water-using processes, CostFW is cost of fresh water ($/ton), CostT is cost of treatment water ($/ton) and HY is working time (h/yr)

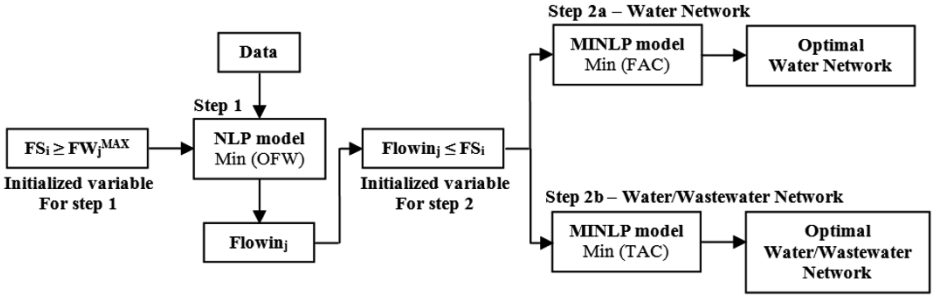

Figure 2. Design flow chart for generating Water Network and Water/Wastewater Network with multiple contaminants

5. Example

This example is a case study from published work of Koppal et al. (2003) consisting of six process sources, six process sinks with the four contaminants (Salts, H_2S, Organics and Ammonia) and three treatment processes. The limiting data of water using units and water treatment units are shown in the original paper. Cost of fresh water in process without treatment process is 2.00 $/ton and cost of fresh water with treatment process at end of pipe regeneration is 0.32 $/ton. The working time is 8400 hr/y. First NLP model calculates $Flowin_j$ as shown in Table 1 and the total annual cost (TAC) of 2.43 Million$^{\$}$/yr. Second MINLP model is run by defining FS_i to be higher than or equal to $Flowin_j$. MINLP model is applied to generate two water networks; one for water-using processes and the other one for water-using processes and wastewater treating processes. Water network alone has six source streams but water/wastewater network has seven source streams (six from water using process and one from end of pipe treatment process). The results from all calculation steps are shown in Table 1. The TAC of water network is 2.031 Million$^{\$}$/yr and one of water/wastewater network is 1.858 Million$^{\$}$/yr. The grid diagrams of water network and water/wastewater network are shown in Figure 3 and 4, respectively the comparison between our results and one from the publication is shown in Table 2.

6. Conclusion

The MINLP model is another method to generate water network with minimum amount of fresh water. Our calculation is easy to do water network synthesis with optimum freshwater flowrate under a set of freshwater data (FW_j^{MAX}). The first calculation by NLP model is to calculate the initial point of flowrate ($Flowin_j$) of the network which is used for the second calculation by MINLP model to get the optimal results as shown in Table 2. The optimal water network and water/wastewater network results are close to the results from literature (Koopal et al., 2003). The computational time for water

network is 0.3 seconds and one for water/wastewater network is 0.8 seconds. Our future work is to do the retrofit design for water/wastewater network.

Nomenclature

FS_i Flowrate of sources i (ton/h)
FW_j Freshwater usage of sink j (ton/h)
SA_i A concentration of sources (ppm)
SB_i B concentration of sources (ppm)
SC_i C concentration of sources (ppm)
SD_i D concentration of sources (ppm)
FD_i Flowrate of sinks j (ton/h)
WW_i Wastewater from source i (ton/h)
DA_j A concentration of sinks (ppm)
DB_j B concentration of sinks (ppm)
DC_j C concentration of sinks (ppm)
DD_j D concentration of sinks (ppm)
$xF_{i,j}$ Flowrate from i to j (ton/h)
FT Flowrate of treatment water (ton/h)
OFW Overall freshwater (ton/h)
OWD Overall wastewater disposal (ton/h)
CWA A concentration of waste (ppm)
CWB B concentration of waste (ppm)
CWC C concentration of waste (ppm)
CWD D concentration of waste (ppm)
FAC Freshwater annual cost ($/yr)
TTC Treatment annual cost ($/yr)
TAC Total annual cost ($/yr)

Abstract

A systematic methodology for screening and designing of Ionic Liquid (IL)-based separation processes is proposed and demonstrated using several case studies of both aqueous and non-aqueous systems, for instance, ethanol + water, ethanol + hexane, benzene + hexane, and toluene + methylcyclohexane. The best four ILs of each mixture are [mmim][dmp], [emim][bti], [emim][etso4] and [hmim][tcb], respectively. All of them were used as entrainers in the extractive distillation. A process simulation of each system was carried out and showed a lower both energy requirement and solvent usage as compared to conventional organic solvent process.

Keywords: systematic methodology, separation processes, ionic liquid, and extractive distillation

1. Introduction

One of several challenging problems in the petrochemical and chemical fields is a separation of binary azeotropic or close-boiling mixtures. The mixtures cannot be easily separated by a simple distillation because the vapor phase has the same composition as the liquid phase. Most of them are homogeneous which are classified as two main systems; (1) aqueous systems (i.e. one component in the mixture is water) and (2) non-aqueous systems such as alcohol + aliphatic hydrocarbons (e.g. ethanol + hexane), aromatic + aliphatic hydrocarbons (e.g. benzene + hexane) and aromatic + cyclic hydrocarbons (e.g. toluene + methylcyclohexane). Several alternative technologies for separation processes have been developed to solve this problem, for example, adsorption, extraction, membranes, extractive distillation and pressure swing distillation (Pereiro et al., 2012). Extractive distillation (ED) is the most efficient separation process considering on the energy requirement and solvent usage (Hernández, 2013).

ED involves the addition of heavy chemical (entrainer) to extract one of the components in the mixtures (target solute) causing the change in the relative volatilities of the mixture (Pereiro et al., 2012). However, some conventional organic solvents, which are usually employed for these separations, may cause some environmental impacts as volatile organic compounds emitted to the atmosphere. A number of environmental issues are influenced how to select the suitable entrainers (Kerton et al., 2013). Ionic liquids (ILs) are proposed as eco-friendly innovative compounds for the next generation, which are initially synthesized from simple anions, cations, and alkyl chains (on cation). Their molecular structures and properties are calculated through group contribution (GC) methods such as liquid densities and critical properties (Valderrama
