$$SP = \sum_{\mathrm{k}=1}^{K}\left(\sum_{i=1}^{n} | \alpha_i^r(k)\times Q_i^r(k) - \alpha_i^p(k)\times Q_i^p(k) | + \sum_{j=1}^{m}\left| S_j^r(k) - S_j^p(k)\right| \right) \tag{6}$$

Where, $Q_i^r(k)$, $Q_i^p(k)$ is the amount of freshwater generated by Unit i at time k according the reschedule and predictive schedule respectively, $\alpha_i^r(k)$ and $\alpha_i^p(k)$ is the on/off status of Unit i at time k according the reschedule and predictive schedule respectively.

2.2. Constraints

The constraints include technical limitations and the design requirements, which are as follows.

The permeate rate $Q_i(k)$ of Unit i at time k is subject to Eq.(7).

$$Q_{i,\min} \le Q_i(k) \le Q_{i,\max}, i = 1,2,\cdots,n; k = 1,2,\cdots,K \tag{7}$$

Where, $Q_{i,\max}$, $Q_{i,\min}$ are the upper and lower limits.

The storage tank capacity is subject to Eq.(8).

$$V_{j\min} \le V_j(k-1) + \sum_{i=1}^{n_j}\alpha_i(k)\cdot Q_i(k) - S_j(k) \le V_{j\max}, j = 1,2,...,m; i = 1,2,...,n_j; \forall k \tag{8}$$

Where, $V_j(k)$ is the capacity of storage tank j at time k; $S_j(k) \geqslant 0$ is the supply of freshwater by storage tank j at time k. $V_{j\min}$ and $V_{j\max}$ are the lower and upper capacity limit of storage tank j.

2.3. Rescheduling approach

A reschedule approach is proposed to deal with uncertain fresh water demand in SWRO desalination process, which works as follow.

Step 1. Generating a baseline schedule (S_0) under a certain condition;

Step 2. Generating a predictive schedule (S_p) by adding redundancy amount of freshwater to deal with some low amplitude uncertainties; the added redundancy according Eq.(10).

$$Redu_i(k) = \frac{Q_i(k) \cdot \overline{R}}{\lambda} \tag{10}$$

Here, $\overline{R}$ is the average amount of changed freshwater demand of each RO unit ($\overline{R} = \omega_{re} R / n$, here R is the total changed amount of freshwater demand, ω_{re} is the coefficient), $1/\lambda$ is probability of freshwater demand changing.

Step 3. When uncertainty happens, a criterion is used to judge whether the reactive schedule should be triggered. If necessary, a RHA is used to build a reschedule; otherwise, operating machines according to predictive schedule S_p.

When the real increment of freshwater demand is higher than $\Sigma Redu_i(k)$ at time k, the reschedule will be triggered, and a RHA works in the following steps.

Step 1. Dividing the remained schedule problem into a series local sub schedule S_r with a K' time horizon as its optimal operation period (here, $K' << K$) ;

Step 2. Computing the rescheduling sub problem to get local rescheduling S_r, then implementing a portion of this reschedule S_i to operate the equipments;

Step 3. If the all the sub scheduling are finished, stop; otherwise, repeat Step 1-3.

The rescheduling horizon and implementing horizon are shown in figure 2.

3. Experimentation and discussion

Here, we take a case in Liuheng Island for numerical experimentation (see details in (Wang, 2013)), which has a capacity of 100,000 m^3 freshwater per day provided by a parallel-unit SWRO desalination plant with 8 RO units. The maintenance plan of RO units is made in advance.

The scheduling time period is K=24, the rescheduling horizon K' is 12, and the implementing horizon is l=1. The objective function of rescheduling is shown as Eq.(1),

let α=β=0.5, $\omega_{DF}(k)$=3.65, ω_{re} =0.01. Assuming the occurrence probability of the uncertainty obeys the exponential distribution D_e and the uncertain amount of change of freshwater demand, ξ, obeys the uniform distribution D_u.

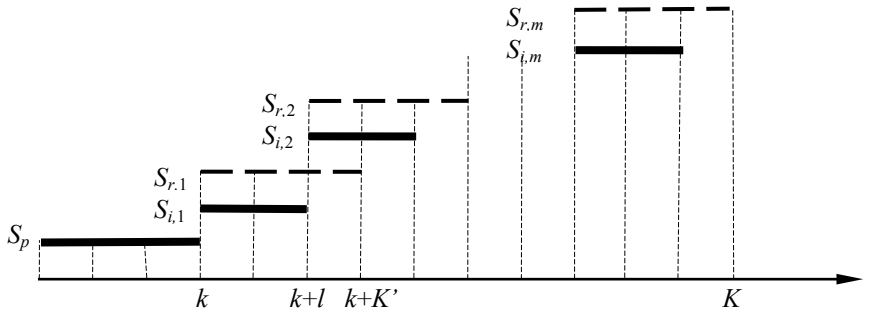

Figure 2: Schematic presentation of rescheduling horizon and implementing horizon

The probability density function of D_e is described by Eq. (11).

$$f_e(x)=\begin{cases}\lambda\cdot x^{e-\lambda x} & x>0\\ 0 & x\le 0\end{cases} \tag{11}$$

The probability density function of D_u is given by Eq. (12).

$$f_u(x)=\frac{1}{b-a}\quad a\le x\le b \tag{12}$$

Here, Eq.(5) is replaced by an expected value model Eq. (13).

$$DF=\sum_{k=1}^{K}\omega_{DF}(k)\cdot\left(\left(D(k)+\mathrm{E}(\xi)\right)-\sum_{j=1}^{m}S_j(k),\right) \tag{13}$$

And, the E(ξ) is described by Eq.(14).

$$E(\xi)=\left(1-\frac{1}{\lambda}\right)\cdot D(k)+\frac{1}{\lambda}\cdot\left(D(k)+\frac{a+b}{2}\right) \tag{14}$$

Here, we use a TSDE algorithm (Wang, 2014) to solve the scheduling problem. The parameters of TSDE are as follows: the maximum number of iterations G_1=300, G_2=700, the population size NP=100, the mutation factor F= 0.1, the crossover rate CR= 0.9, the length of individual D=20, that is, each individual consists of 20 variables: the first 8 variables are real values to represent the amounts of freshwater generated by 8 RO units, the next 8 variables are binary variables representing the on/off states of 8 RO units, and the last 4 variables are real values representing the supplied freshwater by storage tanks.

A comparison of rescheduling with RHA (Case A) and the traditional schedule (Case B, a simulation of workers operating: without adding redundancy, rescheduling when the freshwater demand changes) is shown in table 1 under different conditions. The algorithm is coded in MATLAB R2012 and executed in HP desktop 6300 MT with Intel Core i5-3470 CPU @3.2 GHz and 4 GB RAM. Each of algorithm runs 20 times.

From table 1, it is obvious that the reschedule algorithm has better performance than the traditional schedule, especially for bigger λ values and larger range of (a,b). Additionally, Case A is more time-saving than Case B.

Table 1 the comparisons of different schedules

$[\lambda, (a,b)]$	schedule	Best /￥/×10^4	Worst /￥/×10^4	Meanvalue /￥/×10^4	Std.dev.	Time /s
[0.5,(0,200)]	Case A	93135	94523	93396.8	154.1	423
	Case B	94325	96187	95749.2	138.6	2835
[0.5,(-150,450)]	Case A	88900	89873	89328.8	125.3	438
	Case B	92313	93983	92222.4	189.7	3092
[1.25, (0,200)]	Case A	88166	89365	88381.2	129.7	416
	Case B	93452	94689	93690.4	194	2926
[1.25,(-150,450)]	Case A	89945	91368	90286.2	117.9	433
	Case B	93046	93785	93398.2	137.1	3018

4. Conclusions

This paper discusses the rescheduling problem of a large-scale SWRO desalination plant under uncertain freshwater demand. A rescheduling approach is used to deal with it. A RHA was involved to shorten the computing time by replacing the global scheduling with a series of local schedulings. Experimental results show that the proposed method is satisfactory in solution quality and time consumption. The real-time maintenance plan should be taken into account in future works.

Conflict of interest

The authors declared that they have no conflicts of interest to this work.

Abstract

The current environmental context makes urgent the development of robust methodologies able to design innovative industries. Industrial ecology, and most particularly the concept of eco-industrial parks, aims at proposing at several companies to gather in a same geographical site to share several fluxes (water, energy, utilities…) in order to decrease environmental impacts of their industrial activities. A recent literature analysis has shown the emergence of new works devoted to the application of optimization methodologies to design greener and more efficient eco-industrial parks. In this work, the method of goal programming is applied for the first time to design optimal exchanges of water in an academic case of park. Goal programming is employed to deal with several conflicting objectives: the cost for each company included in the park. This method is proven to be reliable in this context because it proposes to obtain one solution instead of a set of optimal solutions that takes directly into account the preferences of the decision maker. Although the solution obtained in this study is quite interesting and is a good compromise, the main perspective of this work is to be extended by being coupled with a game theory approach so that an more equilibrate solution can be obtained.

Keywords: Eco-industrial Park, Water Network, Multiobjective Optimization, Goal Programming, Game theory

1. Introduction

Over the past ten years, most industrialized countries have invested heavily in environmental research thanks to a general awareness about natural resources depletion. Especially in the case of fresh water, there is a real need to reduce its consumption by redefining and designing industrial networks with a low environmental impact. In response to these environmental problems, the concept of industrial ecology is born. Frosch and Gallapoulos (1989) initiated the scientific community to look very closely at the gathering of industries with a common goal of sustainable development. During the last twenty years, many terms and concepts have emerged in the broad field of industrial ecology. Eco-industrial parks (EIP) are a particular manifestation of industrial ecology and a definition commonly admitted was given by Lowe (1997) as: "A community of manufacturing and service businesses seeking enhanced environmental and economic performance through collaboration in managing environmental and resource issues including energy, water, and materials. By working together, the community of businesses seeks a collective benefit that is greater than the sum of the individual

benefits each company would realize if it optimized its individual performance only." Since these preliminary studies, a lot of concrete examples have emerged through the world including the most famous example of the EIP of Kalundborg in Denmark. Other successful examples even more numerous are built all over the world. Most of them were built in industrialized countries of North America, Europe, or Australia but more recently it is in developing countries that many parks are born (such as China, Brazil and Korea for example).

The approach adopted in this work consists in designing optimal EIP networks (carrying water or energy) before its manufacturing. Optimization methods are then implemented in this context so that optimal networks for EIP can be designed. For a most extended bibliographic review to optimization methods applied to the design of eco industrial parks, the reader can refer to Boix et al. (2015). In this study the increasing interest for this research field during the past few years is highlighted. Figure 1 illustrates the number of studies published and cited during the fifteen past years with "optimization" and "eco industrial parks" keywords in the ISI Web of Science database.

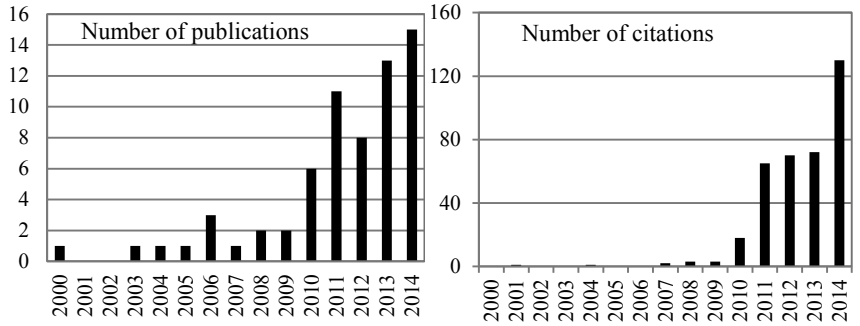

Figure 1. Number of articles referenced in the last 15 years with the keywords: "optimization" and "eco industrial park" (from Boix et al., 2015).

This paper aims at proposing a new methodology to deal with multiobjective optimization of eco-industrial parks. The first part is devoted to the presentation of objective functions, the superstructure and the methodology adopted. Then, a case study illustrates some results applied to the optimal design of a water network in an EIP.

2. Methodology

2.1. Objective functions

The analysis of previous studies has proven the existence of several types of objective functions. The most common is related to the economic cost, one can cite for example: profit of each industry, profit for the local community, transport and logistics or the net present value. However, although the economic cost remains very important for the feasibility of the project, in the context of industrial ecology, many other objectives can also be important. Objective functions in this type of problem are antagonist like for example, the economic cost versus environmental objective. Environmental objectives can be formulated through different ways: minimizing natural resources consumption (water), minimizing greenhouse gases emissions, minimizing water footprint or minimizing health and safety impacts. Another important aspect relative to sustainability development is the social and/or societal criterion. Although most of the time more qualitative than quantitative, social objectives are quite important and include the quality of life of workers, an index of satisfaction for the different participants

(Aviso et al., 2013) or the number of jobs created for example. Finally, topological objectives can also be taken into account as in the work of Boix et al. (2012) so that the network remains feasible.

2.2. Modeling eco-industrial parks

Modeling eco-industrial parks is somewhat a complex problem because of its size (thousands of variables, constraints and hundreds of binary variables) and the number of objectives to take into account. In order to model the network of an EIP, the concept of superstructure is used, it represents all the possible alternatives to connect each process of the network, this systemic approach allows to represent process design. Figure 2 shows the superstructure of an EIP including 3 industries and each industry is composed of process and regeneration units.

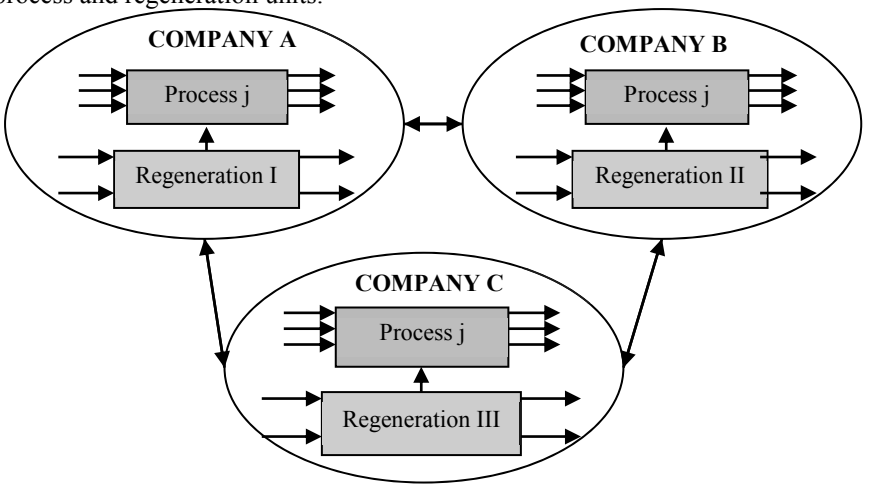

Figure 2.General superstructure of an EIP including 3 industries

After modeling the superstructure, the next step is to model the network with mass balances so that mathematical programming methods can be applied. A "black box" approach is adopted so that each parameter of the different processes are known, for more precision about the modeling stage, the reader can refer to Boix et al. (2012).

2.3. Multi-objective optimization approaches

Resolution methodologies for multiobjective optimization are generally classified depending on the number of generated solutions and on the importance of the decision maker during the resolution. These approaches can be classified into two categories:

- **Generative approaches**: these methods are characterized by the generation of different solutions and the decision maker has to choose one solution among them. These "a posteriori" methods include scalar approaches like weighting method or the epsilon-constraint strategy coupled with mathematical programming and stochastic methods like genetic algorithm. With these methods, a Pareto front is built to propose a set of non-dominated solutions to the decision maker.
- **Preference-based methods**: in this case, decision maker preferences are included along with the resolution and the optimization. These "a priori" approaches like for example, goal programming or interactive methods like NIMBUS directly include the decision maker preferences during the resolution so that one solution is

finally obtained. In this work, we propose to adopt the goal programming approach to solve the case of water allocation in eco industrial parks.

2.4. Characteristics of eco-industrial parks

Boix et al., 2015 highlighted the lack of studies dealing with optimization in order to design optimal configuration of an EIP. However, it is important to develop methodologies able to design an EIP where each industry has a gain compared to the case where it is individual. Furthermore, each company included in a park has its own objective (for example to minimize its costs) and all of these objectives are always antagonists. In this work, a multiobjective optimization approach is adopted in order to take into account each objective function associated to each company of the EIP. This approach has already been applied to the design of industrial water networks but never with the optimal design of the water network in an EIP which is a different problem.

The optimization of eco-industrial parks includes several bottlenecks: one of the main characteristic of this problem is that the structure (represented by the existence or not of connections between processes and numerically modeled by binary variables) is dominating the solution. The resulting model is large and of MILP (mixed integer linear programming) type which constitute a great challenge and it is relatively new to solve this problem with the help of preference-based approaches. Indeed, previous studies have widely explored generation based approaches but some numerical problems were encountered especially when problems involve many binary variables. In most of the cases, the solver does not succeed to return a feasible solution and when it succeeds to build the Pareto front, it remains a very long and tedious task.

In this work, a goal programming (GP) approach is adopted to obtain one solution that already includes the preferences of the decision maker. This approach is based on a recent study (Ramos et al., 2014) where it has been proven that GP can be a very reliable method to design industrial water networks following multiple antagonist objective functions.

Based on an academic example, this paper explores 3 different scenarios of an EIP in order to point out the difficulties encountered with multiobjective optimization of EIP's.

3. Multiobjective optimization through goal programming

3.1. Presentation of the case study

In this study, an EIP including 3 companies is designed, this academic example has been widely explored in the literature (Olesen and Polley, 1996; Boix et al., 2012). For this reason, it remains a good example to test and to validate a new methodology because solutions are well-known. Each company is composed of 5 process units and the parameters are the same as those defined in Boix et al. (2012).

Three different scenarios are explored (Figure 3), where the position of the regeneration unit differs, so that all the configurations are scanned :

- ***Scenario 1***: the three companies exchange water and each company owns its regeneration unit, chosen among three available types (depending on the outlet concentration);
- ***Scenario 2***: the three companies exchange water and share one regeneration unit;
- ***Scenario 3***: a mixed scenario where each company owns its regeneration unit and an additional unit is shared by the three companies.

It is important to notice that for each above mentioned scenario, three objective functions are minimized: the total cost of each company involved in the EIP.

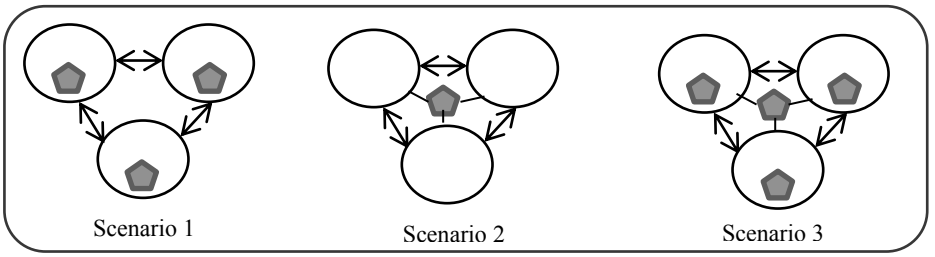

Figure 3. Different configurations of the EIP

In order to show that these objectives are antagonists, table 1 represents the pay-off table that include the values of two objectives while the third is minimized for scenario 2.

Table 1. Pay-off table for scenario 1 (the value in bold is minimized for each line)

Pay-off table	*Cost for ind. A*	*Cost for ind. B*	*Cost for ind.C*
Cost A	**1.143**	4.334	16.985
Cost B	9.349	**1.138**	8.223
Cost C	10.353	9.942	**1.154**

This cost takes into account: fresh water consumption, regenerated water flow rate, cost of external and internal connections between processes and the capital cost of regeneration units.

3.2. Results with the goal programming approach

Results obtained with the goal programming approach are summed up in table 3. Mono-objective optimizations were carried out in a first step in order to obtain minimal (utopia) and maximal (nadir) values of each objective function, that is to say the minimal cost of each company when it is included in the EIP. Then, the goal programming methodology allows to have one solution for each scenario. It is important to note that the optimal solution found by GP leads to an intermediate solutions where all the companies are closed to their personal objective.

Table 2. Results of the multiobjective optimization of the EIP through goal programming, cost are expressed in M$.

	Scenario 1			**Scenario 2**			**Scenario 3**		
	Min	Max	**Solution GP**	Min	Max	**Solution GP**	Min	Max	**Solution GP**
Cost for company A	1.51	6.96	**1.85**	1.14	13.78	**1.98**	1.14	16.09	**2.85**
Cost for company B	1.14	7.05	**1.51**	1.14	6.82	**1.32**	1.14	4.35	**1.34**
Cost for company C	2.81	14.13	**3.52**	1.15	15.36	**2.98**	1.15	12.42	**1.96**

The main interest of this study is to note that for each scenario, one company is favored compared to others. In scenario 1, company A is the closest from its objective whereas in scenarios 2 and 3, it is the company C. Goal programming has been proven to be an efficient approach to design water exchanges in EIP through multiobjective

optimization. Furthermore, it proposes a unique solution that satisfies a goal in very low computational times. Although the optimal solutions are intermediate and satisfying in terms of individual costs, it is of great interest to obtain more balanced solutions so that each company is satisfied at the same time.

3.3. A game theory perspective

Game theory could be a promising approach, particularly adapted to the case of the design of exchanges in an EIP. Several methods can be adopted like a non cooperative approach to preserve confidentiality of companies (Figure 4). Furthermore, the main barrier to integrate an EIP for industry is the lack of confidentiality and this approach could be very promising to overcome this problem. This approach could be useful to overcome the difficulties linked to information exchanges between companies in an IEP. However, it is important to deal with an authority that attends to minimize environmental impacts of the EIP. The existence of an optimal solution satisfying Nash equilibrium could insure that none of each company is prejudiced compared to others.

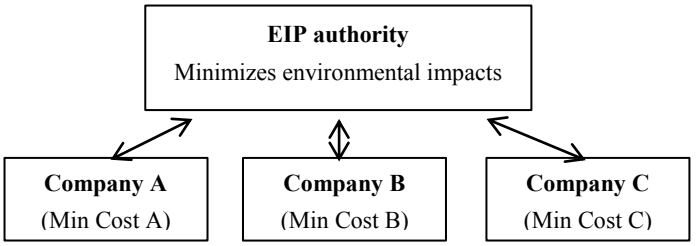

Figure 4. Example of a non cooperative approach to model an EIP through game theory.

4. Conclusions

In this study, water exchanges in an EIP have been optimized by minimizing three objective functions with a goal programming approach. Goal programming is a reliable method of multiobjective optimization and it had been proven to be efficient to find optimal solutions to complex problems. This study dealt with a well-known example to prove the efficiency of the methodology and to make a preliminary study in order to apply further a game theory approach to this work. The development of this method could be coupled with a game theory approach in order to obtain more equilibrate results where no company is favoured to another following the concept of Nash equilibrium.

Conceptual Design of Cost-effective and Environmentally-friendly Configurations for an Integrated Industrial Complex

Chen Chen, Ross Wakelin

Northern Research Institute Narvik AS. Postboks 250, NO-8504 Narvik, Norway.

Abstract

An integrated industrial production complex with natural gas and locally sourced minerals as the main raw materials was studied. Eleven processes including a central synthesis gas plant which uses natural gas were examined in optimization studies considering the exchange of materials and energy. The optimizations included consideration of financial and environmental impacts as well as robustness to unplanned production stops in individual processes.

Material balances for the various chemical processes were built up based on data from literature sources with the production scales assumed according to estimated market demand and economy of scale. Energy quantities and the quality of the streams in and out of the processes were also calculated and are presented in the paper. The potential for material and energy savings by exchange between different processes is quantified by a spreadsheet. The optimization is made using input data from the spreadsheet in Java-based MILP software (reMIND). Apart from improved economic profits, the cases are analyzed also with respect to carbon dioxide emissions and energy requirement in the objective function. A sensitivity analysis examined the response of the financial profit, energy consumption and CO_2 emissions to different operating conditions.

While there are benefits from the integration of the processes, the dependency between different plants also results in exposure to unplanned stoppages by connected processes. The allocation of benefits and liabilities between processes could be calculated in a fair and transparent way by using the model.

Keywords: multi-objective, integration, reMIND

1. Introduction

Norway as the largest source of oil and natural gas reserves in Europe provides gas to all of the major consumer countries in Western Europe. Norwegian gas export covers close to 20 percent of European gas consumption. In contrast, only 1.2% of total Norwegian gas production is consumed in the country (NPD, 2013). The high export of natural gas from Norway and low utilization domestically makes it topical to investigate an added-value integrated industrial complex based on natural gas. With regard to the local situation, the Nordland region is rich in mineral resources and hydroelectric power and is one of the largest export provinces in Norway. In addition the petroleum extraction activities are moving to fields off the coast of Northern Norway. All these conditions support the relevance of a study of the integration of a conceptual industrial production complex with natural gas and locally sourced minerals.

The design of the proposed industrial complex including eleven different chemical processes is aimed at an annual consumption of natural gas around 2-5 billion Sm^3 both as raw materials for chemical reactions and fuel for heating. This amount of natural gas

is considered necessary to justify the costs of building a branch pipeline. More detailed background to the study can be found in an earlier publication publication (Chen and Wakelin, 2013).

2. Method

Material balances for the chemical processes studied were based on data from literature sources with the production scales assumed according to estimated market demand and economy of scale. Energy quantities for the main streams for each process were also calculated and are presented in Figure 3. The potential for financial and energy savings, along with the reduction of CO_2 emissions by exchange between different processes is quantified. A sensitivity analysis of these targets to different operating conditions has also been examined. It is possible to use the model to analyze the industrial complex in order to utilize the internal flexibility for optimization of the operation.

A central process in the study is the production of direct reduced iron (DRI) based on natural gas and iron ore that is currently transported via the ice-free Narvik harbor from mines in Northern Sweden. The DRI produced can either be used in electric arc furnaces for steel production or exported. The other main mineral resources included in the project are carbonates. Based on the large deposits of this mineral in Narvik region (Schaller, A., et al., 2011), it is proposed to produce precipitated calcium carbonate (PCC) with utilization of lower grade carbonates as flux for steel production. Other processes selected to be included in the conceptual complex were mainly for efficient utilization of the syngas and heat as can be seen in Figure 1.

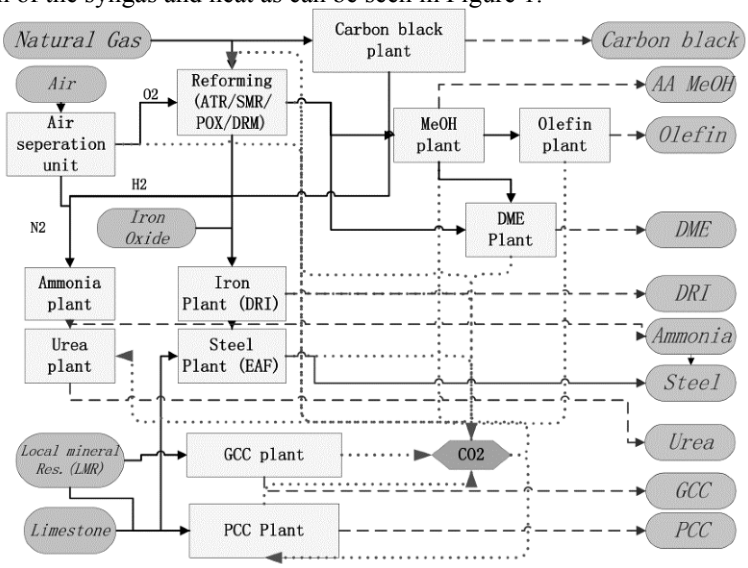

Figure 1 Flow sheet of processes included in the current model

The integration of the processes assists the efficient and profitable utilization of the natural resources by the exchange of by-product materials and energy. The main objective of this study is to quantify the potential savings possible from process integration. Apart from direct cost reductions, savings in energy consumption and carbon dioxide emissions for the integrated production processes are also considered in the objective function. This function has not considered external sale of waste heat. But

the optimization has used the waste heat (of appropriate quality) to offset the consumption of natural gas for heating purposes.
The operational statuses of the individual plants were dependent on variables such as the prices of raw materials and products in the model. Thus, the amount of production is not fixed, instead an upper limit on capacity has been given on each processes except DRI which has a specific capacity set of 1.5 million t/y. Other intermediate products like crude methanol, ammonia in the system have been similarly been assigned 'either-or' choices.
Energy balances for all processes included in Figure 1 have been made with reference to various studies published in the literature on temperature and the pressure of reaction. The changes in enthalpy have been calculated from three parts while treating the reaction processes as black boxes at present. Raw materials are fed to processes after heating them in a preheater to a temperature that is 10°C lower than the reaction temperature. The products then leave the reactor at the temperatures and pressures determined by the various process conditions. It is assumed that the normal state of all the raw materials and products is 298 K and 0.1 MPa.
Enthalpy is a property of state of a substance, having the same value at a given temperature and pressure for a specific material. Then, neglecting work, potential energy and kinetic energy, the thermal energies involved in our study can be calculated based on the rule simplified from the energy balance shown in Figure 2a).

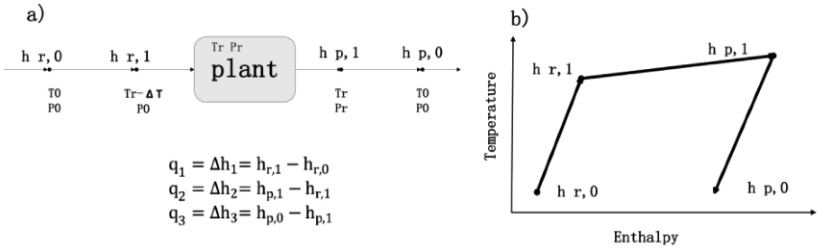

Figure 2a Definition of thermal energies in terms of enthalpy change; 2b Path for enthalpy change

The term q2 is the heat of reaction, while q1 and q3 are thermal energy changes associated with the change of status of inflow and outflow without chemical changes. The amounts of q1 and q3 indicate the potential of energy that could be saved by exchanging heat between high temperature and lower temperature flows, or reusing heat in other ways. Detailed information such as the temperature differences between exchange flows and the efficiency of the transformation of heat energy must be taken into account when considering how to save or use this heat. In the current model, the sum of heat (q1+q2+q3) was considered for each process. Heat from exothermic processes was considered as waste heat which potentially could be used by other processes in the integrated system. All endothermic reactions are assumed to obtain heat from burning natural gas, while pre-heating reactants could utilize waste heat streams.

3. Results

The main heat flows for the base case scenario (natural gas price 2500 NOK/t) is shown in Figure 3. Some exothermic processes with significant reaction heat can be used for steam production. As examples, POX and ammonia production can contribute 8% and 16% respectively of the total heat demand.
Sensitivity analyses for all the prices of raw materials and products have been made using the model. Most of those variables influence the total profit, the amount of CO_2

release and the operational status of different processes. A base case scenario was defined using the current prices of varied materials and other costs. Variation of this base case scenario with respect to natural gas prices greater or lower than 2500 NOK/t is shown in Figure 4a). As expected there is a gradual decrease in total profit with increasing natural gas price. The amounts of consumed and waste heat from the integrated complex are also plotted for each natural gas price level. For natural gas prices between 2500 and 4000 NOK/t the amount of heat consumed (and generated as waste heat) is approximately constant. The waste heat available is around 39% of the heat consumed, indicating potential for energy savings from heat integration. At natural gas prices lower than 1000 NOK/t the optimisation chooses to utilize Steam Methane Reforming (SMR) to generate synthesis gas, with higher heat and CO2 emissions. An increase of the natural gas price to 5000 NOK/t results in the stopping of ammonia production, which releases further heat for reuse.

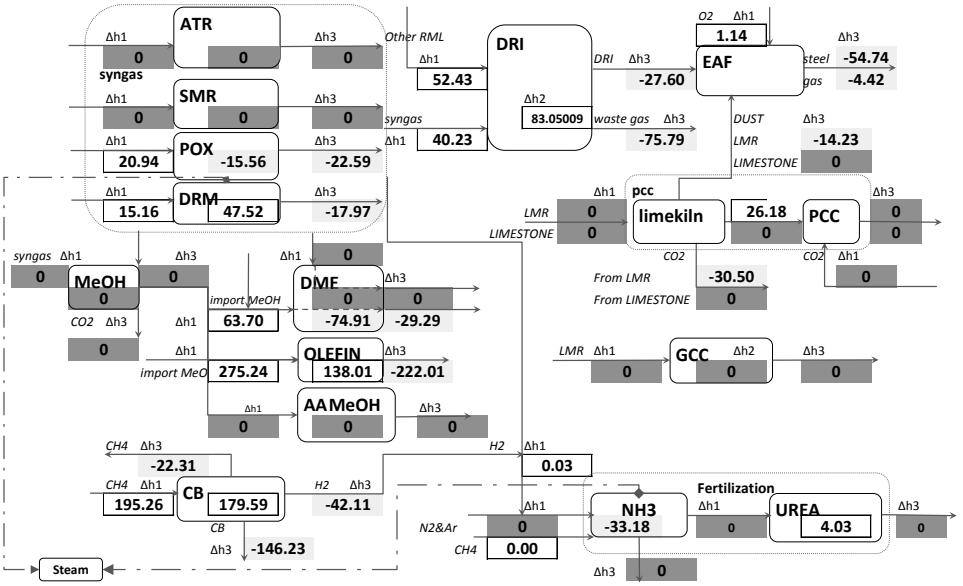

Figure 3 Heat flow in base condition (MJ/s)

Scenarios of CO_2 emission in terms of the total amount and due to burning of natural gas for heating are given in Figure 4b). Since the CO_2 emissions generated from natural gas combustion are the result of providing heat to the system, it shows the same tendency as the heat consumption with changing gas price. CO_2 emissions for a natural gas price under 1000 NOK/t are more than 8 times higher than those for natural gas prices between 2000 and 4000NOK/t, due to the operating characteristic of the Steam Methane Reforming. Once the natural gas price reaches a value of 5000NOK/t, an increase in CO_2 emission is observed due to the stoppage of urea production, which is a CO_2-consuming process. The urea CO_2-sink is also the reason for the net CO_2 emission from system being lower than would be expected from the amount of natural gas consumed.

An important issue within the integrated complex is the inter-dependency between different plants and the allocation of benefits and liabilities between processes. Thus, it is important to find a reasonable way to show the sharing between those processes. The costs for the EAF steel-mill production at the base case scenario is shown in Figure 5. A saving of about 18% on the total cost on steel producing can be seen when comparing

the result from an integrated system with independently operating processes for producing steel at the same capacity. The costs for steel production were divided into five main parts in Figure 5. The Air Separation Unit (ASU) and DRI processes provide the main reactants of oxygen and DRI, respectively to EAF. Meanwhile, the production of DRI is dependent on the up-stream process of syngas production which is selected to be partial oxygen reforming, which in the optimum situation also utilizes oxygen from the ASU.

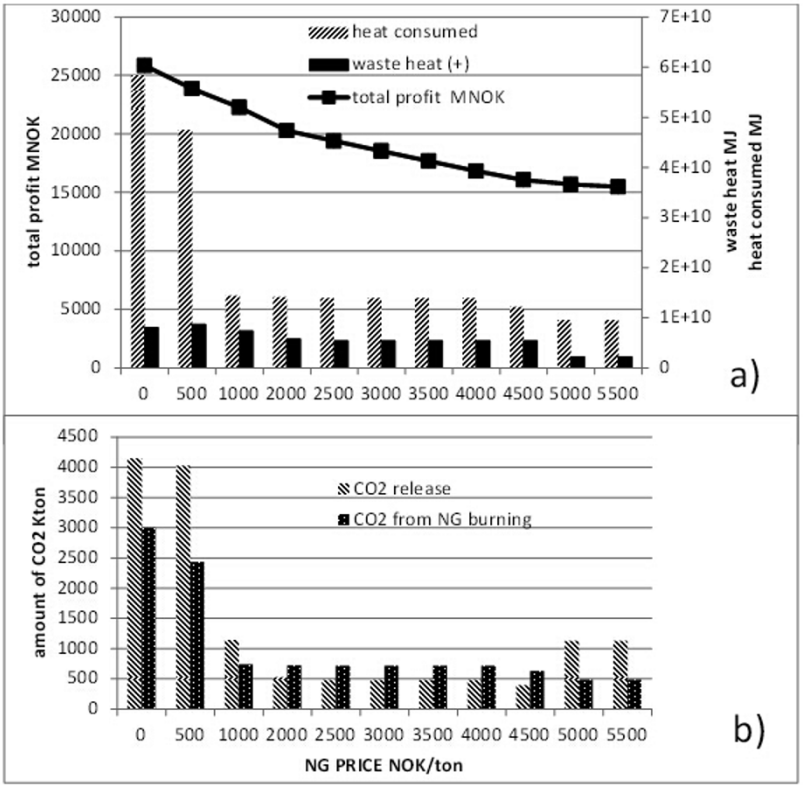

Figure 4 Scenarios of profit, heat, CO_2 and operational status at varied prices of natural gas

The costs or benefits of the up-stream processes were shared by the intermediate product consumer depending on the amount of products utilized, Eq.(1).

$$\text{Allocation of production cost of intermediate product} = \frac{\text{amount of product utilized}}{\text{total amount produced of same product}} \times \text{production cost of that product} \quad (1)$$

In the absence of ammonia production there is a considerable increase in the cost of the ASU, as the ammonia consumes the nitrogen that is 75% by weight of the ASU production. The increase in the specific capital cost of the ASU due to the reduction of production capacity also has been taken into consideration. The costs grouped under 'other' include the cost of raw materials and the cost of heat for the processes. The cost difference on this 'other' part is caused by the lower supply of waste carbonate from PCC processes, requiring the substitution of higher cost flux.

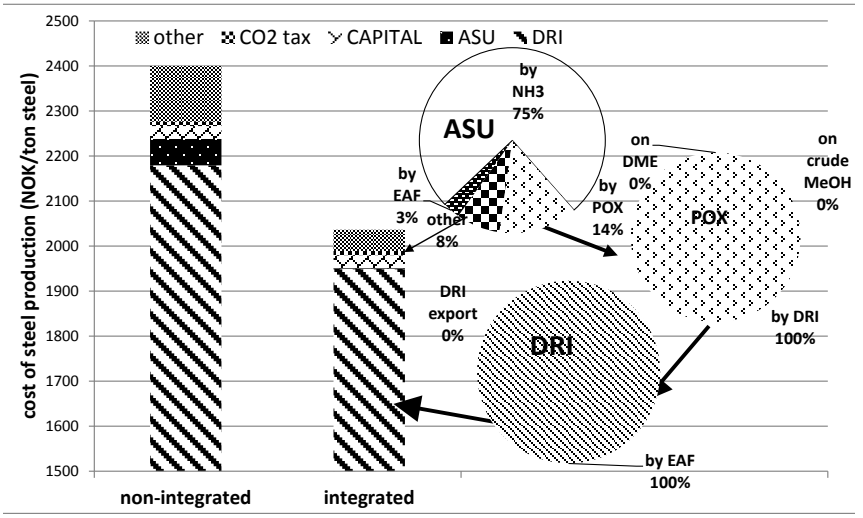

Figure 5 Cost distribution for steel production for the base-case scenario

4. Discussion and conclusion

The results of heat and CO_2 emission changes at various gas prices show a higher consumption of heat and emission of CO_2 from steam methane reforming, while still returning a higher overall economic result. On the other hand, the ammonia and urea processes show advantages from energy saving and CO_2 reduction. The potential for reuse of waste heat can cover as much as 39% of the heat consumed. However, the usability and efficiency on reuse of those heats will depend on their quality. Moreover, it is necessary to consider the influence of the geographical location on the potential for energy saving.

Savings on costs are obtained from several aspects such as effects of scale, sharing of intermediate-products and the utilization of by-products (waste) from other processes. The allocation of production costs for intermediate products used by different downstream processes was presented. In addition, costs arising from unplanned stoppage of specific plants can be included in the optimisation by setting the capacity constraint to zero. This enables the quantification of the contribution of each process to the overall optimal profitability of the system.

The optimisation model responds well to the influence of the variables changing under sensitivity analyses, resulting in different combinations of processes included in the chemical complex. Economic benefits obtained by the exchange of materials have been demonstrated and quantified. Reductions in CO_2 emissions were also observed due to the inclusion of some CO_2 consuming processes (urea production) running at some scenarios.

Abstract

In the last few years, composites have been used increasingly in different applications (aerospace, automobile, industry, sports…). Both environmental and economic factors have driven the development of recycling pathways for the increasing amount of fibre reinforced polymer (FRP) scrap generated. A recycling system for FRP has to be designed to recover and reuse the fibre and matrix content of the scrap. The objective of this paper is to model and compare the different routes of end-of-life FRP from both environmental and economic viewpoint combining Life Cycle Assessment and Cost-Benefit Analysis. More precisely, mechanical recycling, pyrolysis and fluidized bed are investigated and compared to low value end-of-life solutions (incineration, co-incineration and landfill) both for Glass and Carbon FRPs. Pyrolysis turns out to be an attractive recycling solution for CFRP that satisfies both environmental and economic benefit while co-incineration seems more promising for GFRP.
Keywords: composite recycling, fibre reinforced polymers, waste management, environmental impacts, economic benefits

1. Introduction

Fibre reinforced polymers (FRP) are composite material made of polymer matrix reinforced with fibres. Due to their low density, FRP are increasingly used in structural applications to replace more conventional materials (steel, aluminium, alloys…) in order to design lighter products especially in the aeronautics sector. Despite all advantages associated with FRP, the increasing use generates also an increasing amount of FRP waste. Common sources of waste include out-of-date prepregs, manufacturing cut-offs, testing materials, production tools and end-of-life (EoL) components. The global demand of carbon fibres is expected to exceed production capacity in 2015 if growth remains at this rate and recycling could be a fibre supply solution in order to meet future demand (Black, 2012). However, the complex composition of FRP makes recycling more complex than typical thermoplastic recycling. Unlike thermoplastics, the thermoset FRP scrap cannot be melted down and remoulded, as is often done in plastic recycling. Most of the FRP waste is currently landfilled or incinerated but these solutions are far from being satisfactory from environmental, legislation and economic viewpoints (Yang et al., 2012).

The aim of this study is to use process systems engineering methods to model and compare the recycling pathways of Carbon Fibre Reinforced Polymers (CFRP) and Glass

Fibre Reinforced Polymers (GFRP). Unlike glass fibres that are generally ten times cheaper due to their simple fabrication by fusion, carbon fibres are high-value added products because of their high technical properties and complex production. Despite differences in fibre nature, the recycling techniques of these thermoset composites exhibit similar principles. Due to high durability of polymer matrix, the technologies like torrefaction and fast pyrolysis cannot be applied to FRP. The analysis of the relevant literature highlights that if technical solutions are readily available, they are developed at different scales of process maturity, i.e., industrial scale for mechanical recycling and pyrolysis, pilot and laboratory scales for fluidized bed and chemical recycling (Yang et al., 2012). More precisely, mechanical recycling, pyrolysis and fluidized bed are investigated and compared to low value EoL solutions (incineration, co-incineration and landfill) through a combined use of a Life Cycle Assessment (LCA) and a Cost-Benefit Analysis. The inventory, data collection will be described together with the evaluation of the economic and environmental impacts for the selected scenarios.

2. A methodological framework for recycling pathway evaluation

2.1. FRP recycling pathways

The recycling pathway alternatives considered in this work and the system boundaries are summarized in Figure 1. The recycling units are assumed to be located in France. The composite waste is cut on the dismantling site and then transported either to the landfill site or to any other recovery facility. All the different recycling technologies are assumed to be available to treat the FRP. The typical features of each process will be shortly presented together with the analysis.

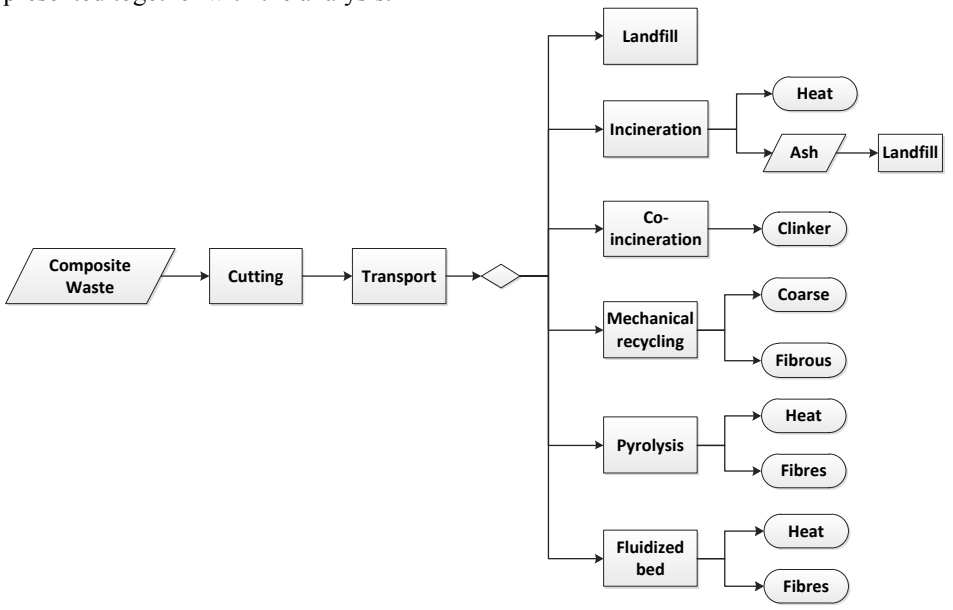

Figure 1: Recycling pathway alternatives and system boundaries

2.2. Life Cycle Assessment

The functional unit (FU) defined for this study is 1 kg of cured FRP waste to be treated by one of the proposed technology. A product life cycle consists in four individual phases: raw material extraction, production, utilization and EoL. Within the limits of this study,

only the environmental impacts of the EoL activities of the composite are assessed. Data on the energy requirements and emissions of the recovered product from the different waste scenarios were collected to analyse the influence of these paths. The calculations are based on elementary environmental impacts coupled with the LCA software SimaPro 7.3. Although LCA is identified as a multicriteria environmental management tool, the analysis is limited in this work to climate change impacts (CCI), evaluated on a kg CO_2 eq. basis performed by the ReCiPe Midpoint (H) v.1.06 assessment method.

2.3. Cost-benefit analysis

Cost-benefit analysis (CBA) is a simple method in which all expenses and incomes of an activity are considered to a cash balance (Farel et al., 2013). Its principle is summarized in Eq. (1).

$$CBA = \sum Benefits - \sum Costs \quad (1)$$

This allows determining whether an activity can promote economic profits or which solutions generate the most profit. This method is applied in this preliminary study to analyse the differences of economic benefits among the pathways of EoL composites. In this context, CBA is simplified and the total expenses are mainly based on the price of the process energy requirement and on the average cost of transport. The benefit of the recovery centres comes from the sale of recycled materials to the manufactures as raw materials and the savings of energy, i.e. "avoided energy", which is released from the production process.

3. Modelling FRP recycling processes and inventory data

3.1. General assumptions

Due to the lack of FRP specific data for recycling, the system is modelled by a "black-box" approach, i.e. changes in waste composition during the treatment are not considered, but only fixed input-output data of the system are studied in this preliminary study. In each process, input-output data are estimated both from typical operating conditions of the considered processed obtained from a literature survey and on the basis of the information available, from SimaPro database. Data were also collected from the European Environment Agency (EEA) and Eurostat. The cost of electricity from French average power mix (with 78 % rate from nuclear energy according to SimaPro 7.3) is fixed at 0.085 €/kWh (Eurostat, 2014). The composite waste is supposed to be a continuous fibre reinforced thermoset resin and composed of 60 vol% in fibre and 40 vol% of resin. No contaminant, metallic insert, flame retardant agent, hazardous substance and filler is considered in the composition of FRP waste. In this study, FRP waste is classified as a non-hazardous waste. In each scenario, the composite is firstly shredded with an amount of energy of 0.0025 MJ/kg (Witik et al., 2013) and then transported over a distance of 100 km from the site of dismantling to the site of treatment by a 40-ton truck with an average cost in Western Europe of 0.14 €/(t.km) (Schade et al., 2006). The avoided impacts and the prices of the recovered products are summarized in the Table 1.

Table 1: Prices and avoided impacts of the recovered products (Witik et al., 2011; Duflou et al., 2012; Job, 2013; SimaPro databases)

	Carbon fibre	Glass fibre	$CaCO_3$
Price (€/kg)	12	1.6	0.25
Climate change Impacts (kg CO_2 eq/kg)	22.4	2.6	0.0132

3.2. Recycling alternatives

3.2.1. Landfill

The environmental impacts of landfill are assessed by the model of "sanitary landfill of mixed plastics" extracted from SimaPro databases because composite material specific data were not available. The total charge of landfill in France is about 80.5 €/t according to EEA (2013).

3.2.2. Incineration

Incineration is a thermal process, which allows recovering energy in heat resulting of waste combustion. The heat can be used directly or converted into electricity. In this scenario, the heat from the process is converted to electricity with an efficiency of 35 % and the process is assumed to be auto-thermal. The emissions of 1 kg FRP from combustion are presented in Table 2. The ash by-product is landfilled as an inert waste.

Table 2: The outputs of 1 kg FRP incineration (Hedlund-Åström, 2005; Job, 2013)

	Ash (wt%)	CO2 emission (kg)	Net heat of combustion (MJ)
CFRP waste	9.65	3.39	31.7
GFRP waste	75	0.61	12

3.2.3. Co-incineration

Although incineration and co-incineration are both based on combustion of waste, co-incineration allows material recovery besides energy recovery. Indeed, in co-incineration, waste is used as a substituted fuel involved in clinker fabrication.

3.2.4. Mechanical recycling

The principle of this technique is to separate fibres from matrix by a grinding process. However, the obtained product is a mixture of polymer and fibres composed of two fractions, i.e., a coarse one, which is rich in matrix and a fibrous part, rich in fibre. Because of the reduction of mechanical properties, the products are generally used for low value-added applications like filler in concrete (Job, 2013). In this scenario, the necessary energy for the process is estimated at 0.27 MJ/kg of composite, the yield is supposed to be 100 %, i.e. all of FRP waste is recovered. In the case of CFRP, according to Palmer et al. (2010), 24 % of composite waste can be used to replace the equivalent quantity of glass fibre in SMC without important degradation of mechanical properties; the remaining is used as calcium carbonate. In the case of GFRP, all products obtained from grinding composite are considered to replace calcium carbonate.

3.2.5. Pyrolysis

Pyrolysis is a thermal recycling process that decomposes the matrix at around 400 to 600 °C according to its thermal properties to recover fibres. The main characteristic of this process is the thermal decomposition in an inert environment or in a controlled atmosphere with a low proportion of oxygen to avoid the oxidation of fibres. A rapid gasification might be needed after the principal step to clean the fibres from char of resin decomposition. Gas fraction produced from the decomposition of matrix can be condensed to be reused as a fuel or burned to recover heat. In this study, the pyrolysis is assumed as the combustion of the matrix. The total energy used in pyrolysis which is estimated at about 30 MJ/kg composite (Witik et al., 2013). This recycling pathway is the most developed until now (Yang et al., 2012). The recovery rate of fibre is considered to be 95 % in this study. The recycled fibres are supposed to be used as reinforcement in composite, such as for SRIM (Structural Reaction Injection Molding).

3.2.6. Fluidized bed

In this process, the sand is fluidized by the hot air flow at a temperature of 450-550 °C with a velocity of 0.4-1.1 m/s. In these conditions, the organic matrix is volatilized and the fibres are thus released. The fibres are sent out of the bed by gas flow. After the fibres are recovered, the gas passes through a secondary combustion chamber where the polymer is completely decomposed. This technique is still at both development stage and pilot scale (Yang et al., 2012). The needs for electricity are estimated at 15.5 kWh/kg of composite and the fibre yield is fixed at 67.5 % in this scenario from the conditions of laboratory test of Pickering et al. (2000). As for the pyrolysis process, the recycled fibres from this technique are used as reinforcement in composite, such as for SRIM.

4. Results and Discussion

4.1. Case 1: CFRP waste treatments

The Climate Change Impacts and the CBA of six EoL scenarios of CFRP are presented in Figure 2 (a). In this case, the material recovery is the most important factor of CFRP waste management because of the high value of carbon fibre in market and reduction of the important avoided impacts by replacement of virgin carbon fibre. All of the recycling techniques studied in this work generate more profits and have less the environmental impacts than the energy recovery techniques (incineration, co-incineration). Composite combustion and landfill of ash are not only penalized from the economic viewpoint since they do not lead material recovery but the resulting emissions also contribute to the total positive Climate Change Impacts of these pathways. At this stage, pyrolysis remains the best solution for recycling CFRP wastes. Indeed, it leads to the best economical profit and generates a low environmental impact. This is probably due to the highest maturity of this technology for carbon fibre recovery compared to other processes.

4.2. Case 2: GFRP waste treatments

In this case (see Figure 2 (b)), the choice of the technology is not as clear as for CFRP if pyrolysis remains a good alternative regarding the economic term. Co-incineration is a better competitor from an environmental point of view. It can also be emphasized that the profit of GFRP pyrolysis is lower than the one of CFRP pyrolysis due to the lowest added value of glass fibre compared to carbon fibre. More generally, the low value of glass fibres influences the environmental benefits of GFRP waste management.

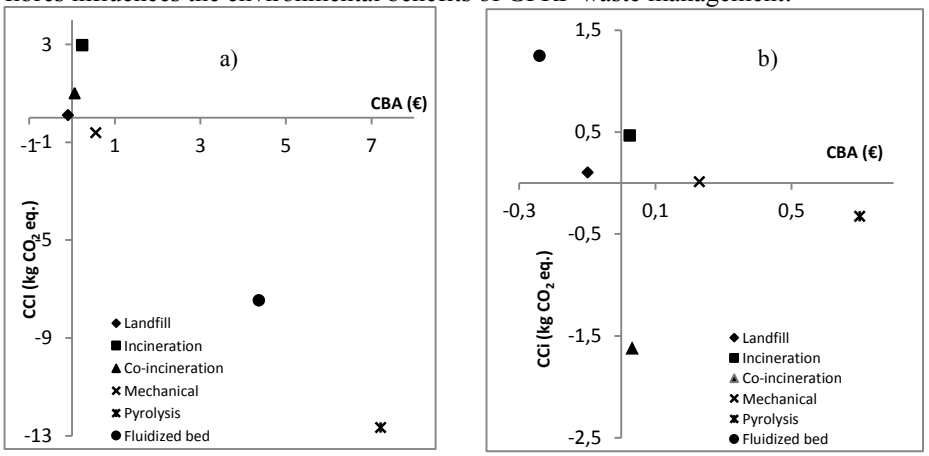

Figure 2: Evaluation of EoL pathways, (a) for CFRP, (b) for GFRP.

A process such as fluidized bed will not present the same advantage for CFRP and GFRP. This technique is outperformed by landfill pathway for GFRP. Since glass fibre is incombustible, the material recovery after combustion in co-incineration seems more promising than the incineration pathway.

5. Conclusions and Perspectives

This study proposed a model of the overall system of FRP waste pathways and an evaluation of environmental and economic impacts of each alternative. The results show the importance of the value of the recovered products and of the maturity of techniques on waste management. For CFRP, pyrolysis is an attractive recycling solution that satisfies both environmental and economic benefit. However, for GFRP wastes, it is not so obvious: mechanical recycling and co-incineration are possible alternatives. A weak point for GFRP waste recycling is the low value of the recovered product that may impact the total benefits.

This model will be then extended to other possibilities for FRP waste management (chemical recycling for example) and to various transport types while considering more complexity in FRP waste composition the multi-purpose nature of the recovered product. Economic impacts will be analysed thoroughly by considering investment, labour cost and other costs (dismantling, collection, stocks…). Environmental assessment will be carried out considering other environmental impacts other than those related to climate change. The recycling chain has indeed to be considered as a whole, and must be managed with respect to all the involved stakeholders. Multiobjective optimization has potential to examine the different compromise solutions to design a recycling system with respect to economic and environmental purposes.

A MILP Transshipment Model to Integrate and Re-Engineer Distillation Columns into Overall Processes

Konstantinos A. Pyrgakis, Kipouros P. Ioannis, Antonis C. Kokossis

School of Chemical Engineering, National Technical University of Athens, Zografou Campu GR-15780, Greece
akokossis@mail.ntua.gr

Abstract

Heat integration of distillation columns can be succeeded using several schemes. These may include multiple effects and thermally-coupled systems, heat pumping, feed preheating or combinations of all of them. Moreover, setting individual integration of distillations in the scope of overall process integration is possible to secure operation even at zero energy cost. This paper focuses on the scheme of multi-effect distillation due to its high potentials for stand-alone and integration with the overall process. The proposed methodology examines the synthesis specifications (number, pressures and feed split fractions) of multiple effects, scoping for promising structures ahead of analytical design and rigorous optimization analyses. A MILP mathematical formulation is presented to optimally synthesize multi-effect distillation systems taking into consideration the integration of the effects with the overall process at the same time. The model is illustrated through a real-life biorefinery including the integration of three different distillation processes succeeding in energy savings up to 82%.

Keywords: heat integration, multiple effect distillation, transshipment.

1. Introduction

Distillation constitutes a widely used and energy intensive separation process that in most cases features a big share of the overall energy consumption and a high impact on process sustainability. Integration of distillation columns appears indispensable in future designs (ex. biorefineries) as well as in retrofit cases. Several schemes deal with stand-alone integration securing better efficiencies than initial designs. In this paper, the scheme of multiple effects is examined, since the technique succeeds in significant energy benefits from both stand-alone and integration with the overall process.

The application involves adding of separation effects that operate at different pressures, enabling that way energy serving from the condenser of a higher pressure effect to the reboiler of a lower pressure effect, while the initial distillation feed is distributed among them. Linnhoff et al. (1983) originally gave fundamentals concerning the thermodynamic background for the integration of distillation heating and cooling demands along the heat cascade of the overall process. The graphical approach of Grand Composite Curves (GCC) has been extensively applied to detect the feasible heat transfer contexts between the multiple distillation effects and the background needs (hot/cold streams of process that remain if reboilers and condensers of distillations are excluded) previewing options about the number, capacities and operating pressures of

the effects that secure maximum energy savings. The graphical tool has been applied in several recent biorefinery applications for the purification of downstream bioethanol (Dias et al., 2011; Kravanja, 2013) while other robust optimization models (Martín and Grossmann, 2011; 2013) has been also used to determine operating pressures and split fractions of effects (up to three) followed by heat integration with the overall process.

The development of multi-effect distillation schemes has to cope with the selection of number, capacities and pressures of effects as well as with their integration with the overall process so as to take full advantage of available heat sinks and sources of background and minimize the overall energy cost. Since distillation effects and their specifications constitute significant degrees of freedom, the development of multi-effect systems should be approached in a process synthesis approach. This paper presents a MILP mathematical formulation with the capacity to address the additional degrees of freedom and synthesize the portfolio of effects that minimizes utilities cost of the process and investment cost of applied effects. The methodology intends to select the appropriate combination of effects (given a set of candidate pressure effects) and their capacities, securing at the same time their integration with the background. An extended transshipment model (Papoulias and Grossmann, 1983) is proposed to formulate heat flows along the heat cascade incorporating new terms associated with the selection and contribution of effects. Finally, the mathematical model was applied in the courses of a real-life biorefinery, which produces bioethanol and lignin from lignocellulosic biomass, for the integration of three different distillation columns involved in the overall process.

2. The synthesis problem of multi-effect distillation

The three critical challenges of the synthesis problem (number, operating pressures and feed split fractions) are graphically previewed in the illustrative GCC of Figure 1. There, a set of candidate effects are possible to be placed over or below the pinch, while the operating pressures (vertical arrows) and their capacities (horizontal arrows) need to be optimized so as to ensure full integration with the available heat sinks and/or sources of the background. The synthesis problem becomes even complicated as far as more distillation units need to get integrated and the effects, which integrate different distillations, are possible to compete for the appropriate placement within the same background profile. In these cases, investment cost plays a significant role for the selection of the appropriate pressures and capacities of competitive effects.

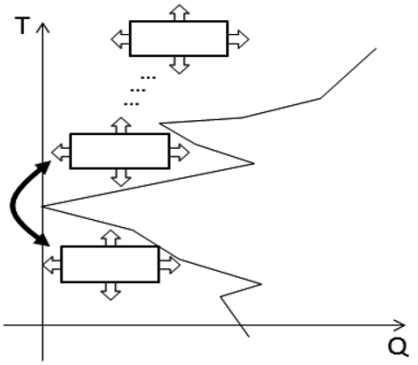

Figure 1: Illustrative Grand Composite Curve and candidate distillation effects

This paper presents a MILP model to describe the heat cascade of the overall process and mathematically formulate the energy interactions between added effects and the background. The proposed methodology intends to select the appropriate portfolio of effects among a given set of effects that operate at a spread range of preselected pressures. The nominal (maximum) heat demands of the candidates can be estimated in advance setting the feed rate and top/bottom product compositions of the initial column. Therefore, the desired compositions of final top/bottom products in the multi-effect system are secured by mixing top/bottom products, respectively, of all effects together. Moreover, the reboiler and condenser heat demands can be safely supposed to be linearly depended on the capacities of distillation effects and consequently approximated as a fraction of their nominal values. This fraction is directly related to the split fraction of the initial distillation feed that is distributed among the effects. As a result, heat demands of all candidate effects can be incorporated into the heat cascade of the overall process as additional streams (condensers are considered as hot streams with Tin−Tout = −1 K and reboilers as cold streams with Tin−Tout = +1 K) and their contribution can be managed through the related split fractions.

In the courses of the proposed mathematical model, the following sets are defined: $K=\{k|k=1,N_K\}$, where N_K is the number of temperature intervals of the heat cascade from higher to lower temperatures; $D=\{d|d=1,N_D\}$, where N_D is the number of distillations of the process that need to get integrated; $H=\{i|i=1,N_H\}$ and $C=\{j|j=1,N_C\}$, where N_H and N_C are the numbers of hot and cold streams respectively including both process streams and condensers/reboilers of candidate effects; $H_k=\{i|i\in H\}$ and $C_k=\{j|j\in C\}$ for hot stream i and cold stream j that are present at interval k; $H_d=\{i|i\in H\}$ and $C_d=\{j|j\in C\}$ for hot stream i and cold stream j that represent the condenser and reboiler respectively of the effect that integrates distillation d; $S=\{m|m=1,N_S\}$ and $W=\{n|n=1,N_W\}$, where N_S and N_W are the numbers of hot and cold utilities respectively; $S_k=\{m|m\in S\}$ and $W_k=\{n|n\in W\}$ for hot utility m and cold utility n respectively that are present at interval k; $HC=\{(i,j)|i\in H,\ j\in C\}$ for i,j pairs that represent the reboiler and condenser respectively of the same effect. Let known parameters Q_{ik}^H and Q_{jk}^C be the heat contents of hot stream i and cold stream j respectively at interval k and c_m and c_n be the unit costs of hot utility m and cold utility n respectively. Let variables Q_m^S and Q_n^W be the heat loads of hot utility m and cold utility n, R_k be the heat residual exiting interval k, y_i^H and y_j^C be the split fractions of hot stream i and cold stream j and the binary variable y_i associated with the selection of hot stream i.

Parameters Q_{ik}^H and Q_{jk}^C for $i\in H_d$ and $j\in C_d$ refer to the nominal heat contents of the related effects, while variables y_i^H and y_j^C are used to manage heat contents of all hot and cold streams as degrees of freedom. On one hand, y_i^H and y_j^C variables for $i\in H\text{-}H_d$ and $j\in C\text{-}C_d$ describe the split fractions of streams that belong to the background and should be fixed to equal to unit, since they must fully contribute the heat cascade in any case. On the other hand, y_i^H and y_j^C variables for $i\in H_d$ and $j\in C_d$ describe the split fractions of the effects and should range between 0 and 1, while in case that $(i,j)\in HC$, y_i^H and y_j^C variables should be equal between them, since they represent split fractions of the same effect and both the condenser and reboiler should be similarly managed.

Adding more separation effects to succeed in better integration with the background has a subsequent impact on the annualized investment cost, which must be retained to

minimum achievable. Therefore, besides energy consumption, investment cost should be also taken into account and needs to be minimized. This cost depends on both pressure and the capacity of the column. The equations of Mullet et al. (1981) were used to estimate the installed cost of towers and trays, while the equations of Douglas (1988) were used to estimate the installed cost of reboilers and condensers. The Annualized Cost (AC) of the effects are then linearly formulated using Taylor series in the form of: $AC = b + a * F$, where F is the capacity and a and b are known parameters that depend on the operating pressure of the effect. In this analysis, capacity F can be decomposed into the form of: $F_{nom} * x$, where F_{nom} is the nominal feed flowrate of the column as defined by the initial distillation and x is the split fraction as selected by the optimization procedure. Consequently, parameter a is redefined by incorporating F_{nom} and further includes the nominal capacity of each distillation. As a result, let a_i and b_i be the costing (known) parameters of each effect and defined through the set of hot streams i (condensers) that belong to set H_d.

3. Mathematical formulation

The mathematical formulation for the selection of the prime portfolio of effects that minimizes (Eq.(1)) utilities and investment cost (Total Annualized Cost–TAC) is presented as follows:

$$min \qquad TAC = \sum_{m \in S} c_m * Q_m^S + \sum_{n \in W} c_n * Q_n^W + \sum_{d \in D} \sum_{i \in H_d} y_i * b_i + y_i^H * a_i \tag{1}$$

s.t.

$$R_{k-1} + \sum_{m \in S_k} Q_m^S + \sum_{i \in H_k} y_i^H * Q_{ik}^H = R_k + \sum_{n \in W_k} Q_n^W + \sum_{j \in C_k} y_j^C * Q_{jk}^C \quad k = 1, \dots K \tag{2}$$

$$y_i^H = y_j^C \qquad \forall (i,j) \in HC \tag{3}$$

$$\sum_{i \in H_d} y_i^H = 1 \qquad \forall d \in D \tag{4}$$

$$y_i^H \geq y_i * MAL \qquad \forall i \in H \tag{5}$$

$$y_i^H \leq y_i \qquad \forall i \in H \tag{6}$$

$$y_i^H = 1 \;\; \forall i \in (H - H_d), \qquad y_j^C = 1 \;\; \forall j \in (C - C_d) \tag{7}$$

$$R_0 = R_K = 0, \qquad 0 \leq y_i^H \leq 1 \;\; \forall i \in H_d, \qquad 0 \leq y_j^C \leq 1 \;\; \forall j \in C_d \tag{8}$$

The above mathematical formulation incorporates the process cascade equation (Eq.(2)) and logical constraints (Eq.(3)-Eq.(8)). A transshipment model is used to formulate the heat flows along the heat cascade (Eq.(2)) by incorporating new terms: $\sum_{i \in H_k} y_i^H * Q_{ik}^H$ and $\sum_{j \in C_k} y_j^C * Q_{jk}^C$, that account for the development of the variable intervals by controlling contribution of streams. Hot and cold streams related to the background are set to fully contribute the cascade by fixing the related y_i^H and y_j^C variables to be equal

to unit through Eq.(7). The heat contents of streams related to the effects are possible to range between zero and their nominal values; thereby, these are managed through y_i^H and y_j^C variables that are set to vary between 0 and 1 through Eq.(8). Eq.(3) secures the simultaneous contribution of the reboiler and condenser streams that belong to the same effect. Full distribution of the initial feed of each distillation d is secured through Eq.(4), where the sum of split fractions related to condensers should be equal to unit. This constraint is also secured for the associated split fractions of the reboilers through Eq.(3). To avoid selection of negligible and industrially impractical capacities of the effects, equations Eq.(5) and Eq.(6) are incorporated into the model to set the lower bound of capacities for the effects that are selected. This is done through a user defined (here is 10%) parameter that determines the Minimum Allowable Limit (MAL) of non-zero split fractions of effects that are selected through binary variables y_i. Equations Eq.(5) and Eq.(6) are also recorded only for split fractions of condensers, since the constraints related to reboilers split fractions are secured again through Eq.(3). The binary variables y_i that refers to the streams of the background will be equal to unit in any case, since the respective split fractions are fixed to unit through Eq.(7). Finally, the transshipment formulation necessitates setting residuals R_0 and R_K to zero (Eq.(8)).

4. Case study

The mathematical formulation has been applied to integrate three distillation columns that are met in the courses of a real-life biorefinery that produces bioethanol and lignin from lignocellulosic biomass. An organosolv process fractionates lignocellulosic biomass into C5 Sugars, C6 Sugars and lignin, while the sugars are then fermented through two separate processes producing C5 based ethanol and C6 based ethanol. Three distillation columns are used along the overall process; the first and most energy intensive is used for the recovery of solvents in organosolv process and the other two for the purification of ethanol from the downstream ethanol/water azeotrope mixtures of the two fermentation processes. The mathematical model selected two effects over the pinch for the first distillation, since more heat sinks are available than the heat sources below pinch, and one effect for each ethanol purification (Figure 2).

The crucial synthesis challenge is identified in the selection of operating pressures for the ethanol purifications, due to tradeoffs between energy and investment costs of the related candidate effects. As long as operating pressure of purification column decreases, the ethanol/water azeotrope mixture becomes richer in ethanol with a subsequent decrease in the energy consumption (easier separation), while investment cost appears minimum prices for operation at atmospheric pressure. This phenomenon appears in both C5-Ethanol and C6-Ethanol purification columns making the synthesis problem more complicated in the courses of simultaneous integration of all three distillations and strongly dependent on the morphology of the energy integrated profile of the background. Eventually, the operating pressures of ethanol purifications were selected so as to operate below pinch, where the background heat sinks are sufficient to integrate both of them, without adding more separation effects and securing full integration of these columns with significant investment cost savings. The energy consumption finally reduced from 129 MW and 120 MW of hot and cold utilities, respectively, to 30 MW and 22 MW, while the selected portfolios of effects contributed 33% of the overall energy savings.

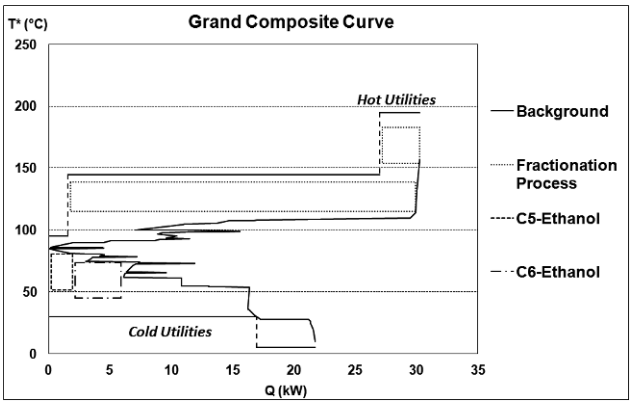

Figure 2: Grand Composite Curve of fully integrated lignocellulosic biorefinery

5. Conclusions

A MILP mathematical formulation is proposed to synthesize multi-effect distillation systems and integrate them with the overall process. Significant answers were given about the number, the pressures and the split fractions of the multiple effects, ahead of analytical design. The model detects promising structures of distillation effects by examining interactions between the synthesis specifications (number, pressure, split fractions) and the morphology of the energy profile of the background, being capable to re-engineer operating conditions without adding more effects (if this is feasible) and secure maximum energy and investment cost savings.

Abstract

The traditional approach for capacity expansion problem aims to balance investment costs with the returns obtained from production. These formulations ignore the behavior of competitive markets in which buyers select their providers according to their own interest. We propose a bilevel optimization formulation that considers the industrial producer and the markets as independent decision makers. The upper-level problem maximizes the profit of a producer whose revenue is subjected to a lower-level linear program (LP) that minimizes markets expenses. As an alternative to the single-level reformulation based on the KKT optimality conditions, we propose an approach based on strong duality of the lower-level LP. Both reformulations are shown to yield the same solution, but the duality-based reformulation achieves a significant reduction in solution time.

Keywords: capacity expansion, bilevel optimization, strong duality

1. Introduction

Mathematical programming has been used extensively to develop plans involving one-time investments that are recovered over long periods of time. Capacity expansion planning in the process industry is not an exception. In industry, producers plan their capacity such that their market position is not endangered by lack of responsiveness to variations in demand. An intuitive approach for capacity expansion planning is to formulate an optimization problem that maximizes profit over a finite time horizon. This approach has the advantage of exhaustively analyzing a set of expansion strategies, but it implicitly assumes that the producer decides which market share to satisfy. In competitive markets, buyers have the freedom to select their providers from different alternatives. In order to model the conflicting interests of a producer and the markets, we propose a bilevel optimization formulation to find the Stackelberg equilibrium between them. The problem implies finding the investment plan for a company whose revenue is determined by markets that minimize their cost. The bilevel formulation includes mixed-integer variables for the leader's decisions and models the markets' decisions in a lower-level linear program (LP).

The standard solution strategy for bilevel optimization problems with lower-level LPs is to replace the lower-level problem with its KKT optimality conditions. This reformulation maintains linearity of the problem except for the introduction of complementarity constraints. In this article, we use an equivalent reformulation that replaces the lower-level problem by its primal and dual constraints, and guarantees optimality by enforcing strong duality (Motto et al., 2005; Garces et al., 2009).

Most of the literature proposing bilevel optimization for capacity expansion is related to electricity markets. Soyster and Murphy (1989) formulated a capacity expansion problem for a perfectly competitive market. A more realistic model assuming an oligopolistic market was presented by Murphy and Smeers (2005). A bilevel formulation for the expansion of transmission networks was developed by Garces et al. (2009) to maximize the average social welfare over a set of lower-level problems representing different market clearing scenarios. Ruiz et al. (2012) modeled electricity markets as an Equilibrium Problem with Equilibrium Constraints (EPEC) in which competing producers maximize their profit in the upper level and a market operator maximizes social welfare in the lower level. In the context of the process industry, Ryu et al. (2004) developed a bilevel programming formulation for supply chain optimization under uncertainty to model different interests for production and distribution operations. Chu and You (2014) presented a bilevel model for scheduling and dynamic optimization of batch processes. Game theory concepts have also been used to model cooperative and competitive environments in supply chain planning (Zamarripa et al., 2012).

The novelty of our research resides on the application of bilevel optimization for capacity expansion planning in a competitive environment. Bilevel programming for these kind of problems can be seen as a risk reduction strategy given the significant influence of external decision makers in the economic success of investment plans. In particular, we propose a mathematical model that includes a rational behavior for the markets. The investment plans obtained from this approach are found to be less sensitive to changes in the business environment in comparison to the plans obtained from single-level formulations.

2. Problem statement

We consider an industrial producer willing to establish the capacity expansion plan that maximizes its profit during a finite time horizon, subject to revenue that is determined by markets that minimize the cost that they pay. The problem is modeled as a Stackelberg game in which the industrial producer (leader) decides its investment strategy first, and then the markets (follower) respond according their own interest. The Stackelberg game is a strategic game with perfect information: the leader chooses his actions with full knowledge of the follower's decision criterion, and the follower reacts after observing the leader's actions.

The industrial producer controls a set of facilities with limited production capacity. It has the possibility of expanding the existing facilities or investing to open new facilities. The goal of the investment plan is to maximize the Net Present Value (NPV) considering the cost of investments, production, maintenance, transportation, and the revenue obtained from selling a single product to several markets. The capacity expansion problem assumes deterministic demands during the finite time horizon; the prices offered to the markets by all providers are also assumed to be given. The products offered by the competing providers are considered homogeneous and the markets have no other preference for providers than price.

3. Formulation

Bilevel optimization problems are mathematical programs with optimization problems in the constraints (Bracken and McGill, 1973). In our formulation, the upper-level problem determines the optimal capacity expansion plan by selecting the investments that maximize the NPV of the leading producer. The expansions are modeled using binary variables such that the capacity increments are discrete. The lower-level determines the response of markets that select providers with the unique interest of satisfying their demands at lowest cost. The decisions of the markets are modeled with continuous variables that represent the deliveries that they obtain from each provider.

It is assumed that the leading producer offers the same price to each market in a given time period,

regardless of the production facility that is used to satisfy its demand. Therefore, markets have no preference among production facilities of the leader and the leading producer is free to choose the facilities it uses to satisfy demands. This modeling framework, in which degeneracy in the lower-level problem is resolved in favor of the upper-level decision maker, is known as the Optimistic Approach (Loridan and Morgan, 1996). The bilevel optimization formulation for the capacity expansion planning in a competitive environment is presented in Eqn. (1) - (9).

$$\max_{v,w,x} \quad \sum_{t\in T}\sum_{i\in I^1}\sum_{j\in J}\frac{1}{(1+R)^t}P_{t,i,j}y_{t,i,j} - \sum_{t\in T}\sum_{i\in I^1}\frac{1}{(1+R)^t}\left(A_{t,i}v_{t,i}+B_{t,i}w_{t,i}+E_{t,i}x_{t,i}\right)$$
$$-\sum_{t\in T}\sum_{i\in I^1}\sum_{j\in J}\frac{1}{(1+R)^t}\left(F_{t,i}y_{t,i,j}+G_{t,i,j}y_{t,i,j}\right) \tag{1}$$

$$\text{s.t.} \quad w_{t,i} = V_{0,i} + \sum_{t'=1}^{t} v_{t',i} \qquad \forall\, t\in T, i\in I^1 \tag{2}$$

$$x_{t,i} \le w_{t,i} \qquad \forall\, t\in T, i\in I^1 \tag{3}$$

$$c_{t,i} = C_{0,i} + \sum_{t'=1}^{t} H_i x_{t',i} \qquad \forall\, t\in T, i\in I^1 \tag{4}$$

$$\min_{y} \quad \sum_{t\in T}\sum_{i\in I}\sum_{j\in J}\frac{1}{(1+R)^t}P_{t,i,j}y_{t,i,j} \tag{5}$$

$$\text{s.t.} \quad \sum_{j\in J} y_{t,i,j} \le c_{t,i} \qquad \forall\, t\in T, i\in I \tag{6}$$

$$\sum_{i\in I} y_{t,i,j} = D_{t,j} \qquad \forall\, t\in T, j\in J \tag{7}$$

$$y_{t,i,j} \in \mathbb{R}^+ \qquad \forall\, t\in T, i\in I, j\in J \tag{8}$$

$$c_{t,i}\in\mathbb{R}^+,\ v_{t,i},\ w_{t,i},\ x_{t,i}\in\{0,1\} \qquad \forall\, t\in T, i\in I^1, j\in J \tag{9}$$

where T, I^1, I^2, and J are respectively, the index sets for time (t), facilities of the leading producer (i^1), facilities of the independent providers (i^2), and markets (j). The first term in (1) represents the revenue obtained from deliveries. Revenue is proportional to the volume of sales ($y_{t,i,j}$) according to the price paid by the markets ($P_{t,i,j}$). The second term includes the cost of opening new facilities, the maintenance cost of open facilities, and the expansion cost. The binary variable deciding if a new facility is open at location i at time period t is $v_{t,i}$; the parameter $A_{t,i}$ determines the cost to build a new facility with zero capacity. The binary variable $w_{t,i}$ indicates if facility i is open at time period t; if the facility is open at period t, a fixed cost $B_{t,i}$ is paid for maintenance. The expansion in facility j at period t is decided with binary variable $x_{t,i}$; the cost of the expansion is given by the parameter $E_{t,i}$. The third term includes production and transportation costs. Production costs are proportional to the volume of sales ($y_{t,i,j}$) according to the unit production cost ($F_{t,i}$). Transportation cost from production facilities to markets is proportional to the volume of sales ($y_{t,i,j}$) according to the unit transportation cost ($G_{t,i,j}$). All terms are discounted with an interest rate (R).

Constraint set (2) is used for the maintenance cost of facilities during the time periods when they are open; the binary parameter $V_{0,i}$ indicates the facilities that are initially open. Constraint set (3) requires capacity expansions to take place only at open facilities. Constraint set (4) determines the production capacity of facilities according to the expansion decisions; parameters $C_{0,i,k}$ indicate the initial capacities and H_k the magnitude of the potential capacity expansions. Constraints set (6) bounds deliveries according to the production capacities. Finally, constraints set (7) enforces demand satisfaction. The domains are given by Eqn. (8) - (9).

4. Single-level reformulation using strong duality

An optimistic bilevel program with a convex and regular lower-level can be transformed into a single-level optimization problem using its optimality conditions (Colson et al., 2007). The key property of convex programs is that global optimal solutions can be described by the set satisfying their KKT conditions. In the case of linear programs, KKT optimality conditions are equivalent to the satisfaction of primal feasibility, dual feasibility, and strong duality (Gale et al., 1951). Based on this equivalence, we can replace Eqn. (5) - (9) from the bilevel formulation with Eqn. (10) - (13).

$$\sum_{t\in T}\sum_{i\in I}\sum_{j\in J}\frac{1}{(1+R)^t}P_{t,i,j}y_{t,i,j}=\sum_{t\in T}\left[\sum_{j\in J}D_{t,j}\lambda_{t,j}-\sum_{i\in I}c_{t,i}\mu_{t,i}\right] \tag{10}$$

$$\sum_{j\in J}y_{t,i,j}\leq c_{t,i} \qquad \forall\, t\in T, i\in I \tag{11}$$

$$\sum_{i\in I}y_{t,i,j}=D_{t,j} \qquad \forall\, t\in T, j\in J \tag{12}$$

$$\lambda_{t,j}-\mu_{t,i}\leq\frac{1}{(1+R)^t}P_{t,i,j} \qquad \forall\, t\in T, i\in I, j\in J \tag{13}$$

The upper-level problem represented by Eqn. (1) - (4) remains unchanged in the duality-based reformulation. The reformulation introduces dual variables $\mu_{t,i}$ corresponding to Enq. (6) and $\lambda_{t,j}$ corresponding to Enq. (6). Strong duality is enforced by equating the primal and dual objective functions as presented in Eqn. (10). Lower-level primal constraints (11) and (12) are kept in the formulation to guarantee primal feasibility. Dual feasibility of the lower level is ensured with constraint (13).

It is important to note that this reformulation yields a nonconvex Mixed-Integer Nonlinear Program (MINLP). The nonconvexity arises from the dual objective function in the right hand side of Eqn. (10), because of the product of upper-level variable $c_{t,i}$ and lower-level dual variable $\mu_{t,i}$. Fortunately, the problem can be reformulated as a MILP because the continuous variable $c_{t,i}$ only takes values in discrete increments as indicated by Eqn. (4). The linearization procedure is based on eliminating variable $c_{t,i}$ from the formulation by replacing it with Eqn. (4). The resulting bilinear terms are products of continuous variables ($\mu_{t,i,k}$) and binary variables ($x_{t',i}$). Therefore, they can be modeled with a set of mixed-integer constraints by including a continuous variable ($u_{t',t,i}$) for each bilinear term.

The resulting MILP formulation is obtained after replacing Eqn. (10) with Eqn. (14),

$$\sum_{t\in T}\sum_{i\in I}\sum_{j\in J}\frac{1}{(1+R)^t}P_{t,i,j}y_{t,i,j}=\sum_{t\in T}\left[\sum_{j\in J}D_{t,j}\lambda_{t,j}-\sum_{i\in I}c_{0,i}\mu_{t,i}-\sum_{t'=1}^{t}\sum_{i\in I^1}H_i u_{t,t',i}\right] \tag{14}$$

and introducing the mixed-integer constraints presented in Eqn. (15) - (16).

$$u_{t,t',i}\geq\mu_{t,i}-M\left(1-x_{t',i}\right) \qquad \left(t,t'\right)\in\left\{\left(t,t'\right):\, t'\leq t,\, t\in T\right\},\, i\in I^1 \tag{15}$$

$$u_{t,t',i}\in\mathbb{R}^{+} \tag{16}$$

It is interesting to remark that only the two terms presented in Eqn. (15) and (16) are necessary for the linearization of the bilinear terms because they are sufficient to bound the values of $u_{t,t',i}$ in the improving direction of the objective function.

5. Illustrative Example

The duality-based reformulation is implemented to solve a small case study from the air separation industry. This example considers the production and distribution of one product to 15 markets during 20 periods of 90 days (quarters of year). Initially, the leading producer has three production facilities with capacities equal to 7,200 ton/period, 22,500 ton/period, and 45,000 ton/period; it also has one candidate location for a new facility. There are three independent providers with constant capacity equal to 27,000 ton/period, 45,000 ton/period, and 9,000 ton/day. In every time period, the production facilities controlled by the leading producer are allowed to expand by installing additional production lines with a capacity of 9,000 ton/period. Selling prices and costs related to investment, maintenance, production, and transportation increase with time. The total demand of all markets grow from 131,400 ton in the first time period up to 149,929 ton in the last time period. The complete data for the illustrative example is omitted because of the space limitation.

The solution of the problem establishes the investment plan and the distribution strategy during the time horizon. We compare the solution obtained from the bilevel formulation with the solution obtained from a single-level optimization problem in which the markets are assumed to be captive by the leading producer. Additionally, we calculate the performance of the single-level expansion strategy in a competitive environment. Table 1 presents the comparison. The results show that the single-level formulation proposes a more aggressive expansion strategy than the bilevel formulation. This is a consequence of planning for a larger market share when the decision criterion of the markets is ignored. When the single-level expansion strategy is evaluated in competitive markets, the investments remain the same but the revenue reduces from MM $1,265 to MM $931. In contrast, the bilevel formulation proposes a more conservative expansion strategy that obtains a 35 % increase in NPV (from MM $441 to MM $338) in competitive markets when compared to the single-level expansion strategy.

In order to illustrate the benefits of the duality-based reformulation we compare it with its equivalent KKT reformulation. The computational statistics for both of them are presented in Table 2. Both MILP reformulations were implemented in GAMS 24.2.3 and solved using CPLEX 12.6.0.1.

Table 2 shows the increase in model size from the single-level formulation to the bilevel formulations. It is important to highlight that the duality-based reformulation does not require any additional binary variables in comparison to the single level formulation. In contrast, the KKT reformulation requires one additional binary variable for each inequality in the lower level, including bounds on the variables. The significant increase in the number of constraints, continuous variables, and specially binary variables dominates the solution time of the KKT reformulation. However, the solution obtained form the KKT and the duality-based reformulations are identical.

Table 1: Comparison of the results for the single-level and the bilevel formulation

Term in objective function	**Single level without competition**	**Single level with competition**	**Bilevel with competition**
Revenue (MM$):	1,265	931	930
New facilities (MM$):	0	0	0
Maintenance (MM$):	94	94	94
Expansion (MM$):	191	191	85
Production (MM$):	412	296	300
Transportation (MM$):	14	12	10
NPV (MM$):	554	338	441
Total market cost (MM$):	1,494	1,355	1,355

Table 2: Model statistics for the proposed formulations

Model statistic	Single level without competition	KKT reformulation	Duality-based reformulation
Number of constraints:	680	8,540	4,380
Number of continuous variables:	2,240	6,140	4,220
Number of binary variables:	240	3,120	240
Solution time (s) [a]:	0.22	210	3.2

[a] using priority branching on the expansion decisions

6. Conclusions

We have presented a bilevel optimization formulation for the capacity expansion problem in competitive markets. The formulation considers the interactions between two independent decision makers: an industrial producer establishing its expansion plan and a set of markets minimizing the cost that they pay to satisfy their demands. The proposed formulation has the advantage that it models markets as rational decision makers, which avoids overestimating the attainable revenue. The illustrative example demonstrates that the bilevel formulation yields an expansion strategy that is more conservative with respect to capital investments and produces higher NPV when evaluated on competitive markets.

We have also proposed an approach to reformulate the bilevel problem as a single level optimization problem. The reformulation is based on the strong duality property of the lower-level LP, and it is equivalent to the reformulation that uses the KKT optimality conditions. The main benefit of the duality-based reformulation is that it does not require the addition of new binary variables; however, in order to obtain a MILP reformulation the decision of the leader must be discrete. The computational performance of the duality-based reformulation is significantly superior to the performance of the KKT reformulation. The proposed reformulation of the bilevel optimization problem for capacity expansion has the potential to address large-scale problems that support decision making for industrial producers.

Abstract

This contribution presents a novel CP/MILP hybrid approach aimed at solving large size multiproduct, multistage batch plants scheduling problems. This three-phase approach accounts for many real world features. In addition, production orders requiring several batches of each product can be fulfilled by operating in a campaign mode, as it occurs in many industrial facilities. Numerical results show that for large scale examples the approach can perform better than standalone MILP and CP models and can solve problems that could not be solved with either of these methods alone.

Keywords: Batch plant scheduling, Resource-constraints, Hybrid approaches, MILP methods, Constraint-programming

1. Introduction

Since scheduling problems are NP hard, the efficient solution of their corresponding MILP models can become computationally very expensive for large-scale problems. This challenging situation can be tackled by means of hybrid approaches (Harjunkoski et al., 2014) combining the complementary strengths of Mixed-Integer Linear Programming (MILP) and Constraint Programming (CP) techniques. This contribution presents a novel CP/MILP approach aimed at solving multiproduct, multistage batch plants scheduling problems addressing a big number of batches that are manufactured under a campaign mode. The methodology has three phases. In the first one, an MILP model tackles the assignment problem. The second phase, addressed by means of a relaxed CP model, has a twofold goal: first, to check the feasibility of the previously obtained assignment, and second, to solve the sequencing problem taking into account sequence-dependent changeover times. When the assignment turns out to be unfeasible, cuts are generated and the first phase is solved again. The iteration between phases one and two continues until a feasible assignment is reached. In such a case, the third phase, which is a rigorous CP model that optimizes performance measures such as makespan, total or mean tardiness, etc., obtains the final solution. The reduction of CPU time is the reason for having both a relaxed (phase 2) and a tightened (phase 3) CP model, instead of just one, as in other hybrid CP/MILP methodologies. Section 3 presents the models corresponding to this three phase approach. The proposal has been implemented in the IBM ILOG CPLEX Optimization Studio (IBM, 2014), in which both MILP and CP models can be defined. Section 4 shows the results that have been obtained when addressing various case studies and Section 5 presents concluding remarks.

2. Hybrid CP/MILP model

2.1. Nomenclature

2.1.1. Sets/Indexs

B/b: batches
C_p/c: campaigns comprising a set of batches of product *p*
$Csol^n_{u,p,c}$: set of index triplets representing those campaign tasks associated with campaign *c* of product *p* on unit *u* contained within solution *n*
Fp/-: product couples that correspond to forbidden production sequences f=<*p,p'*>. When the campaign mode is adopted, it includes same product sequences
Fu/-: units belonging to stage *s+1* that are not connected to unit *u* belonging to stage *s*
Nsol/n: set of MILP model solutions
P/p, p': products that are demanded during the scheduling horizon
S/s: processing stages
$Sol^n_{b,u}$: set of index pairs representing those processing tasks of batch *b* executed in unit *u* that are contained within solution *n*
U/u: processing units

2.1.2. Parameters

changeOverTimes: <*p,p',u*> triplets containing the changeover time between products *p* and *p'* on unit *u*
$cost_{p,u}$: processing cost of a batch of product *p* on unit *u*
dd_b: due-date of batch *b*
lb_p: minimum number of batches of product *p* that is possible to process in a row
$nbCampaign_n$: number of campaigns included in solution *n*
$pt_{p,u}$: processing time required by a batch of product *p* in unit *u*
rd_u: ready time of unit *u*
rt_b: release time of batch *b*
ub_p: maximum number of same product batches that is possible to process in a row

2.1.3. Variables

$taskAsig_{b,u,c}$: binary variable representing the allocation of unit *u* to processing task of batch *b* that belongs to campaign *c*
$campaignAsig_{u,p,c}$: binary variable representing the allocation of unit *u* to processing campaign *c* of product *p*
mws_s: end time estimator of the last processing task at stage *s*
y_n: binary variable that is equal to 1 when the current solution (*n+1*) has a smaller number of campaigns than solution *n,* and 0 otherwise
$cBin_{u,p,c}$: binary variable employed to reach a feasible solution at the second phase when a campaign mode is considered
$bin_{b,u}$: binary variable employed to reach a feasible solution at the second phase when a campaign mode is not considered
$task_{b,u,c}$: optional interval variable that represents a processing task of batch *b* that belongs to campaign *c* on unit *u*. If campaign mode is not considered, index *c* is ignored
$campaignTask_{u,p,c}$: campaign interval variable that spans over all the processing tasks that belong to the campaign *c* of product *p* carried out unit *u*
$unitBatchSeq_u$: sequence variable defined for each unit *u*. It represents an ordering of task interval variables associated with *u*. Each interval variable (task) in this sequence is characterized by an attribute. When the changeovers between tasks are unit-independent, this attribute specifies the product *p* associated with each task variable. In case the changeovers are unit-dependent, the attribute represents both, the product and the unit where the task is assigned

$unitCampaignSeq_u$: sequence variable defined for each unit u. It represents an ordering of campaign interval variables associated with u. Each interval variable (campaign) in this sequence is characterized by an attribute that specifies the product p associated with the campaign variable
tar_b: tardiness of batch b

2.2. First phase: MILP Model

Each batch must be assigned to just one processing unit at each stage (constraint 1) and to just one campaign that is the same at all stages (constraint 2).

$$\sum_{\forall\, u\in U_s, \forall\, c\in C_p} taskAsig_{b,u,c} = 1 \qquad \forall\, b \in B_p, \forall\, p \in P, \forall\, s \in S \tag{1}$$

$$taskAsig_{b,u1,c1} + taskAsig_{b,u2,c2} \leq 1$$
$$\forall\, b \in B_p, \forall\, c1, c2 \in C_p \,|c1 \neq c2, \forall\, p \in P, \forall\, u1, u2 \in U \tag{2}$$

Constraints (3) and (4) fix the lower and upper bounds on the number of batches that belong to a particular product campaign.

$$\sum_{b\,\in\, B_p} taskAsig_{b,u,c} \geq lb_p \cdot campaignAsig_{u,p,c} \qquad \forall\, c \in C_p, \forall\, p \in P, \forall\, u \in U \tag{3}$$

$$\sum_{b\,\in\, B_p} taskAsig_{b,u,c} \leq ub_p \cdot campaignAsig_{u,p,c} \qquad \forall\, c \in C_p, \forall\, p \in P, \forall\, u \in U \tag{4}$$

When a particular campaign is assigned to a given unit, to allocate another campaign of the same product it is necessary to assign a different product campaign to avoid the consecutive execution of campaigns linked to the same product (constraint 5). Similarly, in order to assign campaigns associated with a forbidden product sequence to a certain unit, is necessary to assign to such unit a campaign belonging to a non-forbidden product (constraint 6).

$$\sum_{\forall\, c1\in C_{p1}} campaignAsig_{u,p1,c1} \leq 1 + \sum_{\forall\, c2\in C_{p2}, \forall\, p2\in P\,|p1\neq p2} campaignAsig_{u,p2,c2}$$
$$\forall\, p1 \in P, \forall\, u \in U \tag{5}$$

$$\sum_{\forall\, c2\in C_{p2}} campaignAsig_{u,p2,c1} \leq 1 + \sum_{\substack{\forall\, c1\in C_{p1}, \forall\, p1\in P, \\ (p,p2)\in Fp\,|p1\neq p}} campaignAsig_{u,p1,c2}$$
$$\forall\, p2 \in P, \forall\, u \in U \tag{6}$$

Constraint (7) enforces topology restrictions by ensuring that batches are not assigned to consecutive units that are not physically connected.

$$taskAsig_{b,u1,c} + taskAsig_{b,u2,c} \leq 1$$
$$\forall\, b \in B_p, \forall\, c \in C_p, \forall\, p \in P, \forall (u2, u1) \in Fu, \forall\, u1, u2 \in U \tag{7}$$

For each product, a given batch cannot be assigned to campaign *c+1* if the previous campaign *c* for the same product is not allocated into a given unit (constraint 8).

$$campaignAsig_{u1,p,c1} \geq campaignAsig_{u2,p,c2}$$
$$\forall\, c1, c2 \in C_p, \forall\, p \in P, \forall\, u1, u2 \in U_s | c1 + 1 = c2 \wedge s = 1 \tag{8}$$

When the assignment turns out to be unfeasible, cuts are generated by means of constraints (9) to (11). For each previous solution, constraint (9) ensures that the new one will comprise at least a different task. Since the new solution may have a different

task but the same campaigns, which will retain the infeasibility, constraints (10) and (11) ensure the presence of a different combination of campaigns.

$$\sum_{(b,u,c)\in Csol_{b,c,u}^{n}} taskAsig_{b,u,c} < nbTasks \quad \forall\, n \in Nsol \tag{9}$$

$$\sum_{\substack{\forall b\in B_p,\forall c\in C_p,\forall p\in P,\\ \forall u\in U|(b,u,c)\in Csol_{b,u,c}^{n}}} campaignAsig_{u,p,c} < nbCampaigns_n \cdot y_n \quad \forall\, n \in Nsol \tag{10}$$

$$\sum_{\substack{\forall b\in B_p,\forall c\in C_p,\forall p\in P,\\ \forall u\in U|(b,u,c)\in Csol_{b,u,c}^{n}}} campaignAsig_{u,p,c} > nbCampaigns_n \cdot (1-y_n)\ \forall\, n \in Nsol \tag{11}$$

Expression (12) is the objective function to be minimized when a cost-based criterion is chosen. When makespan is selected, constraints (13) and (14) have to be included to take into account the maximum workload at each stage.

$$minimize \sum_{\forall b\in B_p}\sum_{\forall c\in C_p}\sum_{\forall p\in P}\sum_{\forall u\in U} taskAsig_{b,c,u}\cdot cost_{p,u} \tag{12}$$

$$minimize \sum_{\forall s\in S} mws_s \tag{13}$$

$$mws_s \geq \min_{\substack{\forall u\in S_u\\ \forall b\in B}} (rd_u, rt_b) + s \cdot \sum_{\substack{\forall b\in B_p,\forall c\in C_p,\\ \forall p\in P\forall u\in U_s}} taskAsig_{b,c,u}\cdot pt_{p,u} \quad \forall s \in S \tag{14}$$

2.3. Second phase: CP model-I

The duration of each task depends on the unit assigned to it. Constraint (14) fixes the duration when UIS or NIS/ZW policies are adopted. To handle a NIS/UW policy, a greater than or equal to symbol has to replace the equality one in constraint (14). To handle a NIS/FW policy, a couple of similar constraints, which are not presented due to lack of space, need to be added.

$$\begin{gathered} sizeOf\big(task_{b,u,c}\big) = pt_{p,u} \\ \forall b \in B_p, \forall c \in C_p, \forall p \in P, \forall u \in U | (b,u,c) \in Csol_{b,u,,c}^{n} \end{gathered} \tag{14}$$

Tasks belonging to a batch recipe must be executed without any overlapping, satisfying the prescribed inter-stage storage and waiting policies, as well as the precedence relationships. Constraint (15) corresponds to a UIS policy. To handle the other policies the *endBeforeStart* constraint has to be replaced by an *endAtStart* one.

$$\begin{gathered} endBeforeStart\big(task_{b,u1,c}, task_{b,u2,c}\big) \qquad \forall b \in B, \forall c \in C, \forall u1, u2 \\ \in U, \forall s1 \in S_{u1}, \forall s2 \in S_{u2} | (b,u,c) \in Csol_{b,u,c}^{n} \wedge \mathrm{s1} + 1 = \mathrm{s2} \end{gathered} \tag{15}$$

By using the *span* CP construct, constraint (16) ensures that each processing task associated with a campaign takes place within the campaign spanning interval.

$$\begin{gathered} span\big(campaignTask_{u,p,c}, all\big(b \in B_p | (b,u,c) \in Csol_{b,u,c}^{n}\big) task_{b,u,c}\big) \\ \forall c \in C_p, \forall p \in P, \forall u \in U \end{gathered} \tag{16}$$

Constraint (17) enforces all the interval variables associated with a given campaign sequence variable, *unitCampaignSeq*$_u$, to not overlap each other, being separated by the corresponding transition times when the problem being faced has sequence (unit) - dependent changeover times. Constraint (18) avoids forbidden production sequences.

When a forbidden sequence is present, the binary variable $cBin_{u,p,c}$ is equal to zero. Both, the *typeOfNext* and *noOverlap* constructs are described in detail in IBM (2014).

$$noOverlap(unitCampaignSeq_u, changeOverTime) \qquad \forall\, u \in U \tag{17}$$

$$TypeOfNext\left(unitCampaignSeq_u, campaignTask_{u,p,c}\right) \neq p' \cdot cbin_{u,p,c} \quad \forall c \in C_p, \forall p \in P, \forall u \in U, \forall\, (p,p') \in Fp | (u,p,c) \in Csol^n_{u,p,c} \tag{18}$$

When the campaign mode is not considered, constraints (17) and (18) are replaced by constraints (19) and (20)

$$noOverlap(unitBatchSeq_u, changeOverTime) \qquad \forall\, u \in U \tag{19}$$

$$typeOfNext\left(unitBatchSeq_u, task_{b,u}\right) \neq p' \cdot bin_{b,u} \quad \forall b \in B_p, \forall p \in P, \forall u \in U, \forall\, (p,p') \in Fp | (b,u) \in Sol^n_{b,u} \tag{20}$$

Constraint (21) is the objective function to be maximized. A value equal to card($Csol^n_{u,p,c}$) means that a feasible solution was reached. When the campaign mode is not considered, the variable $cbin_{u,p,c}$ must be replaced by $bin_{b,u}$.

$$maximice \sum_{\forall c \in C_p, \forall p \in P, \forall u \in U | (u,p,c) \in Csol^n_{u,p,c}} cbin_{u,p,c} \tag{21}$$

2.4. Third phase: CP model-II

The model corresponding to this phase is similar to second-phase model. Constraints (18) or (20) must be replaced by (22) or (23), respectively. To minimize makespan, the objective function (24) is required and to reduce total tardiness, expressions (25) and (26) are to be included. Constraint (26) captures the tardiness of each batch.

$$TypeOfNext\left(unitCampaignSeq_u, campaignTask_{u,p,c}\right) \neq p' \quad \forall c \in C_p, \forall p \in P, \forall u \in U, \forall\, (p,p') \in Fp | (u,p,c) \in Csol^n_{u,p,c} \tag{22}$$

$$typeOfNext\left(unitBatchSeq_u, task_{b,u}\right) \neq p' \quad \forall b \in B_p, \forall p \in P, \forall u \in U, \forall\, (p,p') \in Fp | (b,u) \in Sol^n_{b,u} \tag{23}$$

$$minimize\ max\left(task_{b,u,c}\right) \quad \forall b \in B_p, \forall c \in C_p, \forall p \in P, \forall u \in U_s | (b,u,c) \in Csol^n_{b,u,c} \wedge s = nbStages \tag{24}$$

$$minimize \sum_{\forall b \in B} tar_b \tag{25}$$

$$tar_b = max\left(0, endOf\left(task_{b,c,u}\right) - dd_b\right) \quad \forall b \in B_p, \forall c \in C_p, \forall p \in P, \forall u \in U_s | (b,u,c) \in Csol^n_{b,u,c} \wedge s = nbStages \tag{26}$$

3. Case studies

The MILP-CP formulation has been tested with several examples. Case 1 is based on the pharmaceutical facility addressed by Novara et al. (2013) adding the following characteristics: unit ready times, topological constraints, forbidden product sequences, banned unit-product assignments, as well as sequence- and unit-dependent changeover times. Fifty different product orders with distinct release times are to be scheduled. Each order comprises four batches. The goal is to find good quality schedules for the 200 batches, minimizing makespan under UIS, NIS/FW and NIS/ZW polices (Cases 1.1 to 1.3 in Table 1, respectively). The second case study was introduced by Kopanos et al. (2010). It considers the scheduling of 60 orders, including stage-dependent changeover times, as well as UIS and NIS/ZW policies (Examples 3.1 and 3.2 in Table 1). The goal is to minimize makespan.

Table 1. Comparison with other approaches. Examples 1 and 2

	Kopanos et al. (2010)		Novara et al. (2013)		This approach	
	OF value	CPU Time (s)*	OF value	CPU Time (s)*	OF value	CPU Time (s)*

1.2	--	--	NS	NS	**156689**	3595
1.3	--	--	**162471**	3543	163989	3247
2.1	48.548	1502	**42.8967**	1969	49.0680	246
2.2	56.061	1718	**48.6045**	3103	49.4946	610

*Time limit: 3600 seconds

Example 3 corresponds to Case 1 environment. Seven different products are to be manufactured. Nine product orders, having between 3 and 10 batches, need to be scheduled. Each order has a different due date and there are four orders that correspond to just two products. The plant operates under a campaign production policy, having different upper and lower bounds on the number of batches per product. Various interstage storage and waiting policies are considered: UIS (3.1, 3.4), NIS/UW (3.2, 3.5) and NIS/ZW (3.3, 3.6). The goal is to minimize cost. At the CP phase, makespan (cases 3.1 to 3.3) or tardiness (cases 3.4 to 3.6) is minimized as a second criterion.

Table 2. Comparison with other approaches. Example 3

	Novara et al. (2013)				This approach

3.6	nsf	nsf	nsf	nsf	75800	1562640	133290	3508

*Time limit: 3600 seconds nsf: no solution found

4. Conclusions

The proposal has been extensively tested by means of several examples (60 to 200 batches). Numerical results show that for large size cases of plants operating under a campaign mode, the approach can perform better than standalone MILP and CP models, and, more importantly, can solve problems that could not be solved with either of these methods alone. In several instances, the first phase of the approach allows obtaining feasible and efficient assignments, thus avoiding the need for iterations and reducing the required CPU time. This decomposition approach has proved to be quite effective.

Abstract

Production scheduling in pharmaceutical production must consider a complex set of features, including due dates, shelf-life, reduced possibility for task execution during night shifts or weekends. Especially when dealing with the sterile production of liquid drug products, production is prone to short-term rescheduling; mainly caused by material scarcity, process duration uncertainty and holding time restrictions. The mentioned complexity and rescheduling challenges motivate the development of production models that are accounting for these features and include efficient campaigning by minimizing the duration of sequence dependant activities. A slot-based model was developed to solve these problems with the objective of minimizing the overall makespan.

The model was applied to a filling line of liquid drug products in an industrial case study, which allowed the validation of the presented model and revealed a 2 % optimisation potential on a ten batch planning goal. The successful implementation for one filling line has motivated the expansion of the model to two parallel and three consecutive processing units.

Keywords: Mathematical Optimisation, Mixed-Integer Linear Programming, Scheduling, Batch Production, Industrial Application.

1. Introduction

The increasingly competitive pharmaceutical industry calls for advanced scheduling models, tailored to the specifics of drug product manufacturing. Optimized schedules support reducing the number of required format changes and isolator sterilizations by optimal sequencing and campaigning, i.e. the production of multiple batches in a row without intermediate re-sterilisation or re-decontamination. In real-life, realistic schedules can only be achieved reasonably by fulfilling all major production constraints in one model simultaneously; including demand, shelf-life, due date, workforce availability as well as capacity of utilities and equipment. On top of these constraints, redefining an optimal batch size and rescheduling of batches are frequent issues caused by reprioritization of products, raw material scarcity and sterile holding time limitations. Hence, optimal scheduling on the shop floor level results in a very complex activity, of utmost importance for maintaining efficient production.

A large amount of scheduling models is available in the literature, and they have a broad field of application (Maravelias, 2012). The current state of the literature has recently been summarized by Harjunkoski et al. (2014) in a review article on scheduling models and their relevance in process industries. Fumero et al. (2014) introduce a methodology that includes many of the aspects, including campaigning and the minimisation of sequence dependant activities but lacks to model effects of limited sterile holding times. The consideration of these limitations and the efficient modelling of the resulting constraints is achieved in the presented model.

2. Methodology

In this work, most of the aforementioned challenges have been addressed and a slot-based formulation is presented, which is inspired by a liquid vial production line, as described in the case study. While considering demand, shelf-life, due date, product-dependent processing rates and sterile holding times, the formulation allows finding the optimal batch sequence with respect to makespan minimization. This goal is achieved by the introduction of a model similar to the one presented by Kabra et al. (2013) and by applying the concept of two operation modes, as described by Moniz et al. (2014).

Routine production runs are illustrated schematically in the top row of Fig. 1. The operation mode (OM) referred to as OM-A illustrates a "single" batch, i.e. a batch that is produced by interrupting the sterile state of the filling isolator before and after the production of that batch. This represents the most simple but also inefficient operation mode, which requires one sterilisation run for each batch. However, operation modes OM-B, OM-C and OM-D to the right of the top row in Fig. 1 represent an alternative way of producing batch-wise, namely campaign mode. This concept has also been described lately in the work of Moniz et al. (2014). For sterile drug products, this operation mode requires the validation of a certain time period, during which an isolator is considered sterile after having performed a successful sterilisation run. Furthermore, all batches in a campaign must be filled into the same glass container format, so that the isolator must not be opened for a format change. Likewise, the necessary cleaning activities between two such batches must allow for the isolator to remain sealed. Products fulfilling these criteria of campaign production are referred to as members of the same product family in this study. The advantage of campaign modes, consisting of a first (OM-B), last (OM-D) as well as *n* intermediate (OM-C) batches,

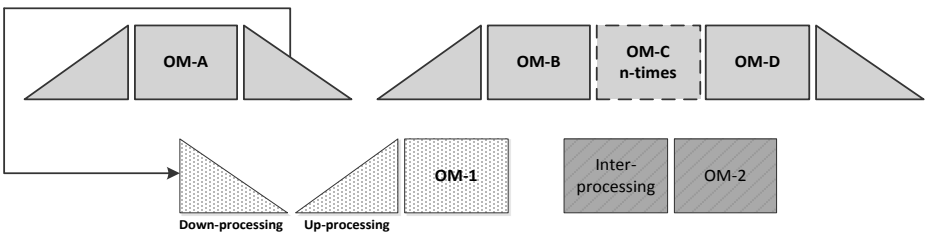

Figure 1: A representation of the operation modes (OM) as performed in pharmaceutical batch production processes. The top row indicates the traditional structure with OM-A as a batch produced individually and the OMs B to D (i.e., OM-B, OM-C and OM-D) in the campaign mode. By performing a task shift, a model reduction to two operation modes OM-1 and OM-2 can be achieved, which requires less computational resources while not reducing the accuracy of the scheduling output.

where *n* can be any natural number including zero, is to maximize production capacity by performing less sterilisation runs per batch.
However, four operation modes (OM-A to OM-D) are computationally expensive and would be difficult to optimise within reasonable time even for small scale problems. A simplification to the problem without limiting the accuracy of resulting scheduling solutions was achieved by executing a task shift, as illustrated by the arrow in Fig. 1, which led to the introduction of OM-1 and OM-2. This model takes advantage of the fact, that up-processing activities must only be performed, if the preceding batch was ending with down-processing and vice versa.
Hence, on the top level the presented solution comprises of batches produced individually (OM-1), and the more time-efficient variant, where multiple batches are produced within a campaign (OM-2), i.e., cleaning and sterilization activities are reduced. A more detailed modelling level is depicted in Fig. 2, which consists of ten tasks and their sequences, which are indicated by arrows.
The execution of all tasks T1 to T7 is necessary for the production of liquid drug product batch in OM-1. However, when filling a batch into the same sort of glass vial as a preceding batch, the format change (T3) must not be executed. Performing tasks T1, T8 and T7 is required for the manufacturing of an OM-2 batch. As can be seen in Fig. 2, the execution of an OM-2 is beneficial when compared to OM-1. The tasks T9 and T10 are included in the model to account for technical services and media fills, respectively. Media fills are batch production runs, during which a culture medium is filled instead of a regular drug product solution in order to assess the sterility of the filling unit.

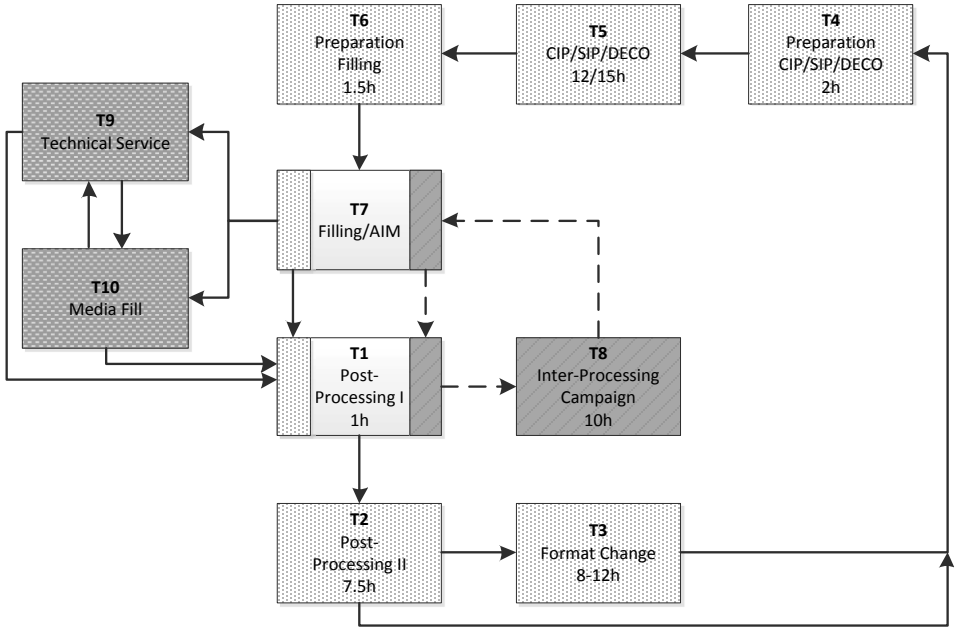

Figure 2: The tasks required for the production of a batch in OM-1 are indicated in the light shaded boxes (T1 to T7). Tasks T1, T8 and T7 are tasks required for executing an OM-2 batch while T9 and T10 are the tasks for technical service and media fill, respectively.

The proposed slot-based scheduling model comprises of Eq. (1) to (13) for a single filling line. The overall objective consists of minimizing the makespan, that is, the sum of the duration of all the batches (Eq. (1)). Eq. (2) defines that the duration of a batch is the sum of the duration of all the tasks that belong to that batch. Therefore, task duration may be either fixed (Eq. (3A)) or batch size dependent (Eq. (3B)). Each batch has to be assigned exactly to one slot (Eq. (4)) and a slot has to be assigned to a single batch (EQ. (5)). In order to determine the operating mode of a certain batch, variable $biS_{s,b}$ is introduced. Eq. (6) imposes that the operating mode of a batch in a certain slot can only be decided if the batch is assigned to that slot. Therefore, the sterility condition imposes that not more than two consecutive batches can be run in OM2 (Eq. (7)). If there is a format change between two consecutive slots, the later has to be run in OM1 (Eq. (8A and 8B)). Finally, it is necessary to define the timing of the different slots. Constraints (9) to (13) assign the starting time of the different tasks of the different slots and impose the conditions on due dates and shelf life.

$$TIME = MIN \sum_{s \in S^{ALL}, b \in B^{ALL}} TB_{s,b} \tag{1}$$

$$TB_{s,b} = \sum_{t \in T^{ALL}} TT_{s,b,t} \quad \forall\, s \in S^{ALL}, b \in B^{ALL} \tag{2}$$

$$TT_{s,b,t} = biT_{s,b} * tasks_t \;\; \forall\, s \in S^{ALL}, b \in B^{ALL}, t \in T^{CONST} \tag{3A}$$

$$TT_{s,b,t} = biT_{s,b} * \frac{q_b}{rf_p} \;\; \forall\, s \in S^{ALL}, b \in B^{API}, t \in T^{VAR}, p \in BP^{ATTACHED} \tag{3B}$$

$$\sum_{s \in S^{ALL}} biT_{s,b} = 1 \quad \forall\, b \in B^{ALL} \tag{4}$$

$$\sum_{b \in B^{ALL}} biT_{s,b} = 1 \quad \forall\, s \in S^{ALL} \tag{5}$$

$$biT_{s,b} \geq biS_{s,b} \;\; \forall\, s, b \tag{6}$$

$$biS_{s,b} + biS_{s+1,b'} + biS_{s+2,b''} \leq 2 \quad \forall\, s \in S^{ALL};\; b, b', b'', p, p', p'' \in BP^{ATTACHED} f, f', f'' \in PF^{ATTACHED};\; f = f' = f'';\; b \neq b' \neq b'' \tag{7}$$

$$biS_{s,b} + biS_{s+1,b'} \leq 1 \quad \forall\, s \in S^{ALL};\; b, b', p, p' \in BP^{ATTACHED};\; f, f' \in PF^{ATTACHED};\; f \neq f';\; b \neq b' \tag{8A}$$

$$biS_{s,b} \geq biS_{s+1,b'} \quad \forall\, s \in S^{ALL};\; b, b', p, p' \in BP^{ATTACHED};\; f, f' \in PF^{ATTACHED};\; f \neq f';\; b \neq b' \tag{8B}$$

$$EP_{s,b,t+1} \geq EP_{s,b,t} + TT_{s,b,t} \;\forall\, b \in B^{ALL};\; s \in S^{ALL};\; t \in T^{ALL} \tag{9}$$

$$EP_{s+1,b,t} \geq EP_{s,b',t'} + TT_{s,b,t} \;\forall\, b, b' \in B^{ALL};\; b \neq b';\; s, s' \in S^{ALL};\; t \in T^{LAST};\; t' \in T^{FIRST} \tag{10}$$

$$EP_{s,b,t} \leq dd_b + M * (1 - biT_{s,b}) \;\forall\, s \in S^{ALL};\; b \in B^{ALL};\; t \in T^{DD} \tag{11}$$

$$EP_{s,b,t} \geq sl_b - M * (1 - biT_{s,b}) \;\forall\, s \in S^{ALL};\; b \in B^{ALL};\; t \in T^{SL} \tag{12}$$

$$EP_{s,b,t} = EP_{s,b',t} \;\; \forall\, s \in S^{ALL};\; b, b' \in B^{ALL};\; b \neq b';\; t \in T^{ALL} \tag{13}$$

Notation: Sets: b,b',b'': batches; s,s',s'': time slots; p,p',p'': products; t: tasks; f,f',f'': product families; B^{ALL}: all batches b; $BP^{ASSIGNED}$: batches b assigned to products p; F^{ALL}: all product families f; $PF^{ASSIGNED}$: products p assigned to product families f; P^{ALL}: all products; S^{ALL}: all time slots; T^{ALL}: all feasible tasks t; T^{CONST}: tasks with a constant

duration; T^{VAR}: tasks with a product dependent duration; T^{DD}: task which is rated as trigger for the due date; T^{SL}: task which is rated as trigger for the shelf life; Parameters: M: big-M; q_b: quantity of all vials in batch b; rf_p: filling rate of product p; dd_b: maximal value of event point $EP_{s,b,t}$ for batch b (i.e. due date); sl_b: minimal value of event point $EP_{s,b,t}$ for batch b (i.e. shelf life); dr_p: product dependent detection rate of AIM; $tasks_t$: duration of all fixed tasks t; Free variables: TIME: makespan of all scheduled batches; Positive variables: $TB_{s,b,t}$: duration of batch b in slot s; $TT_{s,b,t}$: duration of task t of batch b in slot s; $EP_{s,b,t}$ event point of task t of batch b in slot s; Binary variables: $biT_{s,b}$:1 if batch b is performed in slot s; $biS_{s,b}$: 1 if batch b is produced in slot s.

3. Industrial Case Study

The goal of an industrial case study was to validate the proposed model and simultaneously optimize the production schedule, if it was not at optimum yet. As illustrated in Table 1, the case study was performed on a planning horizon of ten production slots and the same amount of batches. Based on expert knowledge and according to the standards of the industry, these ten batches and their respective products were sequenced prior to the study. The production schedule as proposed by company experts is indicated in the second row of the table, termed product.

The case study was performed at a filling line for liquid drug products in a manufacturing facility of Roche in Switzerland. The production at that facility is described in more detail by Eberle et al. (2014), together with a methodology for production time reduction of drug product manufacturing. The sterile production of liquid drug products, so-called Parenterals, is performed batch-wise. Manufacturing processes for Parenterals start with the compounding of a drug product solution, which is then filled into glass vials, sealed and inspected for imperfections before being sent to secondary packaging. The presented case study focuses on the tasks performed at the filling isolator; including the line preparation activities, filling, sealing and post-production tasks. These activities define the line time or makespan necessary for the production of one liquid drug product batch. Since line time is a costly and often scarce commodity, minimizing the required makespan per batch and thereby maximizing the potential productivity is highly desirable.

In Table 1, the third row “family” refers to product families; as described above, these are groups of products that allow for campaign production. The lower three rows of Table 1 indicate the batch sequence for the same ten-slot planning horizon but in the sequence proposed by the presented model. As can be seen, the batches initially scheduled for slots eight and nine were advanced to slots three and four. This change led to the elimination of one format change in the considered planning horizon. However, due to the overall amount of product scheduled for these four batches in product family two, it was not possible to include both batches in one campaign with the batches in slots two and three. The information about the operation modes for the optimized batch sequence is listed in the last row of Table 1. Owing to optimal sequencing, the makespan for the production is reduced by over 2 % compared to the value obtained by company experts; which gives rise to additional production capacities, either for absorbing fluctuations in processing times or for the production of more or larger batches.

Table 1: This table contains the information about the planning horizon considered in the case study. The first line lists the ten production slots in scope, the rest of the table is split in the upper part containing the expert knowledge solution and the corresponding batch sequence as proposed by the presented model. The two batch sequences are in the rows termed product, while the rows termed family indicate whether two batches could be produced in OM-2. The operation mode of the batches as proposed by the model is indicated in the last row, where OM-4 is indicating the media fill scheduled for slot 6.

	Production Slot	1	2	3	4	5	6	7	8	9	10
Expert know-ledge	Product	5	1	4	MF	10	10	10	2	2	5
	Family	I	II	II	III	IV	IV	IV	II	II	I
Model	Family	I	II	II	II	II	III	IV	IV	IV	I
	Product	5	2	1	4	2	MF	10	10	10	5
	Operation Mode	1	1	2	2	1	4	1	2	2	1

4. Conclusions

The proposed methodology allows the simultaneous modelling of multi-product batch production processes, campaign and single-batch operation modes, batch-size dependent processing rates, changeovers, due-date and product shelf-life.

The case study was performed on a planning horizon comprising of ten batches of liquid drug products. The result of the case study validated the usefulness of the proposed model by predicting nearly the same production durations as scheduled by the responsible company experts. On top of that, despite the limited number of batches, a format change could be avoided by more efficient sequencing of batches.

A key feature of this model is the complexity reduction of the filling process, which is performed in several hundred working steps; however, grouping the filling tasks into process elements that need to be performed without major interruptions, e.g., weekends, allowed an efficient modelling with ten tasks only. Due to the promising results on one filling line, the presented model is currently being expanded to account for two additional filling units that run in parallel and the subsequent quality assurance steps.

Abstract

A naphtha price forecasting model based on the time series method is developed to predict the monthly variation of naphtha price using statistics. We used the model to forecast future naphtha prices by looking at historical time series data from January 2008 to September 2011. After forecasting, we perform the normalization of the observed period and implement a simulation using the price forecasting model. In order to check the accuracy of the model, the predicted naphtha price variations are compared with the actual naphtha variation. If the predicted variation of the normalized naphtha price has the same trend as the actual naphtha variation, our prediction value is called "T." Otherwise, the predicted value is called "F." The accuracy of the predicted value is relatively higher than the price forecasting for other products such as crude oil. As a result, our model is useful to industry decision-makers for forecasting the price of naphtha.

Keywords: Forecasting, Naphtha Price, Artificial Neural Network, Exponential Smoothing, Prediction Models

1. Introduction

Naphtha is playing an important role in the world economy, similar to other products such as crude oil. However, the increasing price of naphtha has affected the supply and demand for the product as well as ocean freight costs, both of which have political consequences. Consequently, decision makers hope to reduce the uncertainty of future prices. The naphtha price trend moves mainly in the same direction as that of crude oil, which means that the naphtha and crude oil have a high interoperability. Figure 1 shows the dynamics of WTI (West Texas Intermediate) crude oil and naphtha price in the period between March, 1996 and November, 2011.

Forecasting the price of naphtha is similar to forecasting the price of crude oil and other products. Predictions of crude oil prices have been carried out by many investigators all over the world. Various approach methods of oil price expresses both the linear and nonlinear models. Simple linear regression model predict crude oil prices and stochastic models to calculate patterns of volatility and oil prices. Ye, Zyren and Shore (2006) developed what is known as the multiple linear regression models, which considers

independent variables including GDP, population size, and electricity; a model prediction is then compared with earlier models.

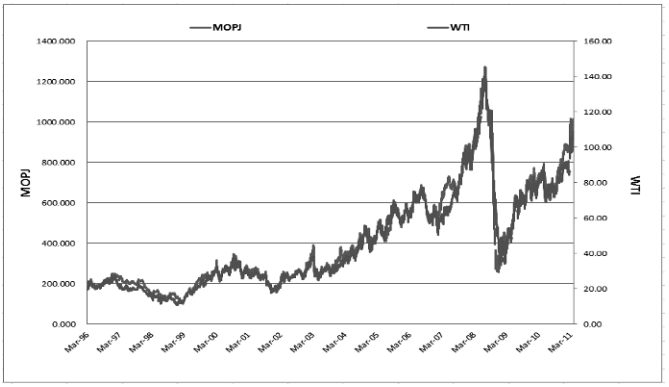

Figure 1. Correlation of MOPJ and WTI.

The purpose of this study is to forecast the correct trend and compare it with the actual naphtha price. In our study, we used two methods based on multiple linear regression and exponential smoothing according to the ratio of training and forecasting intervals. The normalized actual and ANN prediction values are also compared to determine the correct trend for the total period.

2. Forecasting models and simulation results

In this section, the paper considers three different approaches to the forecasting model: (i) statistical; (ii) exponential smoothing; and (iii) the ANN method. The basic concepts of each approach are detailed as follows.

2.1. Statistical model technique

Statistical methods are used to model the linear relationships between dependent and several independent variables. It is based on multiple linear regressions. The statistical model equation, with the error term, is defined as follows:

$$f(x_1, x_{2,} \cdots, x_n) = F_t = \beta_0 + \beta_1 x_{1,n} + \beta_2 x_{2,n} + \cdots + \beta_n x_{n,t} + \varepsilon_n \quad (1)$$

$$F_t = \beta_0 + \sum_{i=0}^{n} i\beta_i x_i \quad (2)$$

β_n is the parameter, and $x_{n,t}$ is each major factor value for a specific time. Each parameter of SMT estimates that the sum of error squares is minimized.

Therefore, the forecasting equation is

$$F_t^{'} = \beta_0^{'} + \beta_1^{'} x_{1,t} + \beta_2^{'} x_{2,t} + \cdots + \beta_n^{'} x_{n,t} \quad (3)$$

Where the symbol ‘ denotes the estimated parameter values. The error term includes multiple regression residuals and, if the model has been predicted, is defined as follows:

$$\varepsilon_n^{'} = F_t - F_t^{'} \quad (4)$$

F_t represents the actual value of a month n; F_t' is the predicted value of a month n. The regression residuals measure the nearness of actual and predicted values in the calibration periods.

The results reported in this section were collected after training data of the statistical models. We proposed a method for time series forecasting using two techniques. In order to carry out the simulation, we divided the data into four datasets (50:50, 60:40, 70:30, and 80:20). The results of each model used for the training and verification parts are compared with real data of the normalized naphtha prices.

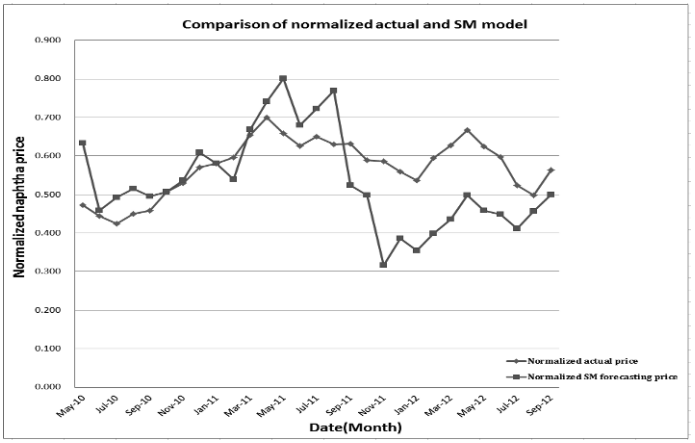

Figure 2. Comparison of normalized actual and predicted SM forecasting values

2.2. Exponential smoothing technique

The exponential smoothing technique was introduced by Robert G Brown. EST can be applies to time series data and is one of the most efficient forecasting methods. When the time series data has no seasonality and no trend, this model is used. The time series data is a sequence of observations. The following simple form of EST is given by

$$F_1 = x_0$$

$$F_t = \frac{Y_1 + Y_2 + \cdots + Y_t}{t} = Y_{t-1} + \frac{Y_t - Y_{t-1}}{t}$$

$$F_t = \alpha x_{t-1} + (1-\alpha) F_{t-1} \tag{5}$$

Where F_t is the forecast value at period t. In this equation, the forecasting value F_t applies the weighting factor of the previous observation data x_{t-1}. α is the weighting factor of EST which ranges from 0 to 1. A small will show a visible EST trend, and a large will provide a quicker response to the recent changes in time series. The exponential smoothing technique was introduced by Robert G Brown. EST can be applied to time series data and is one of the most efficient forecasting methods. When the time series data has neither seasonality nor trend, this model is used.

2.3. Artificial neural network

An Artificial Neural Network (ANN) is a modification of a human brain structure. The neural network (NN) finds a pattern or correlation in a large amount of data with a very complex structure; it is also useful for future predictions. NNs have many features, such as an adaptive system, many simple process elements, and high interconnectivity. ANN is used for computing nonlinear problems and has an enormous number of nonlinear group neurons which fix input and output signals. ANN is a typical method of feed-forward network modeling for time series forecasting. Nonlinear group numbers determine a complex relationship with a high prediction between neurons. The mathematical relationship of ANN between input and output is as follows:

$$F_t = b_0 + \sum_{j=1}^{k} W_j \tan sig(b_{0,k} + \sum_{i=1}^{n} W_{i,j} F_{t-1}) + e_t \tag{6}$$

Where $W_{i,j}$ and W_j are the connecting weight factors of the model parameters, N is the input node number, and K is the output node number. A hyperbolic tangent transfer function is used as a hidden layer, and the equation is as follows:

$$f(x) = \frac{e^x - e^{-x}}{e^x + e^{-x}} \tag{7}$$

This function has a range from -1 to 1. The ANN model using Eq.(7) calculated a nonlinear equation from a past observed date in order to predict a future value.

Figure 3 and figure 4 were comparison of actual and two forecasting models.

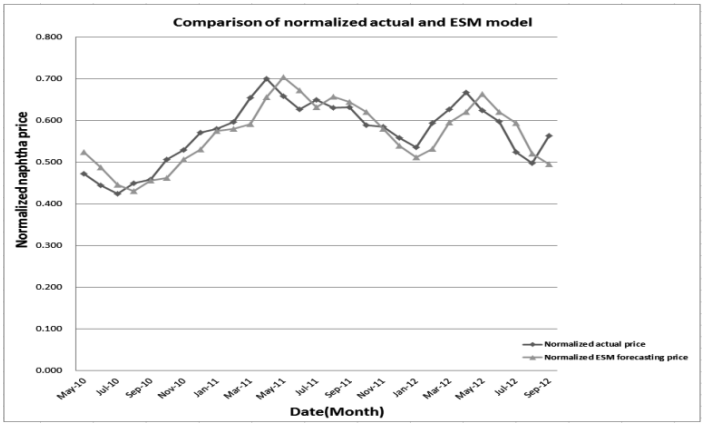

Figure 3. Comparison of normalized actual and predicted ESM forecasting values

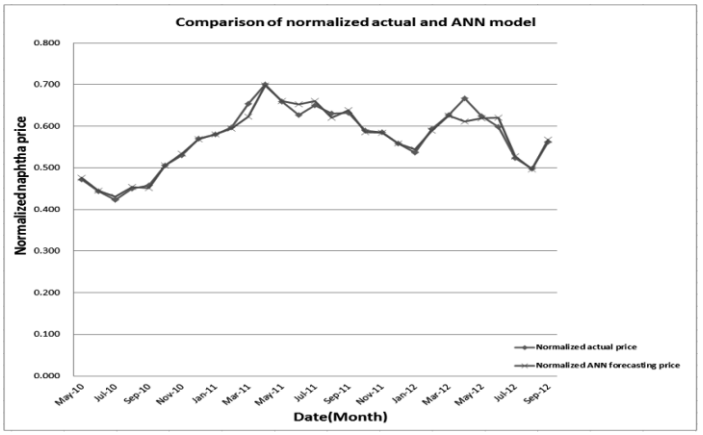

Figure 4. Comparison of normalized actual and ANN model forecasting value

3. Conclusions

In this paper, we developed a method for time series forecasting using two techniques: the EST and statistical methods. This study provides a model to predict naphtha price variation by developing a statistical and EST model. In other words, accurate forecasting for a proportion of a time series is very important for decision making in naphtha purchasing. The best model is analyzed by comparing the forecasting results of the models with the actual values of the naphtha price during several observation periods. The forecasting value of the statistical method is better than the EST method. Furthermore, we predicted the AFP using the ANN method for the time series data. The ANN method was then compared with the actual values and the other two models. The SMT method shows 81.81% and the ANN method shows 93.48% of the total trend AFP. As a result, the AFP of the ANN method is superior to the SMT model.

Abstract

The production of biodiesel from rapeseed in Germany has been conceptualized using the complex adaptive systems (CAS) theory and formalized using the agent-based modelling approach (ABM). The ABM incorporates farmer's decisions on market choice, and biodiesel producer's decisions on biofuel production and capacity expansion. The ABM was calibrated to replicate the pattern in the evolution of rapeseed, wheat, and biodiesel production in Germany in the period 1992-2012. It was found that complex adaptive systems theory could be used as a conceptual framework to analyse supply chains. In the specific case of biofuels supply chains, where it has been proven that exist due to subsidies and incentives from governments, the agent based modelling approach could be an important tool to analyse the impact of different policies.

Keywords: Agent-based modelling, Biodiesel, Supply chains, Complex Adaptive Systems.

1. Introduction

Complex adaptive systems refers to those systems whose overall behavior is extremely complex, yet whose fundamental components parts are each very simple, and constantly adapt to their environment. Examples of such systems are: Economies, ecologies, immune systems, the brain, and supply chains. Traditionally, supply chains (SC) have been modeled as a pure mathematical formulation (equation-based model). However, the interactions and inter-dependencies among different entities, processes and resources that make the SC a complex network are neglected. This network is highly non-linear, exhibits multi-scale behavior, and evolves and self-organizes making it difficult for an equation-based model to approach it (Surana, Kumara, *et al.,* 2005).

Literature does not provide sufficient sources on analysis of supply chains for biofuels from an agent based modelling perspective. It is worth noting in this area the work done by (van Vliet, de Vries, *et al.*, 2010) where an agent based model to analyze motorists' preferences based on real-world choice mechanisms was developed; (Shastri, Rodríguez, *et al.*, 2011) analysed the dynamics in the adaptation of Miscanthus as an agricultural crop and its impact on biorefinery capacity; the work by (Alexander, Moran, *et al.*, 2013) where the UK perennial crop market, including the interaction of

supply and demand, was modelled using an agent-based approach; and (Singh, Chu, *et al.*, 2014) addressed the problem of biorefinery supply chain network design under competitive feedstock markets. An agent-based model was developed to simulate the feedstock markets.

In the specific case of the German biodiesel supply chain (Kaupa & Selbmanna, 2013) analyzed the drivers that led to the origin of the biofuel industry in Germany. The analysis based on actors and discourse coalitions showed that the German biodiesel industry emerged as a result of national and supranational market interventions. In this work, we developed an agent-based model for the German biodiesel supply chain. The aim of the model is to replicate patterns in the production of feedstock and biodiesel in Germany in the period 1992-2012.

Section 2 introduces the agent-based model development. Agent-based model results for the German biodiesel supply chain are described in section 3. Finally, the main conclusions are drawn in section 4.

2. Model development

The construction of the agent based model starts with the formulation of the problem. The problem is formulated using the generative science approach (Epstein, 2006), which identify and describe the problem based on a macroscopic regularity or pattern in the real world. The methodology proposed by (van Dam, Nikolic, *et al.*, 2013) to build an agent based of a socio technical system was followed.

The aim of the agent-based model is to understand how different policies, either individually or collectively, have triggered: Production of feedstock and biodiesel, and conversion capacity. The impact of these policies on the different actors involved in the supply chain for biodiesel are to be modelled, replicating not only the currently observed pattern, but also exploring what conditions might lead to different outcomes.

Figure 1 presents a biofuel supply chain conceptual scheme. The systems is made up of agents (farmers, oil mill companies, biodiesel producers, distributors, and gas stations), objects (farms, refineries, and facilities), and markets (biomass, oil, diesel, biodiesel). It can be observed how different agents are connected directly (physically) through the flow of rapeseed, oil, biodiesel, and blend biodiesel, respectively. The agents can also interact with the different objects through ownership. The agents interact among themselves through the flow of money (dashed lines) as a result of the trading of products. The decision making of different agents is based on the information (prices) provided by different markets. The environment is composed of the government. The government can influence the price of the different products through incentives in the different markets. To simplify the analysis only three agents are included in the model: Farmers, biodiesel producers, and distributors. The system's environment is composed of the German government which through policies, incentives, and regulations affect some or all of the agents mentioned above.

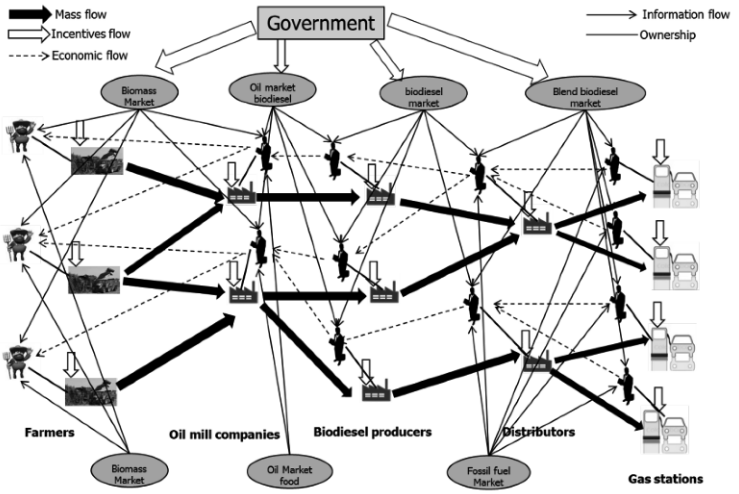

Figure 1. Biofuel supply chain conceptual scheme

Figure 2 shows the simulation sequence used in the agent-based model. The main model's assumptions are summarized below:

- It is assumed that the agents forecast prices for the current year form the very beginning (i.e. 1st January) and schedule their activities for the rest of the year based on the forecasting.
- One tick is equivalent to one year.
- The price of rapeseed does not depend on the type of land (set aside land or arable land).
- Rapeseed transportation costs are charged only to the biodiesel producers.
- Biodiesel transportation costs are charged only to the distributors.
- The penalty is only charged to distributors.
- The length of the link in "NetLogo units" was translated to kilometres based on the longest distance in Germany (North to South, 853 km). Assuming that Germany is a square with 800 km length each patch in the agent based model has a length of 25 km. This value was used as a conversion factor (1 link length = 25 km).

3. Results and discussion

The agent based model for the German biodiesel supply chain was developed in NetLogo. Then, it was calibrated to replicate the pattern in the evolution of rapeseed, wheat, and biodiesel production. From a complex adaptive systems perspective, the German biodiesel supply chain emerged as a result of decisions that are made by the individual agents that cause the collective system behaviour to emerge over time. **Table 1** presents an overview of the base case model parameters. The model was run 50 times to check its robustness. **Figure 3** - **Figure 5** present both historical data and model's results for rapeseed, wheat, and biodiesel production, respectively.

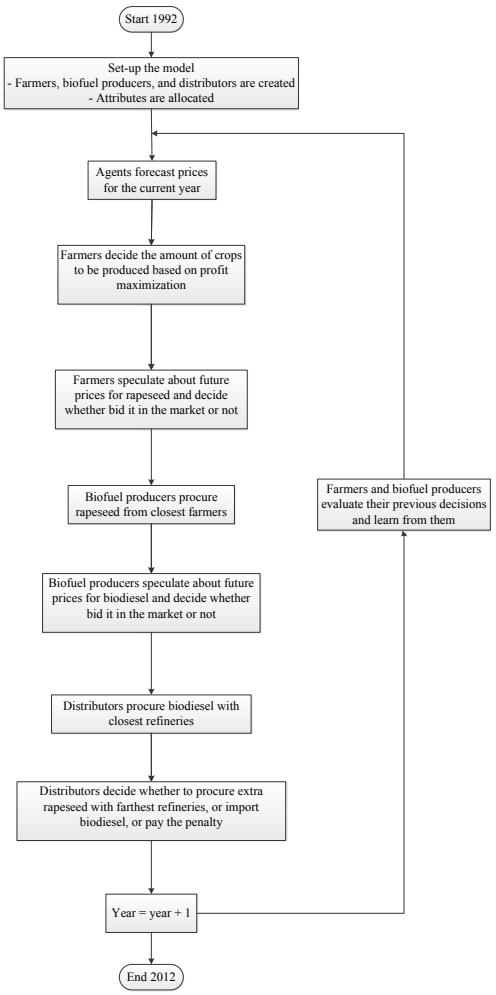

Figure 2. Simulation sequence for the agent-based model

Table 1. Real-world parameter values for the German biodiesel supply chain

Parameter	Value	Unit
Initial land	3,200,000	ha
Set aside land	10	%
Fixed cost biodiesel	0.4 + random[-1.5 - 0.5]	euro/L
Production cost rapeseed	250 + random[-10 - 10]	euro/ton
Production cost wheat	100 + random [-10 - 10]	euro/ton
Yield rapeseed	assigned yearly according to historical data	ton/ha
Yield wheat	assigned yearly according to historical data	ton/ha
Yield biodiesel	1,590	L/ha
Penalty	0.6	euro/L

According to the historical data both production of rapeseed and wheat exhibit an increase in their production as a function of time. Data also shows a higher production of wheat. These characteristics are captured in the model except for the production of rapeseed in 1992 where its production reaches a maximum. This maximum value in the production of rapeseed is due to the high price of rapeseed in 1991 which makes farmers to forecast high prices for rapeseed in 1992 and, as a result it is decided to increase the production of rapeseed. The model's results also exhibits an overproduction of wheat due to it was assumed that farmers are limited to grow only wheat and/or rapeseed. As in the real world farmers have multiple crop choices the wheat overproduction calculated by the model could account for the different crops competing with rapeseed.

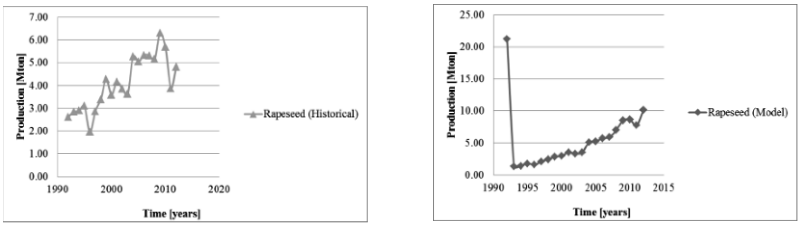

Figure 3. Rapeseed production in Germany according to the historical data (left) and the agent-based model (right)

As shown in **Figure 5** the production of biodiesel reaches a maximum in 2007 since the quota is imposed. Afterwards, the production remains constant. Only a decrease in its production is noted in 2009 possibly because of the economic crisis. The model's results also exhibit these trends. However, the increase in production calculated by the model is not so steep as the reported in the historical data. An explanation for this model's behaviour could be the lack of rapeseed supply close to the facilities. Having an affluence of supply could stimulate the investment on capacity expansion which, eventually, will be translated in bigger productions.

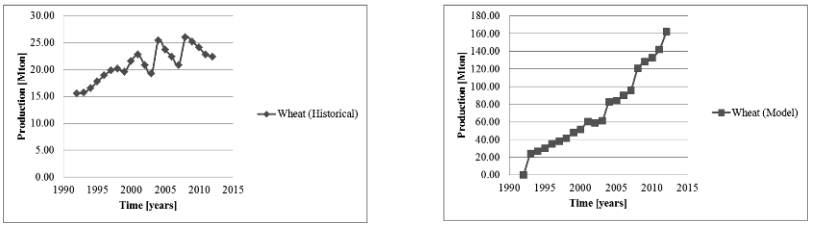

Figure 4. Wheat production in Germany according to the historical data (left) and the agent-based model (right)

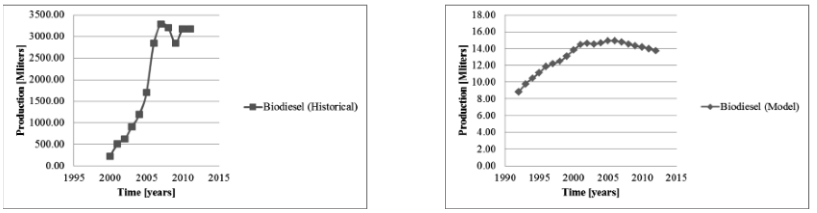

Figure 5. Biodiesel production in Germany according to the historical data (left) and the agent-based model (right)

4. Conclusions

The production of biodiesel from rapeseed in Germany has been conceptualized using the complex adaptive systems (CAS) theory and formalized using the agent-base modelling approach (ABM). Unlike traditional least-cost optimization models, the model includes non-economic attributes and elements of cooperation and competition between different agents. Some lessons were learned:

- Complex adaptive systems theory offers a suitable conceptual frame to analyse complex networks such as supply chains. By using this theoretical framework phenomena such as: emergence, self-organization, and path dependence could be analysed. In this work, the German biodiesel supply chain emerged and self-organized because of the competition and learning effects of the different agents.

- In the specific case of biofuels supply chains (BSC), where it has been proven that exist due to subsidies and incentives from governments, the agent based modelling approach could be an important tool to analyse the impact of different policies on the BSC. Obviously, the validity of the analysis will rely on the model's ability to replicate the actual macroscopic behaviour. Therefore, it is recommended to build the ABM based on historical data if possible.

Finally, it is planned to extend the analysis of the evolution of the German biodiesel supply chain by studying the influence of different policies on the system.

A Study of the Sustainable Development of China's Phosphorus Resources Industry Based on System Dynamics

Shujie Ma, Shanying Hu, Dingjiang Chen, Yuzhong Feng

Center for Industrial Ecology, Department of Chemical Engineering, Tsinghua University, Beijing 100084, China

Abstract

As a non-renewable ore, phosphate rock is a very important strategic resource. However, in the process of the exploitation and utilization, there are severe waste and environmental pollution problems which are disadvantageous to the sustainable development of phosphorus resources. In order to promote the sustainable development of China's phosphorus resources industry, this research proposes a system dynamics model with two sub-models for thermal phosphoric acid and wet phosphoric acid separately, considering to the actual situation of regional phosphorus resources industry. This model focuses on industrial, financial, technological and environmental policies for the development of phosphorus resources industry, such as phosphorus resources exploitation, product structure adjustment, waste management and other policies. To find the optimum policy combination of sustainable development, the model which employs resource productivity, economic benefits, ecological efficiency and social satisfaction as objects, explores development situations of phosphorus resources industry and assesses the impacts of the policies by comparative policy scenarios. Results show that under the condition of excess capacity, optimization of phosphate fertilizer product portfolio is more advantageous compared with capacity expansion to increase production value of phosphorus chemical industry. And the combination of total consumption control policy of phosphate rock and acts to promote technical progress improves resource productivity. The implementation of waste recycling policies is conducive to improve continuously the eco-efficiency, and is not conducive to increase economic benefit due to more investment cost. Finally, this study indicates that an effective combination of total consumption control policy, product structure adjustment and appropriate environmental protection will be beneficial to the sustainable development of phosphorus resources industry. In addition, it contributes not only to the conservation of natural resources, but also to a reasonable disposition of the investment which can promote technological progress in industrial weak links. Moreover, the results can provide relevant references for policy makers to make appropriate decisions.

Keywords: system dynamics; phosphorus resources; industrial policy; sustainable development

1. Introduction

As an essential element in national agricultural and industrial development, phosphorus resource is not only to produce a comprehensive and far-reaching impact of economic and social sustainable development but also a very unique strategic resource (Ma et al., 2014). The scarcity of phosphorus recourse will impact the sustainable development of China economy, even the life safety of human being. It is predicted that there is nearly 70 years life- span for the phosphorus reserves, or 10～15 years life- span for the high- grade

phosphorus reserves[w(P2O5) ⩾30%] in China, based on the current phosphate rock (PR) production (Ma et al., 2013). In China, the extraction, production and processing firms of phosphorus rock (PR) gather most in the southwest provinces, such as Guizhou, Yunnan, Sichuan and Hubei province.

Generally speaking, phosphoric acid can be produced from phosphate ore via two major process routes: the thermal phosphoric processes, which produces elemental phosphorus as an intermediate through the burning of the ore in an electric furnace or in a rotary kiln, and the wet phosphoric processes, which uses strong mineral acids to digest the ore. Phosphoric acid produced through the thermal phosphoric process contains fewer impurities such that the resulting acid can be used in "high added value" areas, such as detergents and food additives, whereas phosphoric acid from the wet processes contains more impurities and is primarily used for fertilizers. As it requires more energy consumption, the thermal process will be replaced by the wet process gradually. It is well known that phosphorus resources are non-renewable resources. Due to the exploitation of phosphorus resources, China is facing a shortage of phosphorus resources, environmental pollution, and excess resource waste. To address these problems, we need to optimize the industrial structure of phosphorus resources, to explore new technologies for P recycling and to increase the “three wastes” treatment technology in the manufacturing process of phosphorus resources.

The sustainable development of phosphorus resource is a complex system, contains resources, economy, industry, society, environment and other comprehensive factors. In order to promote the sustainable development of China’s phosphorus resource industry, this study proposes a system dynamics model including four sections for economy, resource, environment and society to research the utilization of phosphorus resources. After verification the model by historical data, and based on four different scenarios, this paper analyses and forecasts the phosphorus resource efficiency in China. The results of analysis can provide implications for industry and governments in China to establish appropriate policies and laws in order to promote sustainable development of domestic phosphorus resource industry.

2. Methodology: System Dynamics Approach

System dynamics (SD), introduced by Jay Forrester in 1960s, is a methodology and mathematical modeling technique for framing, understanding, and discussing complex issues and problems(Yuan et al., 2014). SD models solve the problem of simultaneity (mutual causation) by updating all variables in small time increments with positive and negative feedbacks and time delays structuring the interactions and control. The validation of the model, different policies can be developed by altering certain variables such as retrofitting rate, energy efficiency, construction rate and leave the rest as defined in the base model. The policies are compared to evaluate their impacts on the system behavior and to see their relative effects respect to the baseline.

SD approach has been applied extensively to address critical problems from various fields of studied including social-economic systems (Yuan et al., 2014), ecological systems (Tian et al., 2014), environment issues and sustainability problems (Rehan et al., 2011; Marzouk and Azab, 2014),such as urban energy consumption and CO_2 emissions (Feng, 2013), residential building stock (Onat et al, 2014) , and waste disposal (Yuan et al., 2014).To the best of our knowledge, not much attention has been paid to the research of phosphorus resources industry form the perspective of system dynamics. In this study, a system dynamics model was employed to solve the problem of phosphorus resource sustainable development.

3. A SD model for the Regional Phosphorus Resource Industry

3.1. Model description

The system dynamics model with two sub-models is constructed based on a practical industrial process. Sub-model 1 is a wet-process phosphoric acid (WPA), and the main products are phosphate fertilizer and purified WPA. The representative solid and gas pollution generated in sub-model 1 are phosphor gypsum (PG) and SiF4. Sub-model 2 is a thermal-process phosphoric acid (TPA), and the prime products and pollutants are yellow phosphate, phosphate, phosphorus slag and tail gas.

Fig. 1 illustrates the simplified system dynamics model used in this study, and the actual operations model is more complicated. In the case of phosphorus fertilizer, which is divided into two categories: high-analysis and low-analysis phosphate fertilizer.

The system dynamics model encompasses four sections: economy, resource, environment and society. Many connections of material production and information transmission existed in these sections. In addition to the supply relationship of the upstream and downstream supply, feedback loops also play essential roles in maintaining normal production.

There are two types of feedback loops: reinforcing and balancing. Here take a balancing loop for example: Total Pollution Emission→ (−) Industrial positive impact on society→ (−) Social satisfaction→ (+) Environmental Investment 1-wet/ 2-thermal → (−) Total Pollution Emission.

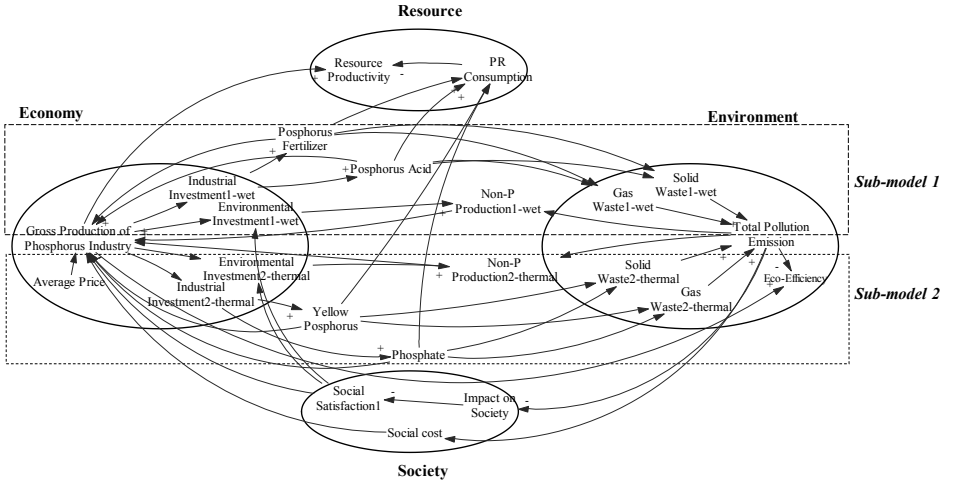

Figure 1. System dynamics model of the phosphorus resources industry illustration

3.2. Variable Definition and Model Assumption

3.2.1 Variable definition

In this paper, Guizhou province is used as a case study. In the current stage, Guizhou also faces the pressures of overcapacity, resource shortages and environmental pollution. The original data available from 2011 to 2013 form the Guizhou phosphate industry are investigated and simplified appropriately. Considering the effect of the five-year plan, the simulation length is 15 years. Given that the comprehension utilization of three types of

waste achieves the required level in Guizhou during this development stage, the societal acceptance of pollution will not be investigated in this study. The indicators of economy, resources and environment are selected as systematic characterizations. These indicators are primarily influenced by the extent of P production. The economic indicators include the gross production of the phosphorus industry and the economic benefit. The environmental indicators include the eco-efficiency and the emission of pollutants. The resource indicators include the resource efficiency and the PR consumption.

3.2.2 Model Assumption and verification

Assumption 1. Considering the constraint of excess capacity and agriculture demand, the production of P fertilizer is assumed to have upper and lower limits. The price of P chemicals are considered to fluctuate according to supply and demand in the market. Assumption 2. In this model, we assume that the environmental impact from the wet and the thermal method follows a 1:1 ratio. Assumption 3. The waste generated from the process is assumed to be discharged according to environmental standards, and environmental investment is used in waste recycling. The comprehensive utilization of wet and thermal wastes is used to produce fine power, methanoic acid and building materials that are based on PG and fluoride-idodine chemicals. Assumption 4. The promulgation and implementation of policies mentioned in this study are almost simultaneous and the time delay is not considered. The model has been verified using operation verification and historical data magnitude verification.

4. Model Simulation and results analysis

4.1. Scenario definition

This study defines four scenarios in which to conduct comparisons and to select different policies, which can be used to draw a rational implementation solution. Specific actions motivating each policy are described below. An expanding industrial policy can be achieved by improving the proportion of industrial investment. The environmental policy can be explained as improving the proportion of the environmental investment and enhancing the comprehensive recycling of solid and gas wastes. Controlling industrial policy can also be achieved by adopting measures contrary to an expanding policy, such as by setting limits on excess P production and by enhancing the deep processing ratio.

Table 1 Strategy and policy description for each scenario

Scenario	Strategy	Policy Description
Baseline	the current situation of P industry	Without compulsive environmental policy
Scenario 1	Expansion of P product production	Individual expanding industrial policy
Scenario 2	Utilization of pollution	Individual environmental policy
Scenario 3	Expansion of P product production, Utilization of pollution	Jointly implement expanding industrial policy and environmental polity
Scenario 4	Improvement of waste recycling efficiency, Control of P products, resource extraction and consumption	Jointly implement controlling industrial and environmental polity

4.2. Analysis of different scenarios

Fig. 2 shows the gross production of the phosphorus industry, the P resource efficiency, the total PR consumption and the P eco-efficiency for different scenarios. The reasons and implications behind the trend curves were analysed. The total PR consumption is coincident with the gross production of the P industry. Similarly, the eco-efficiency follows a similar trend as the resource efficiency. (Refer to Fig. 2. (a), (b), (c), (d)).

Compared with baseline scenario, the gross production has a significant increase in scenario 1, and the increase ranges of the corresponding PR consumption and pollution

emissions can be clearly observed as well. The P resource efficiency and eco-efficiency improve by 50 RMB/ton and 100 RMB/ton, respectively, and the cumulative pollution emissions are reduced in scenario 2. Variations in scenario 2 mean that the comprehensive utilization of the waste can not only reduce the pollution emissions but can also contribute to the economic benefit and efficiencies given the requirements of the technology.

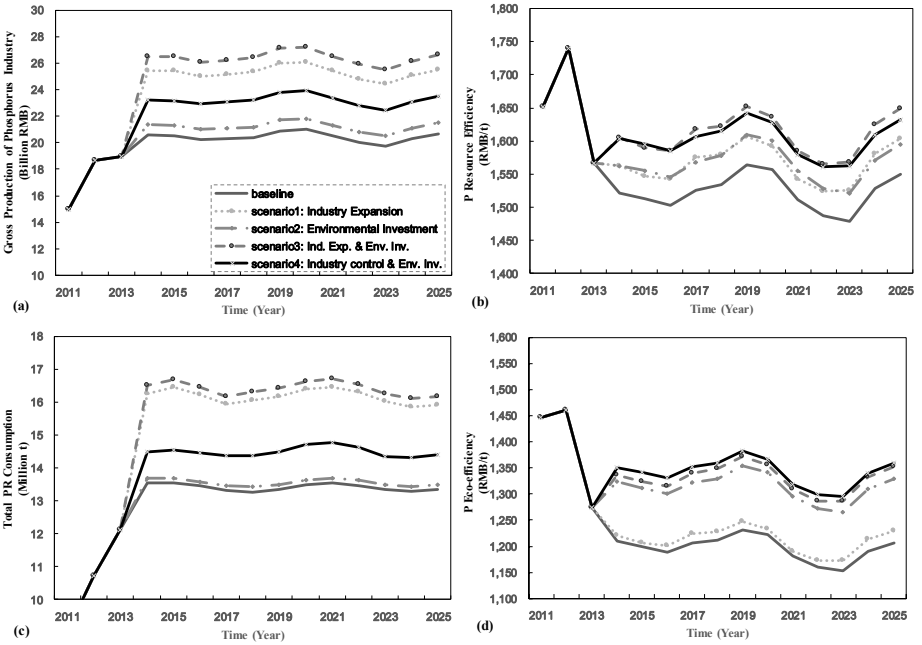

Figure 2. The indicators of economy, resource, environment in each scenario

The P resource efficiencies in scenario 2 are essentially consistent with the change in scenario 1, but the eco-efficiency performs better than in scenario 1. Therefore, compared with a single industrial policy, the implementation of a single environmental policy can both improve efficiencies while compromising fewer economic interests.

Comparing scenario 3 with scenario 1, scenario 2 and the baseline, both the P resource efficiency and the eco-efficiency improve by different amplitudes, which illustrates that the joint implementation of expansive industrial and environmental strategies can achieve a better result than a single implementation. The PR consumption in scenario 3 is greater than in scenario 2 and the baseline and is slightly greater than in scenario 2; however, the gross production increases to 26 billion RMB, which is greater than the other three scenarios, and the pollution emission obviously also declines. Therefore, if the resource consumption remains constant and the two policies are applied together, the amount pollution can be effectively controlled. Meanwhile, a single-minded pursuit of economic growth will not result in a balance between the economy and the environment.

In the case of excess capacity, the P resource efficiency and the eco-efficiency will reach a cyclical peak approximately in the year 2019, correspond to 1643 and 1382 RMB/Ton respectively. Comparing scenario 4 with scenario 1, 2, 3 and the baseline. The gross production and economic benefit in scenario 4 are less than in scenario 3, and the PR consumption is also less, but the resource efficiency is equal. Under these circumstances, the eco-efficiency in scenario 4 is greater than the eco-efficiency in scenario 3. From the perspective of the resource utilization efficiency, the industry should control the production of low-end products and adjust the product structure in a timely manner

instead of consuming more resources, which results in greater pollutant discharge and a smaller increase in income. By comparing scenario 4 with scenario 1, although the former's economic value is higher in the latter scenario, the PR consumption is significantly less than it and the pollutant amount is also less. The results show that even if scenario 4 results in a weaker economy there is the strong advantage with respect to environmental protection, which can be seen in Fig. 2 (b). If the goal is only to expand the product scale without recycling waste, it may not be productive to increase efficiencies. With the main premise of waste management, the curves' performances of scenario 4 and 2 indicate that the consequences of the appropriate expansion of products are beneficial to the productivity efficiency and environment.

5. Conclusions

Based on the theories and methods of system dynamics, we can characterize industrial development situations given different scenarios by adjusting key parameters. By comparing the selected indicators, we can determine the most reasonable and applicable strategies to apply to the current industry standards.

In the case of overcapacity, if increased production is pursued unilaterally by increasing the product scale and if the domestic demand saturation is approached by exporting resource-based, low-end products, the results will not be conducive to the sustainable development of the phosphorus industry. The combination of industrial and environmental policies can contribute to long-term resource productivity and eco-efficiency. Similarly, with respect to technological progress, the comprehensive utilization of waste and the modest expansion of high-end products are favorable conditions to increase the economic benefit, to improve efficiencies and to reduce pollutants. Subsequently, it would be possible to achieve positive outcomes in terms of economic interests, resource conservation and environmental preservation. In the continued studies, the influence of time delay will be added in the system, policies implement and other various factors related with time will also be discussed.

Interplant Carbon Integration Towards Phased Footprint Reduction Target

Dhabia M. Al-Mohannadi, Patrick Linke*, Sumit K. Bishnu, Sabla Y Alnouri

Department of Chemical Engineering, Texas A&M University at Qatar, PO Box 23874, Education City, Doha, Qatar

Abstract

This work presents a first attempt to define and address the multi-period carbon dioxide network synthesis problem for industrial parks. The problem is to determine over time an optimal carbon dioxide reuse networks for reducing the net emissions of the industrial park by utilizing carbon dioxide source flows in carbon dioxide sinks. The formulated optimisation model determines the optimum amount of CO_2 that is to be captured in different time periods with an objective of minimizing total cost of treatment and equipment. It takes into account information on carbon dioxide sources, existing and options for additional sinks, capture and transmission, expansion plans for the industrial park and carbon reduction targets. The approach is illustrated with an example.

Keywords: Carbon Integration, Industrial Park, Multi-Period Optimisation,

1. Introduction

The main purpose of carbon integration is the recovery of carbon dioxide sources into sinks with the goal of reducing the overall carbon footprint of the system at minimum cost. The concept of carbon integration was first introduced by Al-Mohannadi (2014). Other works have been demonstrated in terms of carbon dioxide allocation in geological storage sinks (Middleton and Bielicki, 2009; Tan et al, 2012; He et al, 2013) or in enhanced oil recovery applications (Turk et al, 1987; Alhajaj, 2013; Hasan et al, 2014). Previous work on inter-plant carbon network synthesis (Al-Mohannadi, 2014) does not take into consideration changes to the industrial park over time. In addition, targets for carbon dioxide reductions are typically set over multi-year time periods. This work is a first step towards a systematic approach to explore carbon integration scenarios over time. Such an approach can provide policy makers with important information for the planning of upcoming industrial parks.

2. Carbon Integration in Industrial Parks

Industrial park carbon dioxide emission sources can result either from fuel use or from carbon dioxide byproduct in processes. Therefore, emission reduction can take place at the park input to limit of carbon production and within the park as part of process enhancement through energy integration and the use of clean fuels or at the outlet of the park as end-of-pipe measure by using carbon capture and sequestration. However, carbon dioxide can be converted in many different ways, including chemical or biological conversion into fuel or another value added product (Mikkelsen et al, 2010). Carbon integration presents a systematic approach to integrate carbon dioxide within an industrial park with multiple carbon emitting streams and the potential carbon

utilization options (sinks) that may exist. The approach selects the best sources to be captured with the various utilization options including geological storage and Enhance Oil Recovery (EOR). It determines if the captured carbon dioxide should be purified and takes into account costs of carbon capture, carbon transportation between sources and sinks as well as costs associated with the utilization processes required to determine the most economically attractive footprint reduction solutions. This helps create synergy between plants within the industrial park, help overcome cost limitations in terms of the high carbon capture cost and aids policy makers and designers to plan carbon capture strategies, which cannot be evaluated without considering the aspect of time.

3. Multi-Period Carbon Capture

Multi-period planning helps services and industries negotiate changes over-time.It enables efficient utilization of resources, whether it be for process expansion, or during start up and development phases ensuring smooth transition across various phases of planning. It has been effectively applied for water network synthesis, reactor design, and heat exchange network synthesis. In this work, minimization of cost of carbon network developed across the periods has been set as the objective with aim of reduction of carbon emission. Specific targets have been set for each period and this is one of the constraints in the problem formulation. The concept of specific targets for carbon emission cuts is based on the lines of environmental regulation like GHG protocol, Kyoto protocol and other greenhouse gases emissions reduction agreement.

4. Problem Statement

The model presented aims at synthesizing an optimal cost carbon source-sink allocation network over multiple time periods with target of emission cuts being specified for each period. The problem involves in each time period a number of carbon sources of known flow and composition and a number of carbon sinks with known carbon capture capacity. Carbon flows emanating from can be transferred to sinks either in treated form or without treatment. Both the flows are merged and transported to the concerned sinks using single pipeline.Sinks can collect carbon from various sources and the purity of carbon streams should above specified threshold levels. Emission cuts targets for each period have been specified as a percentage of carbon emission in the first period of planning. Maximum amount of carbon flow from source and sink capacities together with their concentration data are known for each period. Figure 1 presents a general outlay of a carbon network

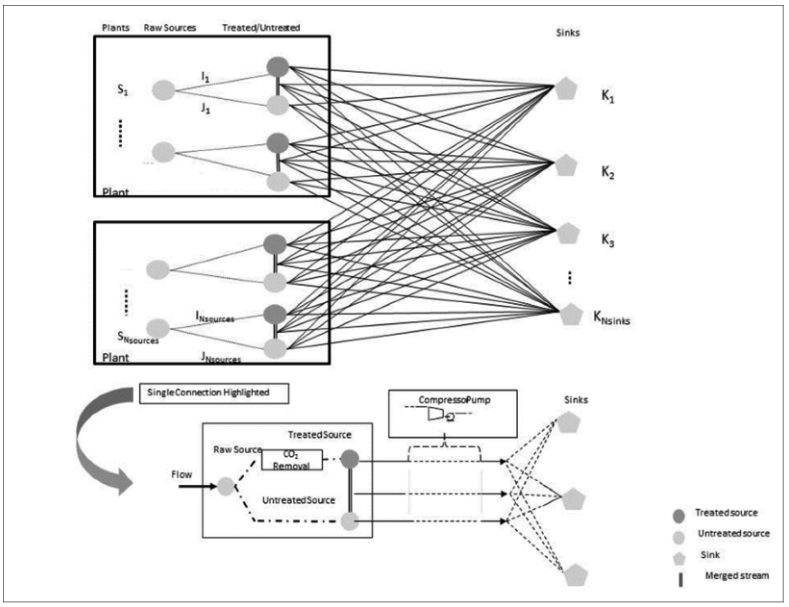

Figure 1. Representation of Carbon Integration Network (Al-Mohannadi, 2014)

5. Model Formulation

The source-sink mapping formulation developed in this work is based on the work by Al-Mohannadi (2014) without consideration of a planning horizon. A Mixed Integer Non-Linear Programming formulation has been developed for the multi-period problem. Each source is split into two kind of streams $F_{i,j,tr,t}$ representing the flow from i^{th} source to j^{th} sink after treatment and a separate stream $F_{i,w,ut,t}$ which represents the flow from each source to sinks without treatment. Constraint on minimum and maximum flow between sources and sinks has been imposed using a binary variable $X_{i,j,t}$ which represents the connection between i^{th} source and j^{th} sink in time period t. The value of X is one if the flow rate associated with the particular stream is non-zero. The objective function used in this work is total network cost over the entire period of planning. The detailed model will be presented in a full-length manuscript.

6. Illustrative example

This example presented here demonstrates the application of multi-period model to a carbon capture network synthesis problem. The case study considers an industrial park layout. The distances are obtained based on a map approximation between different sources and sinks for an industrial park layout in terms of source-to-sink connections is provided in Table 1. Assumptions and calculations of streams data are explained in Al-Mohannadi (2014) based mostly on open literature such as the IPCC Report (Metz et al, 2005).

Detailed information about sources and sinks are provided in Table 2 and Table 3 respectively. Planning has considered for three time periods, each of which spans for three years. Period 1 consists of first three sources while periods 2 and 3 has all the four sources. Carbon capture target for the three periods are 10%, 20% and 30%

respectively. The objective function considered in this work is minimization of total cost which consist of following components-

- Treatment cost of carbon streams.
- Revenues generated from carbon sinks.
- Cost of pipes, pumps and compressors.

Algae, Greenhouses, Storage, Methanol, Urea and Enhanced Oil Recovery (EOR) are the sinks used this work. The capacity of EOR decreases with time. Results may vary according to the estimated capacity for different periods.

Table 1. Distance between Sources and Sinks (km)

Source/sink	Algae	Greenhouse	Storage	Methanol	Urea	EOR
Ammonia	1.72	25.38	1.51	1.51	1.55	1.56
Steel	2.07	25.73	1.86	1.86	1.9	1.91
Power plant	2.77	27.33	2.95	2.95	0.91	0.51
Refinery	2.53	27.09	2.71	2.71	0.66	0.82

Table 2 - Carbon Dioxide Sources

CO_2-EOR	94	8317	15198	-30	0
Saline Storage	94	8317	15198	8.6	0

The optimization problem for was solved using "What's Best 12.0 " LINDO Global Solver for Microsoft Excel 2013, using a laptop with Intel® Core ™ i7-2620M, 2.7 GHz, 8.00 GB RAM, and a 64-bit Operating System. The results obtained for the multi-period optimization is shown in Tables 4 -7. Cost of pipes, pumps and compressors vary from period to period. This concept is implemented by multiplying fixed

parameters in cost functions of periods 2 and 3. These parameters are ratios of area in the above mentioned periods to area in the first period. Flowrates given are in tons/day.

Table 4 - Time Period 1

Source/sink	Algae	Greenhouse	Storage	Methanol	Urea	EOR

Ammonia	0	0	977	0	0	0
Steel	0	0	1096.51	1727.27	0	901.61
Power plant	0	0	0	0	0	501.48
Refinery	1048.15	0	0	0	0	808.87

Table 7 – Piping, Compressors and Pump Cost chart (x 10^6)

Source/sink	Algae	Greenhouse	Storage	Methanol	Urea	EOR
Ammonia	0	0	8.23	0	0	7.02
Steel	3.92	0	9.25	13.06	0	47.05
Power plant	0	0	0	0	0	4.23
Refinery	4.9	0	0	0	0	6.62

The size of a pipe connecting two facilities is chosen in a way that it is able to handle the largest flowrate in any of the time periods in which the connection is present. High pressure natural gas pipes were used to estimate the piping cost while compression cost was approximated using cost correlation based on each connection specific power in a 4-stage compressor. The cost correlations and pumping cost are explained further in Al-Mohannadi (2014). The optimal solution obtained for multi-period optimization has a total cost of - $14958838 over the planning horizon. The negative cost indicates that there is a saving when carbon network integration is done over time.

7. Conclusion

An approach to multi-period planning of carbon network problem has been presented here. A MINLP formulation is solved for a known industrial park expansion plan and emission cut targets for each period of planning. A case study has been developed which illustrates implementation of multi-period optimization. With the assumed parameters for the case study, the solution identifies savings if multi-period optimization approach is adopted for carbon network synthesis especially with the use of EOR. Future works will look into the problem in greater detail and integration of new sinks in the network will be implemented.

Abstract

In simulation-based process design, model parameters, like thermodynamic data, are affected by uncertainties. Optimized process designs should, among different other objectives, also be robust to uncertainties of the model parameters. In industrial practise, it is important to know the trade-off between an increase in robustness and the other objectives – like minimizing costs or maximizing product purities. This contribution describes a practical procedure how to incorporate robustness as an objective into a multicriteria optimization framework. The general procedure is illustrated by a concrete example. Finally, we argue that the same approach is useable for an optimal design of plant experiments.

Keywords: Optimization, robust design, sensitivity analysis, Pareto solutions

1. Introduction

Models for computer-aided process design contain a multitude of physical, chemical and, when it comes to cost functions, also economical and sustainability related parameters. Often these parameters have either been estimated by model adjustment to experimental data, or their values are given by experience. In both cases, these values are not known exactly, but rather within specific uncertainty ranges (we prefer using the term uncertainty range to confidence interval. The term confidence interval has a statistical meaning that is not needed in our discussion). The impact of these ranges on the output functions can be estimated by sensitivity analysis (Saltelli et al. 2008). In sensitivity analysis, different sampling-techniques for scenarios in the space of the uncertain model parameters are available to obtain insight into the importance and the size of the resulting uncertainty ranges in the output functions of the model. The application of Monte-Carlo sampling (e.g. in Xin et al., 2000) demonstrated the importance of analysing the uncertainties in the calculated process designs.
On the other hand, the engineer aims at understanding the influence of the available process parameters on the output functions. This is essential in order to arrive at a process design in the space of process parameters that meets certain criteria in the space

of the output functions. Generally, these optimization problems contain different, often conflicting objectives, like cost and quality measures. In this situation, Multicriteria optimization is a well-established tool to arrive at best compromises (Pareto solutions) between conflicting criteria (adaptive sampling strategies combined with deterministic optimization algorithms have been demonstrated by Bortz et al. (2014)). Navigating the Pareto solutions then visualizes the trade-offs interactively to the planner (Asprion et al. 2011).

In this contribution, we aim at including the sensitivities with respect to uncertain model parameters as further objectives into a multicriteria optimization setting. We call this procedure Robust Planning (RP). The result of RP will be the quantification of trade-offs between increasing robustness to uncertain model parameters and the other objectives. This approach complements the definitions of robust optimization (for a review, see Ben-Tal et al. (2009)) and chance-constraint programming (Ostrovsky et al. 2009). In these approaches, the focus is on an absolute definition of robustness in the sense that solutions can be classified as either robust or non-robust. Our strategy however puts emphasis on the compromise one has to accept in order to arrive at a more robust solution compared to a more sensitive one.

It turns out that in practice, optimal experimental design (OED) is supported in a similar multicriteria setting: On the one hand, the model should be accurate for process designs which are practically relevant (e.g. at low costs, high product qualities). Thus, experiments should preferably be carried out at these designs. On the other hand, in order to reliably estimate model parameters, experiments are favored at which measureable output functions are sensitive to the respective model parameters. A common approach discussed in literature (Franceschini and Macchietto 2008) - focuses on the maximization of different sensitivity measures. Therefore, one defines scalar measures of the sensitivity matrix encoding the sensitivity of certain output functions to relevant model parameters. However, these scalarizations of the sensitivity matrix lead not only to contradictory results (Telen et al., 2012), but also constitute a weighting of matrix entries which has to be known *a priori*. In practice, however, this knowledge does not exist, leading eventually to a loss in optimization potential.

A possible solution suggested in this contribution consists in following a similar route as sketched above for robust process design: For each measurable output function of interest, an adequate sensitivity measure is proposed as one objective to be maximized, among others which also have to be met during the experiment. By doing so, the trade-off between sensitivity, i.e. reliable estimates of model parameters, and good representation of the designs which are practically most relevant is quantified. On this basis, the planner can decide for a process design that realizes the compromise that best suits the current situation. Thus in our approach, RD and OED merely differ in the way how sensitivity measures are treated: As objectives to be minimized for RD, or as objectives to be maximized for OED.

The article is structured as follows. In Section 2 it is described how robustness can be incorporated into a conventional optimization problem. Section 3 contains the illustration of this approach by an example. The article ends with the conclusion in Section 4.

2. Sensitivity as an optimization objective

Sensitivity analysis is used here to quantify the uncertainty range of an output function with respect to given distributions over uncertainty ranges of thermodynamic model

parameters around their reference values. During RP (OED), process parameters are to be adjusted such that, among others, adequate robustness measures derived from the uncertainty ranges of certain output functions are maximized (minimized).
Our starting point is a conventional optimization problem that has been set up and solved, i.e.

- the engineer has chosen one or more meaningful objectives $f_i, i = 1, \dots, N_{obj}$ from the output functions and relevant process parameters $p_j, j = 1, \dots, N_{proc}$;
- one or more (Pareto-) optimal solutions have been obtained by some optimization method. These are given by design points $\boldsymbol{S}_\alpha, \alpha = 1, \dots, N_{Sol}$, with corresponding objective function values $f_{i,ref}(\boldsymbol{S}_\alpha)$. The index *ref* means that the model parameters $x_k, k = 1, \dots, N_{mod}$, are fixed to certain reference values $x_{k,ref}$.

If one now wants to take into account the uncertainty ranges in the x_k one merely has to find out which compromise one has to accept in order to arrive at more (for RP) or less (for OED) robust solutions compared to the $f_{i,ref}(\boldsymbol{S}_\alpha)$. The following steps are recommended:

i. Carry out a conventional sensitivity analysis for a set of design points $\boldsymbol{P}_\beta, \beta = 1, \dots, N_{Points}$, where for each design point a sampling in the N_{mod}-dimensional space of the x_k is done. In order to keep the numerical effort manageable, scenario samplings that scale linearly with N_{mod}, like one-at-a-time or factorial design (Saltelli et al., 2008), should be used. The $\boldsymbol{P}_\beta$ should contain the original Pareto points $\boldsymbol{S}_\alpha$, but do not have to be restricted to them; it is advisable to include some more points, for example, by enumerating points in a suitable neighbourhood around the designs of the Pareto points. The result will be uncertainty ranges in f_i for each $\boldsymbol{P}_\beta$ resulting from the uncertainty of model parameter x_k with lower values $f_{i,k-}(\boldsymbol{P}_\beta)$ and upper values $f_{i,k+}(\boldsymbol{P}_\beta)$. Thus an average relative deviation with respect to the reference value $f_{i,ref}(\boldsymbol{P}_\beta)$ follows:

$$\Delta_{f_i,k}(\boldsymbol{P}_\beta) := \frac{1}{f_{i,ref}(\boldsymbol{P}_\beta)} \sqrt{\frac{1}{2}\left[\left(f_{i,k-}(\boldsymbol{P}_\beta) - f_{i,ref}(\boldsymbol{P}_\beta)\right)^2 + \left(f_{i,k+}(\boldsymbol{P}_\beta) - f_{i,ref}(\boldsymbol{P}_\beta)\right)^2\right]} \quad . \tag{1}$$

This is the measure for robustness used in this contribution. It quantifies the impact of x_k on the objective function f_i at $\boldsymbol{P}_\beta$ and tends to zero if both $f_{i,k-}$ and $f_{i,k+}$ approach $f_{i,ref}$. Without trade-off between the original objectives and minimizing (RP) or maximizing (OED) this measure, then one can stop here.

ii. If there are trade-offs, one includes the corresponding $\Delta_{f_i}(\boldsymbol{P}_\beta)$, into the original optimization problem. In each iteration step during the optimization, a sensitivity sampling has to be done in order to calculate the $\Delta_{f_i}(\boldsymbol{P}_\beta)$, .

It is important that one restricts oneself to the most important *conflicting* objectives in this procedure. The strength of multicriteria optimization is in quantifying trade-offs between best compromises (Pareto-solutions). Objectives that correlate should not be defined as single objectives in the procedure: This would lead to numerical inefficiency and to hiding valuable information.

3. Example

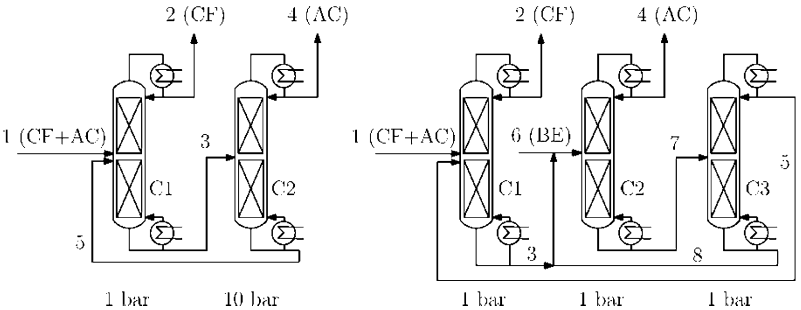

Figure 1: Flow sheets of the pressure-swing (left) and entrainer (right) distillation processes for separating chloroform (CF) and acetone (AC). The entrainer is benzene (BE).

In this section, we want to compare two types of distillation processes for separating a binary mixture of chloroform and acetone into pure components. As these two substances form a maximum boiling azeotrope, a separation in a simple single distillation column is not possible. Two variants for separating the azeotropic mixture are considered: the first is a pressure-swing distillation which takes advantage of the pressure dependency of the azeotrope. In the second one, an entrainer (benzene) is used to influence the phase behavior in a way which makes a separation by distillation feasible. The flow sheets for these two variants are shown in Fig. 1. In Bortz et al. (2014), a comparative multicriteria study of these two variants has been performed with three conflicting objectives: Minimizing the total heat duty and maximizing the product purities in the product streams, i.e. the purity of Acetone in streams 4 and the purity of Chloroform in streams 2; as design parameters, the reboil and split ratios of the columns were taken.

Here we aim at including the robustness of the separation with respect to uncertainties in the VLE data as additional objective that is to be minimized. A NRTL model was taken to model the VLE of the mixtures with reference model parameters given in Bortz et al. (2014). An inspection of original VLE measurements in the Dortmund Data Bank (Onken et al., 1989) revealed that assuming uncertainty ranges in the activity coefficients at infinite dilution, $\gamma^{\infty}_{AC,CF}$ and $\gamma^{\infty}_{CF,AC}$, by ±10 % around their reference values models the accuracy of experimental data well. A Margules approach (Mathias 2014) was then used to incorporate the uncertainties into the corresponding VLE model.

A sensitivity analysis using one-at-a-time-sampling was then performed for a large set of possible design points to analyze the impact of the uncertainty ranges in both $\gamma^{\infty}_{AC,CF}$ and $\gamma^{\infty}_{CF,AC}$. It turned out that the influence of $\gamma^{\infty}_{CF,AC}$ on the objective functions is negligible. Thus in the following, we focus on the impact of the uncertainty range of $\gamma^{\infty}_{AC,CF}$. To keep computational costs moderate, a one-at-a-time-sampling is used here as well to calculate $\Delta_{f_i,\gamma^{\infty}_{AC,CF}}(\boldsymbol{P}_\beta)$, i.e. in Equation (1), one sets $f_{i,k-}(\boldsymbol{P}_\beta) = f_i(\boldsymbol{P}_\beta)\big|_{\gamma^{\infty}_{AC,CF}-10\%}$ and $f_{i,k+}(\boldsymbol{P}_\beta) = f_i(\boldsymbol{P}_\beta)\big|_{\gamma^{\infty}_{AC,CF}+10\%}$. With this set-up, the sensitivity in the product purities of the original Pareto-points was calculated. It turned out that the effect on the Acetone purity dominates the effect on the Chloroform purity by one order of magnitude; furthermore, both effects are highly correlated. Therefore, we restrict ourselves to the uncertainty of the Acetone purity, $\Delta_{Ac,\gamma^{\infty}_{AC,CF}}$, in the following, which we note by Δ_{Ac}. Its values for the original Pareto points are shown in Fig. 3.

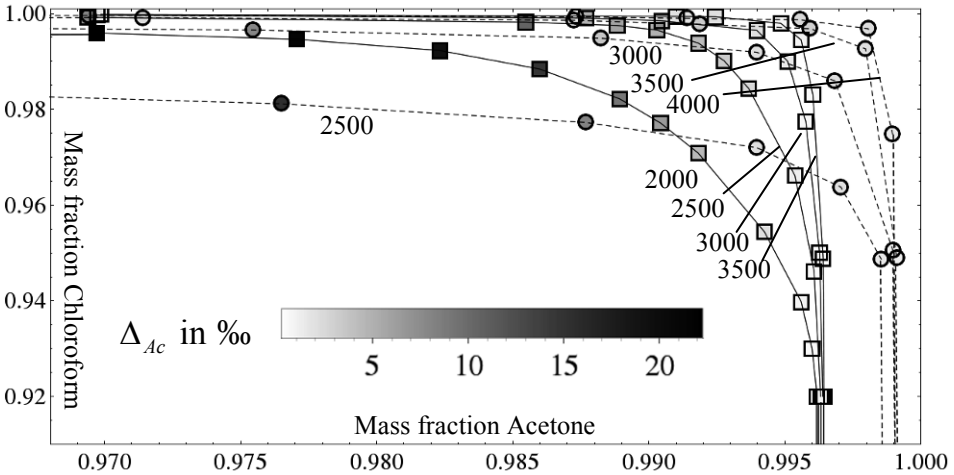

Figure 3: Pareto points for entrainer distillation (squares) and pressure swing distillation (circles) for different heat duties in kW (numbers next to the Pareto sets), calculated by a sandwiching algorithm as in Bortz et al. (2014) maximizing the mass fractions of the two product purities: mass fraction of Acetone (Chloroform) in stream 4 (2)). The grey code denotes the relative uncertainty of the acetone purity.

From the results shown in Fig. 3, two conclusions can be drawn. First, increasing the Acetone purity is not conflicting with its robustness. On the other hand, an increase in the Chloroform purity leads to a decrease in its robustness, which can, however, be counterbalanced by an increase in the heat duty. Thus, in order to achieve certain robustness, one either has to invest sufficient energy, or make a compromise in the Chloroform product purity. This leads to the question how to quantify the trade-off between robustness and product quality.

This question is answered by minimizing Δ_{Ac} as a fourth objective. Since, as argued above, this objective is conflicting with the minimization of the heat duty and the maximization of the Chloroform purity, it can be included into the original Multicriteria framework by introducing appropriate upper bounds and redoing the original problem again. The result is presented in Fig. 4.

Fig. 4 shows the highest possible increase in robustness that can be achieved by accepting a compromise in the Chloroform purity. This gain in robustness at relatively moderate heat duty is similar in value to the robustness obtained by significant increase in the energy invest. Furthermore, Fig 4 demonstrates that the entrainer distillation tends to be more robust to uncertainties of $\gamma_{AC,CF}^{\infty}$ at less energy invest.

4. Conclusions

We presented a practical guideline how to include robustness as one objective among others in a multicriteria optimization framework. If the goal consists in finding robust designs, then robustness as an objective is to be maximized. However, in the framework of optimal experimental design, it is to be minimized. The guideline consists of three steps, starting from the original optimization problem, followed by a sensitivity analysis of the original Pareto points, possibly including an interesting neighbourhood, and leading to the inclusion of robustness as a further objective only where conflicts with the other objectives occur. In order to play to the strength of the multicriteria approach, one should restrict oneself to the representatives of the most important *conflicting*

objectives. The planner then obtains the trade-offs between the objectives. The practicability of our approach was demonstrated by a comparative study between two distillation types, leading to new insights into the competition between maximal product quality, minimal energy invest and maximal robustness.

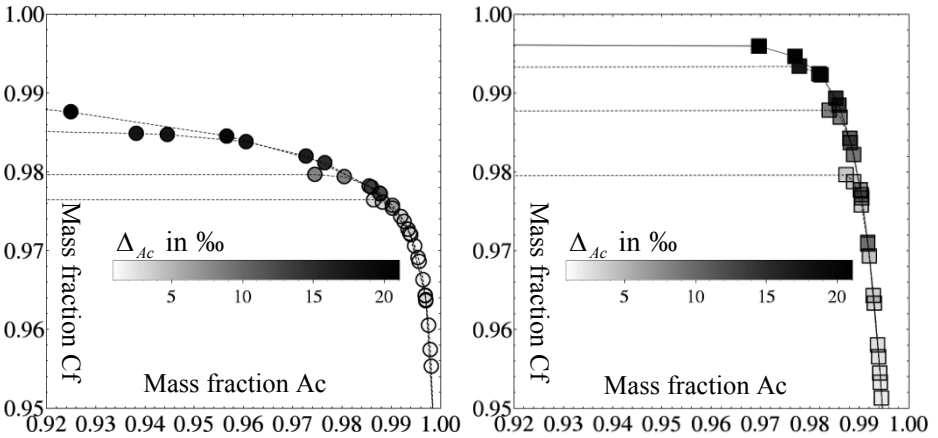

Figure 4: Pareto points for constant heat duty (left panel: 2500 kW, pressure swing distillation; right panel: 2000 kW, entrainer distillation) and bounds on Δ_{Ac}, namely $\Delta_{Ac} \leq 2‰, 5‰, 13‰$ (curves from bottom to top; the grey level is the same in both panels). The uppermost curve represents the case unrestricted in Δ_{Ac}.

Product and Process Network Modeling and Pathway Optimization with Life Cycle Functional Unit Analysis: The Case of Biofuels

Daniel Garcia, Fengqi You*

Northwestern University, 2145 Sheridan Road, Evanston, Illinois, 60208, USA
you@northwestern.edu

Abstract

Biofuels have been promoted as a possible solution to provide renewable fuels and diminish society's dependence on non-renewable energy sources. However, there are a plethora of possible biofuel product and processes, and an ideal choice is unclear. Furthermore, economic and environmental metrics must be chosen that best analyze the performance of the selected pathway. This work presents a functional unit based approach towards optimization of product and process networks. The mass of ethanol produced in a biofuels network is chosen as the functional unit (FU), and the production cost and global warming potential per FU are computed. Solving the resulting NLFP (nonlinear, fractional program) is reduced to iteratively solving a sequence of MILP by integrating a piecewise linear approximation algorithm using branch and refine methods with the parametric algorithm. A case study processing up to 100,000 tons/hr of a variety of biomass to meet an ethanol demand of 2.88 Mgal/yr is presented.

Keywords: Functional unit, global network optimization, sustainability, biofuels

1. Introduction and Background

Biofuels have generated significant attention in recent years in the business, policy, and research arenas. Much has been made of the potential for biofuels to replace fossil fuels in significant quantities to lessen dependence on petroleum (Yue et al., 2014). Certainly, biofuels can have a prominent position in the clean energy landscape of the future; for some sectors – aviation especially – liquid biofuels are the only viable alternative for petroleum fuels. The United States government also requires that a certain percentage of the nation's fuel consumption be satisfied by biofuels, a policy brought about by the Energy Independence and Security Act (EISA) of 2007. Thus, much research has been directed towards making biofuels economical. In recent years there has been a variety of technoeconomic analyses of biofuel production processes with the goal of demonstrating their economy on a large scale. Examples include algal-based fuel processes (Davis, 2011), hydrothermal liquefaction of woody biomass (Zhu, 2014), cellulosic ethanol processes (Seabra, 2010), ethanol production from corn stover (Kazi, 2010), and ethanol production from switchgrass (Tao, 2011), hydrocarbon fuels frm corn stover (Gebreslassie et al, 2013), among many others. With the advent of these sophisticated technoeconomic analyses, it appears prudent to consider the appropriate way to construct, model, and optimize a biofuels product and process network.

Modeling of biofuel and biomass networks has been identified as critical for the successful implementation and commercialization of biofuel technologies (Yue et al., 2014). To that end, a variety of optimization objectives and methods have been

proposed. Rizwan, Lee, and Gani presented a superstructure-based approach to find the optimal processing pathway for biodiesel production form algae (Rizwan et al., 2013), using objective functions of the yield of biodiesel, gross operating margin, and multi-objective maximization of gross operating margins and minimization of waste. Gong and You also optimized algae fuels networks, but with the objectives of biological carbon sequestration and costs per mass of CO_2 sequestered by the facility (Gong et al., 2014a). Clearly, economics and environmental performance are important considerations when optimizing a biofuels product and process network.

Life cycle optimization has also been applied in the case of biofuels and bioenergy production (You et al., 2011). This optimization style utilizes the ideas behind the life cycle assessment (LCA) methodology, which aims to account for material and energy usage as well as wastes throughout the product's lifetime. A key step in performing an LCA is that of choosing the functional unit (FU), a quantitative unit that aims to relate the process's inputs and outputs (ISO, 1997). Multiple studies have explored using the functional unit methodology for biofuels network optimization in recent years. Gong and You (2014) optimized a algal fuel network using life cycle optimization, with a choice of functional unit of 1 gallon of gasoline equivalent, an energy-based metric. Similarly, Yue et al. (2013) optimized sustainable product system networks and supply chains with a gasoline equivalent metric.

Such energy-based functional units are extremely useful if fuels are the only end product, however, when looking at an overall product and process network where not all products are to be used as fuels, the choice of functional unit becomes murky. A recent Argonne National Lab report on bioproducts – chemicals or other substances made from biomass that are not fuels – presents results on a per mass of bioproducts produced basis (Dunn et al., 2014). If such a functional unit is used, the discussion turns from a sustainable fuels focus to a sustainable product focus. In the case of biofuels, the idea of co-production of bioproducts along with fuels has been proposed, reasoning that this could increase profitability of the selected product and process network, allowing for increased production of sustainable fuels and other products (Bozell, 2010). Thus, a functional unit of kg of products produced is chosen in this work to reflect this slight shift in viewpoint. This shift also has the additional benefit of keeping the presented model general and able to represent a wide variety of product and process networks.

2. Methods

A comprehensive biofuels technology network has been previously constructed to find the optimal processing pathway from a comprehensive product and process network (Garcia et al., 2014); the data and network superstructure was taken from this model. In contrast with the optimization model of that work, however, this work aims to incorporate the functional unit in the optimization methodology. The functional unit chosen for this demonstrative communication will be total mass of products produced per year. It is important to note that any functional unit can be used with the solution strategy employed in this work. A bioconversion technology network with corn, corn stover, hard wood, soft wood, algae, and switchgrass feedstocks available is optimized to produce ethanol (Figure 1). Due to functional unit implementation, a nonlinear fractional programming (NLFP) model is constructed in this work instead of a nonlinear program (NLP). Directly solving NLFP's can consume large computational resources. Thus, a new solving methodology is developed and implemented in this work to obtain reasonable solution times. In the interest of brevity, a full list of the variables,

parameters, and equations will not be presented here; only a summary of our methods is presented along with the pseudo algorithm code of Figure 2.

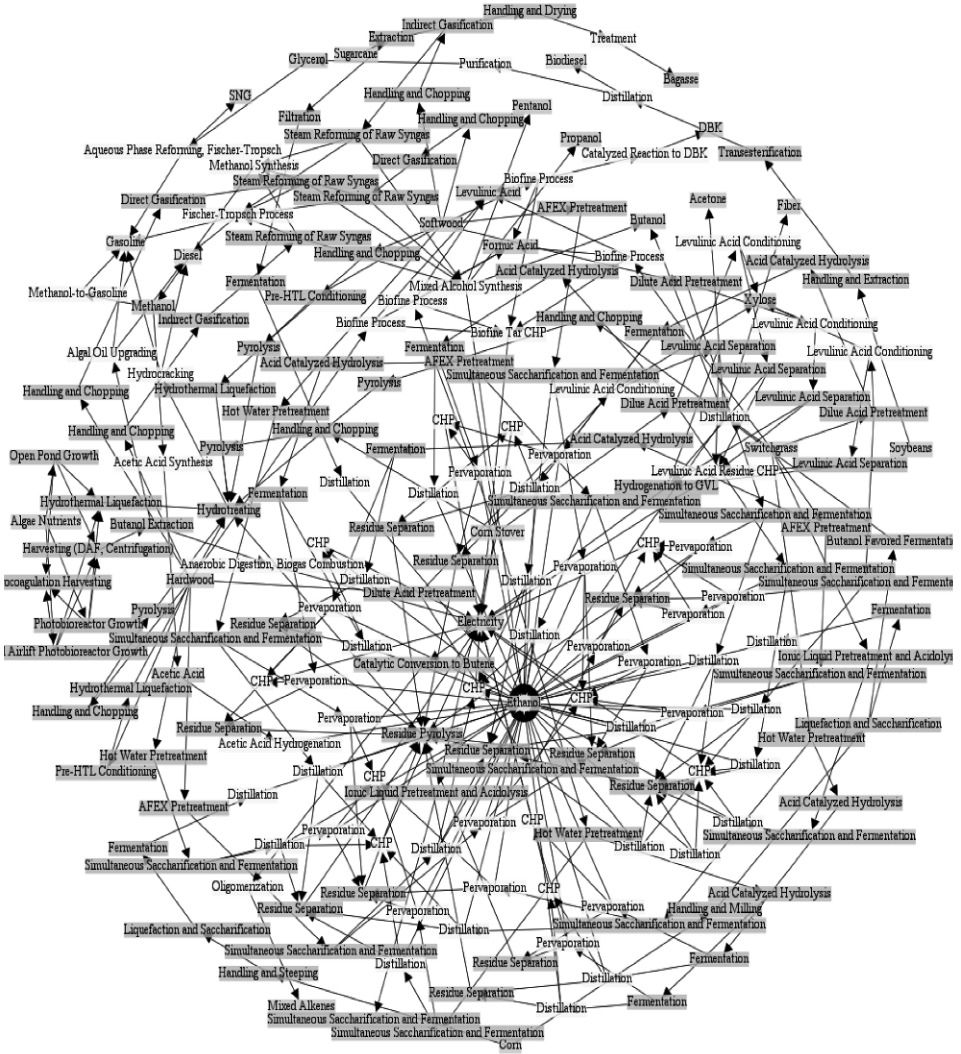

Figure 1. Bioconversion technology network for this problem (Garcia et al., 2014).

The objective function chosen in this work is the production cost per kg of products produced. This choice in objective results in a fractional form of the objective function, potentially complicating the optimization process. A parametric algorithm based on Newton's method is employed to deal with this potential problem, a strategy that has been shown to be very efficient for solving mixed-integer fractional programming problems (Zhong and You, 2014). After implementation of the parametric algorithm, nonlinear, nonconvex terms remain in the calculation of capital costs, as these costs scale nonlinearly with capacity. Once again, in order to reduce the solving times, the capital cost term is approximated by piecewise linear underestimations with an MILP-based branch and refine algorithm (You and Grossman, 2011) using variables of specially ordered sets of type 1 (SOS1), giving a lower bound to the production cost.

This algorithm makes up an inner loop within the parametric algorithm, and iteratively updates its upper and lower bounds until the capital cost convergence is met (see Figure 2). The solution from the branch and refine algorithm is used to update the parametric algorithm parameter. If the parametric algorithm convergence criteria is not met, the parametric algorithm parameter is updated, and the inner loop is revisited. If the convergence criteria of the inner and outer loops are both satisfied, then the solution for the fractional production cost is given by the final value of the parametric algorithm parameter (Gong et al., 2014b). The fractional GWP is then calculated. Prices for feedstocks, fuel products, and bioproducts were taken from a variety of industry, market, and literature sources. Figure 2 describes the procedure for optimizing a model with a fractional production cost objective function.

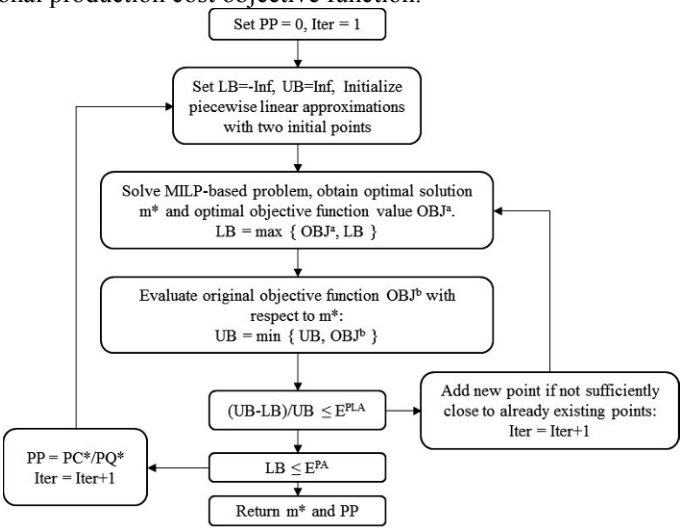

Figure 2. Algorithm flow chart for the proposed parametric algorithm with inner branch and bound piecewise linear approximation loop. PP = parametric parameter; Iter=iteration counter; LB=lower bound; UB=upper bound; Inf=infinite; E^{PLA}=tolerance for piecewise linear approximation; E^{PA}=tolerance for parametric algorithm.

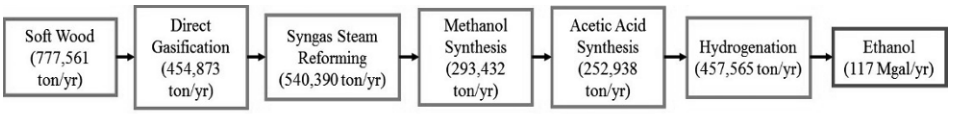
3. Case Study, Results, and Discussion

All experiments were performed on a DELL OPTIPLEX 790 desktop PC with an Intel(R) Core(TM) i5-2400 CPU @ 3.10 GHz and 8 GB RAM. All models and solution procedures were coded in GAMS 24.3.3. The original NLFP problems were solved with BARON 14.0.3. The MILP problem was solved using CPLEX 12.6. The results shown are obtained by solving the MILP problem with the algorithm described above.

An ethanol demand of 2.88 Mgal/yr was to be satisfied by processing any amount of corn, corn stover, switchgrass, hard wood, soft wood, or algae. No feedstock was assigned a minimum purchase amount. The results of this case study are shown in Figure 3. The resulting process makes only ethanol. This is likely due to a lack of demand for other products; making more products will only increase production costs. Another feature of the resulting pathway is the large capacity. The pathway aims to process almost 800,000 tons/yr of soft wood feedstock to make almost 120 million gallons of ethanol per year.



$$\frac{Production\ Cost}{Mass\ of\ Products\ Produced} = \$0.839/kg$$

$$\frac{GWP}{Mass\ of\ Products\ Produced} = 1.413\ kg\ CO_2 - eq/kg$$

Figure 3. Results of the demonstrative case study. Capacities of each technology in the pathway is shown as well as the unit production cost and unit GWP.

The fractional production cost was calculated to be \$0.839/kg of ethanol produced. Since only ethanol was produced in this case study, this production cost can be converted to a cost per gallon: this figure is approximately \$2.50/gal. Thus, the pathway results in a cost per gallon figure that aligns well with current ethanol market prices. The facility produces a large amount of ethanol at an annual operating deficit of less than \$70,000 per year. This large operating scale, however, comes with a high capital cost estimate of approximately \$295 million. Thus, it is clear that reducing the unit production cost arises naturally with economies of scale, as predicted by classical economics.

The fractional GWP of the proposed process is 1.413 kg CO_2-eq/kg of ethanol produced. Similarly to the previous paragraph, we can calculate the kg CO_2-eq/MMBTU as ethanol is the only product; this number is 50.23 kg CO_2-eq/MMBTU. For comparison, burning one kilogram of gasoline results in emissions of approximately 71.3 kg CO_2/MMBTU. No extra GWP is attributed to the combustion of ethanol downstream of the process, as the carbon from the ethanol was assumed to come from the atmosphere during biomass cultivation, resulting in net zero emissions. Thus, this process achieves greenhouse gas savings of ~30% if the produced ethanol is to be used as fuel. A comparison of the performances of BARON 14.0.3 and the proposed algorithm in solving this problem is shown in Table 1. The proposed method displays a clear advantage.

4. Conclusions and Directions for Future Study

In conclusion, it was shown for the first time that functional unit-based optimization of large product and process networks can be seamlessly implemented into existing network optimization methods. In this work, a bioconversion network of

Table 1. Computational performances of the NLP solvers and the proposed algorithm.

	BARON 14.0.3	Proposed MILP-based algorithm
Objective Value (\$/kg)	0.839	0.839
Solution time (s)	2757	20.07

hundreds of technology options and compounds/materials was optimized to find the lowest production cost per mass of products produced. This functional unit was introduced as to offer another analysis method of the impact of potential product and process networks as a whole, instead of focusing on just one aspect of the product portfolio (e.g. fuel/energy content). The algorithm presented was shown to find the optimal solution much faster than off-the-shelf NLP solvers. Thus, this method provides an opportunity for future analysis of integrated product and process network optimization for pathways that produce many types of products – such as the integrated biorefineries of the future.

Abstract

Recent works have demonstrated the efficiency of thermomorphic solvent systems (TMS) in the recovery of homogeneous catalysts, especially for the hydroformylation of long-chain alkenes such as 1-dodecene. In this case, the TMS mixture was comprised of dimethylformamide and decane; however, these solvents were not rigorously screened and may represent a suboptimal solution for catalyst recovery. Also, in view of other homogeneously catalyzed reactions, a systematic approach to solvent selection for catalyst recycling is desirable. In this contribution we propose using an established approach by estimating solvent effects on catalyst solubility with the Conductor Like Screening Model for Real Solvents (COSMO-RS). A framework for TMS solvent screening based on the relative solubility of the catalyst ligand, reactant, and product as calculated using COSMO-RS is proposed.

Keywords: computer-aided molecular design (CAMD), COSMO-RS, solvent design, homogeneous catalysis

1. Introduction

Thermomorphic solvent systems (TMS) were proposed by Behr and Fängewisch (2002) as a promising method for recovering homogeneous catalysts from a post-reaction mixture. A TMS consists of polar and non-polar solvents that form a one-phase liquid mixture during the reaction but can be switched into a biphasic mixture upon cooling, thereby enabling separation of the product from the catalyst. These tunable solvent mixtures have been used effectively in recovering homogeneous catalysts, for example, in Behr and Roll (2005) for hydroaminomethylation and in Behr et al. (2005) for hydroformylation, where a general method for the selection of TMS components based on Hansen parameters was presented. Thus, criteria for solvent selection were based on the thermo-regulated phase separation behavior of two or three solvents. This work was expanded upon in Behr et al. (2008) and included many example TMS systems as well as a classification system for different types of TMS depending on the number of solvents and type of miscibility gap formation. In their work, several TMS compositions were investigated for the hydroformylation of 1-dodecene, the example presented in this work. It was shown that a mixture of dimethylformamide (DMF) and decane provided high retention of the catalyst Rhodium-Biphephos while allowing for simple separation of the tridecanal product. They labeled this a Type III TMS, a mixture consisting of only catalyst and product solvents foregoing the use of a third,

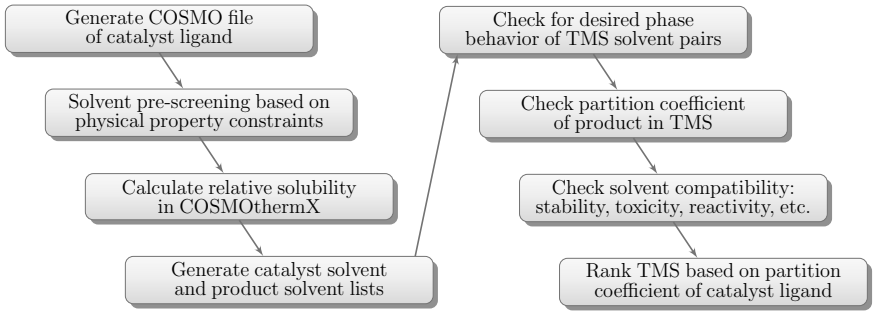

Figure 1: Procedure for TMS design

mediator solvent. This catalyst solvent requires a high affinity for the catalyst while the product solvent should have low catalyst and relatively high product solubilities.

In the present contribution, a method is proposed to identify an optimal type III TMS system with efficiency for catalyst recovery in the hydroformylation of 1-dodecene. This reaction has garnered much attention in recent years, having been the focus of reaction and process optimization by Hentschel et al. (2013). In principle the design of the TMS system should incorporate some aspects of catalyst partitioning into the initial stage of solvent selection. It is proposed that by predicting the thermodynamic properties of the catalyst ligand, a TMS effective at minimizing catalyst loss can be developed from the ground up. Since thermodynamic and experimental data regarding the solvent effects on the catalyst are limited or non-existant, the *ab initio* COSMO-RS model was used as the basis for all thermodynamic predictions.

2. Method and Results

Important criteria for solvent selection have been outlined by Gani et al. (2005), of which several, such as reactivity, solubility, liquid phase at reaction and separation conditions, and phase splitting, are used in this work to judge the physical and mixture properties of TMS solvents. These guidelines as they relate to the task at hand are summarized in Figure 1. The goal is to establish a TMS using a catalyst solvent with high catalyst solubility and to pair it with a product solvent that has low catalyst solubility but also a high affinity for the tridecanal product.

Thermodynamic properties of the catalyst ligand and subsequent solvent screening are calculated using the COSMO-RS method developed by Klamt (1995) as implemented in the commercial software package COSMOtherm by Eckert and Klamt (2014). COSMO-RS is an *a priori* method that combines quantum chemical calculations with statistical thermodynamics allowing for fast calculations of fluid phase interactions. There are many papers in the literature detailing the use of COSMO-RS in its various forms for solvent screening, such as for predicting solubilities of pharmaceuticals by Tung et al. (2008) and Hahnenkamp et al. (2010). A comparison of several thermodynamic models and their ability to predict pharmaceutical solubilities was given by Bouillot et al. (2011). Another important article written relative to this topic is by Wichmann and Klamt (2010), where a detailed description of the COSMO-RS method relating to solvent screening is given. The conclusion in these articles was that COSMO-RS can qualitatively predict the solubility of large and complex molecules in various solvents. Therefore, this method should be suitable for the current task of predicting catalyst ligand solubility.

2.1. Generate COSMO file of catalyst ligand

The first task is to create the COSMO file of the solute used in the process, namely the catalyst ligand Biphephos. Since this molecule is not included in the COSMObase expansion, it must

be computationally modeled and evaluated using a quantum chemical COSMO calculation which evaluates its surface charge in a perfect conductor. The molecular model was developed using TURBOMOLE (2013), at the RI-DFT level of theory from Eichkorn et al. (1997) using the def-TZVP basis set developed by Schäfer et al. (1994). A quantum chemical COSMO calculation for the molecule was performed generating a COSMO file for the Biphephos ligand. This file contains all of the information required for predicting the thermodynamical information required for solvent screening and is used as COSMOtherm input.

2.2. Pre-screening of candidate solvents

To start, a list of candidate solvents from the COSMObase extension is to be generated. Certain molecular properties, such as molecular weight, melting temperature, boiling temperature, screening charge, and component atoms, can be used as constraints to pre-screen solvent candidates. In this example, the search space was left intentionally large with physical property constraints limited to boiling temperature and molecular weight. The boiling temperature was chosen to be between zero and 260 °C, 20 °C less than the boiling point of tridecanal to avoid possible azeotrope formation in a subsequent distillation column. Candidate molecules were also restricted to molecular weights not higher than 200 g/mol leaving 2813 molecules as potential solvents.

2.3. Solvent screening: catalyst solubility

The next step is to estimate the relative solubility of the Biphephos ligand in the candidate solvents. Relative solubility is evaluated using the solvent screening option in COSMOthermX. The relative solubility of Biphephos in all 2813 solvents must be calculated at once in order to compare values. This is predicted using the chemical potential, $\mu_i^{solvent}$, of the solute at infinite dilution in the pure solvent as calculated by COSMO-RS (Eq. 1) based on statistical thermodynamics using sigma profiles of the involved components. All relative solubilities were investigated at 25 °C.

$$\ln(x_i) = \mu_i^{solvent}/RT \tag{1}$$

Two lists are generated: one with solvents predicted to have high relative solubility of the catalyst ligand (HRSC) and the second with those having low relative solubility of the catalyst ligand (LRSC). One solvent from each list will be used as a component in the final TMS. In Table 1 the top five performing HRSC and LRSC solvents are respectfully presented. From the candidate solvents, hydrofluoric acid should have the highest solubility for Biphephos while water should have the lowest solubility, about 18 orders of magnitude less. However, it should be immediately clear that not all molecules in Table 1 are suitable for use as solvents as all of the HRSC solvents are either highly reactive acids, strong oxidizers, or destructive to the ozone. The LRSC solvents are also quite reactive and/or toxic outside of water, which cannot be used due its poor affinity for the product and reactant. Obviously it is undesirable to determine which of the almost 3000 solvents are poor candidates based on reactivity, toxicity, or by some other property at this stage. Therefore, removal of such solvents is done at a later point in the screening process when fewer candidates remain, trading calculation time for research time. To ensure, however, that reliable candidates are found, the HRSC list contains the top 100 solvents for catalyst solubility and the LRSC list contains all molecules from octane down. This is done to compare the effects of shorter alkanes with the performance of decane, for which some data with DMF is available from Brunsch (2013). This leaves 403 solvents in the LRSC list.

2.4. Miscibility gap formation

To generate a functioning TMS, one must ensure that biphasic separation occurs within the post-reaction mixture containing non-converted reactants as well as the product. For this, COSMOtherm was implemented to estimate miscibility gap formation. Liquid-liquid equilibrium calculations were carried out for each HRSC and LRSC solvent pair, 40,300 in total. A temperature of

Table 1: Top 5 high (HRSC) and low (LRSC) relative solubility catalyst solvents

HRSC	$\log_{10}(x_i)$	LRSC	$\log_{10}(x_i)$
Hydrofluoric acid	0.0000	H_2O	-18.4128
Selenic acid	-1.0582	Formamide	-12.7388
Chlorosulfonic acid	-1.2406	Hydroxyacetonitrile	-12.2432
ClO_2	-2.6015	Butanedinitrile	-12.1521
1,1,1-Trifluoro-2-bromoethane	-3.0996	Dicyanomethane	-11.6746

-25 ^{o}C, the lower bound of the method's planned experimental validation, was selected for these calculations. The size of the miscibility gap was not regarded; simple biphasic formation was considered acceptable to avoid potential LLE prediction errors. A total of 5225 TMS mixtures were predicted to form two liquid phases at the desired temperature. Miscibility gap formation at 100 ^{o}C, a reasonable temperature for the reaction, is calculated for the final, valid TMS compositions. Of these, only one did not form a homogeneous mixture.

2.5. Product and ligand distribution

Once candidate solvent pairs have been identified, it is of interest to ensure the TMS extracts the product from the post-reaction mixture as intended. Partition coefficients of tridecanal according to Eq. 2 were used to evaluate this distribution. Solvent mixtures with a partition coefficient of less than 0.25 (lower is better) were considered for further screening, leaving 350 potential solvent pairs.

$$\log_{10}(P_j^{(2,1)}) = \log_{10}(\exp((\mu_j^{(1)} - \mu_j^{(2)})/RT) \cdot V_1/V_2) \tag{2}$$

Here, $\mu_j^{(i)}$ is the chemical potential of species j at infinite dilution in species i, where j stands for the reaction product tridecanal, 1 for the HRSC solvent, 2 for the LRSC solvent, and V for the estimated solvent volume.

2.6. Suitable solvent solutions

At this point, individual solvents were eliminated for the various reasons mentioned in section 2.3. Solvents were also removed when melting temperature data was unavailable, for having a melting temperature above the separation temperature, and for containing double and triple bonds, which may react during hydroformylation. The remaining HRSC solvents included acetaldehyde, DMF, acetone, n,n-dimethylacetamide, n-methyl-2-pyrrolidone, methylacetate, and n,n-diethylformamide, all good hydrogen bond donors with low non-polar profiles. The LRSC solvents are comprised exclusively from linear, branched, and cyclic alkanes. In total, 208 TMS mixtures remain as one TMS was predicted to form a miscibility gap at 100 ^{o}C.

2.7. Analysis

The TMS systems are now ranked according to the partition coefficients in the HRSC and LRSC solvents respectively, calculated using a variation of Eq. 2, with j representing Biphephos and also ignoring the volume quotient of the solvents. Thus, the partition coefficients for Biphephos are simply the logarithm of the relative solubility quotients calculated in the second screening step. The top ten TMS systems based on catalyst partition coefficients are listed in Table 2 (higher is better). Here it can be seen that for good catalyst recovery and functioning product separation, catalyst solvents acetaldehyde and DMF paired with long-chain alkanes as product solvents are recommended. It can also be seen that with increasing alkane chain-length, catalyst recovery

capacity increases due to the increase in non-polarity of the non-polar phase. Tridecanal separation decreases for the same reason.

Since all LRSC solvents are long-chain alkanes, a general comparison of HRSC performance can be made when fixing the LRSC as *n*-decane. This was chosen due to its common use and that some experimental data is available for comparison. Results for the top TMS systems using *n*-decane are given in Table 3. Here we also see acetaldehyde topping the list due to its increased solubility of the catalyst ligand compared to DMF and other HRSC solvent candidates. This might be mainly due to the slight increase in excess entropy when using acetaldehyde over DMF, although both form approximately ideal solutions with Biphephos. It is also noticeable that solvents having similar catalyst solubility have varying tridecanal solubility. For example, DMF and acetone have about the same heat of mixing with tridecanal, but the excess entropy is more negative in acetone leading to a slightly more favorable solution.

A final comparison of solvent pairs with DMF as the HRSC and various length linear alkanes from octane to tridecane as the LRSC are set side-by-side (Table 4). As expected, the solubility of the catalyst and of tridecanal worsens as the length of the alkane chain increases, due to the increased heat of mixing. The change in excess entropy is small, as the molecular order is not drastically influenced by more of the same non-polar interactions. These results are in agreement with the experimental findings by Brunsch (2013).

Table 2: List of top ten TMS mixtures

HRSC	LRSC	$log_{10}(P_{tridecanal})$	$log_{10}(P_{Biphephos})$
Acetaldehyde	Tridecane	0.2060	2.8038
Acetaldehyde	Dodecane	0.1750	2.7655
Acetaldehyde	Bicyclohexyl	0.0663	2.7507

n,n-Dimethylacetamide	*n*-Decane	0.2184	2.5572
n-Methyl-2-pyrrolidone	*n*-Decane	0.3017	2.5193
Methyl acetate	*n*-Decane	0.1777	2.2222
n,n-Diethylformamide	*n*-Decane	0.1880	2.2166

3. Conclusion

This contribution presents a novel method based on quantum chemical COSMO calculations for selecting TMS solvent pairs for the recycling of homogeneous metal-organic catalysts used for the hydroformylation of 1-dodecene. The benefit of using this method is its simplicity and the

Table 4: Comparison of TMS composed of DMF and linear alkanes

HRSC	LRSC	$log_{10}(P_{tridecanal})$	$log_{10}(P_{Biphephos})$
Dimethylformamide	Octane	0.0267	2.4158
Dimethylformamide	Nonane	0.0759	2.4982
Dimethylformamide	Decane	0.1180	2.5635
Dimethylformamide	Undecane	0.1565	2.6152

Dimethylformamide	Tridecane	0.2180	2.6959

absence of experimental data for identifying potential solvents with high and low affinity for a specific catalyst ligand. This method is partially corroborated by its ability to identify mixtures of DMF and longer alkanes as satisfactory TMS solvents for recovering the Biphephos ligand, something already empirically confirmed. It also provides a general starting point for further experiments with new TMS compositions that may increase catalyst retention, product separation, and overall process performance.

4. Acknowledgment

This work was conducted in part in cooperation with the Collaborative Research Centre "Integrated Chemical Processes in Liquid Multiphase Systems". The financial support from the German Research Foundation (DFG) under the grant SFB/TRR 63 is gratefully acknowledged.

Abstract

The objective of this work is to develop a framework to a design dentin adhesive system for water compatibility and efficient photo-polymerization applying computer aided molecular design. A dentin adhesive system consists of monomers and photo-initiators which trigger a photo-polymerization reaction when exposed to visible light. In this study a water compatible visible light photosensitizer was designed for dental applications. Quantitative structure property relationships (QSPRs) were developed for relevant properties (octanol/water partition coefficient and molar extinction coefficient) using molecular descriptors. The QSPRs are combined with structural constraints to form a MINLP, which is then solved to near optimality using Tabu search to generate novel candidate photosensitizer molecules with desired properties. Tabu search, a heuristic optimization method, does not yield globally optimal solutions for MINLPs, but it is an efficient and practical method for solving general combinatorial optimization problems. This framework will provide insight regarding possible functional groups for developing water-compatible visible light photosensitizers for dentin adhesive systems.

Keywords: hydrophilic, initiator, optimization, Tabu search, water compatible, QSPR

1. Introduction

1.1 Motivation

Dentin adhesives are sensitive to moisture and undergo phase separation into hydrophobic and hydrophilic-rich phases, when coming into contact with water within wet demineralized dentin (Spencer and Wang, 2002). The major components of a dentin adhesive are monomers (cross-linker and 2-hydroxyethyl methacrylate, HEMA) and a photo-initiator system which enables initiation of a photo-polymerization reaction. Previous investigations have quantitatively exhibited a limited presence of the most popular hydrophobic photo-initiator system (camphoquinone, CQ and ethyl 4-(dimethylamino) benzoate, EDMAB) in the hydrophilic-rich phase (Ye *et al.* 2012). Limited photo-initiator content indicates sub-optimal polymerization of the hydrophilic-rich phase and can cause unreacted monomers and pendant groups to become trapped. The overall impact would be detrimental to the dentin/adhesive bond integrity. The trapped unreacted monomers can also cause leaching of HEMA, which can elicit a cytotoxic effect (Chang *et al.* 2005). The

presence of photo-sensitizer in a higher concentration within the hydrophilic-rich phase is critical for improving the dentin/adhesive bond integrity and reducing cytotoxicity (Ye *et al.* 2009).

1.2 Physical properties

The efficiency of the photo-polymerization is dependent on the absorptivity of the photosensitizer within the activation range (Neumann *et al.* 2005). The absorption of light at a given wavelength by the photosensitizer is governed by its molar extinction coefficient at that wavelength. Therefore, it is important that the emission spectrum of the curing light unit matches with the absorption spectrum of the photosensitizer. A high molar extinction coefficient of a photosensitizer increases the formation of initiating reactive species, which in turn improves the degree of conversion and the photo-polymerization reaction kinetics (Neumann *et al.* 2005). The hydrophilicity of the photosensitizer also plays a vital role in a dentin adhesive system, since this governs the availability or dispersion of the photosensitizer in the hydrophilic-rich phase after infiltration of the adhesive within the wet demineralized dentin. For the current study, the octanol/water partition coefficient (log P) was used to estimate the hydrophilicity of the photosensitizer.

1.3 Background and objective

In this work, a visible light water compatible photosensitizer for dental applications has been designed by applying computer-aided molecular design (CAMD). Two quantitative structure property relationships for properties, the molar extinction coefficient at 480 nm and the octanol/water partition coefficient (log P), have been developed using topological descriptors, specifically connectivity indices (Randić 1975). CAMD consists of a forward and an inverse problem. The development of QSPRs represents the forward problem, where mathematical expressions for predicting properties using known molecular structures are derived. The next step, where novel molecules with desired properties are designed, is the inverse problem. For the inverse problem, QSPRs are used to design molecules which have properties close to the target values. This is an optimization problem where the molecule is formed from various combinations of different molecular sub-structures. Tabu search, a stochastic optimization algorithm, was employed to solve the optimization problem. This method was used previously to design novel molecules with desired properties (McLeese *et al*. 2010). CAMD and connectivity indices have been successfully used previously to design polymers and small molecules (Eslick *et al.* 2009, Roughton *et al.* 2012, Chavali *et al.* 2004). CAMD has been utilized in the past for polymer design (Venkatasubramanian *et al.* 1994) and for the design of ionic liquids and other solvents (Gani *et al.* 1991, Matsuda *et al.* 2007, Folic *et al*. 2008, Gardas *et al*. 2008).

2. Experimental Data and QSPR Development

To build the QSPR for the molar extinction coefficient (ξ), data was collected for candidate molecules which exhibited their peak wavelength in the visible range (unpublished data). The molar extinction coefficient was determined at 480 nm wavelength, which is approximately the peak wavelength generated by the halogen curing light unit used in dental applications. The nine molecules in the model building set for $\ln(\xi)$ were: New Fuchsin, Victoria blue B, Methylene blue chloride, Eosin Y disodium salt, Bromophenol blue sodium salt, Erythrosin B, Fluorescein sodium salt, [3-(3,4-dimethyl-9-oxo-9H-thioxanthen-2-yloxy)-2-hydroxypropyl]trimethylammonium chloride (QTX) and Rose bengal sodium salt. The octanol/water partition coefficients (log P) of similar molecules were obtained from literature (Pellosi *et al.* 2012, Shiekh *et al.* 1976, Wagner *et al.* 1998, Wainright *et al.* 1999). The molecules in the model building set for log P were:

Bromophenol blue, Eosin Y, Erythrosin B, Fluorescein, Methylene blue chloride, Rose bengal, Victoria blue B and Victoria blue R.

2.1 Descriptor selection and QSPRs

Quantitative structure property relationships (QSPRs) mathematically link physical or chemical properties with the structure of a molecule. For example, QSPRs for organic dyes were developed in the past for solar cell applications for properties such as peak wavelength (Xu et al. 2010, Venkatraman *et al.* 2014). In this work, the statistical software R (R-Development-Core-Team, 2010) was used to develop the QSPRs correlating properties with connectivity indices by linear regression. The leaps package (Lumely, 2004) was used to select the descriptors. Descriptors in the model with higher correlation coefficients (R^2) and lowest Mallow's C_p were selected. The Mallow's C_p statistic is a means of determining the optimum number of descriptors, which takes into account the lack of fit as well as complexity in the correlation (Roughton *et al.* 2012). The octanol/water partition coefficient of molecules has been predicted previously by using the group contribution method (Marrero and Gani 2002). Here, a QSPR for log P was built using connectivity indices for a set of relevant molecules which are specific to this type of design problem. The QSPRs models were cross-validated with the leave-one-out method using the package DAAG in R. The predictive squared correlation coefficient, Q^2, was calculated for each model to evaluate the predictive ability of the models. For a model with good predictive capability, $Q^2 \approx R^2$.

2.2 Computer-aided molecular design using Tabu search

For this study, 42 groups were used to build the structures. Two example groups used in the CAMD are given in Figure 1. Tabu search was employed to solve the optimization problem. The advantage of Tabu search is that it avoids becoming stuck around a local optimum by storing previous solutions in the Tabu list, and comparing the new solutions with those in the list. Tabu search was allowed to choose a maximum of 5 groups from the 42 groups for building the new molecules. Therefore, there were approximately 100 million possibilities at maximum within the search space. Being a stochastic approach, Tabu search can generate locally optimal solutions. Since the property prediction expressions are not exact, identification of multiple near optimal solutions is more valuable than a single globally optimal solution. The CAMD framework used by Roughton *et al.* for carbohydrate excipient design was used in this work (Roughton *et al.* 2012). The optimization problem was formulated as an MINLP due to the use of higher order indices. The objective function minimizes the difference between the predicted and the target property values (Eslick *et al.* 2009, Roughton *et al.* 2012). The optimization formulation is given below:

$$\text{Minimize } s = \sum_M \frac{1}{P_m^{scale}} \left| P_m - P_m^{Target} \right|$$
$$P_m = f_m(\chi)$$
$$\chi = g(a_{ij}, w_i)$$
$$h_c(a_{ij}, w_i) \geq 0$$

where P_m is the value of property m given by the QSPR function $f_m(\chi)$ for a given candidate molecule, χ is a connectivity index computed via functions g which are functions of the adjacency matrix a_{ij}, and the identity vector w_i, P_m^{Target} is the target value for the property m, P_m^{scale} is a scaling factor and h_c are the set of molecular structural constraints.

The target values for ln(ξ) were chosen to be 9 and 10, which were close to the maximum values obtained from the known candidates. For log P, the target value was set to -0.55, which is the log P value for HEMA (Fujisawa and Masuhara, 1981). The target for ln(ξ)

was selected close to the maximum values obtained from the model building set because a high molar extinction coefficient will increase the probability that the photosensitizer will absorb light and be promoted to the excited state. The log P value for HEMA was selected as the target value because the major components of the hydrophilic-rich phase were determined to be HEMA and water.

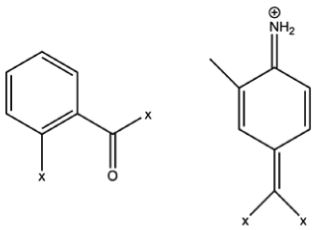

Figure 1. Two example molecule sub-structures (groups) used in CAMD. The connectors are marked as x.

3. Results

A summary of the two QSPRs for ln(ξ) and log P are given in Table 1 along with the C_p values. The QSPR was developed for ln(ξ) using zero and fifth order valence connectivity indices (χ^v) and zero, first, third, fourth order connectivity indices (χ) as given in Eq. (1).

Table 1. Summary of QSPRs for ln(ξ) and log P

Property	Number of descriptors used	R^2	C_p
ln(ξ)	6	0.99999	6.00845
log P	5	0.99996	5.07619

$$ln(\xi) = 32.22723 + (3.95277 \cdot {}^{0}\chi^{v}) - (15.07572 \cdot {}^{5}\chi^{v}) - (4.60663 \cdot {}^{0}\chi) + (0.63374 \cdot {}^{1}\chi) - (0.62536 \cdot {}^{3}\chi) + (4.81887 \cdot {}^{4}\chi) \quad (1)$$

Adjusted $R^2 = 0.99999$, $Q^2 = 0.99272$

The QSPR for log P was obtained using zero and second order valence connectivity indices and first, fourth, fifth order connectivity indices as shown in Eq. (2).

$$log\ P = -9.08869 + (1.61343 \cdot {}^{1}\chi) - (7.86666 \cdot {}^{4}\chi) + (6.86586 \cdot {}^{5}\chi) + (0.98095 \cdot {}^{0}\chi^{v}) - (1.48700 \cdot {}^{2}\chi^{v}) \quad (2)$$

Adjusted $R^2 = 0.99996$, $Q^2 = 0.99813$

It can be seen from above that the Q^2 values are very close to the R^2 values, indicating that the correlations have good predictive capability. The correlations were combined with structural constraints (enforced implicitly by controlling moves) and the resulting MINLP was solved to near optimality via the Tabu search algorithm. Two example potential structures proposed by the CAMD are given in Figure 2 with target ln(ξ) being 9 and 10. In both the cases the target value for log P remained -0.55.

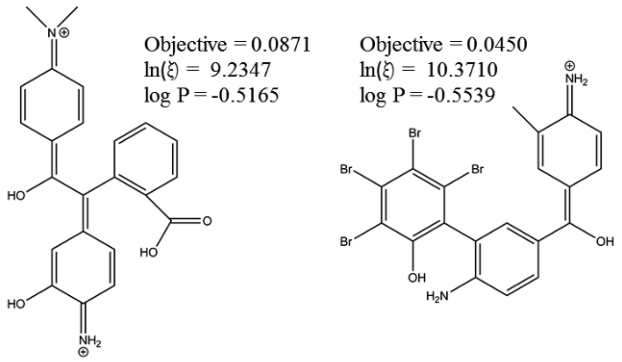

Figure 2. Structures proposed by CAMD for target values, log P = -0.55 (a) $\ln(\xi) = 9$ (b) $\ln(\xi) = 10$

The structures in Figure 2 indicate that combination of amino and/or amine groups with benzene or benzoic acid moieties and hydroxyl groups could play a vital role into imparting desired absorptivity and hydrophilicity to the molecule.

4. Conclusions

Incorporation of a water compatible photosensitizer improves photo-polymerization within the hydrophilic-rich phase of a dentin adhesive system, and also minimizes leaching of monomers. This work demonstrates the design of water compatible photosensitizers by CAMD for dental applications. Tabu search has been employed for solving the resulting MINLPs. The properties for which the photosensitizers have been optimized are $\ln(\xi)$ and log P. The proposed structures provide insight regarding functional groups that possess the potential of imparting desired properties. For design of an efficient water compatible photosensitizer, properties such as the degree of conversion and the rate of polymerization should be taken into account, and this work is currently underway.

Abstract

Orthosiphon Staminues (OS) is a species of herbs locally known in Malaysia as Misai Kucing. This study aims to analyse the performance of existing group contribution models in predicting the solubilities of phytochemical compounds from OS in ethanol. The compounds are oleanolic acid, ursolic acid and betulinic acid which have properties of pharmaceutical importance. The solubility experimental data of the compounds in ethanol were derived from the literature and were compared with the predictions made by the original UNIFAC, Modified UNIFAC (Dortmund), and Pharma Modified UNIFAC. The very high ranges of ARD values of between 40.86% to 98.6% calculated in this work shows that the models presented in this paper are not able to accurately predict the solubility of the studied phytochemical compounds in ethanol.

Keywords: Orthosiphon staminues, Activity Coefficient, UNIFAC, UNIFAC Modified (Dortmund), Pharma Modified UNIFAC

1. Introduction

Orthosiphon stamineus (OS) is a popular medicinal plant that has been used extensively as a traditional medicine to treat rheumatoid diseases, diabetes, hypertension, tonsillitis, epilepsy, menstrual disorder, gonorrhea, syphilis, renal calculus, gallstone, lithiasis, edema, eruptive fever, influenza, hepatitis, and jaundice (Ameer, et al. 2012). The therapeutic effects of OS have been ascribed mainly to its phytochemicals which are directly related to pharmacological properties such as, antioxidant, anti-inflammatory, anti-bacterial, heptoprotective, diuretic, anti-hypertensive and vasodialative properties (Basheer and Majid 2010, Al-Suede, et al. 2014). Several classes of phytochemicals have been identified from OS, including flavonoids, terpenoids, saponins, hexoses, organic acids, phenylpropanoids (caffeic acids derivatives), chromene and myo-inositol (Ameer, et al. 2012, Ibrahim and Jaafar 2012).

These phytochemicals are typically isolated via solvent extraction, where solubility plays an essential role in influencing the yield of extracts. The tendency of each phytochemical to be solubilized, transferred or diffused into a given solvent is governed by thermodynamic factor called activity coefficient (Queimada, et al. 2009). Due to the

lack of physical property data, studies on these prediction data are very scarce even though solubility in solvents is an important factor for the recovery of phytochemicals.

The objective of the study is to predict the solubility of three phytochemicals from OS in ethanol by testing and analysing existing activity coefficient models (original UNIFAC, Modified UNIFAC (Dortmund), and Pharma Modified UNIFAC). These three thermodynamic models were chosen because they apply the group contribution methods. Practically, these established and simple models have been widely used to predict the solubility of organic compounds in solvents. The advantage of the method is that the number of functional groups is much smaller than the number of possible molecules. These models rely on the use of the database known as group-group interaction parameters between functional groups. This database has been developed through regression of available experimental data.

2. Materials and Methods

2.1. Reference phytochemicals

In this paper, oleanolic acid (OA), ursolic acid (UA) and betulinic acid (BA) were chosen as the phytochemicals of OS. These compounds were selected mainly because of the solubility experimental data for the compounds have been reported in the literature by Cheng, et al. (2011), Liu and Wang (2007), Fan, et al. (2011). In addition, these phytochemicals are categorized into the same phytochemical class as terpernoids. The structures of these compounds are shown in Figure 1.

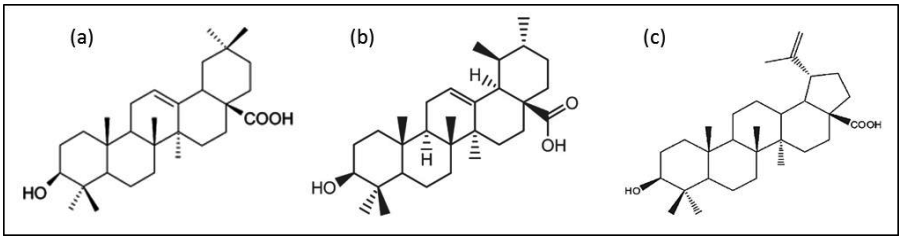

Figure 1. (a) Oleanolic acid, (b) ursolic acid and (c) betulinic acid

2.2. Activity Coefficient Models

The activity coefficient is the thermodynamic property that influences the solubility of solute in solvents. It is a mixture property that provides a measure of the non-ideality of the solution phase. From the solubility data, activity coefficients can be calculated using Eq. (1).

$$\chi_i \gamma_i^l = \exp\left\{ \frac{\Delta H_i^{fus}}{R T_{mi}} \left(\frac{T - T_{mi}}{T} \right) + \frac{\Delta C_{pi}^{fus}}{R} \left[\ln\left(\frac{T}{T_{mi}} \right) - \left(\frac{T - T_{mi}}{T} \right) \right] \right\} \quad (1)$$

ΔH_i^{fus} is the enthalpy of fusion for component i, T_{mi}, the melting temperature for component i, T is the temperature, and ΔC_{pi}^{fus} the difference between the heat capacity of the solid and the liquid phase at equilibrium for component i. However, it is very difficult to measure ΔC_{pi}^{fus} especially for the case of sublimation, decomposition or parallel reactions occuring during melting. Therefore, ΔC_{pi}^{fus} contribution is typically

assumed as negligible (Bouillot, et al. 2011). Equation (1) can therefore be further simplified to give the relationship between solubility and activity coefficients as given by Eq. (2).

$$\chi_i \gamma_i^l = \exp\left[\frac{\Delta H_i^{fus}}{RT_{mi}} \ln\left(\frac{T}{T_{mi}}\right)\right] \tag{2}$$

In this work, the activity coefficients of a phytochemical substance in the ethanol were estimated using the UNIFAC (Fredenslund, et al. 1975), Modified UNIFAC (Dortmund) (Jakob, et al. 2006), and Pharma Modified UNIFAC (Diedrichs and Gmehling 2011) models.

(a) Original UNIFAC

The Original UNIFAC model is a combination of two parts of activity coefficient as stated in Eq. (3):

$$\ln \gamma = \ln \gamma^C + \ln \gamma^R \tag{3}$$

γ^C is the combinatorial term, representing the entropic contribution to the activity coefficient which takes into account the shape and size of the molecules. Expression of $\ln \gamma^C$, as given in Eq. (4) depends on the mole fraction (x_i), area (θ_i), segment fraction (Φ_i), Van der Waals radius (r_i) and volume (q_i). Superscript i designates the type of phytochemical:

$$\ln \gamma_i^C = \ln \frac{\Phi_i}{x_i} + 5q_i \ln \frac{\theta_i}{\Phi_i} + l_i - \frac{\Phi_i}{x_i} \sum_j x_j (5(r_j - q_j) - (r_j - 1)) \tag{4}$$

Meanwhile, γ^R is the residual part which represents the enthalpic contribution (inter and intramolecular interactions). It is a sum of the activity coefficients of the functional groups weighted by their number in solution. The equation for this part is presented in Eq. (5).

$$\ln \gamma_i^R = \sum_k v_k^{(i)} \left[\ln \Gamma_k - \ln \Gamma_k^{(i)}\right] \tag{5}$$

where v_k and v_k^i are the number of groups of type k in the mixture and in component i. Γ_k and Γ_k^i are the residual activity coefficient of group k in the mixture and in a solution of pure component i respectively . They depend on the area and segment fraction of the compounds and adjustable binary interaction parameters a_{mn} that are usually regressed from VLE experimental data. The equations are expressed in Eq. (6) and Eq. (7):

$$\ln \Gamma_k = Q_k \left[1 - \ln\left(\sum_m \Theta_m \psi_{mk}\right) - \frac{\sum_m \Theta_m \psi_{km}}{\sum_n \Theta_n \psi_{nm}}\right] \tag{6}$$

with:

$$\psi_{mn} = \exp\left(-\frac{a_{mn}}{T}\right) \tag{7}$$

(b) Modified UNIFAC (Dortmund) Model

Modified UNIFAC (Dortmund) is a modification of UNIFAC model that takes into account of the temperature in the residual activity contribution. The new combinatorial term and interaction parameter are written as Eq. (8) and Eq. (9), respectively:

$$\ln \gamma_i^C = 1 - \ln \frac{\Phi_i}{x_i} + 5q_i\left(1 - \ln \frac{\Phi_i}{\theta_i} + \ln\left(\frac{\Phi_i}{\theta_i}\right)\right) \tag{8}$$

$$\psi_{mn} = \exp\left(\frac{a_{mn} + b_{mn}T + c_{mn}T^2}{T}\right) \tag{9}$$

(c) Pharma Modified UNIFAC

The Original UNIFAC and Modified UNIFAC (Dortmund) are effective models for many applications. However, these group contribution models have a limited range of applications for active pharmaceutical ingredients (APIs) because of the missing structural groups and group interaction parameters. To overcome this limitation, the Pharma Modified UNIFAC model was developed by Diedrichs and Gmehling (2011) in order to extend the range of applicability of the group contribution methods for APIs. The model is a derivative of the modified UNIFAC (Dortmund) model, created with the intention of overcoming the functional groups diversity limitation of the modified UNIFAC (Dortmund) when applied to API solutions. Therefore, the system of equations of Pharma Modified UNIFAC is the same as the modified UNIFAC (Dortmund) whereby the difference between these models resides solely in the set of available functional groups and its unary (R_k and Q_k) and binary parameters values Ψ_{nm}. Note that, k, n and m represent the functional group indices.

2.3. Models Evaluation

In order to evaluate the performance of these three models, the absolute relative deviation (ARD) was calculated for each method. The ARD was determined using Eq. (10):

$$ARD = \left|\frac{\chi_{\exp} - \chi_{pred}}{\chi_{\exp}}\right| \times 100\% \tag{10}$$

χ_{exp} is the solubility experiment data, and χ_{pred} is the predicted value of solubility point in mole fraction unit.

3. Results and Discussion

The comparison between experimental and predicted values of the solubilities of phytochemicals from OS are shown in Table 1. The experimental value was obtained from the experimental data available from the literature at 288.3 K for oleanolic acid (Liu and Wang 2007), 293.6 K for ursolic acid (Fan, et al. 2011), and 278.2 K for betulinic acid (Cheng, et al. 2011). The predicted values were estimated using the group contribution methods of activity coefficient models at the same operating temperature with the experimental data.

The table illustrates that the Original UNIFAC yields an ARD value of 98.41% (OA), 86.05% (UA), and 98.6% (BA) whereas the Modified UNIFAC (Dortmund) yields an ARD value of 85.71% (OA), 40.86% (UA), and 85.43% (BA). On the other hand, the ARD values obtained from Pharma Modified UNIFAC are 93.87% (OA), 50.61% (UA), and 93.05% (BA). The high ARD values show that all the models are not applicable for the prediction of phytochemicals from OS.

It is known that the original UNIFAC and its modified models are using group contribution method, which do not consider the molecular geometry and isomers of the compounds in the prediction. These may be the possible reasons for the poor prediction results. Moreover, phytochemicals are group of molecules that include hydrogen bonding and strong hydrophobic interactions that can make UNIFAC prediction inaccurate (Sevillano, et al. 2014). Besides, the molecular complexity of the phytochemical compounds makes it difficult to achieve a high accuracy for the models.

Table 1. Comparison between experimental and predicted values of solubility of oleanolic acid, ursolic acid, and betulinic acid.

Phytochemicals	Model	Experimental Value (mol/mol)	Predicted Value (mol/mol)	ARD (%)
Oleanolic acid	Original UNIFAC		0.000083	98.41
	Modified UNIFAC (Dortmund)	0.0052 at 288.3 K	0.000743	85.71
	Pharma Modified UNIFAC		0.000318	93.87
Ursolic acid	Original UNIFAC		0.0004	86.05
	Modified UNIFAC (Dortmund)	0.0030 at 293.6 K	0.0042	40.86
	Pharma Modified UNIFAC		0.0015	50.61
Betulinic acid	Original UNIFAC		0.0001	98.6
	Modified UNIFAC (Dortmund)	0.0038 at 278.2 K	0.0006	85.43
	Pharma Modified UNIFAC		0.0003	93.05

4. Conclusion

In the present work, the capabilities of three thermodynamic models to predict the phytochemical solubility from OS in ethanol were investigated. Very high ARD values of between 40.86% to 98.6% shown in this work indicates that none of the model presented in this paper was able to accurately predict the solubility of the studied phytochemical compounds in ethanol. However, the Modified UNIFAC (Dortmund) showed the lowest ARD value as compared to the ARD values for other models. Work is in progress to increase the prediction accuracy of the models to reduce the ARD value down to 5%.

Abstract

This paper presents a framework for computer-aided design of pure, mixed and blended chemical based products. The framework is a systematic approach to convert a Computer-aided Molecular, Mixture and Blend Design (CAM^bD) formulation, based on needs and target properties, into a mixed integer non-linear program (MINLP). The MINLP is sequentially solved through a decomposed optimization approach to solve the possibly large MINLP in a smaller set of sub-problems. The framework application is highlighted through a solvent design case study.

Keywords: Product Design, Mixture, Blend, CAMD, MINLP

1. Introduction

Design of novel pure, mixed and blended products with process and application considerations is an emerging topic in the field of chemical and biochemical engineering. Methods, such as Computer Aided Molecular Design (CAMD) (Harper *et al.*, 1999), and Computer-aided Mixture and Blend Design (CAM^bD) (Yunus *et al.*, 2014), provide the possibility of designing such products. However, these product design problems can quickly become large and difficult, if not infeasible, to solve through mathematical optimization. In addition, considerations of process, application, special product attributes, economic feasibility, environmental and sustainability metrics that must be included in today's product designs, consequently makes the problem harder to mathematically define and to solve.

Property prediction methods are the backbone of the any CAMD/CAM^bD methods. The property prediction methods ensure that product generation is not hindered by experimental data resources. Group contribution method is a property prediction method where by knowing the molecular groups present in a molecule the properties can be predicted (Cosntantinou and Gani, 1994). For mixtures and blends, the ensemble properties can as well be predicted (Conte *et al.* 2011). This enables the possibly of generating novel pure compounds, mixtures and blends alike (Gani 2004). Here, the precision and detailed description of molecular groups and structure become important. In group contribution methods, molecular groups are represented as 1^{st} order, 2^{nd} order and 3^{rd} order, where an increase in order gives a more detailed representation of the molecule and increase the precision in property prediction. However, difficulties arise when higher order groups must be found from lower order groups, the structure of the molecules has to be estimated, and when missing groups need to be created (Gani et al., 2005; Apostolakou and Adjiman, 2003).

Given the needs, properties and criteria, the solution strategy for a CAMD/CAM^{b}D problem can be of two types: “generate and test”, and “mathematical optimization”. In generate and test, a molecule or a mixture/blend constituting of a set of molecules are generated. From the group contribution method theory that every molecular group contributes to the property of the ensemble molecule, the molecules and mixtures/blends are designed from a reversed engineering approach. The generated product is then tested to see if the needs and properties are met, if not, a new design target is generated. In the mathematical optimization solution strategy mainly two approaches exist: simultaneous optimization and decomposed optimization. In both approaches the needs are translated into a mixed integer non-linear program (MINLP) with an objective function to be optimized. The MINLP formulated problem can then be solved simultaneously, which means that all constraints are solved in the same program. In the decomposed optimization approach; however, the MINLP formulation is solved sequentially so that in each routine the search space is reduced and the MINLP problem is broken down to a MILP problem, which is divided into a set of smaller NLP problems with fixed integers. This decreases search space and solution time systematically and ensures that a global optimum and all feasible solutions can be found.

In this paper, a computer-aided framework is presented for formulating needs into an MINLP problem, which is solved through a decomposed optimization approach. The framework is capable of finding the optimum product based on the specified needs and properties. The optimum product may be a pure compound, mixture or blend. In addition, given the decomposed optimization approach, it is possible to also obtain all feasible solutions, or a set of feasible solutions close to the objective function. The framework is implemented into a computer-aided tool where the MINLP is formulated. The framework application is demonstrated through a case study.

2. Computer-aided Framework

The computer-aided framework for design of pure, mixed and blended products is presented here. The framework utilizes the needs and target properties to construct the CAMD/CAM^{b}D problem into a MINLP formulation. The MINLP formulation is then solved through a decomposed approach. The framework has four steps represented in Figure 1.

2.1. Step 1:Problem Definition

In step one the product needs, target properties and desired product type are defined. These can be thermodynamic properties, economic, sustainability and environmental needs. The product type refers to the type of desired molecule, such as chain size, chain type (cyclic, acyclic, aromatic etc.), and type of functional groups and occurrence of these groups.

2.2. Step 2: CAMD Formulation

In step two the needs, properties and product types are converted into a CAMD/CAM^{b}D formulation. Here, constraints are given for the product structure and needs with upper and lower bounds for target properties. An objective function is defined, which is a function that is to be optimized. Furthermore, relevant process and/or thermodynamic models are formulated, such as mass balances and phase equilibrium equations.

2.3. Step 3: MINLP Formulation

In step three the formulation from step two is set-up as a MINLP formulation. A general CAMD/CAM^{b}D problem is formulated as the following MINLP problem, which is divided into objective function and four types of constraints.

$$\min/\max f_{obj}(\mathbf{X},\mathbf{N}) \tag{1}$$

s.t. structural constraints: $g_1(\mathbf{N},\mathbf{Y}) \le 0$ (2)

pure component property constraints: $g_2(\mathbf{N}) \le 0$ (3)

mixture property constraints: $g_3(\mathbf{X},\mathbf{N}) \le 0$ (4)

process model constraints: $g_4(\mathbf{X},\mathbf{N}) = 0$ (5)

$$\mathbf{X} \in \mathbb{R}^n, \mathbf{N} \in \mathbb{Z}_+^m, \mathbf{Y} \in \{0,1\}^q$$

N is a vector of integer variables, which are related to the numbers of the building blocks and/or molecules (1st and 2nd order groups). **Y** is adjacency matrix which is related to the description of the molecular structure. **X** is a vector of continuous variables, which are related to the mixture and/or process variables. The first constraint deals with the structural stability of the generated molecules. Here, molecules that do not follow rules such as the octet rule (valency) will be rejected as infeasible molecules. The second constraint includes pure component property constraints. These are, for the case of group contribution methods, often linear equations. In the third property constraint the mixture properties are investigated. Here, both mixture composition dependent properties, such as mixture stability, and mixture independent properties,

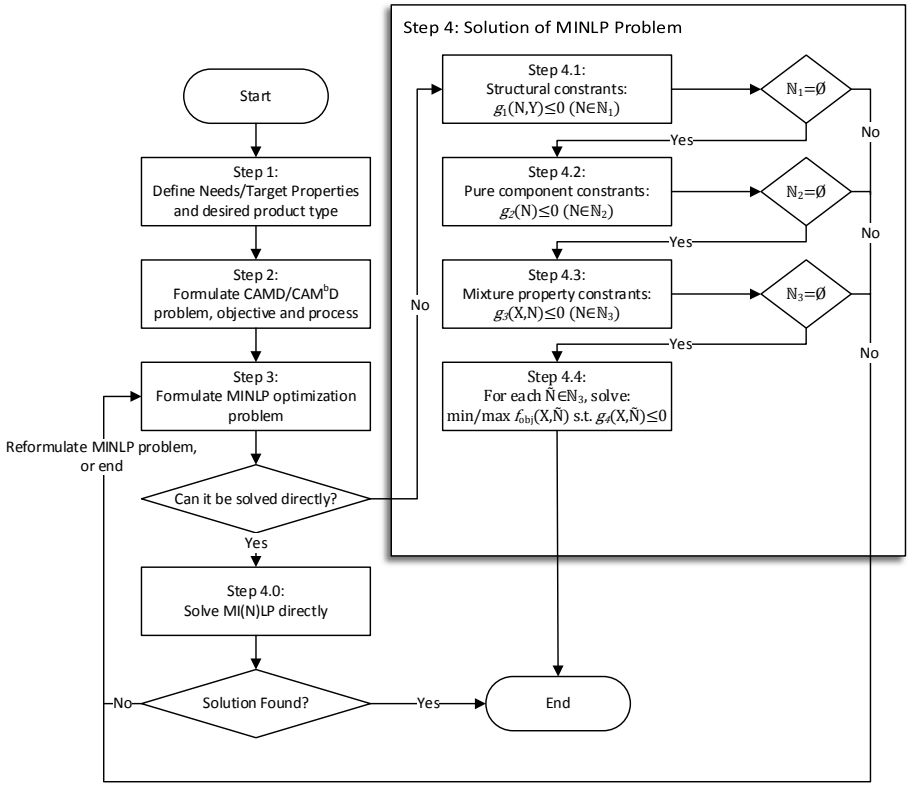

Figure 1: Computer-aided Framework for Product Design

such as solvent selectivity, are considered. There are often nonlinear equations. In the last and fourth constraint type, process models are included, such as mole balance for a unit operation. Other models may also be included here such as phase equilibrium equations.

2.4. Step 4: Solution of MINLP Problem

In step four the MINLP formulation is solved. For this, a database is used for group contribution coefficients for the molecular groups. Group contribution method for pure compound properties used in this work is Cosntantinou and Gani (1994). Mixture/blend group contribution method used in this work is by Fredenslund *et al.* (1975). In most CAM^{b}D problems, the need for using highly nonlinear property models and process models can lead to non-convex and non-smooth problems, which are difficult to solve. Karunanithi et al. (2005) proposed a decomposition-based algorithm to solve this MINLP problem by first solving sub-problems consisting of a set of property constraints only. The search space is reduced by using this decomposition algorithm. The MINLP problem is converted to several Non-Linear Programming (NLP) problems corresponding to fixed values of the integer variables. The decomposition-based algorithm is shown with the rest of the framework in Figure 1 as step 4.1 to 4.4. Step 4.0 is used instead if only linear equations (MIP) are present, or that the problem is small enough to solve simultaneously. Once the decomposed solution strategy is computed, it is checked if the solution or feasible solutions are found. If not, it is necessary to modify the MINLP formulation, thus returning to Step 3, to either loosen the constraints or in another way increase the search space. If the optimum solution is found the framework ends.

3. Case Study

In this case study a solvent is designed for an extraction process. Given a mixture of water (H_2O) and acetic acid (CH_3COOH), find a suitable solvent that is able to extract acetic acid from water. The flow sheet of the extraction process is given in Figure 2. The feed is the acetic acid/water solution, the extract is the acetic acid rich phase, whereas the raffinate (R) is the water rich phase.

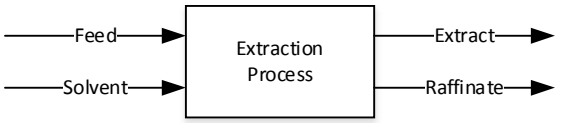

Figure 2: Extraction Process

The combined flow of feed and solvent (F) is 2338.2 mol/h. Mole fractions x_i of acetic acid (A), water (B), and solvent (S) are 0.0077, 0.2951 and 0.6972, respectively. The extraction process is operated at 298 K. Every step of the framework from Figure 1 will be walked through in the following.

3.1. Step 1

From the process description, the process needs can be defined. It is desired to obtain a solvent that likely will split acetic acid from water. Therefore, an efficient solvent for removal of acetic acid from water is needed. As the extraction process is operated at 298 K, it is furthermore needed that the solvent is in a liquid state at this temperature. The boiling point of acetic acid is 391 K. In many cases, the solvent is separated from the solute in the extract phase in a solvent recovery system. Thus, the volatility between solute and solvent must be high.

3.2. Step 2

As the needs have been defined, a CAMD problem can be formulated. Here, the needs will be formulated through lower and upper bounds of the needed properties. It is specified here that, for the sake of this case study, only acyclic solvents containing C, H and/or O atoms are chosen. Thus, the group set u only contains acyclic groups (see Eq. 8) containing C, H and/or atoms ($u \in \{CH_3, CH_2, CH, C, OH, CH_3OH, CHO, CH_3COO, CH_2COO, HCOO, CH_3CO, CH_2O, HCO, COOH, COO\}$). The size of the generated solvents will also be limited. The needs with their respective lower and upper bounds are given in Table 1. N_G is the total number of groups u, N_F is the total number of functional groups. The need regarding efficient solvent is here expressed as distribution coefficient m, solvent loss SL, solvent power SP, and selectivity β.

Table 1: Lower and upper bounds for specified needs

Need	Lower	Upper	Constraint	Need	Lower	Upper	Constraint
$\mathbf{N_G}$	1	6	Eq. 7	**m**	0.49	-	Eq. 12
$\mathbf{N_F}$	0	2	Eq. 9	**SL**	-	0.0038	Eq. 13
$\mathbf{T_m}$	-	270K	Eq. 10	**SP**	0.778	-	Eq. 14
$\mathbf{T_b}$	430K	-	Eq. 11	**β**	11	-	Eq. 15

As the objective function, the molar flow of water in the raffinate and of acetic acid in the extract should be maximized (Eq. 6). The process models will be molar balances for the extraction process and liquid-liquid phase equilibrium (Eq. 16-18).

3.3. Step 3

Based on the CAMD formulation, the MINLP formulation is written:

$$f_{obj} = \max\left(x_A E + x_B R\right) \tag{6}$$

s.t.

$$1 \le \sum_i \sum_j u_{ij} \le 6 \tag{7}$$

$$\sum_i \sum_j u_{ij}\left(2 - v_j\right) = 2 \tag{8}$$

$$0 \le \sum_j u_{ij} \le 2 \tag{9}$$

$$102.425 \times \log \sum_i N_i T_{mi} \le 270 \tag{10}$$

$$430 \le 204.359 \times \log \sum_i N_i T_{bi} \tag{11}$$

$$0.49 \le \gamma^{\infty}_{A,B} MW_B \,/\, \left(\gamma^{\infty}_{A,S} MW_S\right) \tag{12}$$

$$1 / \gamma^{\infty}_{S,B} \le 0.00381 \tag{13}$$

$$0.778 \le 1 / \gamma^{\infty}_{A,\mathrm{S}} \tag{14}$$

$$11 \le \gamma^{\infty}_{B,\mathrm{S}} / \gamma^{\infty}_{A,S} \tag{15}$$

$$\gamma_i^E x_i^E - \gamma_i^R x_i^R = 0, i \in \{A, B, S\} \tag{16}$$

$$x_i^F F - x_i^E E - x_i^R R = 0, i \in \{A, B, S\} \tag{17}$$

$$x_A^p + x_B^p + x_S^p = 1, p \in \{F, E, R\} \tag{18}$$

v, is the free bonds of a molecular group, $\gamma_{i,i}$, is the activity coefficient. Eq. 10-11 are group contribution equations defined in Cosntantinou and Gani (1994).

3.4. Step 4

The MINLP cannot be solved directly due to its size. Thus, the decomposed solution strategy is used (step 4.1 to step 4.4). In step 4.1 constraint 7 to 9 are solved as MIP, which yields 514 solutions. The solutions are screened in step 4.2 through constraint 10 to 11, which yields 196 solutions. These are further screened in step 4.3 in constraints 12 to 15, which yields 19 solutions. These are then solved in a set of 19 NLP with objective function from Eq. 6 with constraints 16 to 18. This yields the optimum solvent, given in Table 2. As it can be seen, a diester (butane-2,3-diyl diformate, groups: 2 CH3, 2 CH, 2 HCOO), was generated that satisfied the constraints and obtained a

maximized objective function value. The recovery is 98.3%. In Seader and Henley (1995) and Karunanithi *et al.*, (2005) methyl ethyl ketone and 2-hexanone were designed, respectively, as solvents for the same problem. It is interesting to note that both of these were in the list of feasible solutions; however, a better solvent was found in this case study, achieving higher recovery. The result should, however, be verified through experimentation. Also, the generate and test approach would have given this results, but not all the constraints can be included.

Table 2: Optimum designed solvent and key properties

Tm [K]	**Tb [K]**	**m**	**SL**	**β**	**Possible Structure**
236.75	455.22	0.7678	0.0021	14.7702	SP	x_A^E	x_B^E	x_S^E	x_A^R	
2.1290	0.00859	0.20005	0.79136	0.00112	
x_B^R	x_S^R	**E [mol/h]**	**R [mol/h]**	f_{obj} **[mol/h]**	
0.99700	0.00188	2059	278.86	295.72	

With the proposed framework other problems have been solved but not reported. These include, but are not limited to, design of polymers based on polymer specific properties (e.g. glass transition temperature) and design of refrigerants for a thermodynamic cycle.

4. Conclusion and Future Works

A computer-aided framework was developed in this work. The framework has been shown to systematically define and solve a large MINLP product design problem. Higher order description of groups both for pure compound and mixture property prediction and the ability to estimate the structure of molecules is subject to future works. In addition, the framework application is to be shown for a larger range of case studies with inclusion of mixture and blend design problems.

urmila@vri-custom.org

Abstract

In-vitro Fertilization (IVF) is the most common technique in Assisted Reproductive Technology (ART). It has been divided into four stages; (i) superovulation, (ii) egg retrieval, (iii) insemination/fertilization and (iv) embryo transfer. The first stage of superovulation is a drug induced method to enable multiple ovulation, *i.e.*, multiple follicle growth to oocytes or matured follicles in a single menstrual cycle. IVF being a medical procedure that aims at manipulating the biological functions in the human body is subjected to inherent sources of uncertainty and variability. Also, the interplay of the hormones with the natural functioning of the ovaries make the procedure dependent on several factors like patient's condition in terms of cause of infertility, actual ovarian function, responsiveness to medication, etc. The treatment requires continuous monitoring and testing and this can give rise to errors in observations. Thus, it becomes essential to look at the process noise and deviations and think of a way to account for them to build better representative models for follicle growth. The purpose of this work is to come up with a robust model which can project the superovulation cycle outcome based on the hormonal doses and patient response in presence of uncertainty. The customized stochastic model results in better projection of the cycle outcome for the patients where the deterministic model has some deviations from the clinical observations and the growth term value is not within the range of '0.3 to 0.6'. It was found that the prediction accuracy was enhanced by more than 70% for some patients by using the stochastic model projections.

Keywords: infertility, assisted reproduction, multiple ovulation, uncertainty

1. Introduction

Infertility is the inability of a couple to achieve conception or to bring a pregnancy to term after a year or more of regular, unprotected intercourse. The World Health Organization has estimated that about 8-10% couples experience some kind of infertility problems. Medical science has come up with ARTs to treat these problems. IVF involves fertilization of oocytes by a sperm outside the body in a laboratory simulating similar conditions as in the human body and then implanting the fertilized eggs back in the uterus of the patient for full term pregnancy (Speroff and Fritz, 2005). The success of superovulation, its first stage, is critical to proceed with the next stages in the IVF cycle. Also it requires maximum medical attention and is cost-intensive when compared to other stages.

The major hormonal drug involved in superovulation is the follicle stimulating hormone (FSH), responsible for follicle growth and development. The deterministic model for

multiple follicle growth, dependent on the amount of FSH dosage was built by drawing similarities with the particulate process of batch crystallization and it fitted very well to the clinical data for most patients. However, the fact remains that IVF is actually a medical procedure involving manipulations in biological functions of human body and specifically to functioning of ovaries, is subjected to inherent sources of uncertainty.

2. The deterministic model

2.1. Model development and validation

The similarities between process of crystallization (Hill et al., 2006) and superovulation used for model development are presented in Table 1. Thus, the concept of moment model in batch crystallization (Hu et al., 2005) was used for modeling superovulation in IVF. The growth term in batch crystallization is temperature dependent and hence it becomes the decision variable for control. On similar lines, in IVF the follicle growth is dependent upon the doses of hormones injected to the patient.

Table 1: Analogy between batch crystallization and superovulation

Batch Crystallization	Superovulation (IVF stage I)
-Production of multiple crystals	-Production of multiple oocytes or eggs
-Crystal quality is determined in terms of maximum size and uniformity	-Oocyte quality is determined in terms of maximum size and uniformity
-The rate of crystallization or crystal growth varies with time and process conditions	-The rate of ovulation or oocyte growth varies with time, drug dosing amounts and interactions
-Process is affected by external variables like agitation, and process operating variables like temperature, pressure, etc.	-Process is affected by externally administered drugs and body conditions of the patient undergoing the process

The follicle size is converted into mathematical moments by assuming the follicles to be spherical in shape. The Eq. (1) is used for converting follicle size to moments. Each moment corresponds to a feature of the follicles; zeroth moment corresponds to the number, first moment to the size, second to area, etc.

$$\mu_i = \sum n_j(r,t) r_j^i \Delta r_j \tag{1}$$

Here, μ_i is the ith moment, $n_j(r, t)$ are number of follicles in j^{th} bin with mean radius as r at time t, r_j is mean radius of j^{th} bin and Δr - range of radii variation in each bin. The follicle growth term (G) is dependent on the amount of FSH injected (C_{fsh}) to the patient at particular time (t) and is represented as Eq. (2). Here, k and α are kinetic constants.

$$G(t) = k\Delta C_{fsh}(t)^{\alpha} \tag{2}$$

In the literature by Baird (1987) it was suggested that number of follicles activated for growth during a particular superovulation cycle is constant for a particular patient, hence zeroth moment has a constant value (Eq. (3)). Also, the 1st to 6th order moments (Eq. (4)) are used in the model, since they help in better prediction of moment values as well as help in efficient recovery of the size distributions.

$$\mu_0 = constant \tag{3}$$

$$\frac{d\mu_i}{dt} = iG(t)\mu_{i-1}(t); \qquad (i = 1,2,\ldots,6) \tag{4}$$

The validation method (Yenkie et al., 2013) requires conversion of predicted moments back to the follicle size and number as a follicle size distribution (FSD) for each day of the cycle. The method (Flood, 2002) is represented in Eq. (5).

$$\bar{\mu} = \mathbf{A}\,\bar{n} \tag{5}$$

Here, $\bar{n}$ is the vector of number of follicles in n bins on ith day; $\bar{\mu}$ is the vector of moments on ith day and **A** is the inversion matrix derived from Eq. (1). The elements in matrix 'A' are evaluated using the formula shown in Eq. (6).

$$a_{i,j} = \bar{r}_j^i \Delta r_j \tag{6}$$

Here, i is the order of the moment (increment in rows), j is the representative bin (increment in columns), $\bar{r}$ is the mean radius of the bin and Δr is the range of the bin.

2.2. Prediction accuracy

The deterministic modelling approach was applied to clinical data on 50 superovulation cycles. The predictions of FSDs were compared with the actual follicle size and numbers reported in clinical data. The mean square error (MSE) for the accuracy of the FSD projections on final FSH dosing day was evaluated using Eq. (7).

$$MSE = \sum \left[\frac{n_{i,obs} - n_{i,sim}}{Max(n_{i,obs}, n_{i,sim})} \right] \tag{7}$$

Here, $n_{i,obs}$ is number of follicles observed and $n_{i,sim}$ is number of follicles predicted by the model in the i^{th} bin on last day of FSH dosing. This error value was evaluated for model projections from the initial two day data. In MSE evaluation, follicles in size bins corresponding to size range of 9-12 mm were used, because it is the desired range for inducing final maturation and egg retrieval. The error analysis as shown in Figure 1 indicates that initial two day data is sufficient for more than 60% cases to project the overall superovulation outcome.

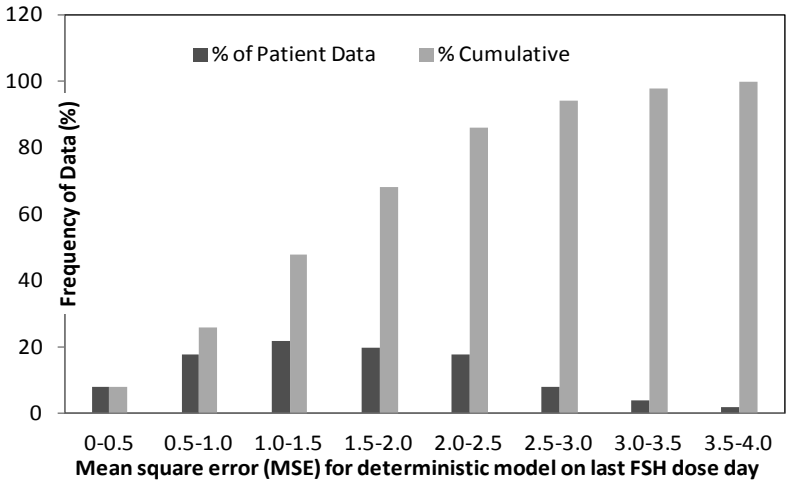

Figure 1. Prediction accuracy analysis for the deterministic model

However, the deterministic model does not match very well for cases with high MSE values and when the growth term (G) value for the patients were not within the range of '0.3-0.6', suggesting the need for additional monitoring and data to predict the superovulation outcome with more accuracy.

3. The stochastic model

In this work, the aim is to develop a stochastic model for the superovulation stage in terms of *Ito* processes. Initially, these *Ito* processes were mostly applied in financial field and stock price modelling to characterize uncertainties. Since they can characterize time-dependent uncertainties and can be integrated and differentiated using rules of *Ito*'s stochastic calculus, they can prove beneficial in modelling biological processes. The simplest example of an *Ito* process is the *Brownian* motion which is also known as *Wiener* process in continuous form. To characterize any stochastic process as a *Wiener* process it must follow following three important properties (Diwekar, 2008).

i. *Markov* property: The probability distribution for all future values of the process depends only on its current value.
ii. It should have independent increments in time. The probability distribution for the changes in the process over any time interval is independent of any other time interval.
iii. Changes in process over finite time interval should be normally distributed, with variance linearly dependent on length of time interval, dt (i.e., N (0, $\sqrt{dt}$) for all t > 0).

The superovulation data is analyzed and checked whether it classifies as a *Wiener* process. As per the current protocols, the hormonal dosage is decided based on daily monitoring of the patient's response from the previous day dose and the follicle size observed. Thus, the next FSD after the injection of hormones is dependent on the FSD at that particular time, hence it is reasonable to categorize the superovulation stage as a *Markov* process. The follicle growth term developed in the deterministic model and which satisfies the data is dependent on the amount of FSH injected (C_{fsh}) to the patient at the particular day (t) in the cycle as shown earlier in Eq. (2). Thus it satisfies the second property, where the FSH dosage can have independent increments.

The follicle growth and number is represented as FSD, where follicle size is divided into equispaced bins and numbers of follicles are represented as discrete markers in each size bin as shown in Figure 2. When these markers are connected with smooth curve, it can be seen that the data tends to follow a normal distribution. As time progresses, it continues to follow the same trend, with a change in mean and variance values. Hence, uncertainties associated with superovulation process can be modelled as *Wiener* processes.

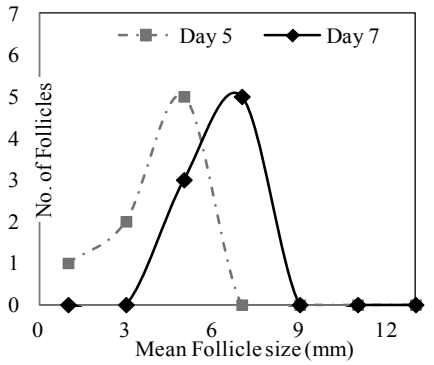

Figure 2. Follicle size showing normal distribution on day 5 and 7.

The *Ito* processes are of various types whose basic building block is a *Wiener* process. Depending upon the behaviour of the system under random influences it can modelled as one of the suitable *Ito* processes. Some examples are simple *Brownian* motion, geometric *Brownian* motion, mean reverting process and geometric mean reverting process. Following a similar approach, we can model the uncertainties associated with the superovulation stage. It was found that the uncertainties could be represented using

the simple *Brownian* motion type of *Ito* process, thus resulting in the following (Eq. (8) to Eq. (13)) set of stochastic differential equations (SDEs).

$$d\mu_1(t) = G(t)\mu_0 dt + \sigma_1 \varepsilon_t \sqrt{dt} \tag{8}$$

$$d\mu_2(t) = 2G(t)\mu_1 dt + \sigma_2 \varepsilon_t \sqrt{dt} \tag{9}$$

$$d\mu_3(t) = 3G(t)\mu_2 dt + \sigma_3 \varepsilon_t \sqrt{dt} \tag{10}$$

$$d\mu_4(t) = 4G(t)\mu_3 dt + \sigma_4 \varepsilon_t \sqrt{dt} \tag{11}$$

$$d\mu_5(t) = 5G(t)\mu_4 dt + \sigma_5 \varepsilon_t \sqrt{dt} \tag{12}$$

$$d\mu_6(t) = 6G(t)\mu_5 dt + \sigma_6 \varepsilon_t \sqrt{dt} \tag{13}$$

Here, μ_i is the i^{th} moment, σ_i are the standard deviation terms for the moment equations corresponding to noise in clinical data, ϵ_t is the set of random numbers derived from unit normal distribution and dt is the time interval.

4. Results and discussions

The parameters for the system are evaluated using the two level approach (Yenkie et al. (2013)), in which parameters in the stochastic part, *i.e.*, the standard deviations (σ_i), are evaluated from variance in the data. The follicle size measurements are converted to moments and the parameters in deterministic part (k, α and integration constants) are evaluated using modified form of objective function involving values of standard deviations. The results for FSDs are shown in Figure 3A and 3B for day 5 and day 9.

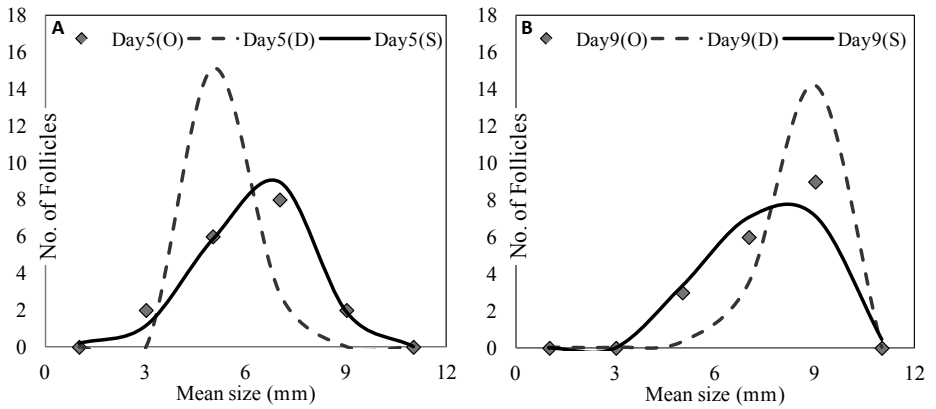

Figure 3. Comparison of FSD from observed clinical data (O), deterministic (D) and stochastic (S) model predictions for Patient-I on day 5 (A) and 7(B).

We can see that the results projected by stochastic model (S) match the data (O) better when compared to the deterministic results (D). Especially when it comes to the final FSH dosing day projections, *i.e.* 9th day in case of Patient-I. This study was done for more patients and the results are reported in Table 2 in terms of the mean square error on final FSH dosing day. For all these patients with a high growth term (G) value, the FSD projections using the stochastic model are greatly improved.

Table 2. Error comparison for deterministic and stochastic model predictions

Patient	Growth term (G)	Mean square error (deterministic)	Mean square error (stochastic)	% Improvement (stochastic over deterministic)
A	0.72	1.1239	0.0748	93.34
B	0.77	0.927	0.1999	78.4
C	1.55	1.4813	1.3740	7.24
D	0.82	1.3009	1.1865	8.79
E	0.70	1.6541	0.9351	43.47

5. Conclusions

The approach to develop a stochastic model for the superovulation stage in IVF in terms of *Ito* form of stochastic differential equations (SDE) is a novel aspect of the study and the results look very promising. The approach used for stochastic model development involving a novel parameter estimation procedure is an added contribution in this work and can eliminate a lot of computation difficulties in development of SDE models.

Predictions obtained from the stochastic model are inclusive of the patient's uncertainty and noise in clinical data and hence match better as compared to deterministic results for the study done on five selected patients with high 'growth term (G)' value. The mean square errors (MSE) in modelling for the deterministic and stochastic cases provide a numerical estimate of the improvements in predictability and robustness of SDE model. The predictions from the stochastic model can be used for predicting robust drug dosing policies using stochastic control methods for achieving desired outcome in superovulation and thus can contribute to the studies on enhancement of success rate of IVF cycles.

Abstract

The cell cycle is a biologically timed process by which cells duplicate. It consists of 4 phases, during which cells undergo different mandatory transformations. Modelling the cell cycle therefore requires capturing the evolution of those processes inside of each phase. A specific three stage biologically supported population balance model employed to simulate evolution of several cell cultures is studied here in detail. The three governing equations of this model are composed by growth and transition terms. A one equation analogue of the multistage model is formulated and it is solved analytically in the self-similarity domain. The effect of initial conditions at the system evolution is studied numerically. The three model equations are then considered by using asymptotic and numerical techniques. It is shown that in the case of sharp interstage transition the discontinuities of the initial conditions are preserved during cell growth leading to eternal oscillations whereas for distributed transition the cell distribution converges to a self-similar (long time asymptote) shape. It is also illustrated that the closer the initial condition to the self similar distribution the faster the convergence to self-similarity and the smaller the oscillations of the total cell number. Exact results are given for the growth parameters of the population balance and lumped models.

Keywords: multistage, cell cycle, population balance, cell growth and death, analytical solutions.

1. Introduction

Normal cell proliferation occurs following a four-step cycle, known as the cell cycle: G1 phase, when cells grow and stock up on nutrients; S phase, when their DNA is duplicated; G2 phase, when DNA is checked for duplication errors and M phase, when the cell divides giving birth to two new cells. These can in turn enter the cell cycle or stay in a quiescent state (G0) until needed. The cell cycle is inherently regulated by the scheduled expression of cyclinsintracellularly, which activate their partner cyclin-dependent kinases (cdks) in a phase-specific manner leading to progression-related events. More specifically, the concentration of cyclins E and B typically fluctuates and reaches a threshold in G1 and G2 phases respectively as cells come closer to transitioning to the next phase. Cyclin concentration and DNA content are thus excellent candidates for use as progress variables within G1 (cyclin E), S (DNA) and G2 (cyclin B).

Cell cycle modelling is of relevance for two specific applications: leukaemia proliferation according to chemotherapy response and phase-specific production of antibodies in industrial cell lines. Population balance models (PBMs) are particularly suitable as they account both for inter- and intra- phase growth, allowing for distributed phases which give greater accuracy.

Leukaemia is a type of cancer of the blood, involving a loss of cell cycle controls. It requires treatment with chemotherapy drugs, which are toxic to proliferating cells only. Their mechanism is cell cycle phase-specific, i.e. they block cell growth at only one of the phases of the cell cycle. Survival relies not only on the eradication of the malignant cells but also on the maintenance of a minimum level of healthy stem cells (which are also affected due to their proliferative nature). It is therefore very important to minimise the number of cycles and to optimise the dose amount and timing. However, current treatment protocols rely basically on the theoretical maximum tolerance level of the patient (correlated to his height and weight). Total cell quantification and cell cycle distribution of cancer and healthy cells, described by a mathematical model, are clearly needed here to optimise the treatment (Pefani et al., 2013; 2014).

The cell cycle description is of industrial relevance due to the intrinsic heterogeneous nature of these systems at different scales (from the molecular to the bioreactor level). Moreover, the cell cycle plays is intimately related to the growth, death, and productivity of mammalian cell cultures. An accurate description of the cell cycle heterogeneity can therefore provide a systematic platform for model-based applications such as optimising product titres, where a balance between cell proliferation and cell cycle specific productivities needs to be found (Dutton et al., 1998). Therefore, relevant mammalian cell cycle models that capture the complex dynamic relations of the system can advantage the commonly industry-adopted design of experiment (DoE) approach.

2. The mathematical problem

After the appropriate change to the variables notation for clarity, the mathematical model can be written as follows:

$$\frac{\partial G(x,t)}{\partial t} + k_g \frac{\partial G(x,t)}{\partial x} = -r_g(x)G(x,t) \tag{1}$$

$$\frac{\partial S(y,t)}{\partial t} + k_s \frac{\partial S(y,t)}{\partial y} = 0 \tag{2}$$

$$\frac{\partial M(z,t)}{\partial t} + k_m \frac{\partial M(z,t)}{\partial z} = -r_m(z)G(z,t) \tag{3}$$

The three stages communicate to each other through the following boundary conditions (continuity of cell number flux between the stages):

$$k_g G(0) = 2\int_0^\infty r_m(z)M(z,t)dz \tag{4}$$

$$k_s S(0) = \int_0^\infty r_g(x) G(x,t) dx \tag{5}$$

$$k_m M(0) = k_S S(2) \tag{6}$$

The above system of partial differential equations must be solved in the domain $0 \le x,z \le \infty$, $1 \le y \le 2$ with initial conditions $G(x,0)=G_0(x)$, $S(y,0)=S_0(y)$, $M(z,0)=M_0(z)$. A particular cell according to the above model undergoes growth of its content and transition from stage to stage. The transition from M to G stage is accompanied by a splitting of the cell leading to an increase of the total cell number. The form of the transition frequency function is of particular importance. A transition zone can be defined as the zone of cell contents (x or z) between a lower value for which the transition frequency is practically zero and an upper limit for which the transition frequency is very large compared to the growth rate. In case of an uniform or step shape of the transition frequency the transition zone is not well defined but in practical applications r is a relatively steep function of the cell content. A ramp function shape is a good candidate for the transition frequency (with parameters the inception content and the ramp slope). A case of particular interest is the one of zero width transition zone (i.e. infinite slope in the ramp model). This is an important case since it allows further mathematical insight in the structure of the model. The equations in this case are singular at the location of transition and an appropriate modification of the model is needed.

3. The one equation prototype

In order to understand the structure of the solution of the mathematical system and the effect of parameters a one-equation prototype of the problem will be considered first. The prototype has the form:

$$\frac{\partial f(x,t)}{\partial t} + k\frac{\partial f(x,t)}{\partial x} = -r(x) f(x,t) \qquad 0 \le x \le \infty \tag{7}$$

with $kf(0,t) = 2\int_0^\infty r(x) f(x,t) dx$ and $f(x,0)=f_0(x)$. The original problem (1-3) can be cast in the form of the above equation in the particular case of zero width transition zone for G stage and $k_g=k_s=k_m$. In the case of zero transition width for f, the right hand side in equation (7) must be set equal to zero, the definition domain is restricted to $0<x<x_m$ and the boundary condition takes the form $f(0,t)=2f(1,t)$. The present problem can be considered as a non-conventional type of growth-breakage population balance (with no internal coordinate conservation by breakage). The total cell number N(t) is given as $N(t) = \int_0^\infty f(x,t) dx$. It is assumed that there is a solution of the form $f(x,t)=N(t)F(x)$. It can be shown that $\frac{dN}{dt} = \lambda N$ with $\lambda = \int_0^\infty r(x) F(x) dx$. The proper mathematical manipulation leads to:

$$F(x)=\frac{2\lambda}{k}e^{-(\lambda x-\int_0^x r(y)dy)/k} \quad (8)$$

where the constant λ can be found from the solution of a transcendental equation.

The corresponding results for the case of zero width transition zone at $x=x_m$ are $\lambda=k\ln(2)/x_m$, $F(x)=\frac{2\ln(2)}{x_m}2^{-x/x_m}$. It is noticeable that the function F does not depend on growth coefficient k. Furthermore, introducing the normalized variable $\eta=x/x_m$ leads to a universal shape for the function $F(\eta)$ (i.e. $F(\eta)=2\ln(2)2^{-\eta}$).

In the above the self-similar solution of the single equation prototype has been derived in closed form. The question now is the realizability of this solution (i.e. if it is really the long time asymptotics of the dynamic problem) and the way it is approached. A first very important assertion is that if the initial cell distribution has the shape of the self-similar one then the self-similarity solution is the **exact** solution of the dynamic problem at any time. In the case of the monodisperse initial distribution the self-similarity solution is never reached (it is non-realizable). The total cell number increases stepwise by doubling each time interval of x_m/k. On the average it can be considered as an exponential growth like the one suggested by the self-similarity solution. An explanation of the system behavior will be pursued here. In general the system attempts to transform the initial cell distribution to the self-similar one in order to converge to the self-similarity regime. In order to do this it must redistribute cells with respect to x variable. The only dispersion mechanism is through transition process. The largest the width of transition zone the higher the dispersion ability of the system and the fastest the approach to the self-similarity. In the particular case of zero width transition zone there is no mechanism for dispersion so the initial distribution can be never transformed to the self-similar one and the system continuously oscillates. The largest the deviation of the initial distribution from the self-similar one, the largest the amplitude of oscillations.

In order to verify the above statements some results on the evolution of the system will be shown here. The evolution of the total cell number N for the zero width transition zone is shown in Figure 1 for several shapes of the initial cell distribution. The content x is normalized by x_m and time is normalized by x_m/k. The case A corresponds to $f_0(x)=\delta(x)$, the case B to $f_0(x)=2x$, the case C to $f_0(x)=2-2x$, the case D to $f_0(x)=2/3(1-x)+2/3$ and finally the case E to $f_0(x)=1$. The asymptotic solution is practically indistinguishable from case E (less than 1% maximum difference) so it is not presented for clarity. There is a repeated shape of the curve for each doubling period. As it is obvious the closer the initial distribution to the self-similar one the closer the proximity of the total number evolution to the self-similar one. In case of zero width transition zone the system retains the discontinuities of the initial distribution. On the contrary, the finite transition zone smeares out very fast the discontinuities allowing the distribution to converge to the self-similar one.

4. The three stage model

A self-similar solution for the three stage model has also been derived. In the particular case of the same normalized growth rate k in each stage the value of λ for the zero width

transition zone is ln(2)k/3. Regarding the realizability of the self-similar solution the situation is exactly the same with the one shown for the one-equation prototype case.

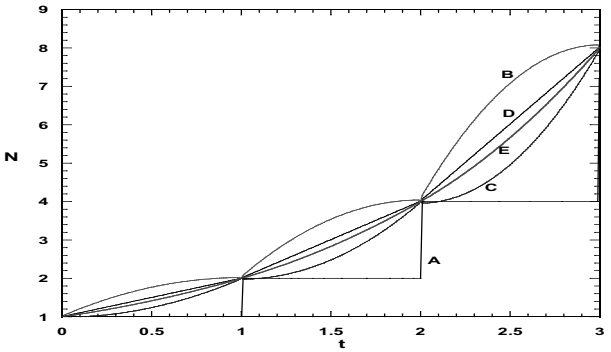

Figure 2: Evolution of total cell number for zero width transition zone and several initial cell distributions (one equation prototype).

The initial distribution of self-similar shape retains its shape during system evolution. The three stage model contains two transition zones (from G to S and from M to G stages). If both transition zones are of zero width then the system oscillates for ever with no convergence to self-similarity. If at least one transition zone is of finite width the system converge to self-similarity for any initial condition.

5. On the reduced (lumped) models

The so called reduced models are mathematical simplifications of the detailed models and they describe the evolution of integral quantities sacrificing higher order information as the detailed cell distribution shapes. Such a model contains parameters with clear physical meaning but different from the parameters of the detailed model. Typically the reduced model parameters can be found using experimental data but it cannot be used to extract the detailed model parameters due to their integral nature. The reduced model for the one equation prototype analysed here is simply dN/dt=KN.

It is clear that the model coincides with self-similar behaviour considering that K=λ. The reduced model is not able to reproduce the approach to the self similarity and the oscillating behaviour but is the best possible single parameter approximation. The parameter K depends on both growth and transition rates as it has been shown for λ.

A reduced model for the three stage model, used extensively in the past has the form (Pefani et al., 2013):

$$\frac{dN_G}{dt} = 2K_M N_M - K_G N_G \tag{9}$$

$$\frac{dN_S}{dt} = K_G N_G - K_S N_S \tag{10}$$

$$\frac{dN_M}{dt} = K_s N_S - K_M N_M \tag{11}$$

where N_i (i=G,S,M) are the numbers of cells in each stage and K_i (i=G,S,M) are the transition between the stages rate constants. The rates K_i are function of the growth rate

and of the transition function in the corresponding stage. The above system admits also a self-similar solution in the sense of $dN/dt=\lambda N$ and of a constant partition between the three stages. By assuming $N=N_o e^{-\lambda t}$, $N_G=\alpha N$, $N_S=\beta N$, $N_M=\gamma N$ substituting in the system (10-12) and performing some algebra leads to

$$\alpha = (1+\frac{\lambda+K_G}{2K_M}+\frac{(\lambda+K_G)(\lambda+K_M)}{2K_MK_S})^{-1} \quad (12)$$

$$\beta = \frac{(\lambda+K_G)(\lambda+K_M)}{2K_MK_S}(1+\frac{\lambda+K_G}{2K_M}+\frac{(\lambda+K_G)(\lambda+K_M)}{2K_MK_S})^{-1} \quad (13)$$

where λ is given from the solution of the algebraic equation $(\lambda+K_G)(\lambda+K_M)(\lambda+K_S)=K_GK_MK_S$ and $\gamma=1-\alpha-\beta$. Let us consider the special case $K_G=K_S=K_M=K$. At this case $\lambda=(2^{1/3}-1)K$ and $\alpha=1/(1+2^{-1/3}+2^{-2/3})$, $\beta=2^{-1/3}/(1+2^{-1/3}+2^{-2/3})$, $\gamma=2^{-1/3}/(1+2^{-1/3}+2^{-2/3})$. Comparing this result with the corresponding zero width transition zone population balance model with equal growth rates reveals that the partition is exactly the same and the ratio of the λ parameters is $3(2^{1/3}-1)/\ln(2)$ (approximately 1.1). The success of the reduced model to describe the self-similarity state of the detailed model should not lead to underestimation of its pathologies. It leads very fast to self-similarity, it is not able to represent complex dynamics of the detailed model and it does not convey any information of cell distribution in the stages. Let us examine here what happens with the addition of a death term with rate constant K_d in S stage. It can be shown that both population balance and lumped models admits self similar solutions. In case of the same growth constant for the three stages the population balance model leads to $\lambda=\ln(2)K/3-K_d/3$ and the lumped model leads to the following equation for λ: $(K+\lambda)^2(K+\lambda+K_d)=2K^3$. The value of λ in the first case decreases linearly with K_d but in the second case exhibits a minimum at $\lambda=-K_d$. In this case the lumped model does not agree with population balance model leading to much smaller apparent cell death rates for the same value of K_d.

6. Conclusions

Multistage population balance models are necessary tools for the study of cell behaviour. A particular model of this type is mathematically examined here. It is shown that the model evolves to a self-similar state or undergoes eternal oscillations depending on the form of functions determining the transition from stage to stage. The amplitude of the oscillations depends on the deviation of the initial cell distribution from the self-similar one. A lumped model can adequately describe the cell growth process but it fails in case of stage-specific cell death.

Oxygen transfer rates and requirements in oxidative biocatalysis

Asbjørn Toftgaard Pedersen, Gustav Rehn and John M. Woodley

Department of Chemical and Biochemical Engineering, Søltofts Plads 229, 2800 Kgs. Lyngby, Denmark

Abstract

Biocatalytic oxidation reactions offer several important benefits such as regio- and stereoselectivity, avoiding the use of toxic metal based catalysts and replacing oxidizing reagents by allowing the use of oxygen. In this contribution the oxygen requirements are analysed for different process scenarios, considering different biocatalyst formats and variation of the desired productivity. Also, the applicability of two different oxygen supply methods (bubbling and membrane aeration) is considered. The results indicate that growing cells could be used to reach productivities up to 3.5 g $L^{-1}h^{-1}$ without oxygen supply being limiting. Also, membrane contactors can provide a feasible oxygen supply method when bubble-less aeration is desired. However, in order to support high productivity the oxygen flux using air may be insufficient, thus requiring the use of oxygen.

Keywords: biocatalysis, oxygen requirements, oxygen supply.

1. Introduction

Process Systems Engineering (PSE) methods and tools are of enormous value for evaluation of new manufacturing processes. In particular they can assist in the development of new biological processes. An interesting case concerns the development of biocatalytic oxidation processes, which is a complex task requiring the simultaneous consideration of several issues regarding the process design and operation. For example, the biocatalyst format and method of oxygen supply must be carefully chosen. Thus, mathematical models for assessing the oxygen requirement using different biocatalyst alternatives and the attainable oxygen transfer rate (OTR) using different aeration methods are valuable for predicting process feasibility. Furthermore, such models are essential to efficiently design new and sustainable bioprocesses for the future.

1.1 Oxygen dependent enzymes

Oxidation reactions are highly important in organic chemistry. However, traditional chemical methods are associated with drawbacks such as oxidants based on toxic metal ions, undesired side reactions, ineffective use of oxygen and the difficulty of performing regio and stereoselective oxidations (Faber, 2011). Biocatalytic oxidations (bio-oxidations) provide opportunities to avoid several of these problems and are especially useful due to their stereoselectivity. Also, they allow the use of molecular oxygen, the most inexpensive and harmless oxidant available. Several different enzymes, belonging to several enzyme classes such as dehydrogenases, oxidases, mono- and dioxygenases and peroxidases are used to catalyze many interesting oxidation reactions including oxidation of alcohols and polyols, hydroxylation of phenols, epoxidation of double bonds and heteroatom oxygenation (Hollmann et al., 2011).

1.2 Biocatalyst format

There are several possible ways to use a biocatalyst, whether in the form of an isolated enzyme or in the form of whole-cells. Also, isolated enzymes as well as whole-cells may be used either in solution/suspension or immobilized using numerous techniques available. The choice of biocatalyst format depends on the requirements of the process at hand. However, the choice of biocatalyst format also influences the way the process can be operated. On the one hand, the whole-cell format is attractive because no enzyme purification is needed, thus lowering the biocatalyst cost. Another advantage is that co-factors (e.g. NAD(P)H) can be regenerated within the cell, thus eliminating the need for an additional enzyme and co-factor. On the other hand, the diffusion of substrates and products in and out of the cell may limit the reaction rate compared to that observed using an isolated enzyme. Moreover, side reactions catalyzed by other enzymes present in the cell may lower the reaction yield and result in a more complex product mixture. Also, the stability of some enzymes can be comparatively lower when used in isolated form. In the following section, implications of the biocatalyst format in oxygen demanding bio-oxidation process are discussed.

2. Oxygen requirements

The oxygen consumption of a biocatalyst arises from the oxygen requirement of cellular processes and the consumption of oxygen in the biocatalytic reaction of interest. The cellular processes cover the catabolism of an energy source (typically glucose) to supply energy (in the form of ATP) used in the anabolic reactions synthesizing cell mass. The cellular processes can be described by Eq.(1-4) (Villadsen et al., 2011), here given on a c-mol basis. Glucose is converted to CO_2, NADH and ATP in the glycolysis and tri-carboxylic acid cycle, Eq.(1), and ATP is synthesized via oxidation of NADH in the electron transport chain, Eq.(2). The anabolic reactions require NADPH, which is produced by degradation of glucose in the pentose-phosphate pathway, Eq.(3). Eq.(4) describes the lumped anabolic reactions responsible for cell mass (X) synthesis. These equations are valid for *Escherichia coli* and other organisms that use similar pathways, but will change dependent upon the specific metabolic pathways used by a given microorganism.

The equations describing the cellular processes contain several parameters that depend on the reaction conditions and the type of microorganism. The amount of ATP formed in Eq.(1) (ε) varies depending on the amount of intermediate species that is required for macromolecule synthesis; the maximum value is 2/3. The efficiency of the electron transport chain (P/O) has a theoretical maximum of 3 ATP per NADH, but most often the value is closer to 1.5. The yield coefficients for NADH, NADPH and ATP (Y_{xNADH}, Y_{xNADPH}, Y_{xATP}) in Eq.(4) depend on the type of organism (i.e. the composition of the cell), the substrate, and the conditions of growth (i.e. substrate limitations, etc.). The CO_2 formation, α, is typical between 0.08 and 0.14, and can be calculated via a redox balance if the cellular composition and the yield coefficients for NADPH and NADH are known.

$$CH_2O \longrightarrow CO_2 + 2\,NADH + \varepsilon\,ATP \tag{1}$$

$$NADH + 1/2\;O_2 \longrightarrow P/O\,ATP \tag{2}$$

$$CH_2O \longrightarrow CO_2 + 2\,NADPH \tag{3}$$

$$(1-\alpha)CH_2O + Y_{xNADPH}NADPH + Y_{xATP}ATP \longrightarrow X + \alpha CO_2 + Y_{xNADH}NADH \tag{4}$$

The last reaction required in order to predict the oxygen consumption of a microbial cell that performs a bio-oxidation, is the oxidation reaction itself, as shown in Eq.(5). In the reaction substrate (S) is oxidized to product (P) requiring stoichiometric amounts of oxygen and co-factor, which, dependent on the enzyme, can be either NADH or NADPH. In the following calculation it is assumed that the enzyme of interest is NADH dependent, however, a NADPH dependent enzyme will only slightly increase the oxygen requirements of the biocatalyst.

$$S + NAD(P)H + O_2 \longrightarrow P \tag{5}$$

By combining Eq.(1-5) an expression for the overall oxygen consumption rate for a given whole-cell biocatalyst can be found. To reduce the number of required input variables quasi-steady state is assumed for the concentration of cofactors (NADH and NADPH), as well as the energy carrier (ATP). The oxygen consumption rate is described by Eq.(6), where the constants A, B, and C are defined by Eq.(7-9). The parameter m_{atp}, included in Eq.(8), describes the energy required for cellular maintenance processes, such as protein turnover and membrane potential maintenance. This parameter is highly depended on the type of organism and the conditions the organism is exposed to. Eq.(6-9) describe the oxygen consumption rate for *E. coli* growing on glucose. The expressions will change if another substrate is applied or an organism with different metabolism is employed.

$$r_{O_2} = (A + 1/2\ Y_{xNADH})\,\mu + B + C\ A_{cat} \tag{6}$$

$$A = \frac{Y_{xATP} - Y_{xNADH}\,P/O}{\varepsilon + 2\ P/O} \tag{7}$$

$$B = \frac{m_{ATP}}{\varepsilon + 2\ P/O} \tag{8}$$

$$C = \frac{1}{2} + \frac{P/O}{\varepsilon + 2\ P/O} \tag{9}$$

The oxygen requirements of growing cells, resting cells, and isolated enzymes carrying out an oxidation reaction are plotted in Figure 1 for different volumetric productivities. The volumetric productivity is based on initial rates, meaning that the observed volumetric productivity can be significantly lower. The reported oxygen requirements can therefore be seen as the maximum requirement observed during a reaction.

The volumetric productivity required by biocatalytic processes differs significantly depending on the value of the product produced, i.e. a pharmaceutical might only require 1-10 g/L/day to be economically feasible whereas a bulk chemical requires much higher productivities. The oxygen transfer capabilities in industrial bioreactors set a limit to the maximum volumetric productivity that can be achieved. Depending on the volumetric productivity required, it will be necessary to intensify the oxygen transfer to overcome this limitation. Intensified oxygen transfer can be achieved by e.g. pressurizing the reactor or using alternative oxygen supply methods, such as feeding hydrogen peroxide to reactor, which can be degraded to oxygen using catalase.

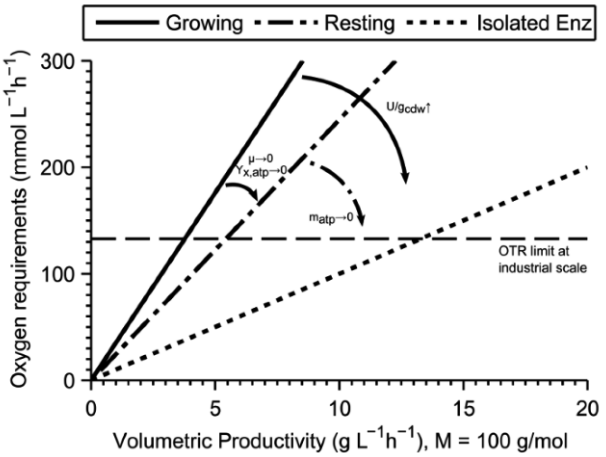

Figure 1 Oxygen requirements of different types of biocatalysts carrying out an oxidation reaction. The calculations are based on *E. coli* and the following parameter values: A_{cat} = 50 U/g_{cdw}, μ = 0.2 h^{-1}, ε = 2/3, P/O = 1.5, Y_{xNADH} = 16.97 mmol/g_{cdw}, Y_{xatp} = 70.2 mmol/g_{cdw}, m_{atp} = 7.9 mmol/g_{cdw}/h(Ingraham et al., 1983; Varma and Palsson, 1994). The maximum oxygen transfer rate (OTR) for bubble aeration at industrial scale is estimated using a $k_l a$ of 500 h^{-1} (Villadsen et al., 2011). The OTR limit is based on the use of air.

3. Supply methods

3.1. Bubble aeration

Supplying oxygen by bubbling air through the reaction medium is the method of choice in most fermentation processes, due to its relatively easy implementation and operation. In general the oxygen transfer rate (OTR) can be assumed to be controlled by the diffusion of oxygen across the liquid boundary layer, and hence described by a simple mass transfer equation, Eq.(10). The OTR depends on the volumetric oxygen transfer coefficient ($k_l a$), the oxygen saturation concentration ($C_{O_2}^{sat}$), and the concentration of oxygen in solution. Several factors influence the OTR; the temperature, pressure, and salt concentration influence $C_{O_2}^{sat}$, while mixing power input, gas flow rate, and liquid viscosity influence $k_l a$.

$$OTR = k_l a \, (C_{O_2}^{sat} - C_{O_2}) \tag{10}$$

The concentration of oxygen in solution is critical in order to ensure that the biocatalyst is not limited by oxygen. The minimum concentration to ensure effective catalysis depends on the affinity of the enzyme of interest towards oxygen and can be as high as 100 μM, corresponding to ≈ 50% air saturation in water at 1 atm. (Duetz et al., 2001). This naturally reduces maximum achievable OTR in such systems, because the driving force for oxygen transfer is lowered. At industrial scale the OTR is also limited by the achievable mixing power input and the maximum aeration rate, typically the maximum OTR for an industrial scale stirred bioreactor is 100-200 mmol/L/h when the oxygen concentration in the reactor is close to zero (Chisti, 1999).

3.2. Membrane aeration

Hollow fibre membrane contactors are widely used for creating large specific areas (area/volume) of liquid/liquid or gas/liquid interfaces and therefore present an interesting alternative for reactor aeration. The contactor can combine a large gas/liquid

interfacial area with bubble-free aeration, thus enabling efficient oxygen mass transfer while also preventing foaming and minimizing undesired evaporation of any volatile components. Due to the modular design of membrane contactors, scaling-up is relatively straight forward (Gabelman and Hwang, 1999), and contactors are implemented for various industrial applications (Klaassen et al., 2005).
The use of isolated enzymes in bio-oxidation processes is potentially challenging because enzymes can be subject to inactivation by the presence of gas/liquid interfaces, with an inactivation rate proportional to the interfacial area (Bommarius and Karau, 2005). Stability data, however, cannot simply be extrapolated to other operating conditions and should therefore be investigated for each case. The successful use of membrane aeration, using a non-porous silicon based membrane, was reported for the oxidation of lactose to lactobionic acid using isolated enzymes (Van Hecke et al., 2011). Based on the above estimations of oxygen requirements, the required specific membrane areas were calculated for different bio-oxidation processes (Figure 2).

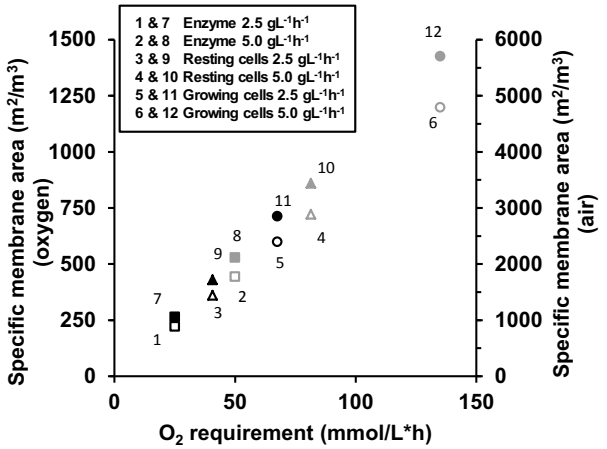

Figure 2 Estimated specific membrane areas required for aeration of bio-oxidation processes, based on a volumetric productivity of 2.5 $gL^{-1}h^{-1}$ (black) or 5 $gL^{-1}h^{-1}$ (grey) respectively. Calculations are based on either the use of oxygen (open symbols) or air (closed symbols). The calculation were conducted as described previously (Côté et al., 1988), assuming an oxygen mass transfer coefficient of 3.8 g $m^{-2}h^{-1}bar^{-1}$) for a polypropylene hollow fibre (Côté et al., 1989) and operation at 1 bar.

Figure 2 indicates that membrane aeration could be feasible for several bio-oxidation processes. Commercially available membrane modules (e.g. from Liqui-Cel®) can provide over 350 m^2 of membrane are in a contactor volume of about 75 L, and several modules can be used in parallel if needed. If air is used instead of oxygen, the lower partial pressure of oxygen results in a lower driving force for the oxygen diffusion. Consequently, the use of air is likely to be limited to processes with relatively low (<50 mmol $L^{-1}h^{-1)}$ oxygen requirement. Similarly, dense membranes with inherently lower oxygen mass transfer coefficients compared to porous fibres may not provide large enough flux of oxygen for many processes, but can be useful for isolated enzyme processes in which the gas/liquid interface causes enzyme inactivation.

4. Conclusions and future outlook

Development a bio-oxidation process is a complex task. While the target productivity is linked to the product value, the maximum achievable productivity is greatly influenced

by the oxygen requirement set by the biocatalyst. The present analysis indicates that a productivity of 3.5 or 5 g $L^{-1}h^{-1}$ could be attainable by conventional bubble aeration, using growing or resting cells, respectively. The use of membrane aeration may necessitate using pure oxygen in order to support whole-cell systems at this level of productivity. Thus, its use may be limited to the production of high value products due to the considerable cost contribution by the pure oxygen. The use of isolated enzymes, however, could benefit from the use of a dense membrane to prevent interfacial inactivation of both the enzyme catalyzing bio-oxidation reaction but also any enzyme used for co-factor regeneration. With the operating conditions assumed here, such a process would require oxygen is used rather than air. Naturally, both the use of oxygen and the membrane contactor would contribute to an increased process cost and the strategy should be evaluated from case to case. In the future, further analysis will be focussed on case-studies of bio-oxidation processes with different characteristics in terms of products, biocatalyst formats and reactor aeration. The use of PSE tools and methods will be important to help provide a clear and excellent quantitative understanding.

Abstract

In this contribution, we present a probabilistic process design approach to derive a robust, optimal process design. Robustness is referred to the consideration of model and process design uncertainties. The probabilistic design approach is based on a hybrid uncertainty propagation strategy using profile likelihood and sigma point samples. At small additional computational effort the presented approach allows to predict the expected process performance and can improve process robustness by identifying design regions of small variability (=variance) in the design objective. As an example, we use the β-carotene production in the microalga *Dunaliella salina* to illustrate the impact of different dynamic nutrient feeding strategies, model and process design uncertainties on the expected biomass yield on absorbed light and its variability.

Keywords: *Dunaliella salina*, uncertainty analysis, profile likelihood, sigma points

1. Introduction

Biotechnological processes using microalgal cell factories are gaining significant importance for sustainable chemicals production based on renewable energy and feedstocks. The biochemical composition of the biomass is strongly affected by environmental conditions such as nutrient availability and light. Mathematical modeling can broaden our understanding of the underlying metabolic mechanisms and enable predictions of dynamics in biomass growth and biochemical composition under different cultivation conditions. Despite the huge progress in analytical cell biology, many model parameters are still unknown and need to be estimated. Natural biological variability in combination with the limited amount of quantitative data results in large parameter uncertainties, and thus model prediction uncertainties. Consequently, model-based process design objectives are rendered uncertain. Additionally, fluctuating operating conditions in combination with general process noise can render a non-probabilistic process design suboptimal (Bestle et al., 2010). Consequently, for a robust biological process design, prediction uncertainties and process design variabilities have to be accounted for. Here we present a hybrid uncertainty propagation strategy joining profile likelihood and sigma point samples (e.g. Royston, 2007; Julier and Uhlmann, 1996). We apply the probabilistic design approach to a growth model of *Dunaliella salina*. *D. salina* belongs to one of the few algal species with commercial relevance, because it accumulates high amounts of β-carotene. High light intensities and the nitrate depletion are the key factors promoting its accumulation. Even though large-scale systems for *D. salina* are already operated in Israel and Australia (e.g. Borowitzka and Borowitzka, 1990), a profound understanding of the optimal process design and operation including the impact of the uncertainties due to

environmental fluctuations and biological variability is largely missing. Indeed, such uncertainties could have a large impact on process yield and robustness especially in view of up-scaling from lab- to large-scale outdoor cultivation scenarios.

2. Methods

2.1. Model formulation

The dynamic evolution of system's states can be described by an ordinary differential equation (ODE) system

$$\begin{aligned} \dot{x}(t) &= f(x(t,\theta_x),u(t),\theta_x) \\ y(t) &= g(x(t,\theta_x),\theta_y)+\varepsilon, \end{aligned} \tag{1}$$

where $x(t,\theta_x)$ represent the states of the system, $u(t)$ indicates external feeds and θ_x a vector of kinetic parameters. Experimental readouts $y(t)$ are modeled by a readout function g, which also accounts for scaling and offset parameters θ_y and an additive white measurement noise model $\varepsilon \propto \mathcal{N}(0,\sigma^2_{\text{exp}})$. Kinetic and readout parameters are combined into the parameter vector θ, including all parameters required to completely characterize the system: $\theta = [\theta_x,\theta_y]^{\text{T}}$.

2.2. Profile likelihood

The profile likelihood is of special use, when analyzing the identifiability of the maximum likelihood estimate (MLE) $\hat{\theta}$ of the model parameters, but also when deriving confidence regions (Venzon and Moolgavkar, 1988; Raue et al., 2009). The profile likelihood of a parameter θ_i is given by (Venzon and Moolgavkar, 1988)

$$\chi^2_{\text{PL}}(\theta_i) = \min_{\theta_{j\neq i}} \chi^2(\theta), \tag{2}$$

which represents a function in θ_i of least increase in the residual sum of squares $\chi^2(\theta)$. For additive, independent, identically and normally distributed measurement noise we have $\chi^2 \propto -2\log L$, with likelihood L. Therefore χ^2 is often referred to as the likelihood. The least increase is achieved by adjusting $\theta_j, j = 1\ldots n_\theta \backslash i$ accordingly. Profile likelihood-based confidence regions CR_θ can be derived via

$$\text{CR}_\theta = \{\theta | \chi^2_{\text{PL}}(\theta) - \chi^2_{\text{PL}}(\hat{\theta}) < \delta_\alpha\}, \tag{3}$$

with δ_α being the α quantile of the χ^2 distribution with $df = 1$ (pointwise) or $df = n_\theta$ (simultaneous) degrees of freedom. A confidence interval of parameter θ_i is given by the borders of CR_θ. Notably, CR_θ represents a set of parameters, which approximates the high dimensional confidence region by n_θ sets of constrained projection samples via Eq. (2).

2.3. Uncertainty propagation by the sigma point method

The sigma point method is a versatile uncertainty propagation method that can be applied to problems of the form

$$Y = h(Z), \tag{4}$$

where h represents a possibly nonlinear function in Z. Z represents a stochastic, possibly multivariate, variable characterized by some known density function ρ_Z or statistical moments thereof.

In the following expectation $E[z]$ and variance-covariance $C[z]$ are used to characterize ρ_Z. Y represents also a stochastic variable that can be characterized by some *unknown* density function ρ_Y, whose shape depends on h and ρ_Z. The capitalized letters Y and Z represent stochastic variables, whereas non-capitalized letters represent the corresponding realizations. As shown by Julier and Uhlmann (1996), the sigma point methods yields efficient and accurate estimates of the first two statistical moments of Y, which can be used to describe ρ_Y. The two statistical moments of Y are derived from the (nonlinearly) transformed stochastic variable Z. The computational effort is of order $\mathscr{O}(2n_z+1)$, with n_z representing the dimension of Z. In brief, the sigma point method works as follows:

1. Select $2n_z+1$ sigma points in the original domain of the stochastic variable according to

$$z^{(0)} = E[z]; \qquad z^{(i)} = z^{(0)} \pm \sqrt{n_z+\lambda}\sqrt{C[z]}^{(i)}, \tag{5}$$

2. Propagate these points through the function h via $y^{(i)} = h(z^{(i)})$.

3. Estimated expectation $E^{\mathscr{S}}[y]$and variance-covariance $C^{\mathscr{S}}[y]$ of Y are given by

$$E^{\mathscr{S}}[y] = \sum_{i=-n_z}^{n_z} w^{(i)} y^{(i)}; \quad C^{\mathscr{S}}[y] = (1-\gamma^2+\beta)\left(y^{(0)}-E[y]\right)\left(y^{(0)}-E[y]\right)^{\mathrm{T}} + \\ + \sum_{i=-n_z}^{n_z} w^{(i)}\left(y^{(i)}-E[y]\right)\left(y^{(i)}-E[y]\right)^{\mathrm{T}} \tag{6}$$

with weights $w^{(0)} = \frac{\lambda}{n_z+\lambda}$, $w^{(\pm i)} = \frac{1}{2(n_z+\lambda)}$ and $\lambda = \gamma^2(n_z+\kappa)-n_z$. The superscript $\mathscr{S}$ indicates that sigma point samples have been used to estimate expectation and variance-covariance. The parameters γ, β, κ can be used to tune the sigma point method (Julier and Uhlmann, 1996).

2.4. Probabilistic process design using profile likelihood and sigma point samples

In this section we show how profile likelihood and sigma point samples can be combined to yield an efficient, probabilistic process design tool that accounts for uncertainty in the model parameters but also variability in the process design. Given significant profile likelihood samples from CR_θ and knowledge on typical process variability, we may derive an expected process design objective and its associated uncertainty in the following way. The scalar design objective O is given by

$$O = h(\Theta, \mathbb{D}), \tag{7}$$

where h represents the simulation of the process model as a function of the stochastic model parameters Θ and stochastic process design variables $\mathbb{D}$. As can be seen, the objective O is also a stochastic variable with realization $o = h(\theta, d)$, which in most of the cases is nonlinearly related to Θ and $\mathbb{D}$. The stochastic process design variable $\mathbb{D}$ can be characterized by mean $\mu_{\mathbb{D}}$ and variance-covariance $\Sigma_{\mathbb{D}}$. Then, using the sigma point approach in combination with a profile likelihood sample $\theta_i \in \mathrm{CR}_\theta$ an expected objective $m_i = E^{\mathscr{S}}[o]_i$ can be derived, including its associated variance $c_i = C^{\mathscr{S}}[o]_i$, to obtain a set of tuples $\{(m_i, c_i)\}$ with $i = 1 \ldots \#\mathrm{CR}_\theta$. From this set, final mean and variance of the process design objective can be derived via

$$\langle O \rangle = E^{\mathscr{S}}[o(\hat{\theta})]_{\mathbb{D}} \tag{8}$$

$$\langle (O - \langle O \rangle)^2 \rangle = \frac{\left(\max(\{m_i + q_\alpha\sqrt{c_i}\}) - \min(\{m_i - q_\alpha\sqrt{c_i}\})\right)^2}{q_\alpha^2} \tag{9}$$

with q_α being the α quantile, which can be derived from the confidence level α of the samples in CR_θ. Assuming normality we have $q_\alpha = 1.96$ for $\alpha = 0.05$. The quantity $\langle O \rangle$ in Eq. (8) represents

the expected process design objective under the fluctuating process design $\mathbb{D}$ at the MLE $\hat{\theta}$. The variability of $\langle O \rangle$ is affected by uncertainties of the model parameters and fluctuations of the process design itself. This range is quantified by the variance $\langle (O - \langle O \rangle)^2 \rangle$ in Eq. (9). A scheme of this hybrid uncertainty propagation strategy is given in Fig. 1a. In this probabilistic formulation, the initial scalar objective is turned into a two criteria objective, consisting of mean and variance of the scalar design objective. In the more general case of a probabilistic multi-objective design approach, we may describe variance-covariances of the objectives in the same way as illustrated here for the scalar case. The computational effort is of order $\mathcal{O}(\#\mathrm{CR}_\theta n_\theta n_d)$.

3. Results

3.1. Model description

The ODE model describing the growth of *D. salina*, proposed by Fachet et al. (2014), is used to demonstrate the here presented probabilistic design approach. The model incorporates light and nutrient effects on growth and pigmentation of *D. salina*. Fachet et al. (2014) further performed a profile likelihood analysis of the parameters, which is used here to supply the profile likelihood samples of the model parameters. The published model equations were slightly modified to solve the proposed equation system explicitly: An estimated biomass yield on absorbed light $Y_{\mathrm{X,E,est}}$ was calculated based on the biomass-specific light availability and nitrogen cell quota ω_{N} as expressed in Eq. (10):

$$Y_{\mathrm{X,E,est}} = \mu_{\max} \cdot \left(1 - \frac{\omega_{\mathrm{N,min}}}{\omega_{\mathrm{N}}}\right) \cdot \left(\frac{\frac{\overline{E}}{\rho_{\mathrm{X,dw}}}}{\frac{\overline{E}}{\rho_{\mathrm{X,dw}}} + K^*_{\mathrm{s,E}} \cdot \frac{\rho_{\mathrm{X,dw}}}{\rho_{\mathrm{Chl}}}} \right) \cdot \rho_{\mathrm{X,dw}} \cdot V_{\mathrm{PBR}} / E_{\mathrm{abs}}, \tag{10}$$

where $\mu_{\max}$ refers to the maximal growth rate and $K^*_{\mathrm{s,E}}$ refers to the light intensity per gram biomass for which the photosynthesis rate is half saturated with respect to light. The parameter values for the additionally introduced parameters $\mu_{\max}$=1 d^{-1} and $K^*_{\mathrm{s,E}}$=5.8 $\times$ 10^{-5} mol m g^{-1} d^{-1} were derived from experiments in batch cultures. Table 1 summarizes the model parameters used for simulations in this work. The carbon-specific photosynthesis rate r_{P}, the growth rate μ and the

(a) (b)

Figure 1: (a) Scheme of the hybrid uncertainty propagation strategy. (b) Illustration of the influence of a day/night light profile (I) on cell density (II), biomass yield (III), extracellular nitrogen density (V) and intracellular nitrogen fraction (VI) at the MLE $\hat{\theta}$ for a deterministic nutrient feeding profile (IV) with $\tau_{\mathrm{N,feed}} = 5\,\mathrm{d}$ and $D_{\mathrm{N,feed}} = 10\,\mathrm{g\,N\,m^{-3}\,d^{-1}}$.

3.2. Formulation of the probabilistic design problem

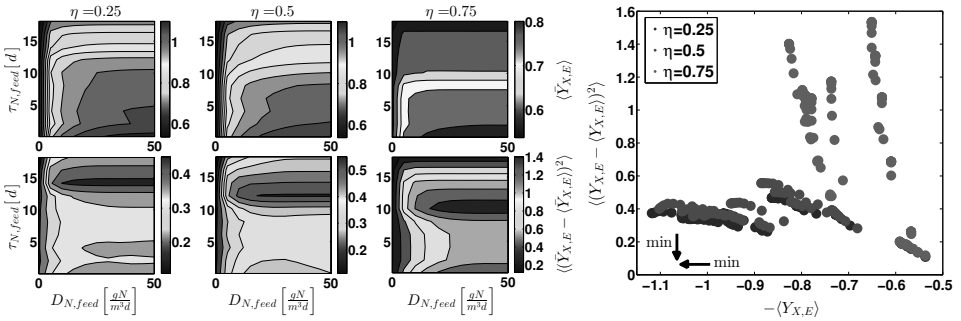
The process design problem is to find an optimal nutrient feeding strategy for a day/night light profile with maximal photon flux density of E_0 (see Fig. 1b). Optimality of the feeding profile is measured with the design objective $\bar{Y}_{X,E} = 1/T \int_0^T Y_{X,E}(t)\mathrm{d}t$, which represents the average biomass yield on absorbed light energy over the process time T (in the example $T = 15\mathrm{d}$). A high β-carotene content of the biomass can be assured through a high light intensity day/night profile in combination with a nutrient feeding profile that ensures low nitrogen cell quota. The design of the nutrient feeding profile is parameterized as

$$u_{\mathrm{N,feed}}(t) = \begin{cases} 0 & \text{if } t \leq \tau_{\mathrm{N,feed}} \\ \frac{D_{\mathrm{N,feed}}}{2}\left(1 + \mathrm{sign}[\sin\left(\frac{2\pi(t-\tau_{\mathrm{N,feed}})}{T_{\mathrm{N,feed}}}\right)]\right) & \text{if } t > \tau_{\mathrm{N,feed}}, \end{cases} \tag{13}$$

which is a square wave with the volumetric flow rate of the nutrient feeding $D_{\mathrm{N,feed}}$, period $T_{\mathrm{N,feed}}$ fixed at one day, and feeding delay $\tau_{\mathrm{N,feed}}$. Therefore, the design space $\mathscr{D}$ consist of only two design variable, namely $\tau_{\mathrm{N,feed}}$ and $D_{\mathrm{N,feed}}$. Fig. 1b illustrates the dynamics of *D. salina* under periodic day/night light and nutrient supply. Fluctuations of the nutrient feeding profile are modeled with $\tau_{\mathrm{N,feed}} \propto \mathscr{N}(m_{\tau_{\mathrm{N,feed}}}, \eta m_{\tau_{\mathrm{N,feed}}})$ and $D_{\mathrm{N,feed}} \propto \mathscr{N}(m_{D_{\mathrm{N,feed}}}, \eta m_{D_{\mathrm{N,feed}}})$, where $\mathscr{N}(\mu, \sigma^2)$ represents the normal distribution with mean μ and parameterized variance σ^2. The scaling factor η is used to control the process noise, i.e. level of fluctuations in the nutrient feeding profile. The uncertainties in the model parameters are accounted by the profile likelihood samples at $\alpha = 0.05$. Applying the approach outlined in Sec. 2.4 yields the probabilistic optimal design problem:

$$\begin{aligned} &\underset{[\tau_{\mathrm{N,feed}}, D_{\mathrm{N,feed}}]^{\mathrm{T}}}{\text{minimize}} && [-\langle \bar{Y}_{X,E} \rangle, \langle (\bar{Y}_{X,E} - \langle \bar{Y}_{X,E} \rangle)^2 \rangle]^{\mathrm{T}} \\ &\text{subject to} && [0,0]^{\mathrm{T}} \leq [\tau_{\mathrm{N,feed}}, D_{\mathrm{N,feed}}]^{\mathrm{T}} \leq [20,50]^{\mathrm{T}}, \end{aligned} \tag{14}$$

within the feasible design space $\mathscr{D}$ defined by the bounds of the box constrains (in units of the respective design parameter). A Pareto optimal solution to Eq. (14) is given by the set of best trade-offs between maximal expected average biomass yield on absorbed light energy and minimal variance thereof (e.g. Pardalos et al., 2008). In Fig. 2a, the design objectives are shown over the design parameter space for different process noise levels ($\{\text{low,medium,high}\} \leftrightarrow \eta = \{0.25, 0.5, 0.75\}$). As can be seen, when increasing the process noise, the maximal expected yield decreases, while the maximal observed variance increases. This can also be seen in Fig. 2b, which shows the



(a) (b)

Figure 2: (a) Design objectives $\langle \bar{Y}_{X,E} \rangle$ and $\langle (\bar{Y}_{X,E} - \langle \bar{Y}_{X,E} \rangle)^2 \rangle$ over the design space $\mathscr{D}$ and associated criterion space (b) for different process noise levels $\leftrightarrow \eta = \{0.25, 0.5, 0.75\}$ and profile likelihood samples from CR_θ at $\alpha = 0.05$.

criterion space for a set of equally sampled design parameters in the feasible design space: In the high level process noise scenario one can only reach the same process robustness, i.e. approximate variance of $\langle (\bar{Y}_{X,E} - \langle \bar{Y}_{X,E} \rangle)^2 \rangle \approx 0.4$ compared to low and medium level noise, by selecting a design point (i.e. nutrient feeding profile) that reduces the expected performance from roughly $\langle \bar{Y}_{X,E} \rangle = 1.1$ to $\langle \bar{Y}_{X,E} \rangle = 0.7$.

4. Conclusions

Here we present a probabilistic nonlinear design approach that allows to account for uncertainties of the model parameters, but also variabilities in the process design, e.g. general process noise or fluctuations of the operation conditions. The approach is based on a hybrid uncertainty propagation strategy using profile likelihood and sigma point samples. The profile likelihood samples are readily available from parameter identification analysis, as for instance performed by Fachet et al. (2014), and can thus be directly used to efficiently sample the confidence region of the typically high-dimensional model parameter space for estimating the uncertainties of the model predictions. Additionally, variability of the process in the form of process noise, e.g. varying feeding profiles or fluctuations of operating conditions, can be efficiently described with sigma point samples. In conclusion, the results of this work pave the way to an efficient probabilistic tool for robust bioprocess design under uncertainties of model parameters and operating conditions.

Abstract

Technological advances in catalytic and biological engineering have created opportunities for the production of high value chemicals from biomolecules such as glucose. Yet, production of such chemicals from real, complex biomass requires the integration with biomass pre-treatment. This study exemplifies the use of a computer aided collaborative environment that integrates biomass pre- and post-treatment via a limited set of intermediate streams. The cost and composition of intermediate streams from two different pretreatment methods, dark fermentation and enzymatic hydrolysis, were simulated using AspenPlus, using the organic fraction of municipal solid waste (OFMSW) as feedstock. Using these streams in downstream processes was found to have a cost advantage over the use of pure substrates. On the other hand, these streams contain by-products with the potential to inhibit downstream bioprocesses and to complicate downstream product separation.

Keywords: biorefinery, computer aided collaborative environment, organic fraction of municipal solid waste, enzymatic hydrolysis, dark fermentation

1. Introduction

The disposal of organic fraction of municipal solid waste (OFMSW), can lead to health risks and the production of greenhouse gases, if not properly managed. Research on waste treatment technologies has focused on optimizing the conversion of the OFMSW to final products with low market value such as biogas or ethanol. However, advances in biomass-based biological and catalytic engineering have defined opportunities for converting the OFMSW to chemicals with significant added-value, thus creating options which are economically more appealing. This study aims at assessing the economic opportunities of valorising intermediates from such processes within the framework of a biorefinery.

The assessment is performed using a computer-aided collaborative environment developed for the evaluation of biorefinery processes. Within the scope of the computer-aided collaborative environment, the overall problem and the associated biorefinery (biomass to high value added chemicals) is decomposed into two interacting problems: the supply of a (limited) set of intermediates (*supply* side) and the use of these intermediates to produce a wide range of products (*demand* side). In the present paper we focus the attention on the supply side of the problem, and we study two

competitive platforms for the conversion of OFMSW into intermediates. The first platform involves dark fermentation to produce an intermediate stream of volatile fatty acids (VFAs) in addition to hydrogen and the second platform involves enzymatic hydrolysis for the production of an intermediate stream of monomeric sugars. The geographic area for the assessment is Abu Dhabi (United Arab Emirates), one of the largest OFMSW producers per inhabitant in the world. The objective is to assess options and establish a feasible path forward in achieving the goal of the government of Abu Dhabi of establishing a sustainable integrated waste management system.

2. Process Description

The processing pathways for the two studied platforms are shown in Figure 1. It follows the general fractionation sequence, proposed in the computer-aided collaborative environment established in AspenPlus V8.4, which divides the supply side into *physical pretreatment*, *recovery of high value compounds*, *chemical pre-treatment and hydrolysis* operation blocks.

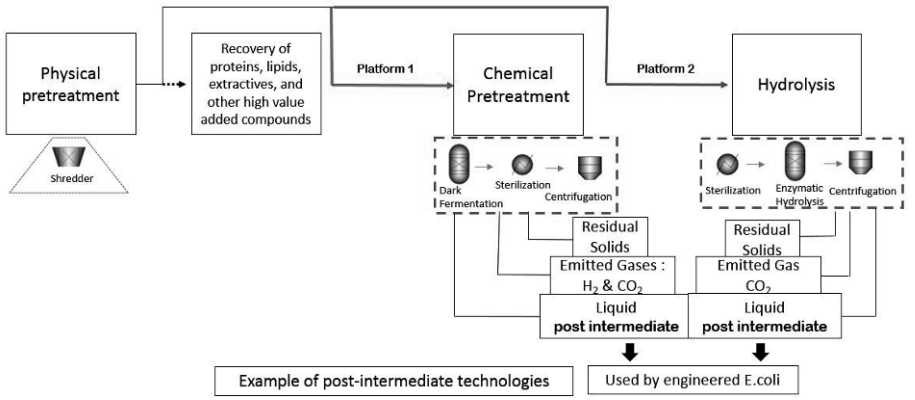

Figure 1: Scheme exhibiting the two platforms for processing the OFMSW stream

The aim of the physical pretreatment is to reduce the size of the OFMSW and give the feed some degree of homogeneity. As the OFMSW encompasses only the organic part of waste from household, commerce, and institutions, such as food, park and garden waste, low speed shearing devices can be used for size reduction (Fitzgerald, 2009). Recovery of protein, lipids and other unknown extractives is not considered in this study. Therefore, this block is by-passed and the homogenized OFMSW stream can either be sent to the "chemical pre-treatment" block, which abstracts the processing flowsheet of the dark fermentation platform, or to the "hydrolysis block", where the processing flowsheet for the enzymatic hydrolysis platform is placed.

Dark Fermentation platform: Dark fermentation is the anaerobic microbial conversion of organic matter to VFAs, H_2 and CO_2. The general biochemical reaction in dark fermentation can be written as:

α Biomass +β $H_20 \rightarrow \gamma$ Acetic acid + δ Propionic acid + ε Butyric acid + ζ valeric acid + θ hexanoic acid + κ H_2 + λ CO_2 + μ Microbial biomass + π others (e.g. ethanol)

The OFMSW is mixed with water and fermented in the dark fermentation reactor. For this study, a mixed microbial culture was chosen, and therefore the stream entering the

reactor does not need to be sterilized prior to the fermentation step. The stream exiting fermentation needs to be sterilized to make it suitable for pure culture downstream processes and to kill pathogens. Sterilization was simulated at 85°C for 1 hour following EU regulations on MSW sterilization (European Comission, 2005). The sterilized stream is then separated into a solid and a liquid intermediate stream. The liquid stream contains the dissolved VFAs, and can be upgraded by the demand side processes, while the solid stream is considered to be a residue.

Hydrolysis platform: The first step of the hydrolysis platform is to sterilize the OFMSW for the same reason as described above. After cooling down the OFMSW to 35 °C, an enzyme mix is added to transform sugar macromolecules into sugar monomers:

Glucan + Xylan + Arabinan + H_2O --> Glucose + Xylose + Arabinose

3. Process Simulation and Techno-Economic Evaluation

Abu Dhabi's OFMSW generation was estimated to be 348,229 t/year, based on 892,895 t/year of MSW generation in 2012 and an organic fraction of 39 % (Statistics Center Abu Dhabi, 2013). Figure 2 shows the assumed OFMSW composition for this study on a dry basis; the moisture content is 64 % (Nwobi et al., 2014).

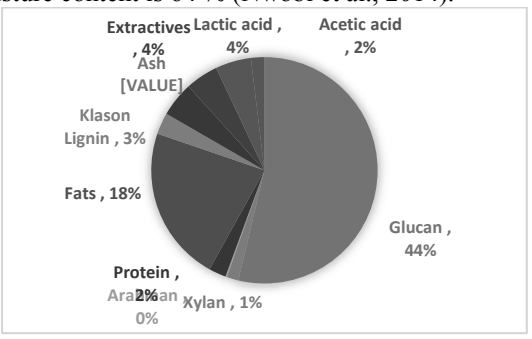

Figure 2: OFMSW composition (dry base) Nwobi et al., (2014)

Yield distribution, based on experimental data from literature, was used to simulate the fermentation reactors in both platforms. The reactor volume was calculated based on the hydraulic retention times (HRT), used in the corresponding experiments. For the sugar hydrolysis platform, an operating temperature of 35°C and a HRT of 12 hours were used (Nwobi et al., 2014). The composition of the enzyme mixture [0.1 % cellulase, 0.1 % amylase, 0.02 % protease, 0.02 % hemicellulase, 0.02 % lipase, and 0.02 % pectate lyase (w/w per TS)] is as reported in the same reference, and the cost of the enzyme was estimated to be USD 2/kg. By-product formation was also based on Nwobi et al. (2014). For dark fermentation a yield of 0.182 gVFA/gOFMSW fed (31 wt.-% acetic, 7 % propionic, 42 % butyric, 20 % hexanoic acid), a temperature of 35 °C, and a HRT of 72 hours were assumed based on literature data (Zahedi et al., 2013). Note that these yields can vary with waste composition and operational parameters.

The simulations were carried out in Aspen Plus V8.4, and equipment and operational costs settings were set at default except for the electricity price in Abu Dhabi, 0.04 USD/kWh (Abu Dhabi Regulation & Supervision Bureau, 2014) and the cost of the fermenters, 380 USD/m^3-working volume (Holtzapple et al., 2002). Centrifugation was modelled with 1% solid load of liquid outlet and 90% liquid to liquid outlet. A plan lifetime of 10 years and a 20 % rate of return were assumed for computation of the total

annualized cost (TAC). The cost of the intermediates streams was calculated by dividing the TAC by the amount of sugar monomers or VFA's produced per year.

4. Results and Discussion

4.1 Composition and cost of the liquid intermediate streams

Under the assumptions made in the previous section, 180 t/h exit as a liquid intermediate product from the dark fermentation process and 24 t/h from the enzymatic hydrolysis process, after solids separation. Figure 3 shows the composition of these liquid streams. It can be seen that the one resulting from the enzymatic hydrolysis process is mainly composed of glucose (75%, on a dry basis), and the presence of minor by-products, such as, acetic and lactic acid (during enzymatic hydrolysis) should be noted, as they could be detrimental to downstream processes. The stream exiting the dark fermentation process is composed of a dilute solution of a mixture of volatile fatty acids. The extractives were excluded from Figure 3 because their fate has not been determined in the referenced experimental data. In addition, many other by-products in small concentrations can potentially occur and hinder downstream processes and product separation.

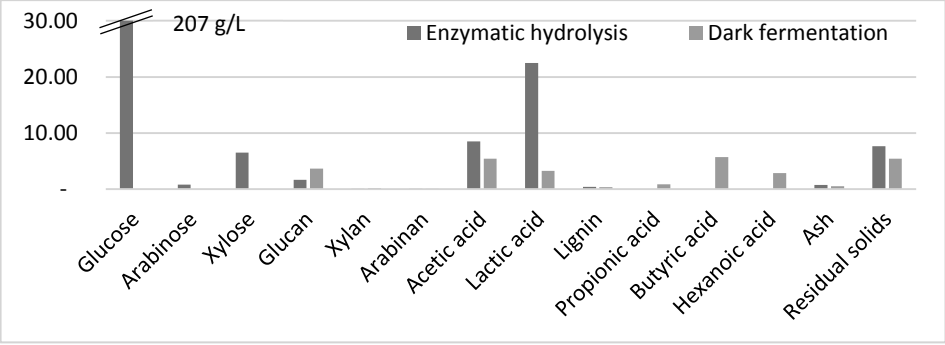

Figure 3: Liquid stream composition for dark fermentation and enzymatic hydrolysis

The cost of the intermediate stream from dark fermentation was estimated to be 335 USD/t-VFA. This cost does not include the separation cost of VFAs from water. The market price of pure VFAs lies between 400 USD/t-VFA (lower range for acetic acid) and 2500 USD/t-VFA (upper range for hexanoic acid) (Zacharof and Lovitt, 2013), and about 1500 USD/t-VFA for the VFA composition obtained in this study, thus leaving an allowance of ~1200 USD/t-VFA for water-VFAs separation and product purification processes.

The cost of the intermediate stream from enzymatic hydrolysis was estimated to be 86 USD/t-sugar monomers. In comparison, the estimated price for a stream containing 127.4 g/l of lignocellulosic sugar monomers is 222 USD/t-sugar monomers (Humbird et al., 2011). This cost is estimated by NREL for intermediate sugar production and is used to distinguish the cost of producing sugars from downstream costs of producing ethanol. The estimated total project capital cost for the dark fermentation platform is USD 13.42 million and operating costs sum up to USD 4 million per year. The estimated total project capital cost of the enzymatic hydrolysis platform is USD 7.07 million and operating costs are USD 1.35 million per year. Figure 4 shows the major cost

contributors for both processes. Operating cost represents the largest component of the intermediate stream cost in both options. In dark fermentation, the share of utilities is higher, due to the higher amount of water to sterilize. The reactor cost is a significant contributor in both cases. The relative contribution is similar in both cases, but the absolute costs for reactor and centrifuge are higher in dark fermentation because of the higher HRT and amount of water.

4.2 Possible uses of the intermediate streams

Following the costs analysis, discussed previously, both intermediate streams seem very promising, when compared to similar streams currently available on the market, and retain ample allowance for covering the cost of separation and purification steps.

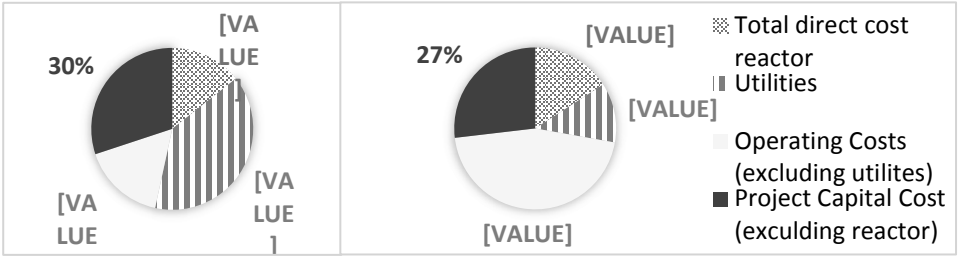

Figure 4: Major contributors to the intermediate stream cost for dark fermentation (left) and enzymatic hydrolysis (right).

However, we would like to explore here their possible use "as is" for the production of value added chemicals. As an example, the glucose-rich stream from the enzymatic hydrolysis process could be used as a feedstock for a pure engineered *E. coli*. Assuming a desired glucose concentration of 15-30 g/l for the downstream process, a dilution by a factor of approximately 10 will be needed. A possible problem is the presence of organic acids like acetic and lactic acid, as they are known to inhibit microbial activity. Vázquez et al. (2011) studied the inhibition of organic acids in *E. coli* CECT 731 at pH 7.4, finding that the concentrations that lead to 50% inhibition of growth were 178 mM (10.7 g/l) for lactic acid and 66 mM (5.9 g/l) for acetic acid. The concentrations of these two acids in the enzymatic hydrolysis stream after considering the dilution will be 2.3 g/l and 0.9 g/l, respectively. Thus, the by-products in the enzymatic hydrolysis stream will probably cause inhibition, but lower than 50%. The inhibition potential of the enzymatic hydrolysis stream depends on various factors, and needs to consider inhibitors produced in the downstream process itself. Inhibition will slow down growth, increasing the reactor volume and thus the capital cost needed. Yet, using the stream "as is" over pure glucose has advantages, such as the presence of micronutrients and other compounds that are necessary for the growth of microbes, which could result in significant savings as they would need to be supplied by, for example, a corn steep liquor of 1 % w/w, which in turn has an estimated price of 200 USD/t (Claypool and Raman, 2013). This idea has been introduced previously by Richter et al. (2013) in the context of coupling dark fermentation with syngas fermentation.

Separation of VFAs is known to be difficult in aqueous solution, due to the presence of azeotropes. Thus, the use of the VFA stream "as is" would be the more cost-effective solution. As an example, VFAs could serve as precursors for biological processes, as demonstrated by Martin et al. (2013), who produced hydroxyacids using VFAs and

glucose as substrate for metabolically engineered *E.coli*. These hydroxyacids can be used for example for the production of biopolymers (Martin et al., 2013).

5. Conclusions

This work studied the generation of streams useful for the manufacturing of value-added chemicals from OFMSW. Two alternative processes for the conversion of OFMSW to intermediate streams were simulated in Aspen Plus and the cost for their production was calculated. The costs obtained, 335 USD/t-VFA for a dark fermentation-based process, and 86 USD/tonne-sugar-monomers for an enzymatic hydrolysis-based process, compare favourably against the market prices of similar compounds. Moreover, these streams are expected to be suitable for use in "as is" form in downstream bioprocesses.

Abstract

This study deals with the development of a structured macroscopic model for the dynamic simulation of the bioethanol production through the fermentation of sugars derived from the hydrolysis of lignocellulosic biomass of the perennial herbaceous species *Phalaris aquatica* L. In the proposed model, the growth of Saccharomyces cerevisiae cultures consuming hydrolysate sugars as carbon source in parallel with the intracellular bioethanol production and excretion are quantitatively described accounting for substrate and product inhibition phenomena. A number of different feeding policies were designed and investigated on a model-base and verified experimentally in a real fermentation process. Substantial improvement on the real process performance was attained, resulting in a final ethanol concentration equal to 59.1 g/L corresponding to 2.19 g/(L·h) overall ethanol productivity.

Keywords: Bioethanol, hydrolysate sugars, fermentation, dynamic modelling.

1. Introduction

Bioethanol production from renewable resources has recently attracted worldwide attention as a strategy of enhancing the countries energy security and autonomy. However, the transition from first to second generation biofuels indicated that the potential of bioethanol as direct complementary fuel, without interfering and competing the human nutrition, is conditionally feasible on the restriction that the main resource for such a biofuel will be the abundant lignocellulosic biomass (López-Arenas et al., 2013). *Phalaris aquatica* [*Phalaris aquatica* (L.)] is one of the most promising lignocellulosic biomass feedstock in the South Europe. It is a perennial herbaceous energy grass with high content of structural carbohydrates (e.g., cellulose, hemicellulose) exceeding 70 % wt. of dry mass of the plant, thus providing an excellent source of monomer sugars (e.g., glucose) upon hydrolysis and other biomass pretreatment steps (Engel et al., 2011). It is cultivated in marginal farmlands with low nutrients and water demands, and the biomass production capacity ranges from 6.3 - 11 t/ha dry mass (Pappas et al., 2014).

The microorganism that is widely used for the fermentative ethanol production from hexoses, particularly glucose, is *Saccharomyces cerevisiae* with plenty of industrial applications. Efficient operation of the fermentation process is unambiguously not a trivial task and cannot be based on heuristic decisions, when considering the maximization of sugar to ethanol yield simultaneously with the maximization of product final concentration. An accurate mathematical model that simulates the cultivation process dynamic behaviour will provide the means for effective process operation on a systematic way.

A great deal of effort has been spent towards the development of simple or complex mathematical models for the dynamic simulation of the alcoholic fermentation process. The influence of aeration and mixing profile on the ethanol yield and productivity has been extensively studied in the open literature for cultures with microbial populations (Wan Teng and Samyudia, 2012). A more systematic modelling approach of the product inhibition was proposed by Sriyudthsak and Shiraishi (2010) who introduced the "metabolic bottleneck parameter" caused by the accumulation of an intracellular metabolite in a purely theoretical study though. Despite the various modelling approaches presented in the open literature little attention has been paid on the model-based design of the optimal operating strategy in terms of medium composition and substrate addition policy that will substantially enhance the sugars to ethanol yield and ethanol productivity. Thus, it is the objective of the present study to develop a dynamic model with predicting capabilities that will serve as a tool to optimise the process performance and to build up sufficient understanding over the influence of various process parameters (e.g., substrate and product concentrations, sufficiency or limitation of nutrients, etc.).

2. Materials and Methods

The *Saccharomyces cerevisiae* strain used was the Sigma Type II and was purchased from Sigma Aldrich. The strain was stocked at 4 ^{o}C in agar plates containing solid yeast extract-peptone rich medium. The seed preculture was prepared in Erlenmeyer flasks placed in an orbital shaker incubator (GFL 3033) at 150 rpm, at 30 ^{o}C, for 8 h. Upon sufficient growth of the preculture (i.e., at $O.D_{600}\approx1.5$), it was used to inoculate the main culture. As glucose feedstock for the main culture it was used the biomass hydrolysate, derived from the herbaceous plant *Phalaris aquatica*. The selected protocols regarding the biomass pretreatment, enzymatic hydrolysis and detoxification of the derived sugars solutions, are described in detail in a recent work (Karapatsia et al., 2014).

Fed-batch experiments were conducted in a 3 l stirred-tank glass bioreactor (BioFlo 110 Bioreactor/Fermentor, New Brunswick Scientific Co. Inc.). The bioreactor was initially loaded with 800 ml of the "main culture" medium with the following composition per litre: yeast extract, 3 g; $(NH_4)_2SO_4$, 5 g; KH_2PO_4, 3 g; Na_2HPO_4, 1 g; $MgSO_4.7H_2O$, 1 g; $Ca_2Cl_2.2H_2O$, 0.1 g and 2 ml of trace elements solution. The former solution contains (per liter): $ZnSO_4.7H_2O$, 0.9 g; $FeSO_4.7H_2O$, 0.6 g; H_3BO_3, 2 g; $MnCl_2.4H_2O$, 1.5 g; $Na_2MoO_4.2H_2O$, 0.8 g; $CoCl_2.6H_2O$, 0.8 g; $CuSO_4.5H_2O$, 0.5 g. Initial glucose concentration was adjusted at 20 g/L or 110 g/L with appropriate amount of biomass hydrolysate in the medium. The pH was regulated at 5.5 and the agitation rate of the bioreactor was manipulated in the range of 150-1000 rpm. The aeration of the fermentation broth was set at 1 vvm. The cultivation temperature was controlled at 30 ^{o}C. The nutrients composition in the feeding stream was 7.5 times concentrated compared to the "main culture" medium.

The optical density ($O.D_{600}$) of the culture was measured as light absorbance of the culture at 600 nm wavelength with the use of a UV-Vis spectrophotometer (Hitachi U-1800). Glucose and ethanol concentration in the medium was measured off-line through frequent sampling. The samples were analysed in a high performance liquid chromatograph (HPLC) with a refractive index detector (RI). A Hi-Plex H^+ Analysis column (300 x 7.7 mm) operating at 60 ^oC with 0.5 % sulphuric acid and 95.5 % water as mobile-phase (ml/min) was used. Relative standard deviations of the replicates of the measurements from the respective mean values were in all cases below 5 %.

3. Structured Model

The fermentative production of ethanol by yeast strains is a complex bioprocess involving the ethanol synthesis either simultaneously with the biomass growth (growth associated) or under relatively constant biomass (non-growth associated) with varying production rates. In the present study a structured dynamic model that accounts for the necessary intracellular and extracellular metabolites at minimum complexity and parameterization is proposed to sufficiently describe the kinetics of these metabolic phenomena and the time evolution of biomass, glucose and ethanol concentrations in the culture. It should be noted that at some critical values of glucose and/or ethanol concentrations in the medium, substrate and product inhibition with respect to biomass growth and ethanol production have been observed to occur at a significant extent (Phisalaphong et al., 2006).

The total biomass (X) is considered to be structured into three compartments. Glucose and ethanol are the two intracellular metabolites representing the two biomass compartments. The residual biomass (X_R) constitutes the third compartment. The intracellular glucose, expressed as glucose cellular quota (q_G), is the carbon substrate pool used by the cells for their metabolic activities and is continuously refilled through a glucose assimilation mechanism, as long as there is sufficient glucose (G) in the medium. Similarly, the intracellular ethanol, expressed as ethanol cellular quota (q_E), is the product pool that is accumulated in the medium through a cells excretion mechanism. Thus, a large number of simultaneous metabolic reactions can be lumped for simplicity into three main cellular activities, namely, the residual biomass growth, the maintenance of the residual biomass and the ethanol production. The system of DAEs describing the dynamic evolution of *S. cerevisiae* cultures in a bioreactor is presented below.

Residual biomass concentration, $[X_R]$: $$\frac{d(V[X_R])}{dt} = V\mu_s[X_R] - Q_{out}[X_R] \quad (1)$$

Glucose concentration, [G]: $$\frac{d(V[G])}{dt} = -V r_{Gu}[X_R] + Q_{in}[G]_{in} - Q_{out}[G] \quad (2)$$

Ethanol concentration, *[E]*: $$\frac{d(V[E])}{dt} = Vr_{Es}[X_R] - Q_{out}[E] \quad (3)$$

Glucose cellular quota, q_G: $$\frac{d(Vq_G[X_R])}{dt} = Vr_{Gu}[X_R] - Vr_{Gc}[X_R] - Q_{out}q_G[X_R] \quad (4)$$

Ethanol cellular quota, q_E: $$\frac{d(Vq_E[X_R])}{dt} = Vr_{Ep}[X_R] - Vr_{Es}[X_R] - Vr_{Ec}[X_R] - Q_{out}q_E[X_R] \quad (5)$$

Culture volume, V: $$\frac{d(V)}{dt} = Q_{in} - Q_{out} \quad (6)$$

Total biomass, $[X]$: $$[X] = [X_R] + q_G[X_R] + q_E[X_R] \quad (7)$$

The specific consumption/production rates (e.g., μ_s r_{Gu}, etc.) are defined in Table 1.

Table 1 – Net specific production/consumption species rates.

Specific residual biomass growth rate:

$$\mu_s=\mu_{s,max}\frac{q_G/q_E}{K_G+q_G/q_E}\left(1+\exp\left(-\frac{G_{max}-[G]}{a_1}\right)\right)^{-1}\left(1+\exp\left(-\frac{E_{max}-[E]}{a_1}\right)\right)^{-1}\{1+\mathcal{H}(G/E-GE_c)\}\,\mathcal{H}(q_G-q_{G_{min}}) \quad \text{(i)}$$

Glucose specific uptake rate:

$$r_{Gu}=r_{Gu_{max}}\frac{[G]}{K_{Gu}+[G]}\mathcal{H}(q_{G_{max}}-q_G) \quad \text{(ii)}$$

Intracellular ethanol specific production rate:

$$r_{Ep}=\left(K_{E1}\mu_s^2+K_{E2}\,\mathcal{H}(q_G-q_{G_{min}})\right)\left(1+\exp\left(-\frac{XE_c-[X_R]/[E]}{a_2}\right)\right)^{-1} \quad \text{(iii)}$$

Ethanol specific secretion rate:

$$r_{Es}=r_{Es_{max}}\left(1+\exp\left(\frac{q_{E_c}-q_E}{a_3}\right)\right)^{-1}-r_{Eu_{max}}\frac{[E]}{K_{Eu}+[E]}\left\{1-\mathcal{H}(q_G-q_{G_{min}})\right\} \quad \text{(iv)}$$

where, $r_{Es_{max}}=K_{E1}\mu_{s,max}^2+K_{E2}$

Glucose specific consumption rate:

$$r_{Gc}=\left[\frac{1}{Y_{XG}}\mu_s+K_{Gm}\{1+\mathcal{H}(G/E-GE_c)\}+\frac{1}{Y_{EG}}r_E\right]\mathcal{H}(q_G-q_{G_{min}}) \quad \text{(v)}$$

Ethanol specific consumption rate:

$$r_{Ec}=r_{Eu_{max}}\,\mathcal{H}(q_E-q_{E_{min}})\left\{1-\mathcal{H}(q_G-q_{G_{min}})\right\} \quad \text{(vi)}$$

Heaviside function defined as $\mathcal{H}(Y-Y_c)=\begin{cases}1, \text{ when } Y>Y_c\\ 0, \text{ when } Y\le Y_c\end{cases}$

The proposed specific rates introduce a number of unknown model kinetic and bioprocess parameters. These parameters were determined from a series of batch and fed-batch cultivation experiments through the fitting of the model predictions to experimental measurements using the gPROMS® (PSE Ltd.) parameter estimator, based on the Maximum Likelihood formulation.

4. Results and Discussion

4.1. Screening of operating strategies- Evaluation of model performance

The proposed mathematical model it was primarily tuned using experimental data form a number of batch and fed-batch fermentation processes representing a wide range of cultivation conditions. Then it was used to design and investigate specific fed-batch operating strategies targeting to the improvement of the process performance and to identify the policy that leads to high ethanol production and efficient utilization of substrate.

Two fed-batch operating strategies with different substrate addition profiles were first designed and evaluated on a model-base and then they were tested in the real fermentation process. Both strategies refer to a bioreactor that was initially loaded with the main culture medium with initial glucose concentration equal to 20 g/L. However, in the first operating policy, the culture was supplemented at a constant feeding rate (*constant addition policy*). The onset of the addition was decided from a relatively early stage of culture growth to create sufficiency of every nutritive ingredient and mainly substrate for a long period. In the second strategy, the feeding profile was adjusted so that the glucose provision rate would be close to the consumption rate (*conservative addition policy*).

In the bioreactor operating under the constant feeding strategy, a state of nutrients and substrate sufficiency (not excess) in the medium was induced for a long period of time. Under such conditions biomass production was favored while the ethanol production was of lower priority as shown in Figure 1. After 24 h over 240 g of glucose were consumed, however ethanol concentration did not exceed 23.54 g/L reflecting a yield of only 9.8 % (of the respective theoretical yield) and ethanol productivity 0.98 g/(L h).

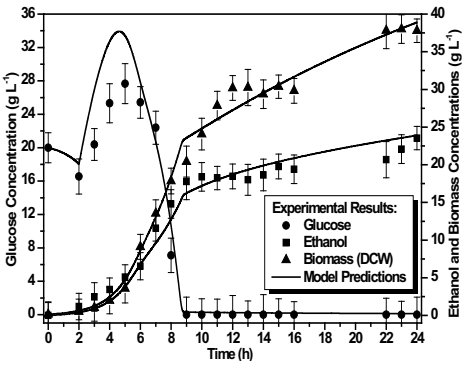

Figure 1. Time profile of glucose, ethanol and biomass concentrations in the bioreactor-scale fed-batch experiment under the *constant addition policy*.

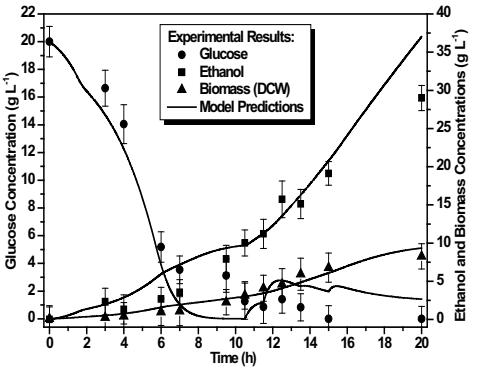

Figure 2. Time profile of glucose, ethanol and biomass concentrations in the bioreactor-scale fed-batch experiment under the *conservative addition policy*.

Upon such a low process performance the *conservative addition policy* was designed aiming at generating such culture conditions under which the culture was exposed at some degree to substrate and nutrients limitation in order to assess the process performance. In that case the feeding started after approximately 10.5 h from the beginning of the culture and the addition rate was progressively adjusted according to the culture response. The final ethanol concentration increased up to 29 g/L raising the ethanol yield to 24.73 % (of the respective theoretical maximum yield) and the ethanol productivity to 1.45 g/(l h). The dynamic simulation of process behavior, with respect to the selected bioprocess variables, is displayed in Figure 2. Note that the model predictions are in satisfactory agreement with the respective experimental data derived under both strategies, which clearly demonstrates adequacy of the estimated model parameters and the predicting capabilities of the proposed model.

4.2. Fed-batch strategy for improved process productivity

In order to investigate the process dependence on the substrate availability at the onset of the cultivation, a bioreactor experiment was conducted with an exponential-like addition policy, initially loaded with 110 g/L glucose. The glucose concentration in the feeding stream was 300 g/L. In Figure 3 the time profile of the three model variables (i.e., glucose, ethanol and biomass concentration) applied in the bioreactor are presented. Due to the high initial glucose concentration and the provoked substrate inhibition effect a retardation of 6 h is observed in both the culture growth and the ethanol production. From that point onwards the cultures progressively proceeded to the exponential growth phase. It should be pointed out that nineteen hours after the beginning of the culture, the ethanol production, the glucose consumption and the biomass growth rates slowed down even though there was sufficient substrate available in the medium. The reason behind this phenomenon was the product inhibition effect which emerged upon a considerable ethanol accumulation in the medium with a consequent osmotic stress on the cells (Maiorella, 1983). The performance criteria for that operating strategy shown a final ethanol concentration equal to 59.1 g/L, however with a large amount of glucose consumed for maintenance of the cells and/or other possible products (such as glycerol), supressing the glucose to ethanol yield to 24.77 % (of the respective theoretical yield), retaining the ethanol productivity to a satisfactory

level, 2.19 g/(L h). That fed-batch strategy was fully verified in the real process. The excellent agreement of the model predictions with the experimentally measured process variables clearly proves the model capability to simulate and predict the metabolic phenomena and the culture growth rate under various environmental conditions.

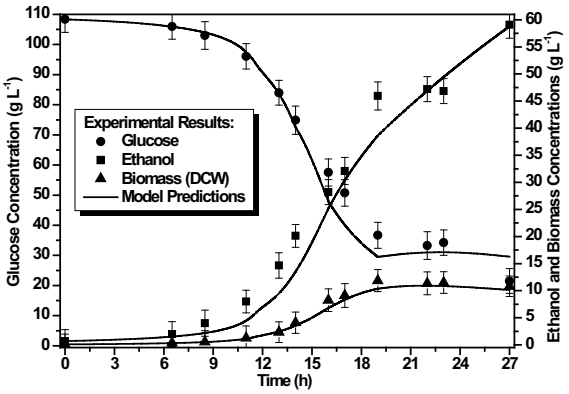

Figure 3. Time profile of glucose, ethanol and biomass concentrations in the bioreactor fed-batch experiment under high initial glucose loading with exponential addition policy.

5. Conclusions

The present work investigated the growth of the *S. cerevisiae* culture and the potential of this culture for ethanol fermentative production on sugars derived from the hydrolysis of lingocellulosic biomass. In this study great emphasis was given on identifying and quantifying the effect of the environmental conditions on the bioprocess dynamic behaviour as well as various inhibition effects (e.g., product and substrate inhibition) and the resulting metabolic bottleneck or metabolic deviations from the desired products they provoke. A comprehensive structured mathematical model for the fermentative ethanol production by *S. cerevisiae* was developed to assist in this objective. The developed model was tuned and validated against experimental data. The predictive capabilities of the proposed model underline its importance as a valuable simulation tool for process optimization and scaling-up studies.

Abstract

For the production of new and more sustainable products, new technologies need to be developed. Within process intensification, reactive distillation which is the integration of reaction and distillation in one apparatus is one known technology. A new concept is to integrate enzymes into the distillation column which enables new or more selective reaction routes. However, matching operating windows is difficult due to for example the temperature sensitiveness of the enzyme. Here, modeling is an important tool for design, scale-up, analysis and optimization of chemical and biochemical processing by enzymatic reactive distillation systems. The lipase-catalyzed transesterification of ethyl-butyrate with *n*-butanol is highlighted, which is an equilibrium-limited reaction. Based on kinetic data and investigations of a surface coating to provide the enzyme into the reactive section, a detailed model of a continuous enzymatic reactive distillation is developed in Aspen Custom Modeler®, including hydrodynamic and mass transfer investigations of coated reactive packings. Subsequently, the detailed model is validated against experimental data of a pilot-scale enzymatic reactive distillation column with a diameter of 50 mm to check the agreement between experiments and modeling.

Keywords: Process intensification, process simulation, catalytic distillation, biocatalysis

1. Introduction

Biocatalytic reactions play an important role in development of more sustainable products and processes. Enzymes are enantio- and regioselective catalysts and capable of using a huge range of substrate molecules. But they are still able to produce the desired product with a high selectivity and a high conversion rate. Reactive distillation integrates reaction and separation in one unit operation which allows overcoming an equilibrium-limited conversion as well as thermodynamic boundaries. This leads to savings in operational and capital costs. Thus, the combination of reactive distillation and enzymatic reaction creates synergies enabling efficient production of totally new products. Paiva et al. (2003) and Heils et al. (2012) presented enzymatic reactive distillation (ERD) in batch mode, but no modeling approach of either batch or continuous ERD has been investigated yet.

The challenge of the process is how enzymes are applied in distillation columns to match the operating window of reaction/enzyme and separation. A homogeneous addition of enzyme is not feasible, since it will pass the reboiler and will denature at high temperatures. For the immobilization of enzymes within the column, the method of choice is the coating of wire gauze packing with a sol-gel that contains entrapped enzymes (Figure 1) (Heils et al., 2012). The coating covers not only the wires of the packing, but also seals the gaps between the wires. Hence, the packings mass transfer features are modified which means that hydrodynamics and mass transfer phenomena need to be experimentally investigated. Here, modeling is an important tool for design, scale-up, analysis and optimization of ERD systems. Therefore, an integrated approach of experiments and modeling is performed at different scales from laboratory-scale up to pilot-scale in which the accuracy of the model, the feasibility and performance analysis of the concept is stepwise increased to reduce experimental effort, costs and process uncertainties.

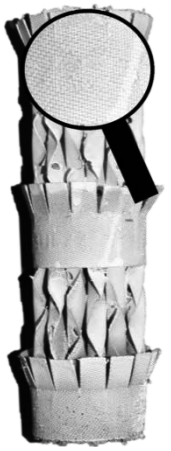

Figure 1: Magnified coated packing Sulzer BX^{TM}.

2. Materials and Methods

The integrated approach is depicted in Figure 2 in which the three subdomains experiments, modeling and process analysis are conducted simultaneously. That is essential to evince process feasibility and to verify the validity and transferability of all three subdomains because of existent uncertainties in model and experiment.

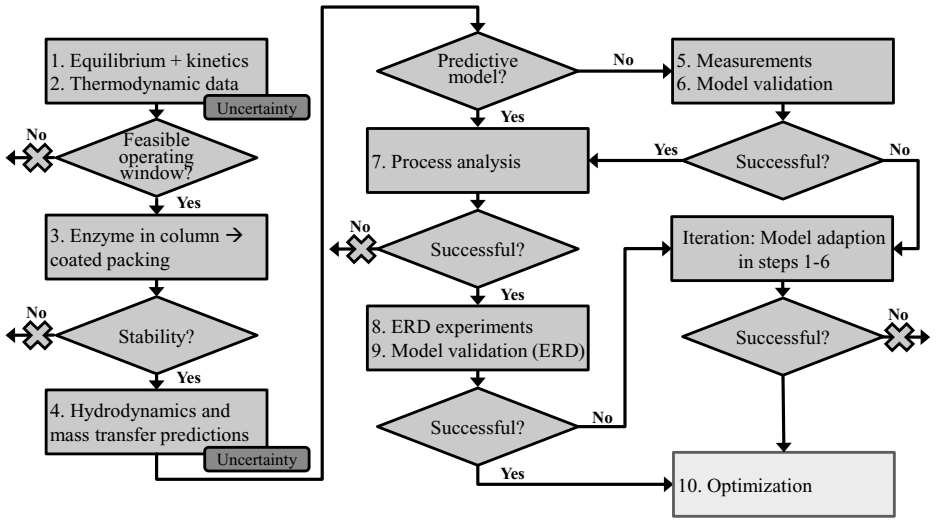

Figure 2: Integrated approach as a way of proceeding for enzymatic reactive distillation (ERD). Rectangles signify steps, that may contain uncertainties and rhombuses signify decisions.

The sizes and features of the experimental set-up as well as the model are shown in the following subsections. As a case-study, the transesterification of ethyl butyrate is used as a model system (Figure 3), catalyzed by *Candida antarctica* lipase B (CalB). For mass transfer investigations of the packing (step 5), the binary system of n-butanol/iso-butanol (nBu/iBu) is used (Table 1).

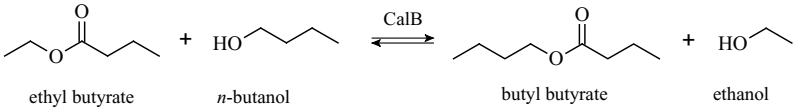

Figure 3: Transesterification of ethyl butyrate (EtBu) and *n*-butanol (BuOH) to butyl butyrate (BuBu) and ethanol (EtOH) catalyzed by *Candida antarctica* lipase B (CalB).

2.1. Experimental set-up

The pilot-scale ERD (step 8, Figure 2) and the distillation set-up to measure HETP values with *n*-butanol/*iso*-butanol (nBu/iBu) system (step 5, Figure 2) are described in Table 1. The column is equipped either with coated or uncoated Sulzer BX^{TM}. The two mid-sections are composed of (enzymatic) reactive packing. The sections are connected by liquid distributors that contain sample withdrawing points and PT100-thermocouples for vapor temperature measurements.

Table 1: Set-up for the distillation column and parameter window for distillation and enzymatic reactive distillation (ERD) experiments.

Distillation Column			
h_{column} [m]		5.12	
d_{column} [m]		0.05	
$N_{sections}$ (reactive/coated) [-]		6 (2)	
Enzymatic reactive distillation		**Distillation**	
Substrate ratio (EtBu/BuOH) [mol/mol]	3.62	Substrate ratio (nBu/iBu) [mol/mol]	9.00
ṁfeed [kg/h]	2	ṁfeed [kg/h]	4
D/F [kg/kg]	0.605	D/F [kg/kg]	-
RR [kg/kg]	2.8	RR	∞
F–factor [$Pa^{0.5}$]	0.96	F–factor [$Pa^{0.5}$]	0.7 – 1.6

2.2. Modeling

Modeling is required in steps 1, 2, 4, 6, 7, 9 and 10 in the integrated approach (Figure 2). An equilibrium stage model by Holtbruegge et al. (2013) and Niesbach et al. (2013) is used for the simulations. It utilizes HETP values to calculate concentration and temperature over the column height, since there is no sufficient knowledge of mass transfer phenomena and hydrodynamic behavior with self-made coated packing (Figure 1) so far.

3. Results

Within this section a short overview on the most important results for each step of the integrated approach is presented.

3.1. Step 1: Equilibrium + Kinetics and Step 2: Thermodynamic data

For kinetic measurements for the enzymatic transesterification of ethyl butyrate granulates of the coating within 1 mm of diameter were used (Heils et al., 2014). The Michaelis-Menten double-substrate kinetic was applied to calculate the reaction rates. Those depend on actual concentrations as well as temperature and are investigated for the concentration and temperature ranges, occurring in the column. Temperature dependency was concerned by using Arrhenius equation. However, the transferability of the lab-scale kinetic measurements based on granulate to the packing concept (step 3) is uncertain. Thermodynamic and physical data, such as vapor-liquid-equilibria and

viscosities, are calculated by Abrams UNIQUAC method (Abrams and Prausnitz, 1975).

3.2. Step 3: Enzyme in Column

Within this work, wire gauze packing with a sol-gel coating that contains entrapped enzymes has been used for incorporating enzymes into the column (Figure 1) and the stability of this coating for several batches has been presented before (Heils et al. 2012). However, within continuous processing the stability is not known. Kinetics and thermodynamic data led to a feasible operating window with a stable enzyme inside the column.

3.3. Step 4-6: Mass transfer and hydrodynamics

The characteristic value to describe mass transfer phenomena in an equilibrium based-on model is the height equivalent to a theoretical plate (HETP). HETP values are received from distillation experiments and differ with liquid and gas load expressed by the F-factor with gas velocity and density (Eq. (1)).

$$F\text{–}factor = w_G\sqrt{\rho_G} \tag{1}$$

In Table 2 the dependency of the HETP-values of coated packing to column pressure and gas loads (F–factor) is presented using measurements of the system nBu/iBu. The HETP-value for F-factors greater than one remains constant at around 0.242 m. For lower F-factors the HETP-value decreases significantly.

Table 2: Measured HETP-values for SulzerBX^{TM} packing depending on the F-factor.

F–factor [Pa$^{0.5}$]	HETP uncoated packing [m]	HETP coated packing [m]
0.75	0.117	0.171
0.94	0.148	0.223
1.18	-	0.241
1.38	0.148 / 0.152	0.242
1.59	-	0.244

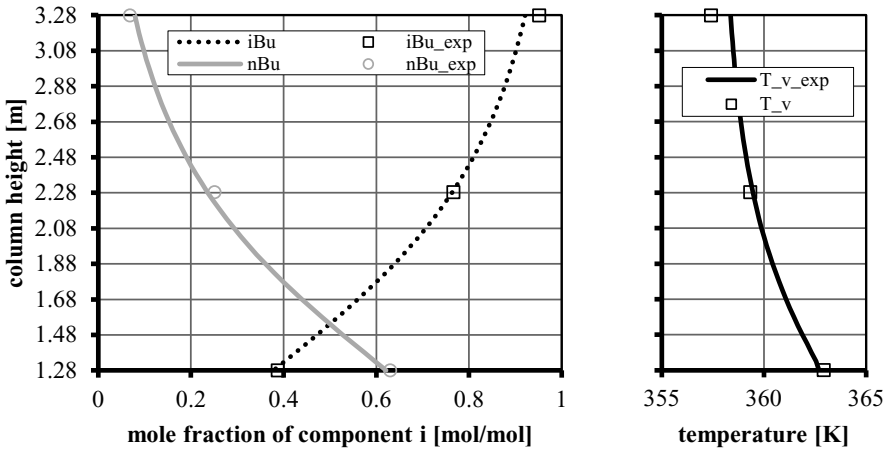

Figure 4: Column profile with mole fractions of the components and vapor temperature, respectively for experimental HETP-value measurements and the simulation thereof for the testing section. Simulated results are represented by lines and the experimental values by marks.

The HETP-values for the coated packing are around 40 % higher than for uncoated packing. The accuracy of the model is shown in Figure 4. The simulated concentration and temperature profile of the coated packing in the column cover the experimental results with only a slight averaged deviation of below 1.5 wt% and 0.27 K. With these results the model is validated regarding mass transfer.

3.4. Step 7-9: Process Analysis, Experiments and model validation of Enzymatic Reactive Distillation

Process analysis is used to assess a suitable operating window (step 7), in which the ERD is stable (step 8). Subsequently, an analysis of experimental data and simulation results is performed for model validation to find out whether prudential adaptions are necessary (step 9). The process analysis (step 7) revealed to a usage of a column pressure of 14.2 kPa and 0.0483 kg/m CalB in the reactive section in order to gain a conversion of 35.79 % for *n*-butanol and 9.90 % for ethyl butyrate with the set-up in Table 1. Nevertheless, experimental conversions (step 8) amount to 85.99 % for *n*-butanol and 23.78 % for ethyl butyrate. Thus, model validation failed (step 9) and the model needs to be improved. Mass transfer issues are not the key for improvement, since conversion is too low. A sensitivity analysis showed that the mass of CalB has a high impact on the conversion, so adjusting the kinetics is a reasonable attempt (iteration step). The kinetics were obtained with granulates of the coating with a diameter of 1 mm (Heils et al., 2014), to the contrary in this study coated packing with a coating width of 34 µm is used. We assume that due to diffusion limitations in the granulate the enzyme in the core of the granulate does not contribute to the conversion. Consequently, the kinetics including the mass of CalB are underestimated. Due to low conversion of the simulation compared to the experiment, CalB mass in the model is increased until simulated and experimental conversions equal each other. This occurs at 0.5 kg/m CalB in the reactive section. A column profile of the simulated (lines) and experimental (marks) components mole fraction and temperature is depicted in Figure 5. The graphs confirm a good agreement of the simulated and experimental profiles.

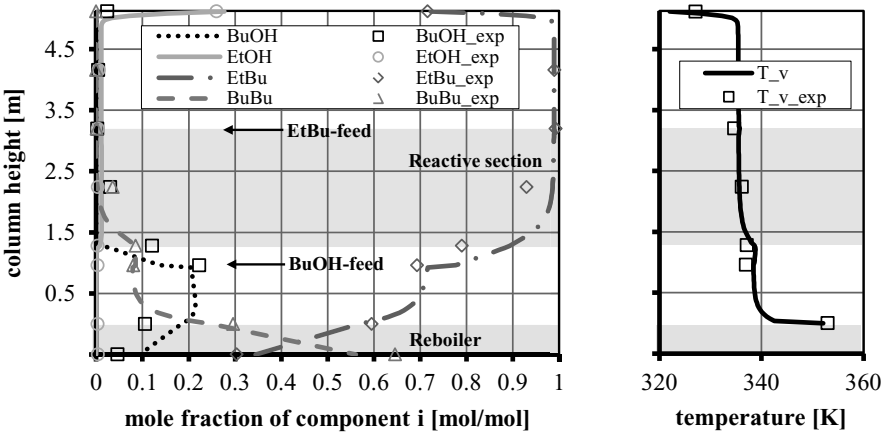

Figure 5: Column profile with mole fractions of the components and vapor temperature T_v, respectively. The reactive section, the reboiling section as well as the position of the feed streams are highlighted in the figure. Simulated results are represented by lines and the experimental values by marks.

Furthermore, it is verified that the temperature in the reactive section below 343 K is sufficient to prevent immobilized CalB from denaturation. Additionally, enzyme leaching from the reactive section into the stripping section of the column might be present due to stability issues of the coating (uncertainty step 3-4). Prospectively, these issues will be investigated. To conclude, an underestimation of the kinetics is only observed because of the simultaneous elaboration of modeling and experimental investigation. Model validation is confirmed by a good agreement of experimental and simulated data. Feasibility of ERD is proven.

4. Conclusions

In this work, feasibility of a continuous ERD was proven. Mass transfer for coated packing to provide enzyme in a distillation column using the HETP was investigated to be 40 % higher compared to uncoated Packing Sulzer BX^{TM}. A simulation model was validated for mass transfer phenomena for coated packing without reaction with only a slight deviation of 1.5 wt%. An approach to investigate ERD being a necessity for a simultaneous elaboration of experiments and modeling is described within this work in order to receive trustful results with small experimental and computational effort. The investigated kinetics are not valid to use in the set-up and an adaption of the kinetics increased the reliability of the model significantly.
In future work, kinetics will be determined for the reactive coated packing in order to validate the ERD model. Additionally, studies for coating stability will be accomplished.

Abstract

This work aims to optimally design a metabolator, which is a metabolic process of Acetyl Co-Enzyme A (Acetyl-CoA) and its co-factors, with a view to incorporate uncertainty. The metabolic process can be described using a dynamic model involving nonlinear differential equations. An artificial neural network (ANN) transformation is utilised in order to transform the dynamic model of the metabolator into a system of simultaneous algebraic equations. The metabolator simulation problem is first solved and then the design problem is formulated as an optimisation problem, where the objective is to control the concentrations of Acetyl-CoA at desired set-points by manipulating the glycolytic flux. A non-linear model predictive control (NLMPC) formulation is then presented for computing the value of the source energy for the system, the glycolytic flux, which is used as the control variable. In this work Zone NLMPC is used to address the effect of uncertainty in the glycolytic flux as the system is allowed to perform within a range rather than at a fixed set point.

Keywords: Artificial Neural Network, Model Predictive Control, Gene Oscillator, Model-Based Design

1. Introduction

Synthetic biology has garnered much interest in the last few years as a means of understanding how biological systems can be adapted or exploited to give more favourable outcomes. Current research within the field of synthetic biology includes research into protein engineering, systems engineering and gene networks. Many of these systems utilise E.Coli as a natural chassis for testing models. E.Coli is used mainly as it can be grown easily in the laboratory and has relatively simple genetics that can be manipulated. Non-infectious strains are able to be constructed for testing purposes; however one of the main disadvantages of using a natural chassis is that one cannot achieve adequate control in biological synthesis.

Early approaches of creating a synthetic oscillatory network have been researched by Elowitz and Leibler (2000) who showed that it is possible to construct gene networks from components that are naturally available in other systems. In this work, we consider the metabolator system presented by Fung et al. (2005). The metabolator consists of two metabolite pools, one for Acetyl-CoA (M1), and another for Acetyl-CoA's upstream and downstream metabolites, Acetate (OAc/HOAc) and Acetyl Phosphate (AcP) respectively. Acetate Kinase (Ack) closes the cycle by catalysing conversion of Acetyl

Phosphate and Acetate and together with this substrate/product pair forms the pool M2. The two pools are connected by a reaction converting Acetyl-CoA to Acetyl Phosphate catalysed by Phosphate Acetyltransferase (Pta) (E1), and a feed-forward reaction from the Acetate formed from Acetyl Phosphate (by Ack in M2 by acetyl synthase (Acs) (E2). The influx of glycerol, fatty acids and sugars (glycolytic flux) into the Acetyl-CoA pool (M1), causes its concentration to oscillate. As a result Pta feeds mass into the metabolite pool M2 to produce acetate. Acetate is then used for various purposes by the cell or protonated and exported or returned to the Acetyl-CoA pool by Acs. However an increase in acetate will also have an additional positive feed–forward effect because the levels of acetate in the M2 pool can upregulate the levels of the Acs enzyme to increase the movement of mass back from the M2 pool to M1. Furthermore the two pools are also connected by a negative feedback reaction to decrease levels of Phosphate Acetyltransferase (Pta, E1) when Acetyl Phosphate concentrations increase and this slows down the rate at which metabolites move from M1 to M2 pools. This synergistic system is presented in Figure 1.

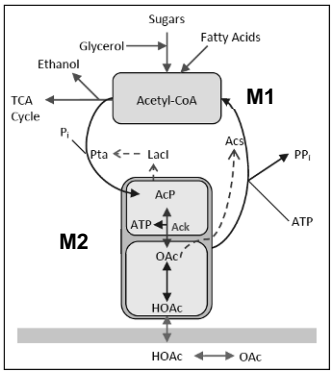

Fig. 1. In vivo realisation of the metabolator. The metabolic pools are represented by M1 and M2, and the enzymes, E1 and E2, are represented by Pta and Acs respectively.

Fung et al. (2005) also formulated a nonlinear ordinary differential equations (ODEs) model that represented the dynamics of the system and simulated the model using MATLAB (Mathworks, 2014). In this paper the main objective is to design the system to deliver a given desired performance by tracking a pre-determined profile of Acetyl-CoA through manipulation of its source energy, glycolytic flux (Vgly). The problem is formulated and solved as a nonlinear model predictive control (NLMPC) problem (Dua, 2006), where concentration of Acetyl-CoA is the controlled variable and the glycolytic flux is the control variable. The resulting NLMPC problem is transformed into a nonlinear programming (NLP) problem by transforming the ODEs into algebraic equations (AEs) using an Artificial Neural Network (ANN) transformation (Dua and Dua, 2012). The resulting NLP problem is solved using GAMS (Brooke et al., 1998).

This work also aims to investigate the use of a control system on a gene metabolator with view to modify the system outcomes through artificial regulation. Further control is achieved using Zone model predictive control (Zone MPC) (Gonzalez et al., 2009) as a means of confining the system in a pre-determined region. It has shown much success in modelling the pancreas and its effect on the glycaemic levels of insulin in the body (Grosman et al., 2010). It is particularly useful in controlling complex dynamic systems as it creates a region within which the system output is constrained, instead of tracking a

fixed set-point. In regards to the metabolator we confine the enzyme and co-factor outputs to a given region. It can also aid with addressing uncertainty in models. In the research by Grosman et al. (2010) the main uncertainty was an external meal announcement factor that affected the glucose levels in the subjects. Three modes were chosen for the meals; announced and unannounced at their normal value and with 40% uncertainty. The results from the Zone-MPC showed that meal announcement decreased the amount of glucose in the body, however once errors in carbohydrate estimation were considered, unannounced Zone-MPC was considered a good alternative in modelling the glycaemic levels in test subjects We believe that in the case of the metabolator Zone-MPC can help with understanding and controlling the effect of uncertainty in the glycolytic flux entering the system, much in the same way as that shown for glucose in patients following meals.

2. Results and Discussion

Figure 2 shows the simulation profiles obtained by using ANNs to transform ODEs to AEs. Here we see a loss of oscillations in the metabolite concentration with an increase in the glycolytic flux rate. The results from the simulation model show good comparison with that of the experimental results achieved in the case study (Fung et al., 2005). Moreover, when the acetate concentration increased there was a distinct change in the system activity and oscillations reach a steady state. This is expected because if acetate is increased there is an increase in the acidity of the environment, which therefore causes breakdown of the metabolator. The simulation results were verified using a Fourth Order Runge Kutta (RK4) method. This was carried out to gain confidence in the ODE to AE transformation using ANNs.

The NLMPC model was then developed with aim to control the system using the glycolytic flux (Vgly). This control variable was able to successfully track the set activity for the enzyme that was programmed into the model. Results for this can be seen in Figures 3 and 4. As can be seen from figure 4a the system is predicted to be able to follow the set points. It can be seen that the system responds well with smaller variation in the set points and is able to track the desired pattern. The next objective was to look at longer time frames and see if the system could adjust to more variations. The system again can be seen to respond well to the variations in the set points. As can be seen in Figure 4b the response from Vgly is expected. When the set concentration of Acetyl-CoA is increased in the system Vgly is also increased to help drive metabolite pool M1. This is typical of the synergistic relationship in the metabolator that was discussed earlier.

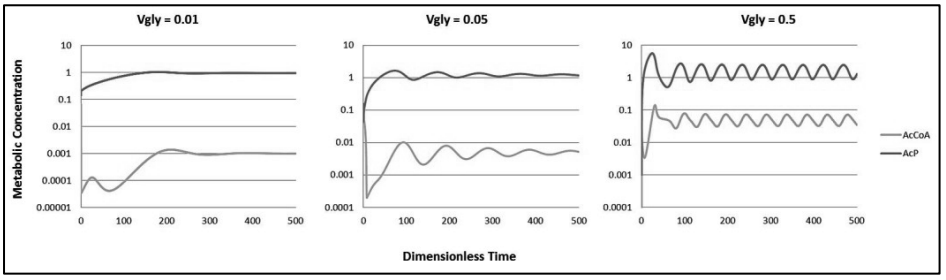

Fig. 2. Oscillation results obtained for the metabolite, Acetyl-CoA, and its co-factor, Acetyl Phosphate against time.

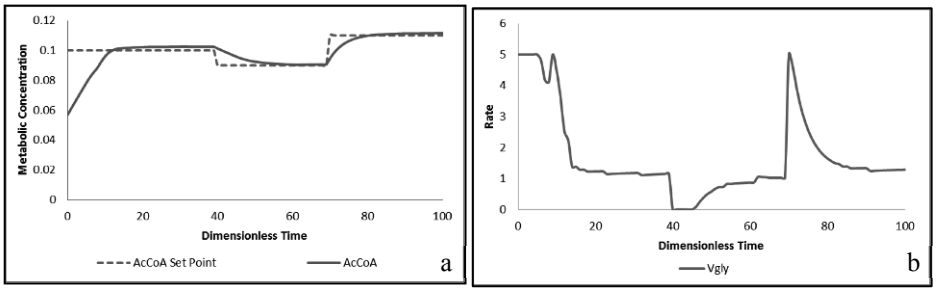

Fig 3. a. graph to show the NLMPC results for Acetyl-CoA at small variations in the set points (dashed) and (solid) shows the tracking of the system, b. graph to show the concentration of Vgly in the system showing the fluctuations required to track the set points.

The Zone NLMPC model was then established with a view to address uncertainty of the glycolytic flux within the model. It creates a range that the system is allowed to oscillate within, and therefore aims to constrain the system output to lie within this range. The results from this can be seen in Figure 5. As can be seen in Figure 5 the system is able to stay within the given range, and the resulting oscillations for glycolytic flux are less varied and extreme when compared to previous NLMPC results. Indeed rapid changes in glycolytic rate are needed only very transiently and are rapidly reset to smaller, stable adjustments in flux that persist until the next desired change in Acetyl-CoA set point. A constraint on the rate of change of Vgly, denoted as Dvgly, is applied to control the rate of glycolytic flux entering the metabolator. This has significant effect on the response of Vgly as the peak values are smaller than when constraints on Dvgly are not imposed. This provides a platform for experimental applications of the metabolator in vivo.

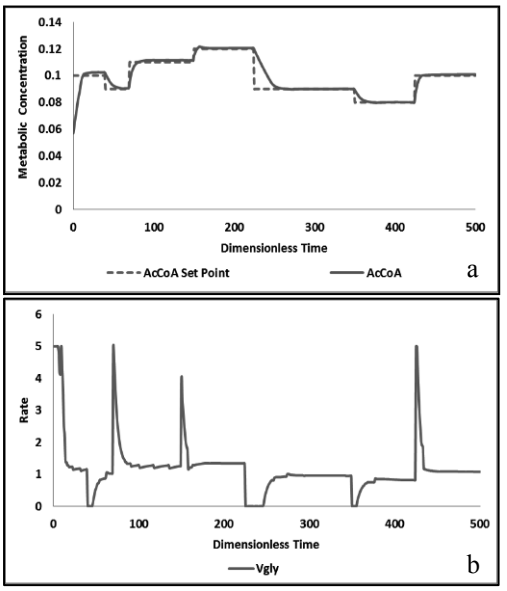

Fig 4. a. graph to show the NLMPC results for Acetyl-CoA at small variations in the set points (dashed) and (solid) shows the tracking of the system, b. graph to show the concentration of Vgly in the system showing the fluctuations required to track the set points.

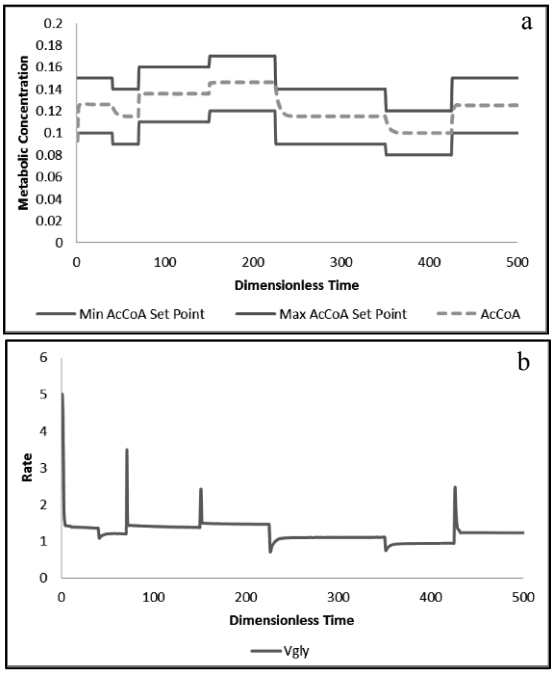

Fig 5. a. graph to show the Zone NLMPC results for Acetyl-CoA at small variations in the set points (solid lines) and tracking of the system (dashed), b. graph to show the rate of Vgly in the system showing the fluctuations required to track the set points, 0.00001 ≤ Dvgly ≤ 10.

3. Methods

A Fourth Order Runge-Kutta transformation (RK4) was utilised in order to validate the metabolator ANN/ODE model. A brief description of the ANN based framework by Lagaris et al. (1998) is presented in Equation (1).

$$G\left(\vec{x}, \Psi(\vec{x}), \nabla\Psi(\vec{x}), \nabla^2\Psi(\vec{x})\right) = 0, \qquad \vec{x} \in D \tag{1}$$

where $\vec{x} = (x_1, \ldots, x_n) \in R^n$, $D \subset R^n$ denotes the definition domain and $\Psi(\vec{x})$ is the solution to be computed. In order to obtain the solution for Equation (1) a collocation method was utilised. This assumes discretisation of the domain D and the boundary S into the set points $\hat{D}$ and $\hat{S}$ respectively. The problem is then transformed into the following Equations (2)-(4).

$$G\left(\vec{x}_i, \Psi(\vec{x}_i), \nabla\Psi(\vec{x}_i), \nabla^2\Psi(\vec{x}_i)\right) = 0, \qquad \forall\vec{x}_i \in \hat{D} \tag{2}$$

If $\Psi_t(\vec{x}, \vec{p})$ symbolises the trial solution with adjustable parameters $\vec{p}$ then the equations is transformed to give:

$$\min_{\vec{p}} \sum_{\vec{x},\in\hat{D}} \left(G\left(\vec{x}_i, \Psi_t(\vec{x}_i, \vec{p}), \nabla\Psi(\vec{x}_i, \vec{p}), \nabla^2\Psi(\vec{x}_i, \vec{p})\right)\right)^2 \tag{3}$$

In their approach the trial solution Ψ_t employs a feed forward neural network and the parameters $\vec{p}$ correspond to the weights and biases of the neural network. A form is

chosen for the trial function $\Psi_t(\vec{x})$ such that it satisfies the boundary conditions by default, Equation (4).

$$\Psi_t(\vec{x}) = A(\vec{x}) + F(\vec{x}, N(\vec{x}, \vec{p})) \quad (4)$$

where $N(\vec{x}, \vec{p})$ is a single output feed forward neural network with parameters $\vec{p}$ and n input units are fed with the input vector $\vec{x}$. The boundary conditions are satisfied by $A(\vec{x})$, which contains no adjustable parameters. The second term, F, is constructed in a way that it does not contribute to the boundary conditions as $\Psi_t(\vec{x})$ must also satisfy them. This term however employs a neural network whose weights and biases are adjustable in order to manage the minimisation problem. It is also noted that the objective function has been reduced from a constrained to an unconstrained optimisation problem.

4. Conclusions

In this paper the metabolator has been successfully simulated using the ANN transformation, with validation achieved through the use of Fourth Order Runge Kutta (RK4). The neural network has been applied to transform the ODEs into algebraic equations and simulation has shown this to mimic results published by Fung et al (2005). The metabolator was then optimally controlled using a control system (MPC) to gauge the effect of glycolytic flux on performance. Uncertainty in flux was then addressed using Zone-MPC, which gave promising results, and will be paramount in future experimental work.

Abstract

The need for high-concentration formulations for subcutaneous delivery of therapeutic monoclonal antibodies (mAbs) can present manufacturability challenges for the final ultrafiltration/diafiltration (UF/DF) step. Viscosity levels and the propensity to aggregate are key considerations for high-concentration formulations. This work presents a novel framework for deriving a set of manufacturability indices related to viscosity and thermostability to rank high-concentration mAb formulation conditions in terms of their ease of manufacture. This is illustrated by analysing published high-throughput biophysical screening data that explores the influence of different formulation conditions (pH, ions and excipients) on the solution viscosity and product thermostability. A decision tree classification method, CART (Classification and Regression Tree) is used to identify the critical formulation conditions that influence the viscosity and thermostability. Polynomial regression techniques combined with the impact of protein concentration-time profiles and flux decay behaviour during UF/DF are used to transform the experimental data into a set of stress maps which show viscosity and thermostability as functions of the formulation conditions and time profiles during UF/DF. Manufacturability indices are derived from analysis of the stress maps and the process conditions experienced in the final UF/DF step. The indices are used to identify the optimal formulation conditions that minimize the potential for both viscosity and aggregation issues during UF/DF.

Keywords: data mining, high-concentration protein formulation, manufacturability index, multivariate regression, viscosity, aggregation.

1. Introduction

Therapeutic monoclonal antibodies (mAbs) have been successful in treating a number of chronic conditions such as autoimmune diseases Subcutaneous delivery of mAbs is becoming increasingly preferred over intravenous routes since they allow patient self-administration in the home; this improves patient quality of life and treatment compliance. However, subcutaneous delivery necessitates high-concentration protein formulations of more than 100g/L (Harris et al., 2004; Rao et al., 2012). This can present manufacturability challenges for the final UF/DF step used to achieve the final product concentration and buffer exchange into the formulated conditions. The high concentrations result in high viscosities that can impact the UF/DF performance (He et al., 2010; Shire, 2009). It is critical to be able to choose the optimal formulation for both efficacy and manufacturability in terms of being able to process the material in the final UF/DF step.

This paper presents a proposed methodology for the derivation of viscosity indices that consider the impact of the protein concentration-time profiles on manufacturability, whilst accounting for the expected flux decay behaviour during UF/DF. Multivariate regression and calculus techniques are used to transform experimental data into a set of viscosity stress maps as a function of the formulation conditions and the time profiles during UF/DF and finally to derive the indices. This work demonstrates that viscosity indices can be used as manufacturability predictors to identify the optimal formulation buffer conditions with minimum viscosity issues during the final UF/DF step while meeting the thermostability requirement. Furthermore, the CART decision tree classification method can be applied to identify the major factors that impact viscosity and thermostability and thus inform future experimental designs.

2. Data description

The datasets used in this work have been published by He et al. (2010). The datasets describe the high-throughput measurements of thermostability and viscosity for an IgG2 mAb sample assessed using differential scanning fluorimetry (DSF) method and dynamic light scattering (DLS) methods respectively. .The data was obtained via a full factorial design of experiment (DoE) with four predictor variables, including two continuous variables (pH and formulation concentration) and two categorical variables (presence of ions and excipient). Table 1 describes the summary of DoE predictor variables.

Table 1. Summary of DoE predictor variables

DoE predictors	**Variables**		
pH	5.0	5.5	6.0
Formulation concentration (mg/mL)	89	119	149
Ion	N/A	Ca^{2+}	Mg^{2+}
Excipient	N/A	Sucrose	Proline

In this work, the final product concentration is 100 g/L. There are four sub-steps in the final UF/DF step: initial concentration, diafiltration, overconcentration and flush. A typical overconcentration ratio of 1.5 was used (i.e. the product concentration would reach 150 g/L). The final flush sub-step dilutes the product back to 100g/L.

3. Decision tree analysis and results

3.1. Classification and regression tree (CART)

CART (classification and regression tree) (Grajski et al., 1986) is a decision tree algorithm that divides the data in homogenous subsets using binary recursive partitions. The most discriminative variable is first selected as the root node to partition the data set into branch nodes. The partitioning is repeated until the nodes are homogenous enough to be terminal. So in a tree structure, the terminal nodes (called leaves) represent class labels and branches represent conjunctions of features that lead to those class labels. In this work, CART is realized in Matlab Statistics Toolbox.

3.2. CART tree for key factors identification

The viscosity dataset has 80 data records. Each data record represents one formulation design in terms of a combination of four variables: pH, formulation concentration, presence of ions and excipient. The critical value of solution viscosity for final UF/DF manufacturing was set as 6 cp (He et al., 2010). According to the viscosity values, each

data record in the DoE dataset was classified into one of two groups: high viscosity (≥6 cp) and low viscosity (<6 cp). Figure 1a shows the CART tree for the viscosity dataset which reveals that the major factors impacting solution viscosity are the formulation concentration followed by the presence of ions and then the presence of excipients. For low formulation concentrations (89 mg/ml), low viscosity is expected while for high formulation concentrations (149 mg/ml), high viscosity is expected. When the formulation concentration is 119 mg/ml, the presence of Ca^{2+} or Mg^{2+} ions can reduce the viscosity except when sucrose excipient is added.

Similar to the viscosity dataset, according to the critical value of hydrophobic exposure temperature (Th), the thermostability dataset was split into two groups: stable (≥50 ^{o}C) and unstable (<50 ^{o}C). The CART tree result as shown in Figure 1b reveals that the pH value, presence of ions and presence of excipients are major factors affecting thermostability.For a low pH value of 5.0, the protein is prone to instability while for a higher pH value of 6.0, the protein is more likely to be stable. When the pH is 5.5, Ca^{2+} ions can reduce the protein thermostability under the condition with no excipient.

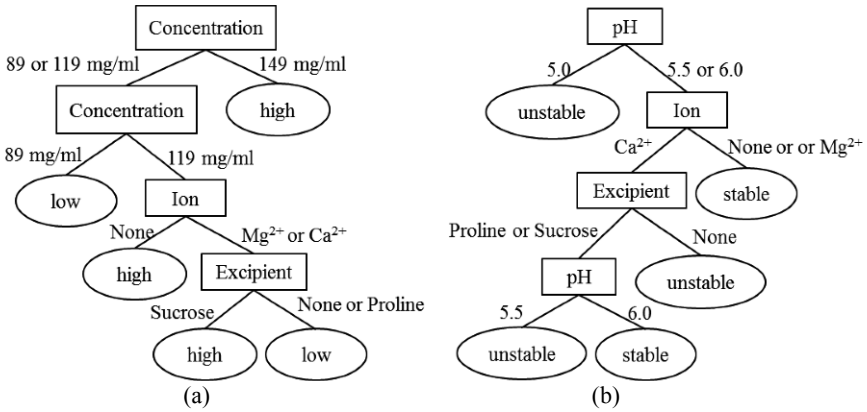

Figure 1. CART tree for (a) viscosity and (b) thermostability analysis. Rectangle nodes are branch nodes (e.g. concentration, pH) which represent the key formulation factors. Values on branches are the threshold levels of the split points for the corresponding split conditions. Circle nodes are leaves representing subsets with different class labels for viscosity (high (≥ 6 cP) versus low (< 6 cP)) and thermostability (unstable (< 50^{o}C) and stable (≥ 50^{o}C)).

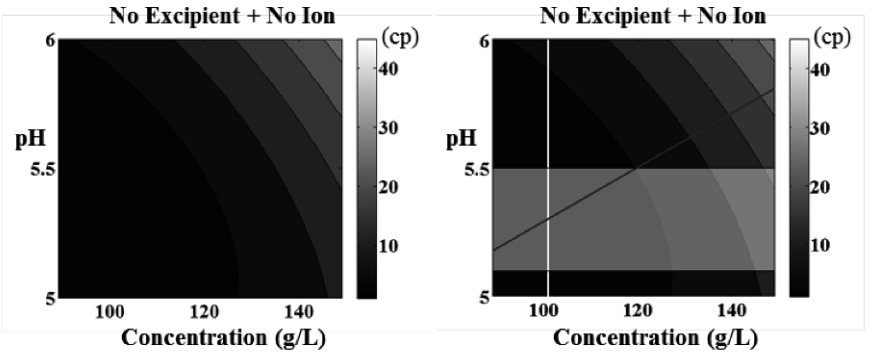
4. Manufacturability index analysis and results

4.1. Viscosity stress maps generation using polynomial regression

The viscosity dataset was divided into nine sub-datasets according to the combination of formulation ions and excipients. Nine quadratic polynomial models which describe viscosity as a function of pH and protein concentration have been built by polynomial regression for all formulation conditions. The contour plots of the regression models, named viscosity stress maps, indicate the viscosity values under different pH and protein concentrations. The viscosity stress map for the formulation condition of no ion with no excipient has been shown in Figure 2a.



(a) (b)

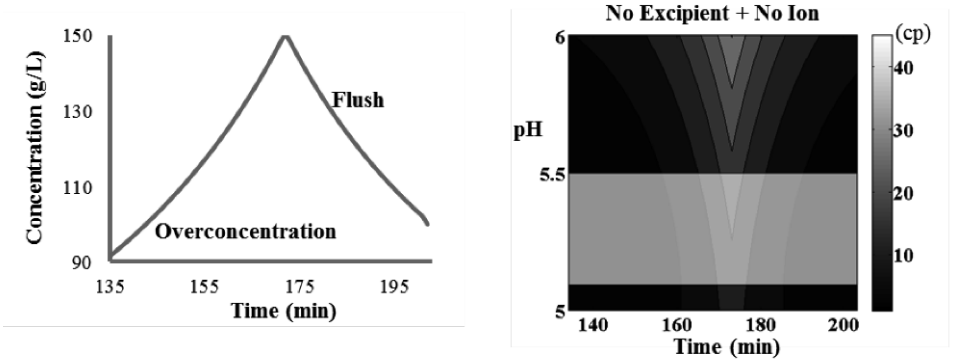
Figure 2. (a) Viscosity stress map for the formulation condition of no ion with no excipient generated by polynomial regression (R^2 = 0.949). Viscosity value is a function of pH and protein concentration and increases from dark to light; (b) Window of operation (rectangular overlay region) for the formulation condition of no ion with no excipient. The window of operation is determined by the the pH value (±0.2) that meets the thermostability criterion across the ranges of concentration experienced during final UF/DF step.

4.2. Window of operation location using the thermostability criterion

Since the thermostability criterion was set as the hydrophobic exposure temperature (Th) ≥50 ^{o}C, a window of operation has been set up for each formulation design to identify the optimal pH range that meets the thermostability requirement. Figure 2b illustrates the identification of the window of operation for the formulation condition of no excipient with no ion. In Figure 2b, the white line indicates the final product concentration of 100 g/L and the dark line indicates the thermostability criterion. The intersection of the dark and white line indicates the pH value for the final product to meet the thermostability criterion. For the formulation condition of no excipient with no ion, the pH required is 5.3. Considering that a typical pH control range is within ±0.2 units, the window of operation is determined by the ranges of concentration and pH which are 90-150 g/L and 5.1-5.5 respectively as indicated by the rectangular overlay region in Figure 2b.

4.3. Processing time exposed to different viscosity levels in final UF/DF

In the final UF/DF step, the concentration of the product stream, and hence its viscosity, are dynamically changing over time. Furthermore, the flux through the membrane can be significantly lowered by membrane pore blockage and protein fouling that occurs as the concentration factor increases. In order to capture the information about the time exposed to different viscosity levels during UF/DF, a mathematical model for the filtrate flux (Ho and Zydney, 2000) was incorporated. This accounts for initial fouling due to pore blockage and subsequent fouling due to the growth of a protein cake or deposit over these initially blocked regions. Using this model, the variation of protein concentration with processing time during the overconcentration and flush stages of the UF/DF step has been captured, as illustrated in Figure 3a. The viscosity stress map has been transformed as a function of pH and processing time in Figure 3b. The window of operation (overlay area) is determined by the ranges of processing time and pH which are 135-204 mins and 5.1-5.5 respectively.



(a) (b)

Figure 3. (a) Time profile of product concentration during overconcentration stage and flush stage of final UF/DF; (b) Transformed viscosity stress map for the formulation of no ion with no excipient as a function of pH and processing time during UF/DF. The rectangular overlay region is the window of operation to meet thermostability criterion.

4.4. Viscosity indices generation and optimal formulation selection

A double integration calculation was applied to the viscosity stress map in order to obtain the average viscosity value within the window of operation, termed the viscosity index. The index indicates the average viscosity value of the product stream during the UF/DF step taking into account the time profiles of pH and concentration. The viscosity index for the formulation condition of no ion with no excipient is 5.5.

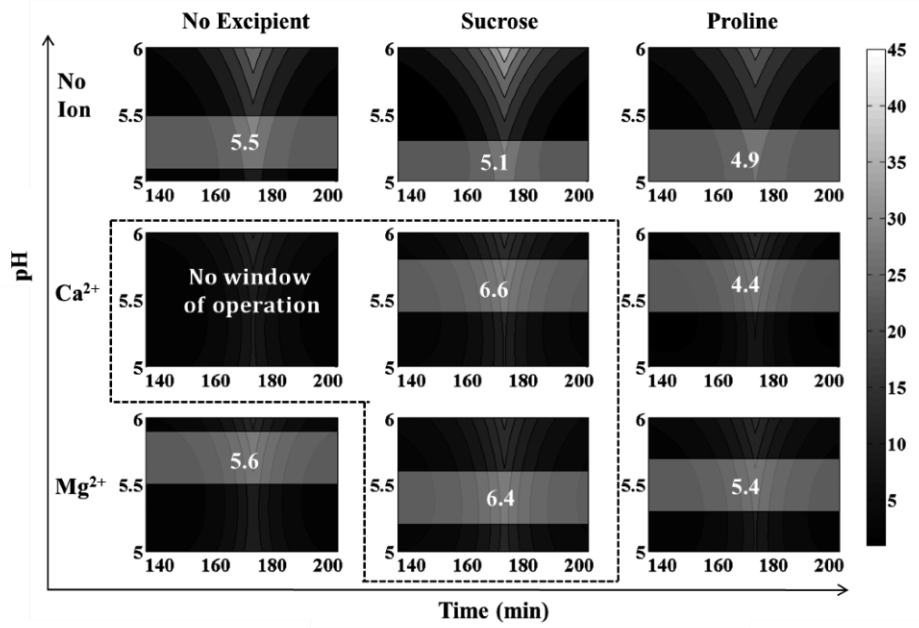


Figure 4. Viscosity indices for all formulation designs. The value of each index indicates the average viscosity value of the product stream during the UF/DF step taking into account the time profiles of pH and concentration while meeting the thermostability criterion (Th ≥50 ^{o}C).

Viscosity indices were generated for all formulation designs as shown in Figure 4. Each set of formulation conditions can be ranked according to their viscosity indices where a low index value indicates a more desirable outcome. From Figure 4, it can be seen that Ca^{2+} with proline excipient is the optimal formulation design with the lowest viscosity index, 4.4. For the formulation of Ca^{2+} ions with no excipient, there is no window of operation since the pH required for the final product to meet thermostability criterion is 6.4 which is outside the experimental range of the dataset (5-6). Furthermore, if the critical acceptable viscosity value for the final UF/DF step is 6 cP, three formulation designs would not be feasible: Ca^{2+} with no excipient, Ca^{2+} with sucrose and Mg^{2+} with sucrose. This approach can be used early in development to rank formulation designs in terms of their potential UF/DF manufacturability.

5. Conclusions

This work presents a novel methodology to derive viscosity indices which can be used as manufacturability predictors to rank different formulation designs. The optimal formulation buffer conditions with minimum viscosity issues during the final UF/DF step that also met the thermostability requirement could be identified. This work also demonstrated that the CART decision tree method could be applied to identify the critical factors for both solution viscosity and thermostability. The decision tree results are meaningful for future high-throughput experimental designs.

Abstract

M. maripaludis, a hydrogenotroph, is capable of reducing CO_2 to methane in the presence of electron donors such as H_2 or formate. To explore the metabolic potential of *M. maripaludis* for CO_2 conversion to methane, it is crucial to quantify its substrate uptake and methane production rates. In this work, we perform a dynamic cell growth study in a batch culture of *M. maripaludis* and estimate three key extracellular fluxes, namely CO_2 uptake, H_2 uptake, and CH_4 evolution for different growth rates. To the best of our knowledge, this is the first study to report CO_2, H_2 consumption and CH_4 production rates under an environment where CO_2 is the sole carbon substrate. We present a process simulation approach for estimating such fluxes from experimentally measured compositional data. Using the same data, we also present an approach to estimate Non-Growth Associated Maintenance (NGAM) energy required for cell survival, and Growth Associated Maintenance (GAM) energy required for growth. We then use *i*MM518, a genome-scale model for *M. maripaludis* [2], to predict the extracellular fluxes (mmol/gDCW-h) and compare the predictions with measured values. Exceptionally high uptake and production rates were observed in *M. maripaludis* with a high growth yield. Based on the results, *M. maripaludis* is capable of reducing 70-95% of CO_2 to methane during exponential phase. This study shows the predictive power of *i*MM518 and helps us investigate the intracellular metabolic profiles underlying the extracellular observations.

Keywords: *i*MM518, hydrogenotroph, extracellular flux, intracellular flux, mass balance

1. Introduction

The ecological role of methanogens to remove CO_2 from environment via methanogenesis has been widely studied. The produced biomethane, major component of natural gas, offers great alternative energy source for heating and electricity. *M. maripaludis* is a rapidly growing, fully sequenced hydrogenotrophic methanogen capable of consuming major components (i.e. CO_2 and N_2) of a flue gas (Jones, 1983; Kessler et al., 2001). It is also a model organism among hydrogenotrophs for studying genetic and regulatory pathways (Kessler & Leigh, 1999; Tumbula et al., 1997; Yu et al., 1994). While several studies have characterized and engineered the metabolic

pathways in *M. maripaludis*, quantitative measurements on carbon utilization and methane production are absent in the literature. To this end, genome-scale models proved extremely useful to quantify specific growth rate, substrate uptake rates, and product production rates.

To understand the metabolic interactions and significant parameters affecting methanogenesis from CO_2, a genome-scale metabolic model of *M. maripaludis* (*i*MM518) has been developed recently (Goyal et al., 2014). Although models are extremely useful to understand hidden insights of metabolism during knockouts or any genetic or environmental perturbations, they need thorough validation. To validate such models, one can accurately measure extracellular fluxes by estimating the change in substrate concentrations in the medium surrounding the cells or measure intracellular fluxes using ^{13}C NMR labeling (Wiechert, 1996). Unlike intracellular measurements, analytes moving in and out of the cells are sensitive indicators of change and measuring them is relatively simpler. Extracellular flux measurements, in combination with genome-scale models can be used for determination of intracellular metabolic fluxes (Zupke & Stephanopoulos, 1995).

In this work, we perform a dynamic batch culture study of *M. maripaludis* and measure cell growth and three extracellular fluxes, namely CO_2 uptake, H_2 uptake, and CH_4 evolution rates. We also present a novel approach to estimate NGAM and GAM with the help of experimentally determined rates. Further, we use *i*MM518 to analyze the distribution of carbon flux between central metabolism and methanogenesis.

2. Flux measurements and flux predictions

2.1. Growth media and culture conditions

Our study used *M. maripaludis* wild type strain S2 from DSMZ-German Collection of Microorganisms and Cell Cultures with accession number DSM14266. The minimal medium used for our growth experiments lacked all possible carbon sources except headspace CO_2. The medium had neither carbon source nor cysteine. Vitamins were also omitted, as they do not affect (Whitman et al., 1987) the growth of *M. mariplaudis*. Reactors were pressurized with 250 kPa 80:20 v/v H_2/CO_2 and incubated at 37 °C under constant stirring at 180 rpm. Cell density and concentrations of CO_2, H_2, and CH_4 in the headspace were measured every hour for about 7 h. The growth experiments were discontinued, when the headspace pressure fell below 100 kPa to avoid the inflow of air into the reactor. All growth experiments were performed in duplicates accompanied by a control.

2.2. Specific growth rates and experimental flux measurements

Specific growth rate (μ) is the rate at which cells divide in the culture. In a chemostat experiment, μ remains constant, as the supply of nutrients is unlimited. However, in a batch culture experiment, the supply of nutrients keeps decreasing continuously with time. The dry cell biomass, X (gram Dry Cell Weight (gDCW)) was computed as O.D. X 0.34 g/L X culture volume. This time profile was then used to compute specific growth rate (μ) at selected points as given in Eq.(1).

$$\mu\left(\frac{1}{h}\right) = \frac{1}{X}\frac{dX}{dt} \tag{1}$$

OD_{600nm} = 1 is chosen to represent 0.34 g DCW/L based on the literature (Lupa et al., 2008).

Estimating extracellular fluxes from a cell culture study is not straightforward, when gases are distributed into both aqueous media and headspace as is the case in our experiment. In order to estimate fluxes precisely, we simulated the dynamics of a 600 ml reactor using Aspen HYSYS V8.2 (Abd Hamid, 2007) for the entire experiment. We accounted for the reduction in medium volume and expansion in headspace at each time point and computed the total moles of H_2 and CH_4 as the sum of moles of gases in headspace and aqueous media. For computing total moles of CO_2, we accounted high solubility of CO_2 into bicarbonates and carbonates. The fluxes (mmol / gDCW-h) for CO_2 and H_2 consumption and CH_4 production were computed by plotting the time profiles of total moles of CO_2, H_2, and CH_4 as shown in Eq.(2).

$$v_i = \frac{1}{X(t)} . \frac{dn(i)}{dt} \tag{2}$$

Where, $n(i)$ are the moles of species i (CO_2, H_2, or CH_4) in the bottle and $X(t)$ is the dry cell mass (gDCW) at time t.

2.3. *In silico flux predictions using i*MM518

*i*MM518 is available in BioModel database as MODEL1304120000 (Goyal et al., 2014). We implemented *i*MM518 in GAMS (build 38380/38394) and used CPLEX and BARON respectively as the solvers for various linear and nonlinear optimization problems. For flux balance analysis, we assumed the cellular objective to be maximum biomass given in Eq.(3). Then, to predict cell growth rate for a given CO_2 uptake rate, we solved the following LP (Linear Programming) using *i*MM518.

$$Maximize\ Biomass = \sum_{j=1}^{j} c_j v_j \ subject\ to\ \ S.v = b \tag{3}$$

Where, maximize biomass is represented as a weighted sum of metabolite fluxes v_j (j = 1,2,..,j) with weights c_j. S is an $I \times J$ matrix of stoichiometric coefficients of the metabolic reactions, I is the number of metabolites, and J is the number of metabolic reactions, and v is a ($j \times 1$) vector of reaction fluxes and b is a ($I \times 1$) vector of net metabolic fluxes.

3. Results and Discussion

M. maripaludis grew extremely well on CO_2 with negligible lag phase and without needing any complex substrates such as acetate, yeast extract, amino acids etc. The dry cell biomass increased by 15.49 mg over a period of 7 h. The doubling time was about 2 h, which is consistent with the literature (Jones, 1983). The lag phase duration varied with the state of inoculum, and found to be the shortest for an inoculum from the late exponential phase. Figure 1 shows the profiles of specific growth rates and extracellular fluxes obtained using cell growth and concentration profiles of gases in the headspace respectively.

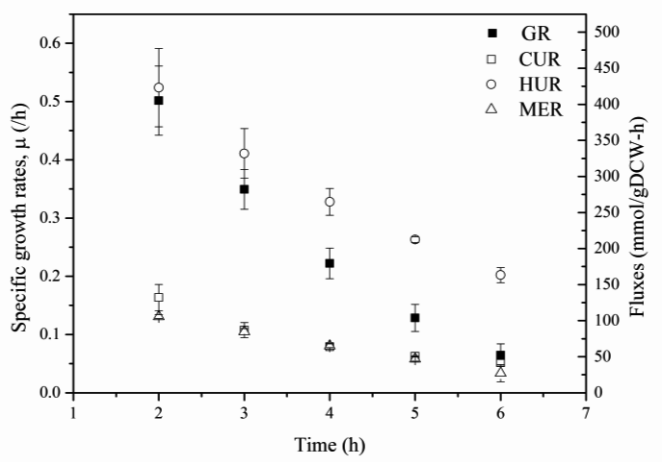

Figure 1: The time profiles of experimentally measured specific growth rates (growth rate denoted as GR) and fluxes (CO_2 uptake rates denoted as CUR, hydrogen uptake rates as HUR, and methane evolution rates as MER).

Based on 95% confidence, the maximum growth rate was estimated to be 0.50 ± 0.05 /h for a CO_2 uptake of 132.13 ± 15.13 mmol / gDCW-h, H_2 uptake of 423.06 ± 44.94 mmol / gDCW-h, and CH_4 production of 105.61 ± 17.75 mmol / gDCW-h. Our study is the first to give a full range of comprehensive growth and flux data for *M. maripaludis*. In fact, in spite of our best efforts, we could not find similar data for any other methanogen except for one study (Adam M Feist, 2006) on *Methanococcus barkeri*. This study reported a maximum hydrogen uptake of 41 mmol / gDCW-h with a corresponding CO_2 uptake of 11.61 mmol / gDCW-h and CH_4 production of 8.82 mmol/gDCW-h. Clearly, our observed fluxes are one order of magnitude higher than those reported for *M. barkeri*. This could be attributed to the much shorter doubling time (~2 h) of *M. mariplaudis* compared to *M. barkeri* (~30 h).

From the plot of dry cell weight (g) versus methane produced over time, we obtained a growth yield of 3.549 ± 0.149 gDCW per molCH_4 for *M. maripaludis* during the exponential phase. This yield matches well with the 2-4 gDCW per mol CH_4 reported for other hydrogenotrophic methanogens growing on H_2/CO_2 in batch cultures (Taylor & Pirt, 1977; Woese et al., 1978). The linear CO_2 flux vs growth rate relationship given in Eq.(4) tells us that cell growth is zero for a CO_2 uptake rate below 23.51mmol / gDCW-h. Using this uptake rate and *i*MM518, we computed NGAM = 7.836 mmol / gDCW-h as the amount of energy spent for maintenance during non-growth.

$$v_{CO2} = 203.25\mu + 23.51 \quad (4)$$

For estimating GAM, we computed total weighted Sum of Squares of Errors (SSE) (Eq.5) between experimentally measured fluxes and model predicted fluxes for different values of GAM. GAM value = 27.14 mmol/gDCW-h resulted in minimum total weighted SSE for *M. maripaludis*. Note that the energy required for growth increases linearly with growth with a slope of GAM. Our measured GAM of 27.14 mmolATP / gDCW-h agrees very well with our theoretically estimated GAM of 30.0 mmolATP / gDCW-h) (Goyal et al., 2014) for *M. maripaludis*. Thus, we fixed

GAM = 27.14 mmolATP / gDCW and NGAM = 7.836 mmolATP / gDCW-h in *i*MM518 and performed further analyses.

We also estimate ATP gains from our NGAM as 0.33 molATP / molCO_2, 0.35 mol ATP / molCH_4, and 0.238 molATP / molH_2. While the ATP gains from CO_2 and CH_4 are close, that from H_2 is much lower. This could be due to the deviations observed in our flux predictions for H_2 in total SSE. The value of 0.35 molATP / molCH_4 is in the acceptable range of 0.2-0.8 molATP / molCH_4 reported for microbes with autotrophic growth on H_2/CO_2 (Kates et al., 1993). Kaster et al., 2011 suggested an ATP gain of less than 1 molATP / molCH_4 for methanogens without cytochromes (e.g. *M. maripaludis*) and more than 1 molATP / molCH_4 for methanogens with cytochromes (e.g. *M. barkeri*). Thus, our estimate of 0.35 molATP / molCH_4 is consistent with the literature.

With GAM = 27.15 mmol / gDCW and NGAM = 7.836 mmol / gDCW-h in *i*MM518, we fixed CO_2 uptake rate at various values and predicted cell growth, MER, and hydrogen uptake rate for maximum biomass growth. Figures 2 compare experimental results with our model predictions. As we can see, our model predictions and experimental results match very well.

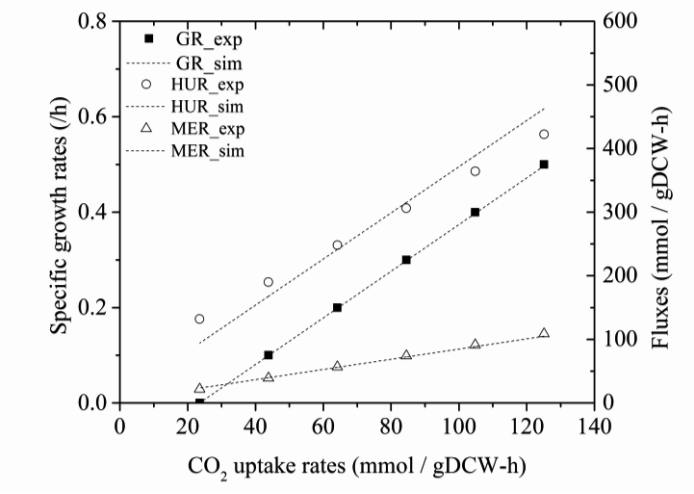

Figure 2: Comparison of experimentally measured fluxes and model predicted fluxes for fixed CO_2 uptake rates at GAM = 27.14 mmol / gDCW and NGAM = 7.836 mmol / gDCW-h

Intracellular flux distribution map for methanogenesis and central metabolic pathways shows the quantitative distribution of CO_2 towards methane production and towards formation of amino acids, cofactors, coenzymes, and other biomass precursors. We observed that CO_2 conversion to CH_4 decreases with increase in CO_2 uptake rate (or equivalently cell growth). This is consistent with the fact that cell growth competes with methanogenesis for carbon (Goyal et al., 2014). The ratio of flux directed towards methanogenesis to the amount of flux directed towards biomass formation can be altered by altering genetic and environmental perturbation, media compositions, growth phase, etc. We identified several environmental factors such as key amino acids, limiting nutrients and genetic perturbations i.e. genes / reactions knockouts to enhance methane production in *M. maripaludis*.

4. Conclusions

In this work, we demonstrated a process simulation approach for flux measurement of gases that partition between headspace and aqueous medium of a batch reactor. Using this experimental flux measurements and genome-scale model of a microbe (in our case *i*MM518), we estimated two key parameters NGAM and GAM along with ATP gain. In this work, *in silico* predictions by *i*MM518 were in excellent agreement with experimental measurements, thus allowed us to elucidate the physiological and metabolic states of the cells during batch culture.

Abstract

The cell cycle is the biological process used by cells to replicate their genetic material and give birth to new cells that are in turn eligible to proliferate. It is highly regulated by the timed expression of proteins which trigger cell cycle events such as the start of DNA replication or the commencement of mitosis (when the cell physically divides into two daughter cells). Mathematical models of the cell cycle have been widely developed both at the intracellular (protein kinetics) and macroscopic (cell duplication) levels. Due to the cell cycle specificity of most chemotherapeutic drugs, these models are increasingly being used for the study and simulation of cellular kinetics in the area of cancer treatment.

In this work, we present a population balance model (PBM) of the cell cycle in leukemia that uses intracellular protein expression as state variable to represent phase progress. Global sensitivity analysis highlighted cell cycle phase durations as the most significant parameters; experiments were performed to extract them and the model was validated. Our model was then tested against other differential cell cycle models (ODEs, delay differential equations (DDEs)) in their ability to fit experimental data and oscillatory behavior. We subsequently coupled each of them with a pharmacokinetic/pharmacodynamic model of chemotherapy delivery that was previously developed by our group. Our results suggest that the particular cell cycle model chosen highly affects the outcome of the simulated treatment, given the same steady-state kinetic parameters and drug dosage/scheduling, with our PBM appearing to be the most sensitive under the same dose.

Keywords: Cell cycle, population balance model, chemotherapy optimization, leukemia, model selection

1. Introduction

AML is a type of leukemia characterized by the sudden increase in immature cells with highly proliferative features. Chemotherapy treatments rely on cell cycle phase-specific (CCS) agents, which act on cells going though one of the four phases of the cell cycle (G1: growth, S: DNA duplication, G2: preparation for division, M: mitosis (cell division)). Efficacy of current treatment protocols is hampered by a lack of patient-specific information related to drug action and cell

cycle kinetics. Blood samples from patients receiving chemotherapy cannot be collected due to their medical condition and to weakening treatment effects. Therefore, modeling patient response *in silico* could provide valuable insights as a helper tool for clinicians. To this end, a complete pharmacokinetic/pharmacodynamic (PK/PD) model of patient response was previously developed by Pefani et al. (2013, 2014). The model considered the infusion, transport and degradation of chemotherapeutic drugs inside the body, as well as the drug effects at the point of action (bone marrow), where leukemia resides. The leukemic cell cycle was represented as a set of 3 ODEs, one per compartment (G1, S and G2/M). Global sensitivity analysis revealed that the cell cycle phase durations (τ_{G1}, τ_S and $\tau_{G2/M}$) were the most significant parameters for treatment outcomes. Since ODEs provide only a simplified representation of cell cycle progression, we hypothesized that the cell cycle model itself, in addition to its parameters, would have an impact on simulated chemotherapy response. More complex types of models such as population balance models (PBM) which are distributed in a second progression-related variable, or delay differential equation models (DDE) which account for the phase-induced time delay, could be more suited for the purpose.

In this paper, we present two new cell cycle models composed of 3 compartments (G1, S, G2/M): a PBM distributed in protein concentration (G1, G2/M) or DNA content (S), and a DDE model featuring phase-specific time delays. All three models (ODE, PBM, DDE) are compared in: (i) their ability to fit chemotherapy-free experimental data Fuentes-Garí et al. (2014); (ii) chemotherapy outcomes when embedded in the pharmacokinetic/pharmacodynamic (PK/PD) model of Pefani et al. (2013).

2. Results

2.1. Developing cell cycle models that can be experimentally validated

The three models are presented with increasing levels of complexity. Phase distributions (percents) will be of importance here as they account for oscillatory behavior, in contrast with phase numbers which increase over time. They can be experimentally measured by aggregating data from single cell measurement techniques such as flow-cytometry. The cell cycle can initially be modeled as a set of ODEs (one per compartment), with the parameters needed being the transition rates and the initial cell populations for each phase. A general example of this scenario with three compartments (G0/G1, S and G2/M) can be found in Pefani et al. (2013) (a chemotherapy death term is added here with value zero for this section and a positive value in the other three models for the results of the next section):

$$\frac{dG}{dt} = 2 \cdot 1/\tau_M \cdot M - 1/\tau_G \cdot G \quad - k_{D,G} \cdot G \tag{1}$$

$$\frac{dS}{dt} = 1/\tau_G \cdot G - 1/\tau_S \cdot S \quad - k_{D,S} \cdot S \tag{2}$$

$$\frac{dM}{dt} = 1/\tau_S \cdot S - 1/\tau_M \cdot M \tag{3}$$

This model quickly stabilizes to its steady-state when subject to a disturbance. In order to account for the fact that stabilization takes 1-2 cell cycles experimentally, a time delay equal to the phase duration can be introduced in each phase by using DDEs:

$$\frac{dG(t)}{dt} = 2 \cdot 1/\tau_M \cdot M(t-\tau_M) - 1/\tau_G \cdot G(t) \quad - k_{D,G}(t) \cdot G(t) \tag{4}$$

$$\frac{dS(t)}{dt} = 1/\tau_G \cdot G(t-\tau_G) - 1/\tau_S \cdot S(t) \quad - k_{D,S}(t) \cdot S(t) \tag{5}$$

$$\frac{dM(t)}{dt} = 1/\tau_S \cdot S(t-\tau_S) - 1/\tau_M \cdot M(t) \tag{6}$$

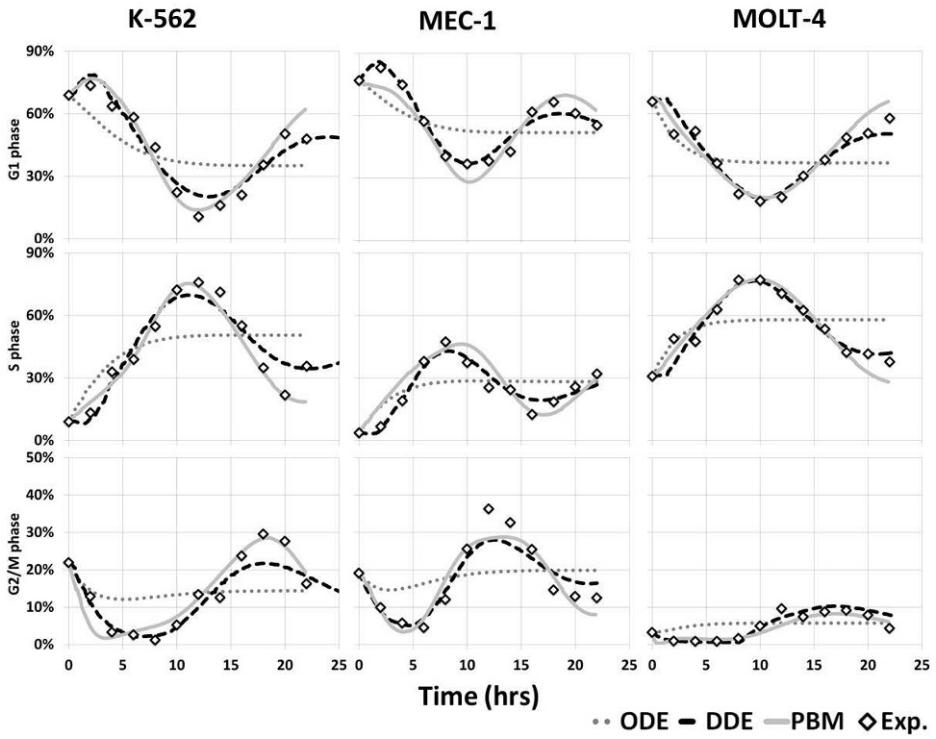

Figure 1: Comparison of experimental phase percents in 3 leukemia cell lines (K-562, MEC-1, MOLT-4) with simulation results for ODEs, DDEs, PBM.

An important advantage of this type of model is that it adds synchrony to the system (i.e., cell populations are not eligible to exit a phase as soon as they enter), so any disturbances in time will be well captured. Furthermore, DDEs do not require any additional parameters and maintain a fast computational execution. Because DDE systems' asynchrony is based on total phase numbers at earlier times, not intra-phase cell numbers, properties related to phase progression cannot be deduced. In order to account for properties varying within each phase, distributed systems such as PBMs must be used. To make this biologically relevant, those properties should be experimentally measurable. In Fuentes-Garí et al. (2014), we presented a PBM of the cell cycle with cyclins (proteins related to phase progression) and DNA as state variables, which was discretized and validated for 3 leukemia cell lines (K-562, MEC-1, MOLT-4) experimentally:

$$\begin{aligned}\frac{dG_e}{dt} =& G_{e-1}\cdot r_G\cdot \nu_E - G_e\cdot r_G\cdot \nu_E - G_e\cdot r_{G\to S,e}\cdot \nu_E + \delta(e-1)\cdot 2\cdot \sum_{b=1}^{n_B} M_b\cdot r_{M\to G,b}\cdot \nu_B \\ & - k_{D,G}\cdot G_e \quad \forall e\in\{1,\ldots,n_E\}\end{aligned} \tag{7}$$

$$\begin{aligned}\frac{dS_d}{dt} =& S_{d-1}\cdot r_S\cdot \nu_D - S_d\cdot r_S\cdot \nu_D + \delta(d-1)\cdot \sum_{e=1}^{n_E} G_e\cdot r_{G\to S,e}\cdot \nu_E \\ & - k_{D,S}\cdot S_d \quad \forall d\in\{1,\ldots,n_D\}\end{aligned} \tag{8}$$

$$\begin{aligned}\frac{dM_b}{dt} =& M_{b-1}\cdot r_M\cdot \nu_B - M_b\cdot r_M\cdot \nu_B - M_b\cdot r_{M\to G,b}\cdot \nu_B + \delta(b-1)\cdot S_{n_D}\cdot r_S\cdot \nu_D \\ & \forall b\in\{1,\ldots,n_B\}\end{aligned} \tag{9}$$

Growth rates (r_G, r_S and r_M) correlate phase progression to its state variable; transition rates ($r_{G\to S,e}$ and $r_{M\to G,b}$) account for the transition probability according to the state variable level.

Table 1: Phase time parameters estimated in each of the three models as compared to the experimental ones

Cell line	Duration	PBM	DDEs	ODEs	Exp. value
K-562	T_G	9h	4.4h	5.8h	6 ± 2h
	T_S	10h	6.6h	12h	10 ± 2h
	T_M	5h	2.7h	3.9h	4 ± 2h
MEC-1	T_G	8.5h	4.6h	8.4h	7 ± 2h
	T_S	7.5h	2.9h	5.6h	8.5 ± 2h
	T_M	3h	2.6h	4.7h	5 ± 2h
MOLT-4	T_G	12h	5.0h	4.2h	10 ± 2h
	T_S	15h	8.5h	10.3h	12 ± 2h
	T_M	2h	1.4h	1.1h	2 ± 2h

In order to compare the ability of all three models to fit experimental data, we used the synchronous experimental data of Fuentes-Garí et al. (2014) together with the PBM simulation results reported. Parameter estimation and simulations are all performed in gPROMS for ODEs and DDEs. Results for all three models can be seen in Figure 1. The PBMs and DDEs presented here can capture synchronous oscillatory behavior while the ODEs fail to account for this intra-phase heterogeneity, resulting in a lack of fit of this particular model. Either a spatial (such as protein expression in PBMs) or temporal (such as the delay history in DDEs) distribution is needed in order to capture the synchronous cell behavior. The model parameters (Table 1) are always lower for DDEs, higher for PBMs and unpredictable in ODEs (likely due to the fact that the parameter estimation optimizer cannot find a good solution for the minimization problem). In addition, the PBM cell cycle times are consistently the closest to the ones measured experimentally and are thus the most biologically meaningful.

2.2. Evaluating cell cycle model sensitivity to chemotherapy

The previous section showed that both PBMs and DDEs are capable of fitting synchronous experimental data, a fact that is critical in modeling chemotherapy due to its phase-specific action (G1 and S phase) and subsequent aggregation of cells into synchronized populations (Sherer et al. (2006)). In this section, each model will be embedded into a PK/PD model of chemotherapy delivery in leukemia (Pefani et al. (2014) and tested for its sensitivity to chemotherapy (as captured by the chemotherapy drug effect parameters $k_{D,S}$ and $k_{D,G}$ for S and G1 phases respectively, see equations 1-9; delayed terms in the DDEs were also subject to the chemotherapy effect over time).

For the comparison to be fair, the total kinetics (so that the cell number is equal) and the cell cycle distribution (so that the percentage of cells likely to be affected when chemotherapy starts) have to be equal at steady-state. All three systems of equations are solved at steady-state resulting in the following three equalities for log-growth (α: ODE; γ: DDE; β: PBM):

$$\alpha = \frac{dT}{dt}\frac{1}{T} = k_3 \cdot M_{SS,\%} \tag{10}$$

$$\gamma = \frac{dT}{dt}\frac{1}{T} = k_3 \cdot M_{SS,\%} \cdot \left(2e^{-\gamma\cdot\tau_M} - 1\right) + k_1 \cdot G_{SS,\%} \cdot \left(e^{-\gamma\cdot\tau_G} - 1\right) + k_2 \cdot S_{SS,\%} \cdot \left(e^{-\gamma\cdot\tau_S} - 1\right) \tag{11}$$

$$\beta = \frac{dT}{dt}\frac{1}{T} = \sum_{b=1}^{n_B} M_{b,SS,T\%} \cdot r_{M\to G,b} \cdot \nu_B \tag{12}$$

In the PBM form, equations are first translated as $\frac{dG_{e,G\%}}{dt} = 0 \quad \text{with} \quad G_{e,G\%} = \frac{G_e}{\sum G_e}$. Next, all populations in each phase are summed: $\frac{dG}{dt} \cdot \sum_{e=1}^{n_E} G_{e,G\%} = 2 \cdot \sum_{b=1}^{n_B} M_b \cdot r_{M\to G,b} \cdot \nu_B - \sum_{e=1}^{n_E} G_e \cdot r_{G\to S,e}\nu_E$. Summing all three phases, the result in Equation 12 is obtained. Similar equations can be derived for cell cycle distributions at steady-state. Equating $\alpha = \gamma = \beta$ and each of the phase fractions

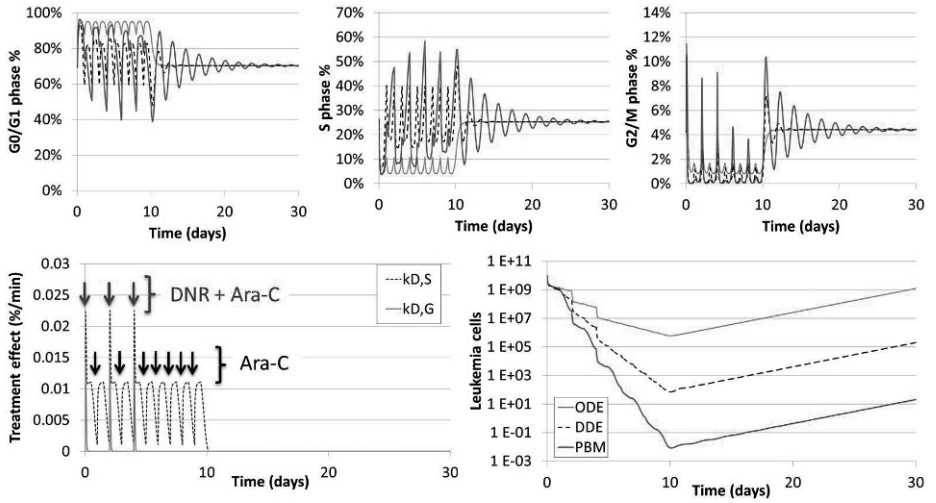

Figure 2: Comparison of cell cycle distribution (top 3 panels) and total cell number(bottom right) under chemotherapy treatment (bottom left panel) in: ODEs, DDEs, PBMs under equivalent growth kinetics (converted from DDE to equivalent parameters in ODE and PBM - see equal cell cycle distribution and total growth kinetics after 10 days of treatment)

($G_{SS,\%,ODE} = G_{SS,\%,DDE} = G_{SS,\%,PBM}$...), cell cycle times can be converted from one system (ODE, DDE, PBM) to another. Given the cell cycle times in the DDE system (which is the most complex to solve practically), all other cell cycle times can be obtained through this process of equaling the total growth rate and the phase distributions at steady-state (Table 2). This lays the foundations for our PK/PD kinetics comparison as we choose a hypothetical female patient that is 156cm tall and 60.7kg in weight, over 60 years old, receiving a chemotherapy treatment of 160 mg/m^2 Ara-C (12h infusion once a day for 10 days) and 80 mg/m^2 DNR (pulse dose on days 1, 3 and 5). The latter are the input parameters for the PK model.

Table 2: CC times converted from DDEs to PBM and ODEs for the steady state conditions chosen ($G_{SS,\%} = 70.36\%$, $S_{SS\%} = 25.23\%$, $M_{SS\%} = 4.41\%$, $\alpha = \beta = \gamma = 0.0161h^{-1}$)

	PBM	DDEs	ODEs
T_G	31.0554h	14h	33.7000h
T_S	13.5147h	7h	15.0075h
T_M	3.0674h	1.4h	2.7380h

Comparing the total cell evolution over the treatment period in the three models (Figure 2), we observe that the ODE sensitivity to chemotherapy is effectively lower due to its inherent tendency to allow the passage of cells from phase to phase (absence of intra-phase distribution). Conversely, the DDE and PBM models allow for cells to be distributed in each phase (temporally and spatially respectively). This can be further confirmed by observing the cell cycle phase distributions: ODEs reach much higher G2/M phase percents, representing the higher fraction of S phase cells coming in and contributing to the overall total cell duplication. Although G1 phase percents are higher throughout the treatment in ODEs, duplication remains the single most important factor affecting overall growth. DDEs response seems to be halfway between PBM and ODEs, in that cell kill is 5 orders of magnitude above PBM and below ODEs, while the oscillatory behavior can be broadly said to be a combination of ODEs (peak timings) and PBMs (peak heights). Oscillations post-treatment are the most sustained for PBM, while DDEs take 1-2 cell cycles to stabilize and ODEs immediately reach steady state.

3. Discussion

Three different models representing cell cycle kinetics were presented here and analyzed for their ability to capture oscillations and their response to chemotherapy under the same steady-state behavior. When fitted to experimental data, only DDEs and PBM performed well, with PBM having the most biologically relevant parameters (additionally to accurately predicting intracellular protein expression as reported in Fuentes-Garí et al. (2014)). In order to compare those cell cycle models under the effect of chemotherapy, cell cycle model parameters were obtained by equaling the steady-state distributions and total exponential growth for all three models and equivalent cell cycle times were obtained. Each of the models was then embedded in a PK/PD model of chemotherapy for AML and a hypothetical case was run. Throughout the treatment, ODEs had the highest percent of cells in the G2/M phase and the lowest amount of cell kill, which was explained by its inability to capture intra-phase distributions, letting cells transition to the next phase as soon as they have entered (thus escaping the chemotherapy effect). Conversely, PBM and ODE put a spatial or temporal restriction to the eligibility of cells to transition to the next phase, and subject those cells for a minimum phase time to the effect of chemotherapy (leading to a lower percent of G2/M cells and a higher cell kill at the end of the treatment).

A strikingly different behavior was observed when using different cell cycle models to simulate patient response to treatment. Current standards in PK/PD rely on cell cycle models that are not always accurate enough and that have not necessarily been validated. The PBM model presented here provides a good trade-off between capturing more complex pathway and protein kinetics, which are normally reported in single-cell models only, and maintaining a computationally efficient solution representing global cell kinetics, of which the ODEs discussed are a clear example. Importantly, treatment personalization requires defining measurable parameters representing patient heterogeneity. Our PBM is seamlessly linked to experimentally measurable parameters that have been reported to be highly heterogeneous among AML patients (Raza et al. (1990); Gong et al. (1994)). Future work will focus on unraveling heterogeneous response of patients to chemotherapy treatments .

Abstract

Continuous twin-screw granulation has received increased attention as it can be embedded in a continuous manufacturing line allowing 24/7 production capacity eliminating scale-up requirements and intermediate storage. The screws have a modular structure (interchangeable transport and kneading discs) allowing greater flexibility in equipment design. However, process knowledge should be further developed both under steady state and dynamic conditions. Mechanistic models incorporating the underlying mechanisms are therefore applied. In this study, the principle constitutive mechanisms such as aggregation and breakage are included in a population balance modelling framework. Based on an experimental inflow granule size distribution and mean residence time of the granulator, predictions of the outflow granule size distribution were made. Experimental data was used for calibrating the model for individual screw modules in the twin-screw granulator. The results showed that the successive kneading blocks lead to a granulation regime-separation inside the twin-screw granulator. The first kneading block after wetting caused an increase in the aggregation rate, which was reduced after the second kneading block. The breakage rate increased successively along the length of the granulator. Such a physical separation between the granulation regimes will be promising for future design and advanced control of the continuous granulation process.

Keywords: continuous manufacturing, population balance modelling, wet granulation.

1. Introduction

Continuous manufacturing of pharmaceutical solid dosage forms has received great interest in the last decade due to several process and economic benefits associated with it. A continuous process with 24/7 production capacity may eliminate scale-up requirements and intermediate storage. With this in mind, twin-screw granulation has emerged as promising method for particle size enlargement to achieve better flow properties and avoid segregation during successive unit operations. A twin-screw granulator (TSG) can be embedded in a continuous manufacturing line which also includes dryer, screening unit and tabletting machine making continuous powder to tablet production

possible. Moreover, the screws used in the granulator have a modular structure (interchangeable transport and kneading discs) providing flexibility towards adaptation in equipment and process variables depending upon on feed characteristics to achieve the required product characteristics. The available studies have primarily focused on the effect of process variables (such as screw configuration, material throughput, screw speed etc.) (Vercruysse et al., 2012; Dhenge et al., 2011; Thompson and Sun, 2010) and formulation properties (El Hagrasy et al., 2013; Dhenge et al., 2013) on granule properties at the outlet of the TSG due to the opacity of the multiphase system. Thus, little is known about the effect of these variables on the evolution and kinetics of granule formation in the TSG and the resulting granule structure. In a recent study, granule size distribution (GSD) evolution along the TSG screw was experimentally mapped in order to understand the dominant constitutive mechanisms of a granulation system such as growth, aggregation and breakage (Kumar et al., 2014a). However, such measurements provide a semi-quantitative insight regarding the GSD at discrete time steps, making it difficult to apply in process design applications. Population balance equations (PBEs) are a frequently used mathematical tool to describe particulate processes such as granulation (Kumar et al., 2013). An extensive review of the applications of such equations to particulate systems in engineering is given by Ramkrishna (2000). Barrasso et al. (2015) used a multi-component population balance model (PBM) for tracking the liquid content and porosity of each particle size class during the twin-screw granulation. The experimental data from El Hagrasy et al. (2013) used for the study originated from samples collected from the granulator outlet and therefore a lumped-parameter approach was adopted for the development of the model.

In this study, the principle constitutive mechanisms of a granulation system such as growth, aggregation and breakage are included in a population balance modelling framework to track particle size evolution in the different individual screw blocks of a continuous TSG. Based on an experimentally determined inflow GSD (Kumar et al., 2014a) and mean residence time ($\bar{t}$) (Kumar et al., 2014b) of the granulator, predictions of the outflow GSD were made. The experimental data was used for calibrating the model for individual screw modules in the TSG.

2. System analysis and model formulation

2.1. Continuous wet-granulation using TSG

The TSG consists of a barrel enclosing two co-rotating self-wiping screws. At the entrance, raw materials are fed into the transport zone and the granulation liquid is added via two nozzles, one for each screw, before the material reaches the mixing zone which consists of kneading discs (Fig. 1). The powder is hence wetted by the granulation liquid in this region. Further down, since the granulation occurs by a combination of capillary and viscous forces binding particles in the wet state, the wetted material is distributed, compacted and elongated by the kneading discs of the mixing zones, changing the particle morphology from small (microstructure) to large (macrostructure) (Vercruysse et al., 2012). The rotation of the screws conveys the material in axial direction through the different zones of the TSG by the drag and flow-induced displacement forces and thus causing mixing and granulation. The rheological behaviour of the material also changes based on liquid-to-solid ratio (L/S) (Althaus and Windhab, 2012).

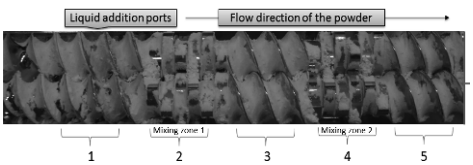

Figure 1: TSG screws with two mixing zones, each containing six kneading discs. Numbers indicate experimental sampling locations used for model calibration and validation.

2.2. Population balance model for twin-screw granulator

A TSG consists of a wetting zone and several mixing zones containing a finite number of kneading elements, which significantly drive the granulation process. The compartmentalisation into two mixing zones for simulation solved the challenge of inhomogeneous distribution in particle properties along the TSG length, due to the geometry of the screw as well as position of the liquid addition port. Introducing an external coordinate can be another possibility to model this inhomogeneity, but that will require implementation of the discrete element method together with population balances which is computationally challenging. In order to model the change in GSD across the individual mixing zone, these mixing zones were assumed as well mixed systems. The granulation rate processes which are considered dominant in the kneading element regions of the granulator, i.e. aggregation and breakage, were included in a population balance modelling framework, which can be represented as:

$$\begin{aligned}\frac{\partial n(t,x)}{\partial t} =& \frac{Q_{in}}{V} n_{in}(x) - \frac{Q_{out}}{V} n_{out}(x) + \frac{1}{2}\int_0^x \beta(t,x-\varepsilon,\varepsilon)\, n(t,x-\varepsilon)\, n(t,\varepsilon)\, d\varepsilon \\ & - n(t,x)\int_0^\infty \beta(t,x,\varepsilon)\, n(t,\varepsilon)\, d\varepsilon + \int_0^\infty b(x,\varepsilon) S(\varepsilon) n(t,\varepsilon)\, d\varepsilon - S(x) n(t,x)\end{aligned} \tag{1}$$

where, $n(t,x)$ is the number density function of particle volume as the internal co-ordinate at time t, Q_{in} and Q_{out} were inflow and outflow of the material based on throughput and V was the volume of the mixing zone. Assuming the material transport across the mixing zone to occur at a steady state, inflow and outflow can be eliminated from Eq. 1. The primary challenge for using PBE is to model the kinetics of the twin-screw granulation process in $\beta(t,x,\varepsilon)$ and $b(x,\varepsilon)$, because of their strong dependence on the time and in a fairly complex way on operating parameters and material properties. The constant aggregation kernel ($\beta(t,x,\varepsilon) = \beta_0$) describing the frequency that particles with diameter ε and $x-\varepsilon$ collide to form a particle of size x was used in this study. For the breakage process, the quadratic selection function, $S(y) = S_0(y)^\mu$, where S_0 and μ are positive constants for reasons of simplicity. The breakage function, $b(x,y)$ proposed by Austin (2002) (eq. 2) describing the formation of particles of size x from the breakup of a particle of size y was used.

$$b(x,y) = \frac{\frac{\phi\gamma x^{\gamma-1}}{y^\gamma} + \frac{(1-\phi)\alpha x^{\alpha-1}}{y^\alpha}}{\frac{\phi\gamma}{\gamma+1} + \frac{(1-\phi)\alpha}{\alpha+1}} \tag{2}$$

where γ, ϕ and α are dimensionless material constants. The term ϕ is called the weight parameter to quantify the mass content of the first breakage distributions. The exponents γ and α represent the width of the fragment distributions ϕ and $1-\phi$, respectively.

2.3. Numerical solution of PBM

To solve this equation numerically we first fix a computational domain]0,R] with R $<$ 1 and the truncated equation is obtained from Eq. 1 replacing 1 by R. A logarithmic grid with 50 bins was used for the discretisation of internal coordinates in order to accommodate particles of a wide size range with a minimal number of bins. Thereafter, a sectional method known as the cell average technique (CAT) was applied to solve the equation (Kumar et al., 2006). As the volumes of the newborn particles due to aggregation and/or breakage may lie between the bins of the logarithmic grid, the CAT allocates these particles into the corresponding nodes.

2.4. Model parameter estimation

The experimental data provided evidence that the aggregation and breakage are the dominant mechanisms in twin-screw granulation (for details see Kumar et al. (2014a)) and a model framework was developed to include these phenomena. However, various parameters in this model are

Table 1: Estimated model parameters with corresponding confidence intervals (95.44 %) at different screw speeds and mixing zones.

Screw speed	Low		High	
Mixing zone	I	II	I	II
β_0	3.02E-03 ± 1.47E-04	1.95E-01 ± 4.56E-02	9.18E-02 ± 4.07E-03	4.99E-02 ± 1.80E-02
S_0	2.53E-02 ± 5.91E-03	7.99E-01 ± 4.35E-02	3.11E-02 ± 2.25E-03	5.72E-01 ± 3.55E-02
α	1.13E-05 ± 8.83E-06	6.11E-01 ± 3.19E-02	1.26E-03 ± 3.29E-04	4.38E-01 ± 9.30E-02
γ	4.05E+00 ± 7.60E-01	3.81E-03 ± 2.18E-04	2.63E-01 ± 9.02E-03	4.49E-02 ± 3.78E-03
ϕ	1.03E+00 ± 2.31E-01	5.43E-02 ± 2.24E-03	1.18E+00 ± 3.89E-01	1.50E-02 ± 2.13E-03

unknown and can vary based on process settings and material properties. Experimental data of volume distributions of granule samples from various locations inside the granulator (Fig. 1) were used to estimate values of five parameters: three dimensionless material constants, γ, ϕ and α and the aggregation constant β_0 and selection function constants S_0. Based on available literature, selection function constants μ was fixed at 0.33. The estimation of these parameters was done by minimising the RMSE as an objective function (eq. 3):

$$\text{RMSE} = \sqrt{\frac{\sum_{i=1}^{n}(\hat{y}_i - y_i)^2}{n}} \tag{3}$$

where $\hat{y}_i$ and y_i are the predicted and experimentally measured values for n bins of the granule size range. In order to find the global minimum of the objective function, the `brute force` method was used, which computed the objective function's value at each point of a multidimensional grid of points, to arrive at the global minimum of the function. This multidimensional grid contained ranges of β_0 (1e-5, 0.4), S_0 (0.001, 3.5), α (3.3e-6, 1), γ (1.6e-4, 5) and ϕ (0.01, 1.5) with linear step length of 0.005, 0.005, 0.000005, 0.05 and 0.05, respectively. The estimated parameter sets were useful to check any correlations between estimated parameters, and also to determine the confidence interval of the fitted parameter using the bootstrap estimation Efron and Tibshirani (1986). Later, to obtain a more precise (local) minimum, the downhill simplex algorithm was used applying the estimation result of brute force minimization as initial guess (Nelder and Mead, 1965). The implementation of PBM solution and parameter estimates were performed using the Python programming language, employing built-in functions in scientific libraries NumPy and SciPy (Oliphant, 2007) and Odespy (Langtangen and Wang, 2014).

3. Results and discussion

3.1. Parameter estimation for predictive modelling

Experimentally measured size distributions from location 1, 3 and 5 in Fig. 1 for runs at low (500 rpm) and high (900 rpm) screw speed were used for model calibration. In order to quantitatively represent these trends in the simulations, the unknown rate parameters of the aggregation and Austin breakage kernels were estimated by comparing the simulation results with experimental data. The estimated parameters used for the numerical computations and their confidence intervals (95.44 %) are listed in table 1. The error estimates (RMSE and R^2) are mentioned in Fig. 2. The low RMSE and high R^2 values for all the screw speeds and mixing zones indicate that numerical results were in excellent agreement with the experimental data for each location inside the granulator subject to different optimal model parameters.

3.2. Simulated dynamic behaviour in the mixing zones of TSG

The simulation results showed that when the screw speed is low (Fig. 2.a), the D_{90} and D_{75} reduced and the D_{25} and D_{50} increased slightly when the material passed the first mixing zone. This indicates that the primary role of the first kneading block at this condition was the breaking of larger wetted lumps. The granules resulting from breakage caused increase in D_{25} and D_{50}. The

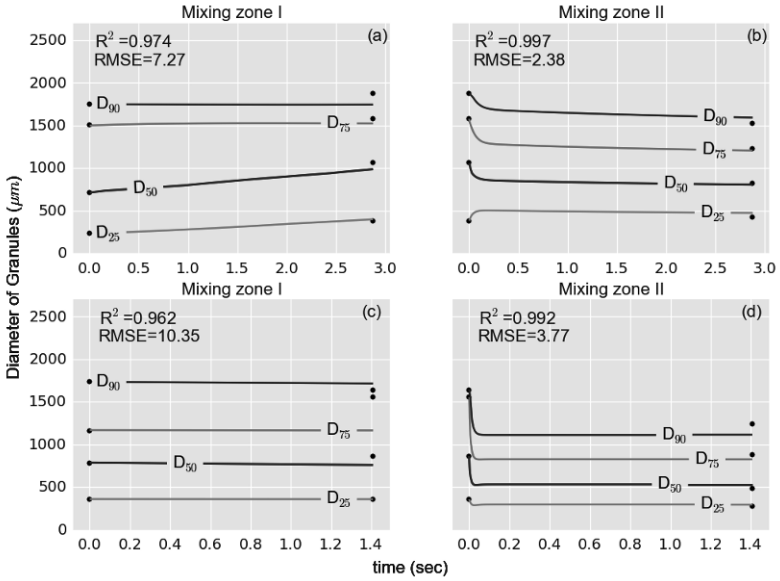

Figure 2: Experimental (•) and simulated (—) trends for dynamic change in quartiles of GSD (D25, D50, D75 and D90) at low (a and b) and high (c and d) screw speeds for first (a and c) and second (b and d) mixing zones.

second mixing zone at this condition caused further breakage of the granules leading to reduction in D_{50} as well together with D_{75} and D_{90} (Fig. 2.b). However, the D_{25} of the GSD remained unaffected by the mixing in the second zone. Overall, the barrel at this condition was highly filled due to the low screw conveying rate at low screw speed leading to less space for material to get distributed. This was also the reason that in experimental study this condition led to an undesirable level of high torque Kumar et al. (2014a).

The simulation of the high screw speed condition showed a significant change in the granulation behaviour in two mixing zones (Fig. 2.c and d). Unlike low screw speed, when the material passed through the first mixing zone at this condition all the quartiles of the GSD increased (Fig. 2.c). This indicates that aggregation was the most dominant mechanism in this condition in this mixing zone, while the level of breakage was very low leading to no reduction in any fraction with time. However, when the material was introduced to the second kneading block, the quartile values D_{90}, D_{75}, D_{50} dropped significantly, which indicates that breakage returned as the dominant mechanism in the second mixing zone (Fig. 2.d). This observation by process simulation is very important as it established that the successive kneading blocks led to a granulation regime-separation inside the twin-screw granulator under this condition. The mixing of the wetted powder in the first kneading block caused an increase in the aggregation rate, which was reduced after the second kneading block. However, the breakage rate increased successively along the length of the granulator. Such a physical separation between the granulation regimes will be promising for future design and advanced control of the continuous granulation process.

In order to further improve the model, future work will focus on introducing the wetting kinetics in the model framework and to obtain particle flux data and collision frequencies using DEM to avoid the parameter estimation by model inversion. Additionally, dedicated mechanistic kernels for the twin-screw granulation can be developed in order to improve the sensitivity of the model towards the change in process condition and other field parameters. Finally, a validated model can be used to define the design space of the process for the future optimization and model-based control of the granulation process.

4. Conclusions

A 1-D PBM including aggregation and breakage subprocesses for a continuous twin-screw granulation process was presented. Unknown model parameters and their 95% confidence range were estimated using experimentally measured particle size distributions from inside the granulator. The calibrated model was then used as a predictive tool within the experimental space. The results showed strong agreement with experimental data. This approach is the better way forward for the development of twin-screw granulation models as multiple factors of twin-screw granulator leading to a experimental output can now constrain the model during calibration. Further analysis revealed that, at high screw speed, the successive kneading blocks can lead to the dominance of different constitutive granulation mechanisms inside the twin-screw granulator. An ability to achieve a physical separation between the granulation regimes inside the granulator can be promising for future design and advanced control of the continuous granulation process using the twin-screw granulator. Furthermore, the study suggested that a model-based approach can be adopted to develop a better understanding of twin-screw granulation processes. A validated model can ultimately be used to define the design space of the process to facilitate process optimization and model-based control.

Abstract

We present a method for reducing product losses in sterile drug product manufacturing processes. The method consists of five steps that guides the effort of process improvement, and serves as a fundament for the Plan phase of the Plan-Do-Check-Act (PDCA) cycle. The method considers all product components of the process, e.g., Active Pharmaceutical Ingredients (APIs), excipients and primary packaging materials. In addition, a couple of mechanisms are newly developed for generating effective improvement scenarios as well as comparing effect and effort of different scenarios in a multiobjective manner. In the case study, the method was executed step-by-step using industrial data and the effectiveness of the method was demonstrated.

Keywords: pharmaceutical processes, process improvement, yield

1. Introduction

Due to the increase of healthcare costs and R&D expenses, pharmaceutical manufacturing is requested to become more cost-effective without compromising the product quality. As to the manufacturing cost, one of the major factors is the material cost. With the aim of reducing raw material costs, several authors worked on the yield of APIs, the most value-added component of products. Dassau et al. (2006) applied quality control techniques for improving the API yield as well as product property such pH in the bio-pharmaceutical production processes. With a focus on fractional batch distillation processes, Yang and Tjia (2010) applied process simulators for creating better process understanding, which lead to the enhancement of API throughput and yield. Sugiyama and Schmidt (2013) proposed an indicator for prioritizing loss causes of API, and applied the indicator in a biological drug product manufacturing facility.

However in these previous contributions, there are still rooms for improvement regarding applicability. For instance, the focus so far is more on the effectiveness of reducing losses, and less on the associated efforts or quality risks. Regardless of the effectiveness, no process improvement will be accepted that does not comply with quality regulations known as Good Manufacturing Practice (GMP). In addition, the above mentioned work considers only APIs, and other materials are outside of the scope, e.g., excipients or packaging materials. These raw materials, which also have pharma-grade, can be a relevant factor of the entire material cost.

In this paper, we propose a planning method for reducing product losses in the pharmaceutical manufacturing processes. The primary target of the method is the manufacturing processes of sterile drug products, such as injectables, infusion solutions,

or eye-drops. The method consists of five steps: (1) Analyze process flow, (2) Collect process data, (3) Characterize loss causes, (4) Generate improvement scenarios, and (5) Perform multiobjective evaluation. The outcome is a set of promising improvement scenarios for reducing product losses, which supports the Plan-phase of the PDCA cycle of process improvement. A couple of novel mechanisms are proposed in order to help generating effective improvement scenarios as well as to compare different scenarios in a multiobjective manner. The consideration scope is extended to cover not only API, but also other component materials such as excipients or packaging materials. An industrial case study is performed in order to show the effectiveness of the method.

2. Method

Figure 1 shows a general process for producing sterile drug products. The process is batch-wise. There are different causes of product losses in the process. For instance, a number of samples are taken for quality control (QC) or In Process Control (IPC), for complying with the GMP requirements. The nature of the batch production results in losses associated with the start and the end of the production, e.g., pre-flush of the product solution from the filter unit.

The effective way to reduce these losses would be to investigate the mass flow of the entire process, and to identify the relevant loss causes with high economic damages. However in the pharmaceutical batch processes, this simple work can face difficulties because (i) the concept of taking overall mass balance is weak; (ii) some of the loss data are not measured due to the high-value given to the product; (iii) even when the data are available, they are stored in different places in the organization. Thus, as shown in Figure 2, our method first starts with creating an overview of the process and material flow, before working on concrete improvement.

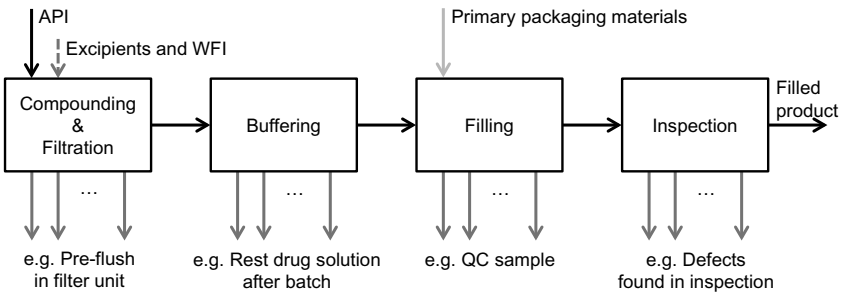

Figure 1 Typical processes of sterile drug product manufacturing

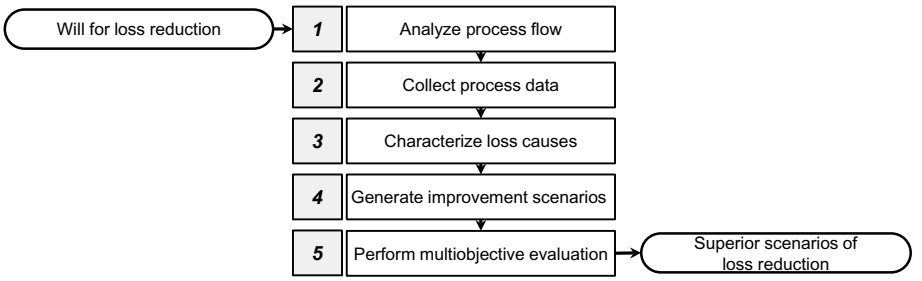

Figure 2 Five-step method for reducing product losses

2.1. Step 1: Analyze process flow

The aim of Step 1 is to create a process flow diagram as shown in Figure 1, where all manufacturing steps as well as entering/exiting flows are identified.

2.2. Step 2: Collect process data

In Step 2 data are collected for the process flows and the quantities of the loss flows m are obtained for product i, loss cause j, batch k, and material l. The term m can have different units such as L, kg, or unit, depending on the material. Manufacturing recipes can provide the quantity of the flows that are fixed over batches, e.g., API inlet, whereas batch record data need to be collected for variable flows, e.g., defectives found in the inspection. In parallel, purchase price P for unit amount of material l is also collected, using information from the financial department.

2.3. Step 3: Characterize loss causes

Based on the collected information, economic damage of each loss cause is calculated. In this method we introduce an indicator termed Annual Cost of Losses (ACL) for loss cause j of product i as:

$$ACL_{i,j} = \frac{N_i}{n_i} \sum_{k,l} \left(P_l \, m_{i,j,k,l} \right) \tag{1}$$

where N_i and n_i are the numbers of batches planed in the year and covered in the data collection, respectively. With this simple indicator, all loss causes that have different units can be now compared on the same basis. The indicator is also flexible in terms of the time span considered, and it can be adjusted from yearly to quarterly or monthly according to the interest of the company. Apparently the value of m needs to be stable over batches, and n_j needs to be sufficient, for the realistic estimation of ACL.

In addition, we propose a qualitative method in Table 1 for distinguishing causes into four categories according the reason of the loss. Category I is the samples collected due to the GMP requirements. If the reduction of the loss is desired, the sampling method needs to be investigated, e.g., frequency or quantity. Category II is the losses planned at the start or the end of the batch production, such as discharge of the product solution in the tank remaining after a batch. Such planned losses are usually defined in the manufacturing procedure, and thus its validity needs to be investigated. Category III covers the losses due to trouble in the production, which happens so frequently that the discard procedure is defined in the procedure. For reducing this type of losses, one approach is to scrutinize the procedure itself, or the other is to identify and prevent the root cause of the trouble. Losses in Category IV are due to unplanned troubles such as defectives found in the visual inspection. The only approach for this type of loss is to identify the root cause and to implement preventive actions.

Table 1 Categorization of product losses as a guide to generate effective improvement scenarios

Category	Reason of the loss	Points to be investigated
I	Sampling due to GMP	Sampling method, frequency and quantity
II	Start and end of batch production	Discard procedure
III	Frequent trouble	Discard procedure, root cause of the trouble
IV	Sudden trouble	Root cause of the trouble

Table 2 Calculation scale for evaluating product quality risk using FMEA. The terms of *SV*, *OC* and *DT* stand for the evaluation scores of severity, occurrence and detectability, respectively.

Severity	*SV*	Occurence	*OC*	Detectability	*DT*
Recall from the market	5	Every batch	5	Patient notices for the first time	5
Total batch rejection	4	Once in a month	4	Not checked in the inspection	4
Partial batch rejection	3	Once in a year	3	Checked in the inspection but judgment is subtle	3
Re-inspection	2	Once in ten years	2	Spot check	2
No effect	1	Once in 100 years	1	100% inspection	1

2.4. Step 4: Generate improvement scenarios

Improvement scenarios are generated in Step 4. A scenario can be an imaginary situation, e.g., abolish the planned discard of remaining solution after a batch, but with a concrete and realistic technical countermeasure. Preliminary measurements would be helpful to justify the appropriateness of the scenario, e.g., quality measurement of the effluent solution. Brain storming by different experts from manufacturing, quality, engineering would be effective for enhancing comprehensive generation of scenarios.

2.5. Step 5: Perform multiobjective evaluation

In this step, all scenarios generated are evaluated in different criteria. Our method gives an evaluation score S to each improvement scenario regarding the following six aspects: reduction potential of ACL (S_1), investment cost (S_2), impact for shift operation (S_3), timing of implementation (S_4), effort of change management (S_5) and product quality risk (S_6). The score S ranges from one to five, with five as the most favorable and one as the least favorable, respectively. Economic evaluation scores (S_1 and S_2) are based on the actual quantities, while the other scores (S_3 to S_6) are assessed in a semi-quantitative manner.

This paper presents the calculation of S_6: product quality risk using Failure Mode and Effect Analysis (FMEA). The first action of this well-established quality method is the generation of failure mode, each of which is secondly evaluated in terms of severity *SV*, occurrence *OC* and detectability *DT*. Table 2 shows the calculation scale. Lastly all the scores are multiplied to obtain so-called Risk Priority Number (*RPN*) for failure mode *f*, and the maximum value represents the *RPN* of a scenario, as defined in Eq. (2).

$$RPN = \max_{f}(SV\ OC\ DT)_f \tag{2}$$

The score S_6 is then obtained by the Eq. (3).

$$S_6 = 6 - \left\lfloor \sqrt[3]{RPN} \right\rfloor \tag{3}$$

Trade-offs between different scenarios can be discussed based on the obtained scores. For supporting management decision, Pareto optimization can be helpful in identifying superior scenarios, which can be selected for detailed planning. If no desirable solution can be found, alternative scenarios need to be generated by repeating Step 4.

3. Case Study

An industrial case study was performed to demonstrate the method. The target of the case study was a plant, which produces two sterile drug products of A and B in different production lines. Although these lines are similar, the products A and B are different in regard to the therapeutic area, pharmaceutical prices, annual production amount and product property. Thus, for the plant management, it was difficult to judge which product loss should be worked on with which priority and approach.

3.1. Step 1: Analyze process flow

As Step 1, process flow diagrams as in Figure 1 were created for the products A and B.

3.2. Step 2: Collect process data

For all the loss causes identified in Step 1, quantities of the mass *m* were collected from different sources in the manufacturing area, e.g., batch record and QC data.

3.3. Step 3: Characterize loss causes

The value of ACL were then calculated for the loss causes of both products A and B, and the major results are shown in Figure 3 (left). Loss categorization in Table 1 was applied.

The first four dominant causes belong to Category II, i.e., losses associated with the start/end of batch production. The first one was found in product A, and was the discharge of the remaining product solution from the buffer tank at the end of the batch. When the process was designed, there were some technical difficulties to fill all the solution in the tank, and a certain amount was set to be discarded in every batch. The second most relevant was in product B, and was due to the pre-flush of the filter unit during the preparation of a batch production. This is commonly practiced in the industry because the product properties, e.g., concentration, are considered to be unstable, when the solution is introduced into the filter. Since the amount to be discarded was determined with a large safety allowance, this cause appeared in a prominent position.

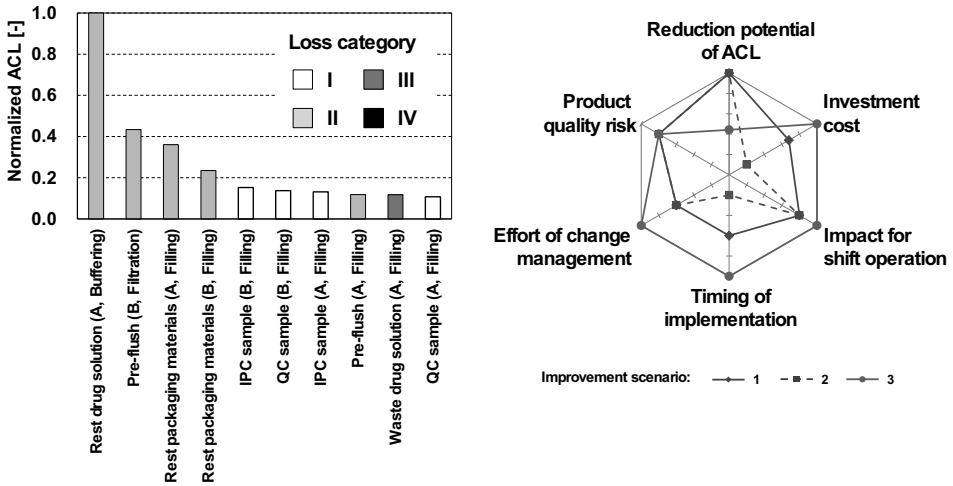

Figure 3 ACL evaluation result (left) and multiobjective evaluation result (right)

3.4. Step 4: Generate improvement scenarios

Regarding the first and second loss cause, an analysis indicated that the discarded solution can have the same quality as the regular product. Based on this preliminary analysis, three scenarios were generated (Scenarios 1 and 2 for the first cause, and Scenario 3 for the second cause). All scenarios are basically to set the discard amount to be zero by implementing either of the following facility changes.

3.5. Step 5: Perform multiobjective evaluation

Figure 3 (right) shows the evaluation of three scenarios in regard to the multiobjective criteria defined the previous chapter. Different characters of all scenario are visualized. Scenarios 1 and 2 show the largest reduction potential of ACL, whereas they are the best in none of the other criteria. Scenario 2 involves construction activities for a long period, which resulted in the worst result of all in investment cost and timing. Scenario 3 has the second largest potential in reducing ACL, and the best score in all other criteria. The score S_6 was four for all scenarios. In Scenario 1, *SV*, *OC* and *DT* of the worst failure mode were 4, 3 and 1, respectively, which resulted in $RPN = 12$ and $S_6 = 4$.

In Figure 3 (right), it can be seen that Scenarios 1 and 3 are the Pareto optima, or the set of non-dominated scenarios. Trade-off can be observed in these two scenarios, i.e., compared to Scenario 1, Scenario 3 is less lucrative regarding ACL reduction, but is easier to be implemented. In this way, Step 5 can help characterization of all scenarios and prioritization of the effort on process improvement.

4. Conclusions and Outlook

In this paper, we presented a process-based method for reducing product losses in sterile drug product manufacturing processes. Five steps defined in the method can guide the effort of process improvement, and support the Plan phase of the PDCA cycle. The method considers all product components used in the process, and both effect and effort of an improvement in the evaluation. Another novelty can be found in the following mechanisms: ACL indicator for comparing different loss causes with different units; loss categorization for generating improvement ideas effectively; multiobjective evaluation indicators for considering economy, operational feasibility and impact on quality management. The method was demonstrated in an industrial case study, where two improvement scenarios are obtained as promising ones. In the future, the method can be combine with process simulation techniques, which can support model-based generation of various scenarios.

Abstract

Since large molecules are considered the key driver for growth of the pharmaceutical industry, the focus of the pharmaceutical industry is shifting from small molecules to biopharmaceuticals: around 50% of the approved biopharmaceuticals are freeze-dried products. Therefore, freeze-drying is an important technology to stabilise biopharmaceutical drug products which are unstable in an aqueous solution. However, the freeze-drying process is an energy and time-consuming process. The use of mechanistic modelling to gather process knowledge can assist in optimisation of the process parameters during the operation of the freeze-drying process. By applying a dynamic shelf temperature and chamber pressure, which are the only controllable process variables, the processing time can be decreased by a factor 2 to 3.

Keywords: Dynamic Design Space, Modelling, Optimization, Pharmaceuticals

1. Introduction

Nowadays large molecules receive more attention and the interest in these molecules is growing. The list of the Food and Drug Administration (FDA) and European Medicines Agency (EMA) with the approved biopharmaceutical products (> 300) contains approximately 50% freeze-dried products (Constantino and Pikal, 2004). This is an indication that freeze-drying is the preferred way of stabilizing biopharmaceutical drug products that are unstable in aqueous solution. However, the high cost and energy consumption and long processing time are disadvantegeous (Burns, 2009; Gieseler, 2012). Among the freeze-dried biopharmaceutical products the largest fraction are therapeutic protein formulations and vaccines (Pikal, 2002; Patel et al., 2010).
Conventionally, freeze-drying (or lyophilization) is a batch process, consisting of three consecutive steps: freezing, primary drying and secondary drying. Therefore, vials filled with a solution are placed on temperature-controlled shelves in the drying chamber. The lyophilization process starts with the cooling of these shelves down to approximately -45 °C. During this freezing step most of the water crystallizes to ice. The solutes gradually concentrate between these ice crystals, until they start crystallizing (at the eutectic temperature T_e) or form an amorphous glass (at the glass transition temperature T_g'). After complete solidification, the primary drying step begins by introducing a vacuum, conventionally between 50 and 300 μbar, in the drying chamber.

Additionally the temperature of the shelves is increased to provide the energy necessary for ice sublimation. The sublimation front, the border between the ice crystals and dried product, gradually decreases during the progress of primary drying until ice sublimation is complete. Finally, during the secondary drying step, the remaining unfrozen water is removed by desorption and a dry cake is obtained.
Several Critical Quality Attributes (CQA) are identified for freeze-dried biopharmaceuticals. These product characteristics should be within an appropriate limit to ensure product quality (ICH guidelines on Pharmaceutical Development (Q8)), e.g. the Active Pharmaceutical Ingredient (API) needs to stay stable throughout the lyophilization process to guarantee optimal therapeutic activity (e.g. avoiding loss of protein conformation by adding lyo- and/or cryoprotectants) or the residual moisture level of the dried cake needs to be adequate to ensure product stability (e.g. water-mediated degradation pathways). One of the most important CQA's is cake appearance. For aesthetic purposes and to ensure fast reconstitution of the drug product, loss of structure (cake collapse) should be avoided throughout the lyophilization process. Therefore the product temperature T_p at the sublimation front should always be kept below the collapse temperature T_c and T_e for amorphous and crystalline materials respectively (Kasper and Friess, 2011). T_c is generally a few degrees higher than T_g' because the high viscosity of the glass near T_g' limits molecular motion. On the other hand, primary drying asks for T_p to be as high as possible to shorten the sublimation time. Therefore, the adaptable process variables, shelf temperature T_s and chamber pressure P_c, should not be chosen too conservative. Mechanistic modelling allows to determine the optimum combination of T_s and P_c keeping T_p at the sublimation front below the critical temperature during primary drying. Mechanistic modelling is a powerful tool for both cycle development and optimization. The information obtained from the models allows the development of the Design Space for a specific formulation. The limits of the Design Space are determined by the efficiency of primary drying, the dried cake appearance and the equipment capability. The target T_s and P_c should therefore be within these limits to acquire a good cake within an acceptable process time. The use of the Design Space highly improves the efficiency and control of the lyophilization process.
Since T_p depends on a wide range of varying parameters during sublimation, the optimal combination of T_s and P_c is not constant during drying. For instance, along with the progress of primary drying the thickness of the dried product layer L_{dried} increases which simultaneously leads to an increase in product resistance R_p and T_p at the sublimation interface. Because of the continuous dynamics of dependent variables, the Design Space also changes continuously throughout the lyophilization process and, hence, requires a dynamic Design Space.

2. Objectives

The objective is to use the freeze-drying model (Fissore et al., 2011b,a) to obtain the optimal values for the shelf temperature T_s and the chamber pressure P_c, i.e. a dynamic Design Space is created.

3. Freeze-drying model

The mathematical model consists of two phases, and the equations are based on the principles of mass and energy transfer. In the first instants the chamber pressure is gradually decreasing till the calculated sublimation rate $\dot{m}_{sub}$ (kg/s) is higher than zero. An exponential decrease of the chamber pressure P_c from 100,000 Pa to 10 Pa in 10 minutes is assumed. A faster decrease of the chamber pressure is restricted by the freeze-drying equipment. During this first phase it is assumed that the shelf temperature T_s (K) remains constant at the initial shelf temperature and the temperature at the sublimation front T_i (K) equals the shelf temperature. Moreover, the temperature difference across the ice layer ΔT is fixed at 0 K. As long as the calculated sublimation rate is lower than zero, the sublimation rate is set to zero.

During the second phase, starting when the sublimation rate is higher than zero, the thickness of the dried layer L_{dried} (m) increases.
The full mathematical model describing the freeze-drying process consists of several equations of which some have to be solved simultaneously. The model calculates the evolution of the thickness of the dried layer in function of time. For a fixed set of input values the temperature at the sublimation front T_i (K) and the temperature difference across the ice layer ΔT are calculated using the following equations (Fissore et al., 2011b; Murphy and Koop, 2005):

$$e^{9.550426-5723.265/T_i+3.53068\ln(T_i)-0.00728332T_i} = -\frac{(-A_p\Delta H_{sub}P_c - A_vK_vM\,T_s + A_vK_vR_pM\,T_i + A_vK_vR_pM\Delta T)}{A_p\Delta H_{sub}} \tag{1}$$

$$\Delta T = \frac{24.7\frac{(L_{total}-L_{dried})(P_i-P_c)}{R_p+R_s} - 0.0102\,(L_{total}-L_{dried})\,(T_s-T_i)}{1-0.0102\,(L_{total}-L_{dried})} \tag{2}$$

with A_p and A_v the product and the vial area (m^2), which are respectively equal to the inner and the outer surface of the vial, ΔH_{sub} the latent sublimation heat of ice (J/mol), P_c the pressure in the drying chamber (Pa), K_v the vial heat transfer coefficient (J/(m^2sK)), M the molecular weight of water (kg/mol), T_s the temperature for the temperature-controlled shelf (K), R_p the dry product resistance (m/s), R_s the stopper resistance (m/s), ΔT the temperature difference across the ice layer (K), L_{total} the total thickness of the product layer (m) and L_{dried} the thickness of the dried layer (m). The latent sublimation heat of ice ΔH_{sub} is given by (Murphy and Koop, 2005):

$$\Delta H_{sub} = 46782.5 + 35.8925T_i - 0.07414T_i^2 + 541.5e^{-\left(\frac{T_i}{123.75}\right)^2} \tag{3}$$

The vial heat transfer coefficient K_v is calculated by (Fissore et al., 2011a):

$$K_v = \alpha + \frac{\beta P_c}{1+\gamma P_c} \tag{4}$$

with α (J/(m^2sK), β (J/(m^2sKPa) and γ (1/Pa) constants, which are determined using experimental data.
The dry product resistance R_p is given by (Fissore et al., 2011a):

$$R_p = R_{p,0} + \frac{A_{Rp}L_{dried}}{1+B_{Rp}L_{dried}} \tag{5}$$

with $R_{p,0}$ (m/s), A_{Rp} (1/s) and B_{Rp} (1/m) constants, which are dependent on the product that is freeze-dried and its concentration. The constants are determined by fitting to experimental data.
Once the temperature at the sublimation front is known, the pressure at the interface P_i (Pa) can be calculated using the following relation (Murphy and Koop, 2005):

$$P_i = e^{9.550426-5723.265/T_i+3.53068\ln(T_i)-0.00728332T_i} \tag{6}$$

The sublimation rate $\dot{m}_{sub}$ can be calculated using (Fissore et al., 2011a,b):

$$\dot{m}_{sub} = A_p\frac{(P_i-P_c)}{R_p} \tag{7}$$

The evolution of the thickness of the dried layer is then given by (Tang et al., 2006):

$$L_{dried} = \frac{m_{sub}}{\rho_I\varepsilon A_p} \tag{8}$$

with m_{sub} the mass of ice removed by sublimation (kg), ρ_I the density of ice (kg/m^3) and η the porosity of ice.
The total thickness of the product layer L_{total} is calculated based on the amount of liquid that is filled in the vial:

$$L_{total} = \frac{V 10^{-6}}{\pi r_i^2} \tag{9}$$

with V the volume in one vial (mL).
The nominal values of the parameters are given in table 1. With the inner radius r_i and outer radius r_o of the vial the product area A_p and vial area A_v can respectively be calculated.
The critical temperature at the sublimation front is set at 238.15 K (-35 °C). The limits for the

Table 1: Nominal values of the parameters of the freeze-drying model

Parameter	Numerical value
r_i	0.011 m
r_o	0.0115 m
α	3.2 J/(m^{2}sK)
β	0.7 J/(m^{2}sKPa)
γ	0.02 1/Pa
R_s	0 m/s
$R_{p,0}$	1.1 10^4 m/s
A_{Rp}	2.7 10^8 1/s
B_{Rp}	2.5 10^3 1/m
V	2.5 mL
ρ_I	919.4 kg/m^3
ε	0.97
M	0.018015 kg/mol

freeze-drying equipment for respectively the chamber pressure (Pa) and the shelf temperature (K) are $[10\ 10000]$ and $[-233.15\ 303.15]$.
The sublimation rate is limited by the freeze-drying equipment, known as the Equipment Capability Curve (ECC)-restriction which is function of the chamber pressure:

$$\dot{m}_{sub,max} = -2.7075\,10^{-9} + 8.1232\,10^{-9} P_c \tag{10}$$

To optimise the freeze-drying process the objective is to maximise the sublimation rate without exceeding the critical temperature at the sublimation front and the ECC-criterion. The degrees of freedom are the chamber pressure and the shelf temperature which do not necessarily have to be fixed throughout the process.

4. Results

During freeze-drying the thickness of the dried layer L_{dried} increases over time until L_{dried} equals L_{total}. To determine the optimal values for the chamber pressure and shelf temperature during freeze-drying a grid-search method is used. For each combination of P_c and T_s, feasible using the equipment under study, the sublimation rate is calculated. For each grid point two criteria are verified: (1) the temperature at the sublimation front and (2) the ECC-criterion. As the thickness of the dried layer changes during freeze-drying the optimal values for P_c and T_s are changing as well. To limit the calculation time the limits for the grid-search are restricted to $[5\ 800]$ and $[-16\ 20]$. The underlying reason for the extension of the pressure towards 5 Pa instead of using the equipment limitation of 10 Pa is that the optimal chamber pressure seemed to be on the lower limit. By

using 5 Pa it was possible to verify if a lower value for the chamber pressure would be even more optimal.

In figure 1 the evolution of the thickness of the dried layer is presented. Initially, L_{dried} remains constant at a value of zero, because the sublimation rate is zero. As long as the chamber pressure is higher than the pressure at the interface P_i sublimation does not occur. Once sublimation kicks in, a gradual increase of L_{dried} is observed. The evolution of the chamber pressure and the shelf temperature is presented in figure 2 (logarithmic axes on the right). A steep decrease of the chamber pressure can be noticed. The process starts at ambient pressure and during the first 10 minutes the pressure is decreasing exponentially. Initially, the shelf pressure is kept at -45 °C, subsequently the optimal value for T_s is relatively high, without the risk that the temperature at the sublimation front is exceeded. After this increase, the shelf temperature should be gradually decreased in order to meet the quality standards. Due to the resolution that has been chosen for the grid-search, the evolution of P_c and T_s is step-wise instead of a smooth evolution. The resolution for the grid-search has been limited in order to be able to perform the simulation study in a reasonable time frame. The sublimation rate, presented in figure 3 is initially equal to zero, then evolves to a maximum value, after which it exponentially decreases till it reaches a steady-state value.

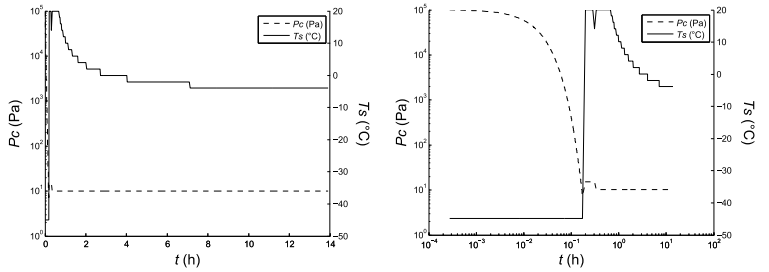

Figure 2: The evolution of P_C and T_s in time. The figure to the right zooms in on the initial time steps by using logarithmic axes

5. Conclusion & further perspectives

The use of a mechanistic model to develop the Design Space is interesting and a cost-effective approach, as it requires no energy and material. However, the model should be a reliable representation of the reality before the model predictions are useful to draw conclusions. Therefore, a

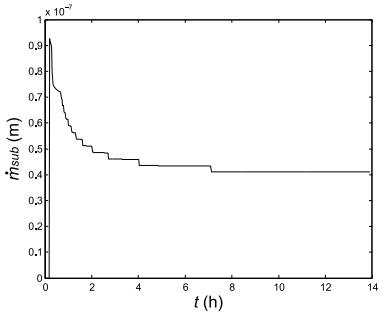

Figure 3: The evolution of $\dot{m}_{sub}$ in time

validation of the model using experimental data is required. Once a validated model is available, it can be used to gather process knowledge and to develop the Design Space.
Additionally, the freeze-drying process will be dependent on the product that is freeze-dried and its concentration and the used equipment. These elements have an influence on the parameters used to calculate the model predictions, and as such, have an effect on the calculated Design Space. An uncertainty analysis is useful to incorporate the impact of parameter uncertainties on the predictions. In order to guarantee the final product quality of the freeze-dried product, the temperature at the sublimation front should be kept under the critical temperature, which is again product-dependent. Therefore, instead of using a shelf temperature and chamber pressure which maximize the sublimation rate, it is recommended to incorporate the uncertainties and work at the 5% percentile. In this case, there is 95% probability that the true sublimation rate will be higher in reality, but only 5% probability that the true sublimation rate is higher. As such, the probability that the critical temperature at the sublimation front is exceeded is relatively low.

Abstract

The pharmaceutical industry is strictly regulated, where precise control of the end product quality is necessary to ensure the efficiency of the drug products. In this work, a combined feed-forward/feedback (FF/FB) control system has been developed for a direct compaction continuous tablet manufacturing pilot-plant. The feed-forward controller takes into account the effect of process disturbances and raw material variability proactively while the feedback control system ensures the end product quality consistently. The feed-forward control loop is based on real time monitoring of the powder bulk density while the feedback control loops are based on the powder level of instrumented hopper, drug concentration, tablet weight and hardness. Powder blend density has significant effects on the end product quality of the pharmaceutical tablets and therefore has been selected as the feed-forward variable. The coupled FF/FB control system ensures minimum variability in the final product quality irrespective of process and raw material variations.

Keywords: Continuous manufacturing, Control, PAT, QbD, feed-forward.

1. Introduction

Continuous pharmaceutical manufacturing integrated with PAT (Process Analytical Technology) provides a suitable platform for the automatic control of the end product quality as desired by the QbD (quality by design) paradigm, that is mandated by the regulatory authorities (Singh et al., 2014a, 2014b). The precise control of the quality of the pharmaceutical product involving solid dosage forms requires corrective actions on the process/raw material variability before they can influence the product quality. A feedback standalone strategy is therefore insufficient to provide efficient control of the pharmaceutical process. Therefore, this motivates the need for a feed-forward control system to be coupled with the feedback control system. Variations in raw material properties (e.g. particle size), feeder hopper level, amount of lubrication, milling and blending action, applied shear in different processing stages can affect the blend density significantly and thereby tablet weight, hardness, and dissolution. Therefore, the inline real time monitoring of the blend density and its incorporation into the control system so that it cannot affect the end product quality is highly desired.

In the last few years, very few attempts have been made toward the control of a continuous tablet manufacturing process utilizing feedback control algorithm. Singh et al. (2012a) have designed a feedback control system for a roller compaction route of the

continuous tablet manufacturing process. Singh et al. (2013) have developed a model predictive control system (MPC) for direct compaction continuous tablet manufacturing process. Singh et al. (2014a) have implemented a MPC based feedback control system into the direct compaction tablet manufacturing pilot-plant. The performance of the implemented feedback control system utilizing PAT tools have been also demonstrated (Singh et al., 2014b). The control system for wet granulation route of continuous tablet manufacturing process has been also proposed (Singh et al., 2014c). García-Munoz et al. (2010) have proposed a feed-forward controller using latent variable regression methods. However, no attempt has been made to design a plant-wide combined feed-forward/feedback control system for an integrated continuous tablet manufacturing process.

In this work, for the first time a plant-wide combined feed-forward/feedback (FF/FB) control strategy for direct compaction tablet manufacturing process has been developed, tablet weight and hardness control loops have been decoupled and an NIR (Near Infrared) based real time monitoring of the blend density for feed forward control has been proposed.

2. Systematic framework for design and implementation of the combined feed-forward/feedback control system

The design and implementation of the combined feed-forward/feedback control system involves ten hierarchical steps as shown in Figure 1. The starting point is to define the problem in terms of process and product quality specifications. Then the control relevant transfer function process model needs to be developed through step response analysis (steps 1 - 2). The next step is to design the control system (step 3). The design of the control system involves identification of control variables, pairing of control variables with corresponding manipulating variables, identification of the control variables for which a cascade loop is needed and for which single loop is sufficient, and pairing of the control variables with real time inline/online monitoring tools (Singh et al., 2009). Subsequently, the process variables that need to be fed-forward to the control system need to be identified in step 4. Sensitivity analysis can be used to identify the feed-forward process variables. For each identified feed-forward process variables the real time inline/online monitoring tools need to be identified. In step 5, a transfer function model relating a feed-forward variable with corresponding control variable need to be developed. Similarly, in step 6 a transfer function model relating an actuator with the corresponding control variables need to be developed. The feed-forward controller can then be implemented into the process model (step 7). In step 8, feedback control loops need to be implemented. The performance of the combined feed-forward/feedback control system can be analyzed in step 9. If the performance is satisfactory then it can be implemented into the plant in step 10 otherwise steps 5-9 need to be repeated until the satisfactory performance is achieved. Commercially available control platform (e.g. DeltaV (Emersions), PCS7 (Siemens)), PAT data management tools (e.g. synTQ (Optimum), SiPAT (Siemens)), Chemomatric tools and OPC communication protocol can be used to implement the control system. After experimental verification of the performance the combined control system can be used for regular plant operation and control.

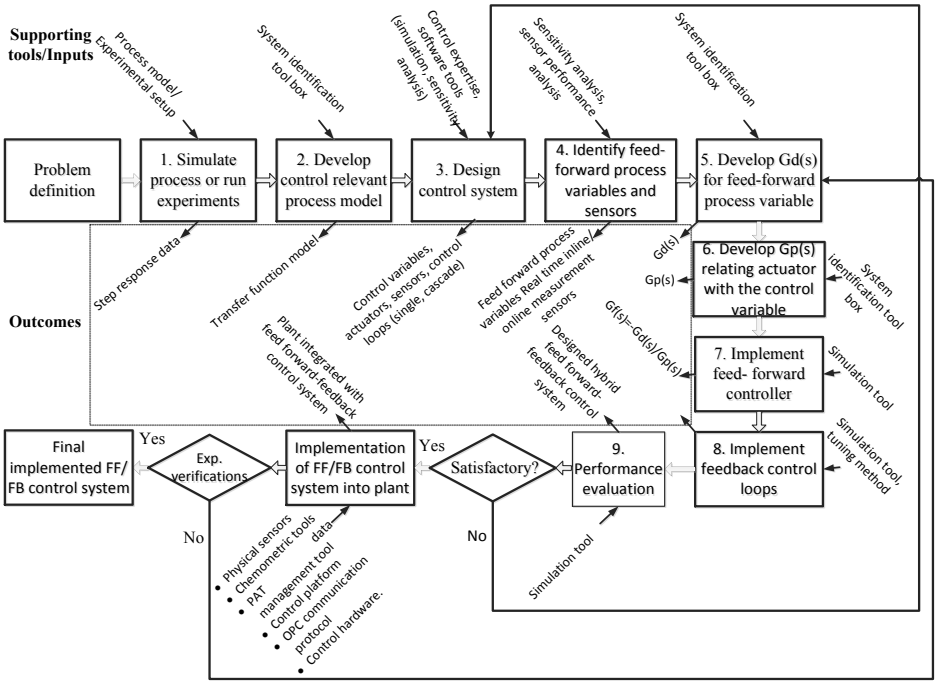

Figure 1: Systematic framework for design of combined feed-forward/feedback control system

3. Continuous tablet manufacturing process and pilot-plant

A continuous direct compaction tablet manufacturing pilot-plant has been installed and situated at C-SOPS, Rutgers University. The snapshot of the pilot-plant is reported in Singh et al. (2014a). The pilot-plant is built at three levels of different heights to take advantage of gravitational material flow. The top level is used for feeder placement and powder storage, the middle level is used for delumping and blending, and the bottom level is used for tablet compaction. There are three gravimetric feeders -with the capability of adding more- that feed the various formulation components (active pharmaceutical ingredient (API), excipient, lubricant). A co-mill is also integrated after the feeder hopper primarily for de-lumping the powders and creating contact between components. The co-mill eliminates any large, soft lumps within the powder. The lubricant feeder is added after the mill to prevent over lubrication of the formulation in the mill. These feed streams are then connected to a continuous blender within which a homogeneous powder mixture of all the ingredients is generated. Subsequently, the outlet from the blender is fed to the tablet press via a rotary feed frame.

4. Plant-wide control architecture of continuous tablet manufacturing process

The local level controllers are inbuilt in each feeder in order to control the powder flow rate. A ratio controller has been added that provides the flow rate set points of API, Excipient and Lubricant feeders for a given total flow rate and API composition. Six supervisory control loops have been then added. First loop is for feed-forward control (FFC) which takes the corrective action on variations in powder bulk density. NIR

sensor together with chemometric tools have been used for real time inline monitoring of the powder blend density. The signal of powder blend density has been then sent to the feed-forward controller that manipulates the fill cam depth of the tablet press proactively. The second loop has been added to control the main compression force of the tablet press. This control loop is in cascade arrangement with a master controller (loop 3) specifically designed to control the tablet weight. The input of this master controller is weight and it generates the set point of main compression force. The loop four has been designed to control the tablet hardness by manipulating the punch displacement. Checkmaster (Fette) has been used for real time monitoring of tablet weight and hardness. This control mechanics allows controlling the tablet weight and hardness independently. The control loop 5 has been added to control the powder level in instrumented hopper. Webcam has been used for online monitoring of powder level. The drug concentration has been controlled through 6th control loop. The NIR sensor has been used for inline real time monitoring of drug concentration. The powder bulk density and drug concentration has been monitored using a single NIR probe. Two PLS models have been used to predict the powder bulk density and drug concentration separately. In order to implement the designed feed-forward/feedback control into the pilot-plant, the signal from the NIR sensor (raw spectrums) has been sent to a chemometric tool that utilizes the NIR calibration models for blend density and drug concentration and real time prediction tool to generate the signals of the control variables in real time. The generated signals are then sent to a commercially available control platform via an OPC communication protocol where the combined FF/FB control loop has been implemented. The blend density is the input for the feed-forward controller while the blend composition together with powder level, tablet weight and hardness are the inputs of the feedback control system. The actuators generated from the control platform are then communicated with the plant through fieldbus devices and serial ports.

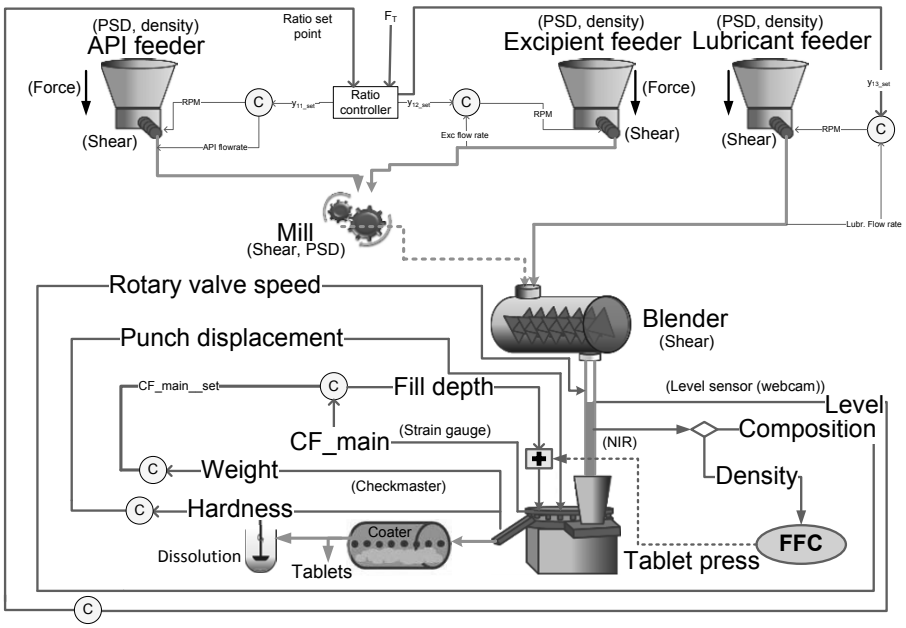

Figure 2: Plant-wide combined feed-forward/feedback control architecture.

5. Results and discussion

The tablet press has been considered to demonstrate the performance of combined feed-forward/feedback control system. The ability of the control system to track the set point and reject the disturbances has been evaluated. A step change in the hardness set point has been introduced while keeping the tablet weight set point at constant value. The powder blend density acts as the disturbance and can affect the tablet weight and hardness significantly. Random disturbances have been added to the blend density throughout the operation. A step change in the blend density has been also introduced at t = 2500 s in order to analyze its effects. Figure 3 shows a closed-loop response of the tablet hardness under two control strategies. As shown in the figure, under the combined control strategy, the feed-forward controller rejects the variation in the blend density before it can affect the tablet hardness. Therefore, in this case, the tablet hardness has been controlled better. A significant variation in the achieved hardness can be seen in case of feedback only control scheme. It should be noted that the hardness variation is more at t = 2500s where the step change in the blend density has been introduced. The results shown in Figure 3 demonstrate the advantages of coupling feed- forward controller with the feedback control system.

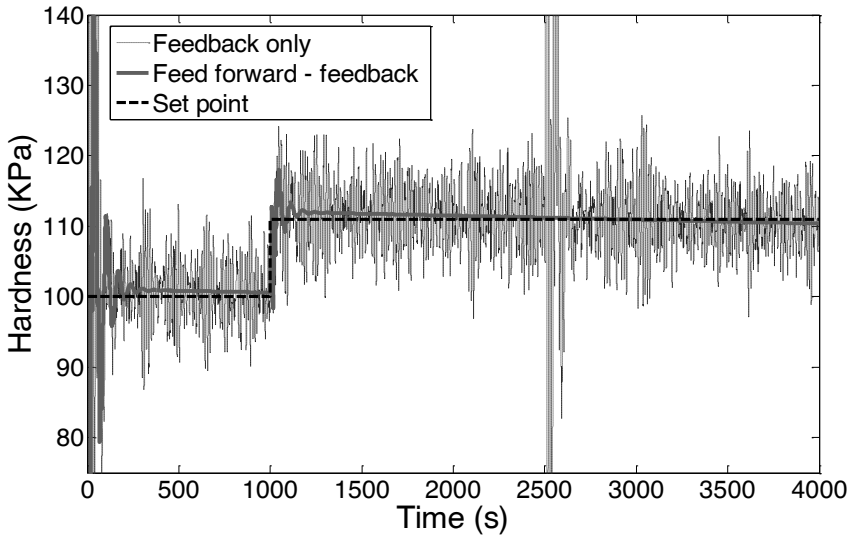

Figure 3: Performance evaluation of combined feed-forward/feedback control strategy.

The closed-loop response of the tablet weight under the combined feed-forward/feedback control strategy and only feedback control strategy is shown in Figure 4. As shown in the figure, the variation in tablet weight is less under combined control scheme in compare to only feedback control scheme. A small oscillation can be seen at t =1000 s where the step change in the hardness set point has been made and this is essentially because the hardness and weight control loops are highly interactive. At t = 2500 s, a step change in the blend density has been introduced but the combined feed-forward/feedback control system has efficiently rejected its effect and thereby a consistent desired tablet weight has been achieved. Similarly, the performance of other combined FF/FB control-loops has been analysed and found to be satisfactory. The tablet content uniformity depends on powder blend uniformity that should be controlled at blending operation (Singh et al., 2014b). For product acceptance, the critical quality

attributes should be within a specified control limits (Singh et al., 2012). The feed-forward controller can only compensate the variation in powder bulk density (or any other variables) within the process capability limits. The main challenges associated with implementation of FF/FB control strategy is the complexity associated with real time monitoring of powder bulk density and control variables.

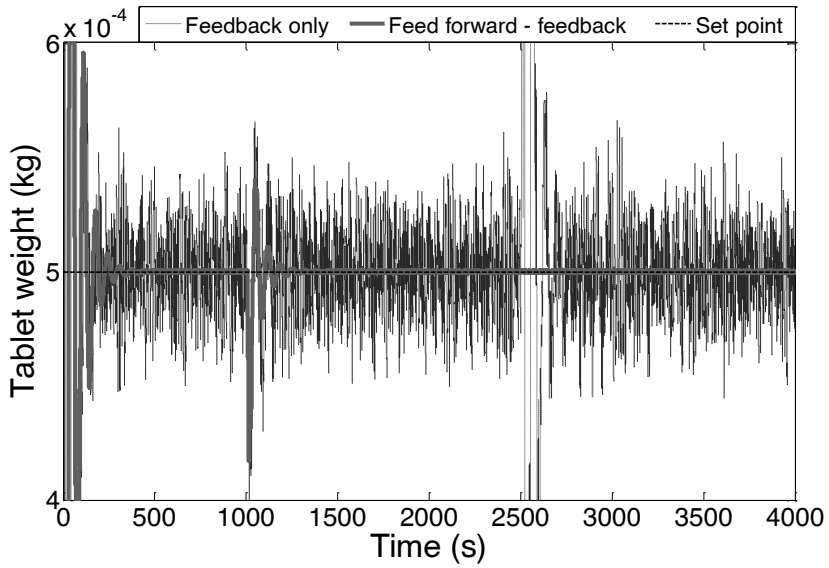

Figure 4. Performance evaluation of combined feed-forward/feedback control strategy.

6. Conclusions

A plant-wide control system has been developed for a direct compaction continuous tablet manufacturing pilot-plant. The control architecture consists of integrated feed-forward and feedback (FF/FB) control loops. The performance of the combined FF/FB control strategy is found to be better in comparison to the feedback only control strategy and therefore demonstrates potential to improve industrial pharmaceutical tablet manufacturing operations. The future work includes the implementation of FF/FB control strategy in our pilot-plant facility.

Abstract

Process optimization has become an increasingly important issue in the pharmaceutical industry in recent years. Due to the high competition, companies are obliged to make quick decisions, with sometimes ending up in sub-optimal solutions. In this paper, we propose a systematic retrofitting methodology for process optimization as method for the optimization of post-design pharmaceutical processes. The use of the combination of measurements, process modeling and computer-aided simulation provides a structured procedure for understanding and quantifying the improvement potential of the plant. The methodology consists of five tasks: gain process understanding (I), create process model (II), recognize constraints and optimization parameters (III) optimize the process model (IV). These tasks are supported by an interpretation/verification/validation step (X). The primary target of this methodology is the recrystallizatoin of thermally unstable Active Pharmaceutical Ingredients (APIs) The secondary target is to elucidate the many features contained in the modeling process. As a case study, the method was demonstrated in an actual plant with dissolution, filtration and crystallization (DFC) units. After performing the five steps, we could identify a better temperature and flow rate of the process with a 0.9% improvement of API yield.

Keywords: Pharmaceutical process, retrofitting, API sterilization, optimization, reactive dissolution

1. Introduction

Process optimization has become an increasingly important issue in the pharmaceutical industry in recent years. Expiration of patents protecting the companies from the competition and increase of the R&D expenses cause economic pressures for many companies. The strong competition forces the realization of the feasible solution in a short time, frequently leading to sub-optimal design in many cases. The high value of the products, especially in pharmaceutical manufacturing, furthermore justifies poor optimization in the first steps of creating a new production line. Currently simulation and process modeling have a secondary importance, however, the pharmaceutical industry could profit from a more engineering-based analysis, including computer simulation. Modeling and problem-approaching skills are crucial for the success of an optimization (Troup and Georgakis, 2013), leading to time and cost reductions. A limitation here is the presence of tough constraints, which need to be satisfied for ensuring the product

quality, e.g., Good Manufacturing Practices (GMP) and the condition set by the Drug and Food Administration (FDA). During the creation and optimization of a process model these constraints have always to be considered. Srinivasan et al. (2002) offered an overview of analytical and numerical technics for the optimization of general batch processes. In a second study, Srinivasan et al. (2003) discussed the role of measurements and their application in the creation, validation and implementation of process models. In this work we aim to develop a systematic methodology capable to assist the retrofitting of pharmaceutical processes. The methodology consists of five tasks: gain process understanding (I), create process model (II), recognize constraints and optimization parameters (III) optimize the process model (IV). These tasks are supported by an interpretation/verification/validation step (X). Altough the entire procedure is structured in a general manner, the second task is the most prominent and specialized for the purification of the crude and thermally unstable API in the crystalline form. The methodology is applied to an industrial case study to prove its effectivness.

2. Methodology

The flowchart (Figure 1, left) shows the sequence of tasks to be followed, while tackling with the model creation and optimization of a running plant. Gain understanding about the plant and its behavior is necessary to ensure the creation of a valuable process model. Measurements coupled with path-flow decomposition (PFD) (Figure 1, right) help in this task (Task I). The PFD facilitates the visualization of the material flow of the process. Task II is responsible for the reproduction of the processes as mathematical models, aiming to imitate the current plant. Subsequently, the model created in Task II is subjected to optimization (Task IV). In order to perform Task IV, the necessary constraints and the optimization parameters have to be identified and defined (Task III). Task X consists of interpretating and verifying the results of each task and validating the process models and the assumption made during the model formulation. Task X is connected to all four tasks and represents a decisional step, which permits to re-evaluate the decisions or eventually re-iterate the tasks.
The primary target of this methodology is the recrystallization plant of crude APIs with dissolution, filtration and crystallization (DFC) operations. The details will be presented in the next section.

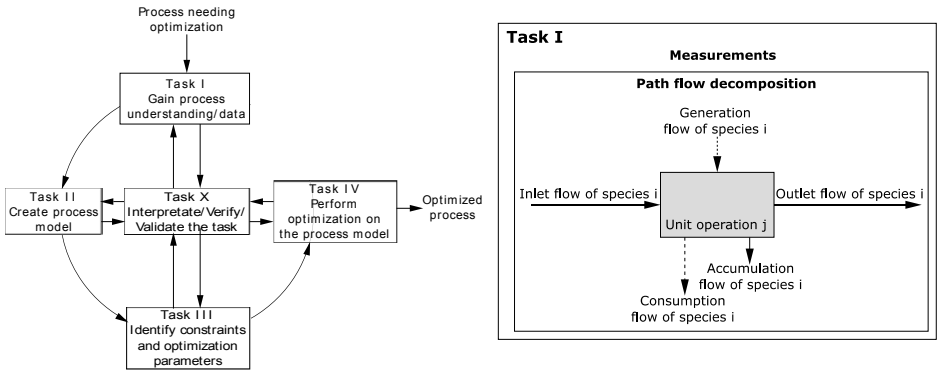

Figure 1: Flow diagram showing the procedural order (left) Insight on Task I showing a generic path flow decomposition (right).

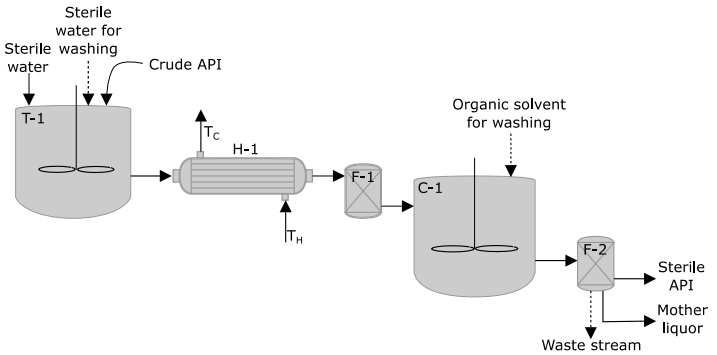

Figure 2: Sketch of the plant performing the dissolution-filtration-crystallization (DFC) process

3. Case Study: Purification of solid drug by DFC process

3.1. Gain process understanding/data

Figure 2 shows a typical process of a DFC plant, consisted of a charge tank (T-1), a heat exchanger (H-1), a filtration unit (F-1), a crystallizer (C-1) and a filter/dryer (F-2). When the API is dissolved in the liquid phase—i.e. over the entire process before the crystallization an endothermic degeneration reaction occurs, reducing the yield of the API. These unwanted reactions are reppresented by the following equations:

$$\text{API} \rightarrow \text{B} \tag{1}$$

$$\text{API} + \text{B} \rightarrow \text{C} \tag{2}$$

Mass balance, temperature profile and particle size distribution (PSD) were measured. The crystals are cylindrical shaped with a narrow PSD (within two order of magnitude). The solubility of the API in water and its reaction rate were characterized. The degradation is a first order reaction with the kinetic constant k_{deg} [s^{-1}]. From the PFD it was possible to recognize five different phenomena affecting the mass balance of the API: reaction coupled dissolution of the API crystals inside H-1, adsorption of the API on the filtration material, reaction during the filling of C-1, crystallization and accumulation of the API along the equipment. Measurements and PFD visualization enabled the partial closure of the mass balance. The mass deficit resulting from the mass balance was attributed to the reaction; the assumption was subsequently confirmed by the result of the modeling, which enabled the closure of the mass balance.

3.2. Create process model

The model aims to imitate the reality as accurate as possible. The dissolution of the crystals in medium-turbulent environment inside T-1 was modeled as follows:

$$\frac{dm}{dt} = -kM_W S(c_s - c) \tag{3}$$

Equation 3 describes the mass transfer between the fluid and the solid phase, where m [kg] represents the mass of the crystal, k [m s^{-1}] the mass transfer coefficient, S [m^2] the surface of the crystal, c [mol m^{-3}] the actual API concentration in the bulk liquid phase, c_s [mol m^{-3}] the saturation concentration of the API and M_W [kg mol^{-1}] the molecular weight of the API. Eq. 3 was reformulated, resulting in the following equation:

$$\frac{dl}{dt} = -\frac{2kM_W}{\rho}\frac{r(l)+l}{r(l)+2l\frac{dr}{dl}}(c_s - c) \tag{4}$$

Equation 4 describes the rate of change of the characteristic length of the crystal, where l [m] represents the height of the crystal, r [m] its radius and ρ [kg m^{-3}] its density.
A mass transfer correlation (Eq. 5), describing the dissolution of cylindrical crystals in a turbulent fluid environment (Bernstein and Churchill, 1977) was employed to solve the ordinary differential equation (ODE) Eq. 4, providing the characteristic length profile along H-1.

$$k = \frac{D}{l}\left[0.3 + 0.62 \cdot Re_D^{0.5} \cdot Sc^{0.33} \cdot \left(1 + \left(\frac{Sc}{0.4}\right)^{-0.66}\right)^{-0.25} \cdot \left(1 + \left(\frac{Re_D}{282000}\right)^{0.63}\right)^{0.8}\right] \tag{5}$$

The parameters Re_D, Sc and D [m^2 s^{-1}] are the particle Reynolds and Schmidt numbers and the molecular diffusion coefficient of the API, respectively.
The crystal length profile was used to characterize the size exclusion phenomena in the filter (F-1). A constant crystal aspect ratio was assumed. The constant B was defined as the diameter to height ratio and was implemented in the population and mass balance, resulting in the following system of ordinary differential equations (SODE)

$$\begin{cases} \frac{dl_i}{dt} = -\frac{2k \cdot M_W}{\rho}\,\frac{(2B+1)}{3}\,(c_s - c); & i = 0,1,2,3,\ldots \\ \frac{dc}{dt} = \frac{\sum_i^M (l_i^2 \cdot N_i \cdot k_i)}{V} \cdot \pi\,\frac{(2B+1)}{2B^2}(c_s - c) - k_{deg} \cdot c \end{cases} \tag{6}$$

The parameter M [–] represents the number of different crystals sizes, the index i indicates the crystal initial size, N_i is the number of crystal of every type of crystals, V [m^3] is the volume of the batch. The measured PSD of the crude product was used as initial values of the sizes l_i [m], to solve the SODE. The slurry exiting T-1 enters in the heat exchanger (H-1), in which the crystals dissolve. The dissolution in this unit was according to Eqs. 3, 4 and 6, considering the mass transfer coefficient proposed by Bedingfield and Drew (1950) (Eq. 7). This mass transfer correlation describes the mass transfer between solid and liquid phase for a cylindrical crystal in turbulent continuous flow:

$$k = 0.281 \cdot v_f Re_D^{-0.4} Sc^{-0.56} \tag{7}$$

The parameter v_f [m s^{-1}] is the fluid velocity in the unit. The temperature profile inside H-1 was modelled with a one-shell, one-tube heat exchanger model (Welty, et al. 2007). The model takes in consideration the heat transfer between the heating and the process fluid along the wall separating the two phases, considering the heat transfer inside the wall as well.

$$\begin{cases} \frac{d^2T_w}{dx^2} = 4 \cdot \frac{(U_s d_o \cdot (T_w - T_s) - U_t d_i \cdot (T_t - T_w)}{k_w \cdot (d_o^2 - d_i^2)} \\ \frac{dT_t}{dx} = \frac{\pi d_i U_t (T_w - T_t)}{c_{p,t} F_t} \\ \frac{dT_s}{dx} = \frac{\pi d_o U_s (T_s - T_w)}{c_{p,s} F_s} \end{cases} \tag{8}$$

The operation properties were defined through the boundary condition. In fact the heat exchanger was operated counter-currently.

$$\begin{cases} T_s(L_{HEX}) = T_H \\ T_t(0) = T_{in} \\ \frac{dT_w}{dx}(0) = 0 \\ \frac{dT_w}{dx}(L_{HEX}) = 0 \end{cases} \tag{9}$$

In Eqs. 8 and 9 T_w [K] is the temperature of the tube-shell wall, T_t [K] the temperature of the liquid inside the tube and T_s [K] the temperature inside the shell of the heat exchanger. The parameters d_o [m] and d_i [m] describe the outer and inner diameter of the tube, while L_{HEX} represents for the length of the heat exchanger. The parameters U_t [W m^{-2} K^{-1}], U_s [W m^{-2} K^{-1}] and k_w [W m^{-1} K^{-1}], are the overall heat transfer coefficient of the tube, shell and the thermal conductivity of the wall, respectively. The coefficients $c_{p,s}$ [J kg^{-1} K^{-1}], $c_{p,t}$ [J kg^{-1} K^{-1}] and the variables F_t [kg s^{-1}] and F_s [kg s^{-1}] are the heat capacity of the fluid in the shell and in the tube, and their flow rates, respectively. Finally T_{in} [K] and T_H [K] are the temperature of the process stream at the inlet of the heat exchanger and the temperature of the heat medium at its inlet. The parameters U_t, U_s, and k_w were obtained through fitting to the measured data. The mass balance measurements performed on the chemical filter revealed the accumulation of API in the unit, enabling the calculation of its efficiency, which was 99.4%. The reaction inside the piping was modeled with an ideal plug flow reactor model. The filling up of the crystallizer (C-1) was represented as homogeneous chemical reaction in a semi-batch reactor. Due to lack of measured data, the crystallization process was modeled with an empirical correlation relating the amount of by-product at the beginning of the crystallization with the total amount of crystals obtained in this process. The amounts of product ending up in the wastewater and in the organic washing streams were modelled in the similar way. The total process had a loss of 10% with respect of the initial amount of crude API. The measurement performed on the plant showed the same loss supporting the reliability of the model. Figure 3, left shows the position of the loss along the plant

3.3. Identify constraints and optimization parameters

The pharmaceutical character of the process led to the consideration of some constraints. The GMP and the quality of product could not be affected by an intervention on the plant. Therefore in this case study, the filtration and the crystallization units were considered to be unchangeable due to their impacts on the product quality. The remaining units and parameters were considered to be modifiable, with exception for the current pipe diameter. The sensitivity analysis performed on the model recognised the process stream flow rate F [–] and the temperature of the heating medium T_H [–] as reasonable parameters for process optimization.

3.4. Perform optimization on the process model

The model created in the previous task was optimized (Eq. 10) with an aim of increasing overall API yield.

$$max\big(f(\boldsymbol{x})\big) \qquad with\ \ \boldsymbol{x} = [x_1, x_2]^T$$
$$h(\boldsymbol{x}) < L_{\text{pore}} \tag{10}$$
$$0 < x_2 < F_{max}$$
$$x_1 < T_{H,max}$$

The variables x_1, x_2 and $h(\boldsymbol{x})$ are the optimization parameters T_H and F, and the function describing the size of the crystals at the inlet of the filtration unit, respectively. The parameters L_{pore}, F_{max} and $T_{H,\,max}$ are the boundary values characterising the maximal crystal size, the flow rate and the heating medium temperature, respectively.

4. Result

In Figure 3, right, all the values are normalized with respect to the current parameters and yield, i.e., base case to indicate only the improvements. The optimality is denoted

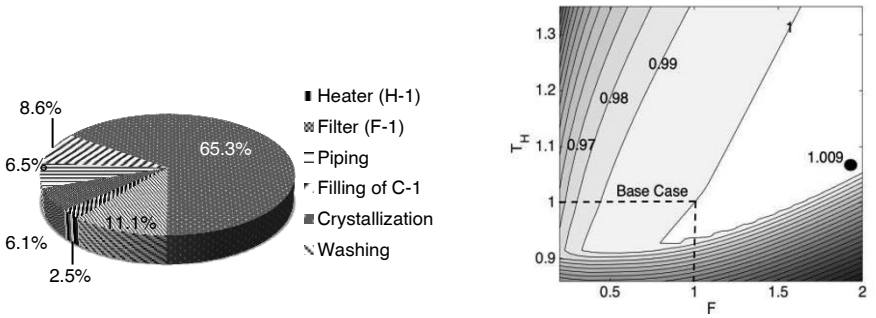

Figure 3: Portion of production relative to the lost position (left). Optimization results (right).

by the dot and shows 0.9% of improvement with respect to the base case showed by the intersection of the dashed lines. Due to the proximity of the current process to the optimum, the process holds a contained margin of improvement within the constraints. From Figure 3, right it is notable that T_H has a bigger influence if compared to F. This effect is justified by the exponential dependency of the temperature of the saturation concentration of the API. Indeed at temperatures lower than the current one, the amount of undissolved crystals increases, decreasing the yield drastically. F plays an important role only at high temperatures; influencing the time, during which the API undergoes the degeneration reaction.

5. Conclusions and Outlook

In this paper we presented a systematic retrofitting methodology applied on a process of recrystallization of a thermally instable API. The results provided a detailed mathematical model of the process. This was subsequently employed for the optimization of the production of sterile API. The mathematical design of the reactive dissolution of an organic API crystals characterized by a PSD is an additional novelty brought by the paper. Moreover the use of an accurate model describing the temperature profile inside the heat exchanger is an additional feature of the model. Furthermore the consideration of specific aspects like GMP and product quality increases the applicability of the methodology in the retrofitting of pharmaceutical production plants. In future studies the optimization could be enlarged to the plant layout, performing therefore a mixed integer non-linear programming (MINLP) optimization. Indeed the introduction of intercooling unit could reduce the loss of API along the piping, therefore increasing the overall yield of the process.

Modelling of Crystallization of Solid Oral Drug Forms in a Dropwise Additive Manufacturing System

Elçin Içten*, Zoltan K. Nagy, Gintaras V. Reklaitis

School of Chemical Engineering, Purdue University, West Lafeyette, IN, 47906, USA
**eicten@purdue.edu*

Abstract

Melt-based solid oral drug forms are produced using a dropwise additive manufacturing process for pharmaceuticals. A model based on non-isothermal Avrami kinetic equation is developed to model the solidification and crystallization processes of the drug deposits under different cooling profiles using temperature dependent crystallization kinetics. Using the proposed model, the temperature profiles leading to the desired solid-state parameters such as the minimum mean size are determined.

Keywords: crystallization kinetics, solidification, temperature control, drop on demand

1. Introduction

Traditionally, the pharmaceutical industry uses batch processes to manufacture pharmaceutical products, which provide significant challenges for the industry. In recent years, US Food and Drug Administration introduced the Quality by Design approach and Process Analytical Technology guidance to encourage innovation and efficiency in pharmaceutical development, manufacturing and quality assurance. As part of this renewed emphasis on improvement of manufacturing, the pharmaceutical industry has begun to develop more efficient production processes, including the use of on-line measurement and sensing, real time quality control and process control tools. Under the US National Science Foundation supported Engineering Research Center for Structured Organic Particulate Systems (NSF ERC-SOPS), a dropwise additive manufacturing process for solid oral drug production has been developed as an alternative to conventional pharmaceutical manufacturing methods (Hirshfield, et al., 2014). This mini manufacturing process for the production of pharmaceuticals utilizes drop on demand (DoD) printing technology for automated and controlled deposition of melt-based drug formulations onto edible substrates (Içten, et al., 2014a). The advantages of DoD technology, including reproducible production of small droplets, adjustable drop sizing and flexible use of different formulations, enable production of individualized dosing even for low dose and high potency drugs. A supervisory control system, consisting of on-line monitoring, automation and closed-loop control, is implemented on the process, in order to produce individual dosage forms with the desired dosage amount and crystal morphology (Içten, et al., 2014b). Since the product morphology depends on the crystallization temperature, the drop solidification process following the drop deposition on the substrate should be controlled (Nagy and Braatz, 2012). This paper presents a modelling approach for the solidification and crystallization processes of the drug deposits using temperature dependent crystallization kinetics and cooling profiles monitored via an optical microscopy with a hot stage. Using the proposed model, the temperature profiles leading to the desired solid-state parameters such as the mean size can be optimized.

2. Production of Dosage Forms via Dropwise Additive Manufacturing

The dropwise additive manufacturing system consists of a precision positive displacement pump, xy-staging, a hot air based heating system, online imaging and sensing, and temperature, pump and stage controllers. Using this system, melt-based systems, i.e. co-melted polymer-drug systems, or solvent-based systems can be produced reproducibly. For the melt-based formulation, a low melting point polymer such as polyethylene glycol, in which the drug dissolves once the polymer becomes molten, is used. In order to maintain constant rheological properties of the printed formulation, temperature control is established on the whole process using a counter-current hot air based heating system and heating elements with PID controller units. After passing through the precision P/D pump, the drops are ejected through the nozzle and deposited onto an edible substrate. The xy-staging and synchronization logic allows precise drop positioning on the substrate while printing. The main process units and melt-based formulations deposited onto polymeric films are shown in Figure 1.

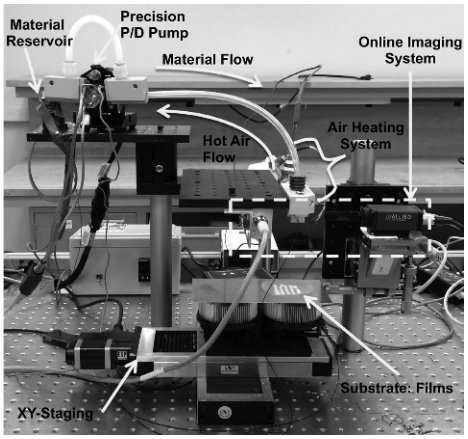

Figure 1. Dropwise Additive Manufacturing System and Melt-based Products

The temperature of the deposited drops is controlled indirectly by controlling the temperature of the substrate using a Peltier device placed beneath the substrate on the xy-stage. This allows control of the rate of solidification of melts and thus control of nucleation and crystallization phenomena. Precise control of the drop solidification process occurring on the substrate is very important since the crystallization temperature profile has a direct effect on product solid-state characteristics, influencing the dissolution properties and hence the bioavailability of the drug (Içten, et al., 2014b). Recently, Içten et al. (2014b) reported that applying a fast cooling rate of 10 °C/min to the deposits containing naproxen results in faster dissolution profiles compared to a slow cooling rate of 1 °C/min. Controlling crystallization temperature profiles can be used to enhance the solubility of dissolution limited drugs such as naproxen.

3. Modelling of Crystallization of Melt-based Dosage Forms

We have modelled the solid-state transformation of the melt-based solid oral dosages produced using the dropwise additive manufacturing process based on the modified Avrami (1939) kinetic equation. The model formulation consists of 15 % drug, naproxen, and 85 % polymer, PEG 3350. The drops are deposited at 60 °C and cooled to 20 °C using two different controlled cooling rates, 1 °C/min and 10 °C/min. In order

to determine the nucleation and growth kinetics experimentally, the solidification process under the same conditions are monitored using optical microscopy with a hot stage. The model formulation undergoes sporadic nucleation and spherical crystal growth. Determination of kinetic parameters is described in Section 4.

The Avrami equation describes isothermal solid-state transformation reactions based on nucleation and growth kinetics, which is widely used for various processes including metal, fat and polymer crystallization. The Avrami model equation for different growth geometries and types of nucleation is given by Eq.(1), where m_s is total mass of solids present in the system at a particular time, m_{max} is maximum total mass of solid at infinity, $(m_{max} - m_s)$ is mass of supercooled material that has not crystallized yet, t is crystallization time (min), s is the geometrical shape factor, I_c is the number of crystals per unit volume in the system (cm^{-3}), A_g is the area of crystal involved in growth (cm^{-2}).

$$\frac{\partial m_s}{\partial t} = (m_{max} - m_s) \cdot s \cdot I_c \cdot A_g \tag{1}$$

For spherical crystal growth, the geometrical shape factor is $s = 4\pi/3$ and crystal growth A_g is described by Eq.(2), where r is linear growth rate of crystal radius in time (cm) and g is growth rate constant for crystals radius per time (cm min^{-1}).

$$A_g = r^2 = g^2 \cdot t^2 \tag{2}$$

For sporadic nucleation, the change in the number of nuclei as a function of time, I_c is described by Eq.(3), where j is nucleation rate constant (cm^{-3} s^{-1}).

$$I_c = j \cdot t \tag{3}$$

In the dropwise additive manufacturing process, we apply different controlled temperature cooling profiles to the deposited drops in order to achieve the targeted dissolution behaviour (Içten, et al., 2014b). Temperature profiles applied to the drug deposits as a function of time and cooling rate are shown in Eq.(4), where the induction time is defined as a function of cooling rate $t_{ind} = t_{ind}(r_{cool})$.

$$T(t) = T_i - r_{cool} \cdot (t + t_{ind}) \tag{4}$$

In order to capture the effect of temperature on crystallization kinetics we use the modified Avrami equation, which is extended for non-isothermal kinetics by using temperature dependent nucleation and growth rates (Ozawa, 1971). Since the cooling profiles are represented as a function of time, the crystallization model we are using can be expressed as in Eq.(5), where both $j(T)$ and $g(T)$ are temperature and therefore time and cooling rate dependent.

$$\frac{\partial m_s}{\partial t} = (m_{max} - m_s) \cdot \frac{4}{3}\pi \cdot j(T) \cdot g(T)^2 \cdot t^3 \tag{5}$$

The growth rate constant is described as $g(T) = \alpha_1 \cdot T + \alpha_2$. The parameters α_1 and α_2 are a function of cooling rate which are determined experimentally as described in Section 4.2. The nucleation rate constant is described as $j(T) = \beta_1 \cdot T + \beta_2$. The parameters β_1 and β_2 are a function of cooling rate which are also determined experimentally as described in Section 4.3.

4. Determination of Kinetic Parameters

The kinetic parameters of the model formulation consisting of 15 % naproxen and 85 % PEG 3350 are determined experimentally, based on the crystallization behavior observed using an optical microscopy with a hot stage when a particular cooling profile is applied. The two cooling rates used in this study are 10 °C/min and 1 °C/min.

4.1. Induction Time

The cooling rates applied to the deposits effect the induction time. Induction times corresponding to 10 °C/min and 1 °C/min are determined experimentally as 2.2 min and 12 min, respectively. In the model development, we assumed that the changes in the induction times are linearly proportional to the change in the cooling rates.

4.2. Nucleation Rate

For a cooling rate, the change in the number of nuclei per volume as a function of time is determined from the images captured using optical microscopy at different times. For the same cooling rate, the parameters β_1 and β_2 are determined by fitting a linear relation to experimental data points. The nucleation rate parameters determined for the two cooling rates used in the experiments are shown in Figure 2a. Next these parameters are used to calculate the nucleation rate parameters β_1 and β_2 when cooling rates $10\ ℃/min \geq r_{cool} \geq 1\ ℃/min$ are applied to the deposits. Here it is again assumed that the changes in the parameters are linearly proportional to the change in the cooling rates.

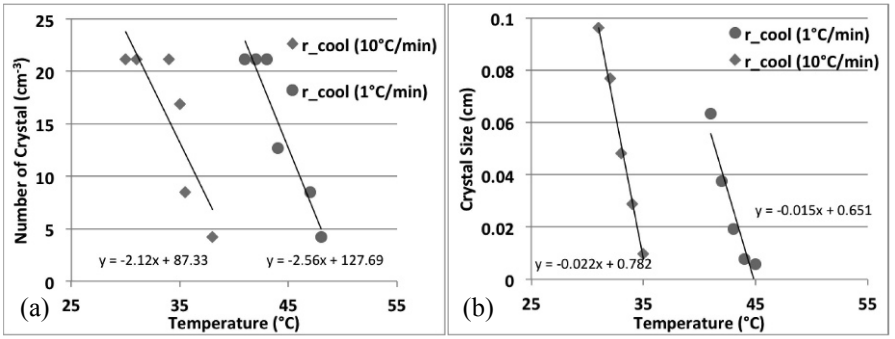

Figure 2. Crystallization Kinetics for Different Cooling Rates (a) Nucleation and (b) Growth

4.3. Growth Rate

For a particular cooling rate, the linear growth rate constants of crystal radius as a function of time is determined from the images captured through optical microscopy. The calculation of linear growth rate of crystal radius is depicted in Figure 3. White arrows represent the dynamic changes in the linear growth rate of crystal radius in consecutive images, when a cooling rate of 1 °C/min is applied to the deposits. By measuring the changes in the growth front throughout different cooling profiles, the dynamic growth rate constants parameters α_1 and α_2 are determined. The growth rates determined for the two cooling rates used in the experiments are shown in Figure 2b. These parameters are used to calculate the growth parameters α_1 and α_2 when cooling rates $10\ ℃/min \geq r_{cool} \geq 1\ ℃/min$ are applied to the deposits. Here it is again assumed that the changes in the crystallization parameters are linearly proportional to the change in the cooling rates.

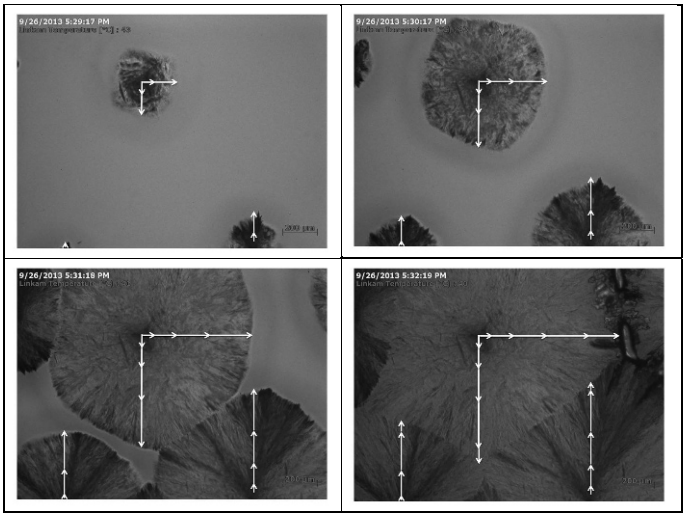

Figure 3. Optical microscopy images used for growth rate estimation with cooling rate 1 °C/min

5. Results and Discussion

Using the modified Avrami model, the solid fraction of the dosage forms produced of the model melt-based formulation by the dropwise additive manufacturing process with different cooling rates is calculated as a function of time. The differential equation, Eq.5, is solved numerically. The time and cooling rate dependence of kinetic parameters are taken into account as explained in Section 3. The nucleation and growth kinetic parameters presented in Section 4 are used in the model. The solidification rates of the dosage forms solidified with cooling rates of 1 °C/min and 10 °C/min is shown in Figure 4. For 10 °C/min, complete solidification occurs after 1.1 min, whereas in experiments this time was observed as 0.8 min. For 1 °C/min, complete solidification occurs after 5 min, whereas in experiments this time was 7 min. The mismatch between the experimentally observed and modeled solidification times could potentially be reduced by using experimental data points corresponding to intermediate cooling rates and checking the validity of the linearity assumptions made during the kinetic parameter estimation.

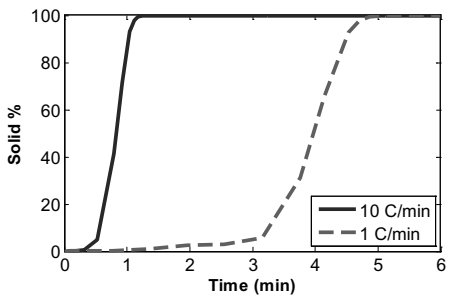

Figure 4. Solid Percentages of the Dosage Forms using the Developed Crystallization Model

The developed model is used to determine the mean size of crystals when different cooling rates are applied. For different cooling rates, the time, t*, to reach 100 % solidification is calculated. The number of nuclei formed per image area at t* is calculated and mean crystal radius is calculated, which are plotted in Figure 5 for cooling rates from 1 to 10 °C/min. By increasing the cooling rate from 1 to 10 °C/min,

the mean size is decreased from 434 to 307 μm, which is in accordance with the increase in the dissolution rate observed by Içten et al. (2014b) when fast cooling rate of 10 °C/min is applied to the same model formulation containing 15 % naproxen and 85 % PEG 3350. According to model results, the minimum radius of 217 μm can be achieved with a cooling rate of 5.5 °C/min. This can be used to further increase the dissolution rate of naproxen for which dissolution is limiting.

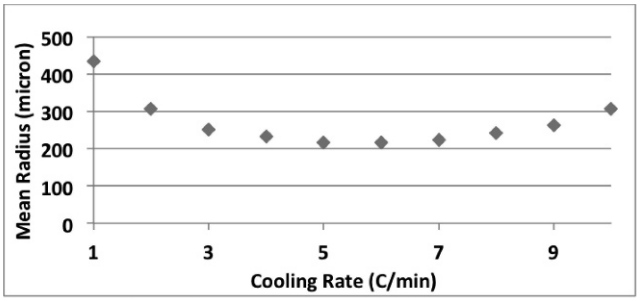

Figure 5. Crystallization model results for mean crystal radius vs cooling rate

6. Conclusions

In this work, we have developed a crystallization model based on non-isothermal Avrami kinetic equation for the cooling temperature dependent solid-state transformation of the melt-based solid oral dosages produced using the dropwise additive manufacturing process. The model is used to calculate the solidification times of the dosage forms and their mean crystal sizes under two different cooling profiles. The experimentally observed and modeled solidification times have the same trend, and the accuracy of the model can be improved by using experimental data points corresponding to intermediate cooling rates and by validating the linearity assumptions made during the kinetic parameter estimation. Using the model, a mean crystal size can be achieved which would lead to the desired product quality, such as dissolution.

Abstract

Powders and particles from biodegradable polymers and based on biologically active materials of the protein nature were obtained. The way of obtaining such powders is presented and the main characteristics and also possible paths of use of the obtained powders are described.

Keywords: vacuum freeze drying; atmospheric freeze drying; macroporous; microparticles; powders for inhalation.

1. Introduction

Microparticles and fine powders are becoming more and more widely used in different areas. In medicine such particles can be applied as material for implants and surgery, as sorbents for viruses and protein purification, as embolization agents, fillers for cosmetology, plates and matrixes for cell growth and may have many other applications. They can be used in pharmaceutical industry as components of drug delivery systems, as a base for inhalable and nasal products. However, production of particles of a size less than 20 μm today can be done either by using grinding technology, or by the way of atomizing a liquid followed by drying of the formed droplets (Wean Sin Cheow, 2011).
Main disadvantage of the grinding process in comparison with the atomizing technique is that the form of the particles obtained by the first one, is not spherical and uniformed. In the same time, many types and models of atomizing devices with various characteristics were developed and introduced to the market for the last 30 years (A. Troyankin et al., 2009).
Chemical, pharmaceutical industries and medicine are interested in particles of spherical form, low bulk density of about 0.2 g/sm3, with residual moisture content 3% and less, with good stability and flowability. Possibility of production of such particles in an ease and efficient way will significantly increase their areas of applications and usability. It is important to provide new ways of production of micropowders and particles suitable for pharmaceutical and other applications (A.Yu. Troyankin, 2012).
There is also a challenge to create an equipment capable to produce microparticles with predesigned properties, shape and size, that will gently handle product being produced saving its biological properties (N.V. Menshutina, 2008).
Drying process under vacuum, also known as sublimation freeze drying and lyophilisation – is one of the most known, popular and widespread process for the last decades. The process became famous due to high quality of obtained products and nowadays it is very important for pharmaceutical, food industries, biotechnology because it allows drying of heat sensitive, easily oxidized pharmaceutical substances, proteins that require gentle handling (grinding can lead to protein degradation due to

mechanical impact). The process is also widely used in chemistry and other areas (N. Menshutina et al., 2009).

2. Methods for preparing and basic characteristics of the microparticles

At MUCTR new laboratory scale equipment consisting of 3 units combined into 2 technological schemes were created, Figures 1 – 3. The process of production of microparticles with predefined properties and sizes were developed. The formation of the particles in the abovementioned process is done by of atomizing the solution, using two different types of nozzles: pneumatic and ultrasonic, into cryogenic liquid (liquid nitrogen and other) with rapid freezing process followed by freeze drying process.

Microparticles and powders produced were made of different materials:

- chemically cross-linked modified polyvinyl alcohol, modified PVA were provided by prof. M.I. Shtilman, MUCTR (A.A. Artyukhov et al., 2011);
- physically cross-linked polyvinyl alcohol hydrogels, material provided by Prof. V.I. Lozinskiy, A.N. Nesmeyanov Institute of Organoelement Compounds of Russian Academy of Sciences (V.I. Lozinsky et al., 2014);
- particles of protein based pharmaceutical substance (cytokines), provided by A.I. Burnasyan Federal Medical Biophysical Centre of Federal Medical and Biological Agency.

To produce chemically cross-linked modified polyvinyl alcohol particles of hydrogels, a special atomizing technique was used that combined atomizing of modified PVA in aqueous solution together with catalyst system in Liquid nitrogen followed by radical polymerization and storage and crosslinking at cryogenic conditions (-20ºC) leading to hydrogel matrix formation. Freeze drying, vacuum and own designed atmospheric freeze drying process, was used to produce final dried particles, Figure 4.

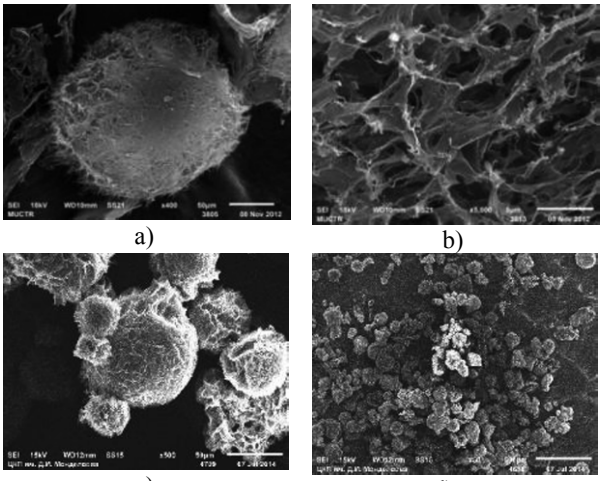
c) d)

Figure 4. SEM photos of produced chemically cross-linked PVA hydrogel particles (external view and macroporous structure): a), b) pneumatic nozzle and vacuum freeze drying used; c), d) ultrasonic nozzle and atmospheric freeze drying used.

The process of production of physically cross-linked PVA hydrogel particles consisted of two stages: first stage - atomizing of PVA aqueous solution into cryogenic liquid, storage of the frozen particles under cryogenic conditions (-15ºC) and second stage - slow defreezing at the rate of 0,03 ºC/min to ambient temperature or vacuum freeze drying. Pictures of produced particles are shown in Figure 5.



a) b) c) d)

Figure 5. SEM photos of produced physically cross-linked PVA hydrogel particles (external view and macroporous structure)
a), b) pneumatic nozzle and atmospheric freeze drying used;
c), d) pneumatic nozzle and vacuum freeze drying used.

PVA-hydrogels have unique properties and characteristics that make them attractive materials to use in biomedicine and pharmaceutical industry.
Some characteristics of hydrogels produced using two types of nozzles (pneumatic and ultrasonic ones) and two methods of drying – vacuum, Figure 2, and atmospheric freeze drying, Figure 3, respectively, are presented in Table 1.
Such hydrogels are non-toxic, biocompatible materials with high elasticity and good swelling properties. Polyvinyl alcohol macroporous hydrogels are widely used as membranes, components of controlled drug release systems, plates for cell and tissue engineering and have other applications in modern medicine.

Table 1
Characteristics of produced powders

Characteristic	**Pneumatic nozzle**		**Ultrasonic nozzle**	
	Vacuum freeze drying	**Atmospheric freeze drying**	**Vacuum freeze drying**	**Atmospheric freeze drying**
Residual moisture content, mass. %	5,2	6,5	3,89	5,74
Bulk density, g/sm^3	0,18	0,3	0,09	0,25
Mean particle diameter, μm	400		40	
Mean pore diameter, μm	10		5	
Overall porosity (calculated)	~0,95			
Swelling degree, g water/ g PVA hydrogel	~1200 %			

Application of PVA hydrogel as a matrix for drug delivery allows for sustained release drug delivery site in.
Developed process allows to produce spherical macroporous particles with a range of particle diameter of 200 – 1000 μm using pneumatic nozzles and with a range of particle diameter of 10 – 100 μm using ultrasonic nozzles, with overall material porosity up to 95 % and pore diameter of 2 - 10 μm. Pore network is rich and sponge like, that predefines high swelling and adsorption properties.
Development of dry particulate of proteinaceous nature drugs for inhalation applications is being undertaken at MUCTR at the present moment. The process of creating such particles is arranged in a periodic mode of two steps: through atomizing an aqueous solution of the proteinaceous nature drugs into the cryogenic liquid (liquid nitrogen Tb = -196 ºC) or through complete aqueous solution freezing in a flask without spraying and vacuum freeze-drying at the temperature of -50 °C ÷ -5 °C. Powders received in such a way are shown in Figure 6.

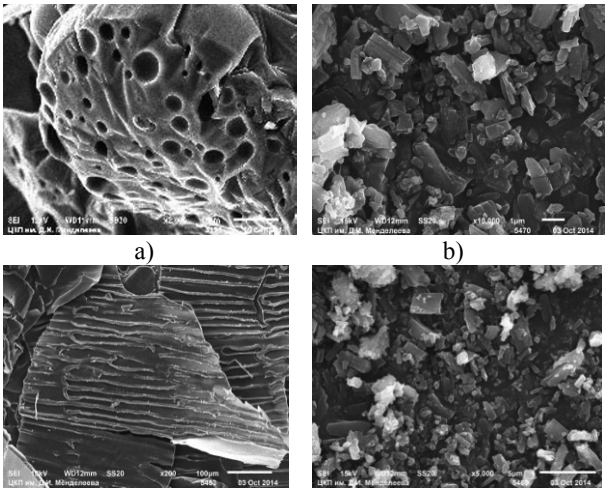


Figure 6. SEM photos of produced proteinaceous nature powders (external view and macroporous structure):
a), b) ultrasonic nozzle and atmospheric freeze drying used;
c), d) pneumatic nozzle and vacuum freeze drying used.

The resultant proteinaceous powders hava a high dispersibility, porosity, rapid and complete solubility in suitable solvents, high flow, it also has a narrow particle size distribution - the particle diameter is of 2 - 20 micrometers, the residual moisture content, is of 1 - 3 mass. % and the bulk density is of 0,09 – 0,18 g/cm3. In addition, the powders are 100 % reducible after freeze drying process without aggregating and do not contaminate due to the excipients.
The finished product – proteinaceous powder - may be used for inhaled, nasal, and transdermal applications. Due to micron particle size, regular shape and their excellent aerodynamic characteristics these powders can be used to create effective drugs based on biologically active substances of protein origin to deliver active ingredients of immunostimulating agents properties by virtue of their specific pharmacological activity, which is higher than that of similar synthetic drugs.

3. Conclusions

Conducted in MUCTR investigation of the powders indicates that the materials created by the higher described method exhibits a high biocompatibility, thermally stable,

substantial water absorption (the total degree of the hydrogel particles swelling in units of g water/g of PVA is 1200 %), mechanical resistance, good adsorptive properties: adsorption rate constant (Brilliant green dye) (k_{ad}) 6,98×10-3 min^{-1}, the effective diffusion coefficient inside the particle(k_p) 1,32×10-5mmol / g×$min^{1/2}$. The developed process allows to produce powders based on resistant to heat substances as well as heat-labile ones.

Biosafety of the obtained powders protein materials and their reducing from a dry powder have been by A.I. Burnasyan Federal Medical Biophysical Centre of Federal Medical and Biological Agency. The results showed excellent biocompatibility and biosafety of the obtained bio-product as well as excellent efficiency of targeting the immune system of experimental animals-rats and no immunotoxic effects of the powders.

There have been conducted an examination of the adhesion of eukaryotic cells to the surface of the particles of PVA by the N.K. Koltzov Institute of Developmental Biology of Russian Academy of Sciences. The results indicate a high cell adhesion and normal proliferation to the surface of the particles, which allows the resulting material to be regarded as a matrix for use in the tissue engineering.

Abstract

Chromatography is an essential step of biopharmaceutical production. High-throughput screening (HTS) is widely used in the biopharmaceutical industry to identify optimal conditions for chromatography processes. At the early stage of the purification process development, different resins are tested under various operating conditions, resulting in the generation of large amounts of data. To facilitate the decision-making process, we develop an optimisation-based decision support approach to process data generated from microscale experiments in order to identify the best resins to maximise key performance metrics of the biopharmaceutical manufacturing process. A multiobjective mixed integer nonlinear programming (MINLP) model is developed, for optimal resin selection for chromatographic sequence used for protein purification. The proposed model is solved using the ε-constraint method and applied to an industrially-relevant example with two chromatography steps. The computational results show that the developed approach is an efficient way to identify the best resins.

Keywords: high-throughput screening, chromatography, multiobjective optimisation, mixed integer programming, ε-constraint method

1. Introduction

In the biopharmaceutical industry, high-throughput screening (HTS) is an early critical step in drug development (Bensch et al., 2005), in which the combination of robotic methods, parallel processing and miniaturisation of bioprocess unit operation has allowed a large number of potential process parameters to be examined within a short time. However, facing a huge volume of data generated from microscale experiments, there is a critical need to analyse them rapidly in order to arrive at conditions that result in optimal overall process performance. Different types of resins may be tested using ultra scale down robotic platforms. Various operating conditions, including different pH values, salt concentrations, and flow rates, may then be optimised in order to maximise chromatographic yield and product purity. Thus, determining optimal resins/conditions from the HTS data becomes a critical problem. The optimal resin found through the microscale experiment is usually the best one for the specific conditions that are tested in that experiment. However, in the real practice of commercial manufacturing, a

chromatography sequence, including multiple chromatography separation steps, is implemented. Thus, the selection decision for each resin should not only depend on this resin's performance, but also is related to the selection of other chromatography resins in the chromatographic sequence, and their operating conditions and performance.

Optimisation-based approaches in the biopharmaceutical industry have become more popular recently (Liu et al., 2013, 2014, 2015; Allmendinger et al., 2014). However, the use of systematic approaches for resin selection in HTS is still largely uncommon. Currently, there are only limited optimisation approaches available for the HTS data analysis problem, as well as statistical tools (Malo et al., 2006). Nfor et al. (2011) presented a model-based rational strategy for the selection of chromatographic resins, in which multiple performance metrics, including yield, purity, productivity, resin/solvent cost, and concentration factor, are optimized using a genetic algorithm. This work addresses the rapid selection of resins for HTS data by developing an optimisation-based systematic decision support framework to select optimal resins for integrated chromatographic separations. The approach is based on experiments involving single resins in each, in order to highlight the benefits of the use of optimisation techniques in drug development.

2. Problem Statement

The optimisation problem considered is described as follows:
Given are:

- target protein, and impurity proteins;
- chromatography sequence and candidate resins;
- chromatography operating conditions for each resin;
- multiple time periods dividing the whole chromatography purification process;
- protein mass loaded under each condition in each time period for each resin;
- protein mass collected under each condition in each time period for each resin;
- salt concentration level for elution in each time period for each resin;

to determine:

- resin selection;
- chromatography operating conditions;
- starting and finishing time for protein collection;

so as to maximise key performance metrics of the chromatography sequence, including yield and purity of target protein.

3. Mathematical Formulation

To solve the above optimisation problem, we formulate a multiobjective mixed integer nonlinear programming (MINLP) model.

3.1. Resin selection constraints

At each chromatography step s, only one resin r can be selected:

$$\sum_{r \in R_s} Y_{sr} = 1, \quad \forall s \tag{1}$$

where Y_{sr} is a binary variable that is equal to 1 if resin r is selected at step s; R_s is the set of resins available at step s.

3.2. Operating condition selection constraints

For each resin *r*, only one operating condition *c* should be selected, out of all operating conditions:

$$\sum_{c\in C_s} Z_{sc} = 1, \quad \forall s \tag{2}$$

where binary variable Z_{sc} is equal to 1 if condition *c* is selected at step *s*; C_s is the set of conditions available at step *s*.

3.3. Starting and finishing time constraints

At each step *s*, during the whole chromatography purification process, including load, wash, elution and regeneration stages, there is only operating starting cut-point, as well as finishing cut-point:

$$\sum_t Xs_{st} = 1, \quad \forall s \tag{3}$$

$$\sum_t Xf_{st} = 1, \quad \forall s \tag{4}$$

where binary variables Xs_{st}/Xf_{st} is equal to 1 if the beginning/end of time period *t* is the starting/finishing time cut-point at step *s*. Thus, the time periods selected for protein collection are determined as follows:

$$X_{st} = X_{s,t-1} + Xs_{st} - Xf_{s,t+1}, \quad \forall s,t \tag{5}$$

where binary variable X_{st} is equal to 1 if time period t is selected at step s.

3.4. Logic constraints

The binary variable W_{srct} is defined as $X_{st} \cdot Y_{sr} \cdot Z_{sc}$, i.e., = 1 if time period *t* of resin *r* under condition *c* is selected at step *s* for collection, which can be expressed as follows:

$$\sum_{r\in R_s}\sum_{c\in C_s} W_{srct} \le U \cdot X_{st}, \quad \forall s,t \tag{6}$$

$$\sum_{c\in C_s}\sum_t W_{srct} \le U \cdot Y_{sr}, \quad \forall s, r \in R_s \tag{7}$$

$$\sum_{r\in R_s}\sum_t W_{srct} \le U \cdot Z_{sc}, \quad \forall s, c \in C_s \tag{8}$$

$$W_{srct} \ge X_{st} + Y_{sr} + Z_{sc} - 2, \quad \forall s, r \in R_s, c \in C_s, t \tag{9}$$

where parameter *U* is a large number.

3.5. Step integration constraints

Between the two successive chromatography steps, the salt concentration of elution at the finishing cut-point at a former step ($conc_{st}$) should be less than that of the starting cut-point at a later step ($conc_{s+1,t}$):

$$\sum_t conc_{st} \cdot Xf_{st} < \sum_t conc_{s+1,t} \cdot Xs_{s+1,t}, \quad \forall s \tag{10}$$

3.6. Yield constraints

The yield after each step (Yd_s) is the fraction of the collected mass and the loaded mass of the target protein, *dp*:

$$Yd_s = \sum_{r\in R_s}\sum_{c\in C_s}\sum_t \frac{m_{src,dp,t} W_{srct}}{lm_{src,dp}}, \quad \forall s \tag{11}$$

where $m_{src,dp,t}$ is the mass of target protein *dp* collected under condition *c* in resin *r* in time period *t* at step *s*, while lm_{srcp} is the mass of protein *p* loaded to resin *r* under condition *c* at step *s*.

3.7. Purity constraints

The purity after each step (Pu_s) is the fraction of the collected mass of the target protein and that of all proteins *p*:

$$Pu_s = \frac{\sum_{r\in R_s}\sum_{c\in C_s}\sum_t m_{src,dp,t}W_{srct}}{\sum_{r\in R_s}\sum_{c\in C_s}\sum_p\sum_t m_{srcpt}W_{srct}}, \quad \forall s \tag{12}$$

3.8. Objective functions

We aim to maximise both overall yield and purity of the integrated chromatography steps. We use an performance indicator, z^{Yd}, equalling the product of the yields at all steps, for the overall yield of the whole process (Eq. 13). Also, another performance indicator, z^{Pu}, is used to represent the overall purity, which is approximated by the average purity of all steps involved, in order to reflect all steps' effects on it (Eq. 14).

$$z^{Yd} = \prod_s Yd_s \tag{13}$$

$$z^{Pu} = \sum_s Pu_s / |s| \tag{14}$$

3.9. Summary

Based on the above constraints, the multiobjective optimisation problem can be presented in the following format as problem (15). Note that when $|s| = 1$, this MINLP model can still deal with single-step separation.

$$\begin{aligned} &\max \{z^{Yd}, z^{Pu}\} \\ &s.t. \text{ Eqs. (1)-(14)} \end{aligned} \tag{15}$$

4. Solution Approach

To solve the above multiobjective optimisation problem (15), we apply the ε-constraint method (Haimes et al., 1971), in which all but one objective are converted into constraints by setting an upper or lower bound to each of them, having only one objective to be optimised. Thus, the multiobjective optimisation problem (15) can be transformed into a set of single-objective optimisation problems (16):

$$\begin{aligned} &\max\ z^{Yd} \\ &s.t.\ z^{Pu} \geq \bar{z}^{Pu} \\ &\quad \text{Eqs. (1)-(14)} \end{aligned} \tag{16}$$

where $\bar{z}^{Pu}$ is the minimum bound of the purity indicator. By using multiple values of $\bar{z}^{Pu}$, the Pareto frontier can be achieved. When single-step separation is considered, a mixed integer linear programming (MILP) model is solved in the ε-constraint method.

5. Case Study

Here, we consider a real case study of a biopharmaceutical company, wishing to purify a monomer protein from a protein mixture with aggregates and fragments as the main impurities. We consider a two-step chromatography sequence, including cation-

exchange chromatography (CEX) as step 1 and mixed mode chromatography (MM) as step 2. For CEX, there are 8 candidate resins (CEXR1-CEXR8) with two operating conditions/pH values for each resin (C1-C2), while for MM, there are 4 candidate resins (MMR1-MMR4) with 8 to 12 operating conditions (C1-C12) for each resin. These CEX and MM resins investigated are all commercially available and were selected for evaluation based on their different chemical characteristics and purification capabilities. The whole purification process at each step is divided into 29 time periods (T1-T29). The developed models were implemented in GAMS (Brook et al, 2012) on a Windows based machine with 3.2 GHz processor and 12 GB RAM. BARON was used as the MINLP solver and CPLEX as the MILP solver. The optimality gap was set to 0%.

Firstly, we select the optimal resin for CEX and MM steps, separately, by solving a number of MILP models in the ε-constraint method. Each MILP involved took less than 1 second to find the optimal solution. Figure 1 shows the Pareto frontiers which are obtained by increasing $\bar{z}^{Pu}$ from 85% to 95%. The labels on Figure 1 show the corresponding optimal resin and condition. We can see that CEXR3, CEXR4 and CEXR7 can achieve both high yield and purity, while MMR1 and MMR3 show dominant performance for the MM step. A particular note was that different performances for the same resin and condition result from their different starting and finishing cut-points. Secondly, we consider the integration of the above two steps, including CEX as the first step and MM as the second one. The average CPU time for each integrated MINLP model was around 50 seconds. By increasing $\bar{z}^{Pu}$ from 85% to 95%, we have the Pareto frontier as shown in Figure 2. In the Pareto-optimal solutions, the best chromatography sequence is CEXR7-MMR3. This sequence is able to achieve both high yield and high purity (>90%). Other sequences result in slightly higher purity, but significantly lower yield (<85%). The difference between the best resin for each single chromatography step and the best resins for the two chromatography steps shows the value of the proposed optimisation-based decision support framework of HTS, although the validation in larger scale experiment is still needed.

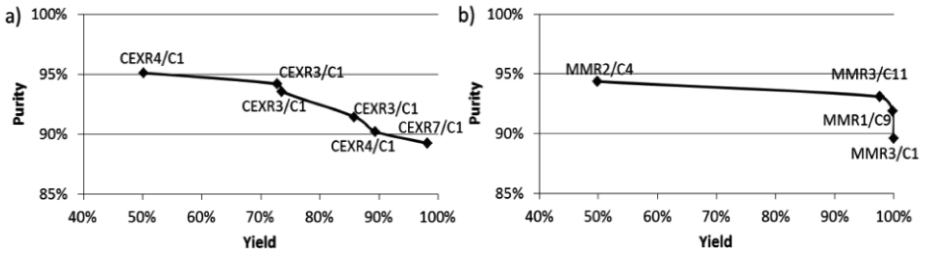

Figure 1: Pareto frontier for a) CEX step and b) MM step.

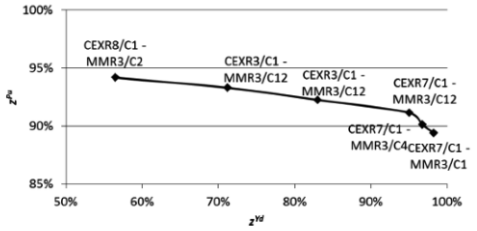

Figure 2: Pareto frontier for the integrated CEX and MM steps.

6. Conclusions

In this work, we address the rapid resin selection problem for the integrated chromatographic separations made available during HTS, by developing an optimisation-based decision support systematic framework for optimal resin selection. A multiobjective MINLP model has been developed to maximise both yield and purity of the integrated chromatographic separations. Then, the classic ε-constraint method has been adapted as the solution approach, in which only yield was optimised in relation to the purity constraints. Then, the developed framework was applied to a real case study to show its applicability. The results show the benefits of the decision-making based on integrated chromatographic separations, by comparing the best resins in terms of yield and purity to be used in each chromatography step independent from the other steps and the optimal best resins when the two chromatography steps have been integrated.

The limitation of this work is the indicator of overall purity is calculated based on the data from experiments for each single resin only. In future work, we will seek to link the two chromatography steps using protein mass balances, and hence calculate the overall purity in a more accurate way.

Plantwide Design and Economic Evaluation of Two Continuous Pharmaceutical Manufacturing (CPM) Cases: Ibuprofen and Artemisinin

Hikaru G. Jolliffe, Dimitrios I. Gerogiorgis

School of Engineering, University of Edinburgh, Edinburgh EH9 3JL, UK

Abstract

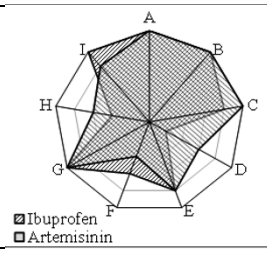
Continuous Pharmaceutical Manufacturing (CPM) is a rapidly expanding research field with growing industrial importance: challenging the current batch production paradigm, it has a documented potential to deliver key cost, efficiency and environmental benefits. Ibuprofen, the potent painkiller, and artemisinin, a highly effective anti-malarial drug, have been identified as promising CPM candidates, and steady-state flowsheet models have been developed on the basis of published continuous organic synthesis pathways. Reactor design has been conducted using original kinetic parameter estimation results. A comparative economic analysis via published recoveries has computed performance indices which indicate that both CPM designs exhibit high economic potential, even if conservative profit and climate estimates are used to derive capital and operating costs. More detailed technoeconomic analyses can facilitate quicker CPM implementations.

Keywords: Continuous Pharmaceutical Manufacturing (CPM), ibuprofen, artemisinin.

1. Introduction

Continuous Pharmaceutical Manufacturing (CPM) is a vibrant research field addressing challenges due to the ever-increasing R&D costs and globalised corporate competition. Offering a cost-effective alternative to traditional batch processes (Roberge et al., 2008), CPM can reduce cost (Schaber et al., 2011) at high yield, solvent and energy efficiency, allow for easier process scale-up and eliminate intermediate storage needs, while also reducing environmental impact and increasing sustainability (Poechlauer et al., 2013). Process synthesis, modelling and simulation can rapidly assess process potential (Gerogiorgis & Barton, 2009) toward sound CPM business cases (Gernaey et al., 2012). Recently, a series of Active Pharmaceutical Ingredients (APIs) have been identified as promising CPM candidates (Jolliffe & Gerogiorgis, 2015): ibuprofen and artemisinin ranked highest among all, using a set of nine specific technoeconomic criteria (Figure 1)

Ibuprofen is recognised as an essential non-steroidal anti-inflammatory drug (NSAID) by the World Health Organisation; its global annual production exceeds 13,500 tonnes. Artemisinin is the parent substance of the fastest acting and most effective anti-malarial drugs, currently extracted in batch from sweet wormwood, *Artemisia annua* (Tu, 2011). Demand fluctuations and production timescales induce supply and cost unpredictability: between 2005 and 2008, market price varied by an order of magnitude, \$120÷1,200/kg (Artemisinin Enterprise, 2008), with a recent report at \$400/kg in 2013 (Peplow, 2013). This paper focuses on a technoeconomic CPM analysis and comparison of these APIs. Process mass balance simulations for two CPM designs have been performed, and reactor design has relied on novel kinetic and thermodynamic parameter estimations. Annual capacity for both APIs (50 kg) is chosen toward comparative economic analysis.



A. Is the process fully continuous?
B. Is the final product a currently marketed API?
C. Low to medium complexity process?
D. Has the process been implemented?
E. Feedstock/reagent availability.
F. Ease of process scale-up.
G. Are intermediate separations eliminated?
H. Price of commercially available product.
I. Global sales volume.

Figure 1. Systematic analysis of CPM potential for the two APIs (Jolliffe & Gerogiorgis, 2015).

2. Continuous flow synthesis of APIs

Continuous organic flow synthesis pathways for ibuprofen (Bogdan et al, 2009) and artemisinin (Kopetzki et al, 2013) illustrate their acknowledged therapeutic importance and serve as precedents for developing both steady-state process models reported here.

2.1. Ibuprofen

Ibuprofen is produced using three reactors: in the first PFR, Friedel-Crafts acylation converts isobutyl benzene (IBB) into intermediate $\mathbf{2_A}$, then transformed in the second PFR (by 1,2-aryl migration) into intermediate $\mathbf{3_A}$. The latter undergoes base hydrolysis in the third PFR, yielding the potassium salt of ibuprofen: we consider this entirely acidified prior to final separation, as the salt is unsuitable for commercial formulations.

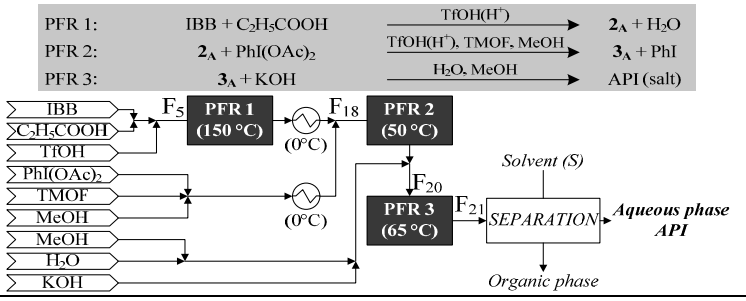


Figure 2. Demonstrated process flowsheet for ibuprofen CPM production (Bogdan et al, 2009).

2.2. Artemisinin

Artemisinin is attainable via a series of two reactors: dihydroartemisinic acid (DHAA, a conventional artemisinin batch extraction waste) is photo-oxidised in a chilled PFR, producing intermediate $\mathbf{3_B}$ and by-products. In the second PFR, $\mathbf{3_B}$ undergoes multiple transformations in presence of trifluoroacetic acid (TFA, acid catalyst), before eventual oxidation to artemisinin; additional by-products are generated (Gilmore et al., 2013).

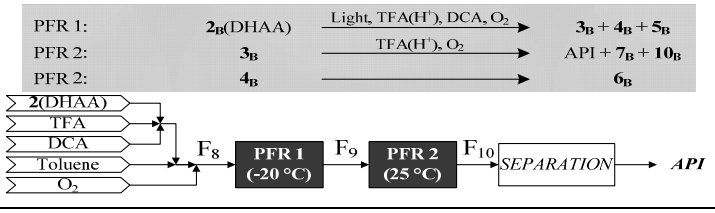

Figure 3. Demonstrated process flowsheet for artemisinin CPM production (Kopetzki et al, 2013).

3. Mass balances and reactor design

Process mass balances for both CPM flowsheets appear in Fig. 4; some flows are scaled for clarity, and by-products (BPD: salts, methyl formate, iodobenzene) are all grouped. For comparative economic evaluation, the annual production is set at 50 kg of pure API without considering any losses in downstream processing or final dosage formation. The summary of essential kinetic parameters for PFR design is presented in Table 1.

3.1. Kinetics

Kinetic rate constants and conversions for the first two ibuprofen reactions are extracted from literature data, using SPARC software for the third (Jolliffe & Gerogiorgis, 2015). Possible side effects (e.g. esterification reactions between organic acids and methanol), the chemical action of by-products and the presence of solids are assumed negligible; reaction orders and constants (hr^{-1} /1st order, $Lmol^{-1}hr^{-1}$ /2nd order) are given in Table 1.

Kinetic parameter estimation for both artemisinin reactions has relied on the first-order assumption, given their nature (large organic molecules react with an excess of e.g. O_2); published conversion and reactor volume data have been used (Kopetzki et al., 2013). The photo-oxidation reaction in the first PFR can achieve a DHAA conversion of 98%. For the second PFR, a conversion of 79% is obtained for the first reaction ($\mathbf{3_B}$→API), using DHAA conversion (98%), artemisinin (59.9%), $\mathbf{7_B}$ (4.5%) and $\mathbf{10_B}$ (2.5%) yields.

The conversion of $\mathbf{4_B}$ (61%) is similarly calculated on the basis of data for overall yield (i.e. including species from the reaction of $\mathbf{3_B}$) of $\mathbf{6_B}$ (6.18%) (Kopetzki et al., 2013); yields have been adjusted to account for small by-product (BPD) quantities (< 1% mol).

3.2. Reactor design

For both CPM plant designs, the present design analysis considers that all PFR reactors perform well at isothermal operation and that sufficient heat transfer can be achieved. Selecting a suitably small diameter ensures radial temperature gradients are negligible. Well-circulating heating media and controlled environments (e.g. ovens, baths) are established state of the art for several CPM reactor prototypes (Bedore et al., 2010).

Plug Flow Reactor (PFR) design has been performed by determining required lengths via integration: a small ID (5 mm) has been selected to ensure adequate heat transfer, in accordance with proven CPM PFR designs at similar length scale (Mascia et al., 2013). No phase change during flow is considered (precipitation can be prevented by design).

Table 1. Continuous reaction parameter estimates and summary of reactor (PFR) design results.

PFR # (reaction)	***T*** (ºC)	k_i (resp. units)	**Flowrate** ($g\ hr^{-1}$)	**Conversion** (%)	***ID*** (mm)	**Volume** (mL)	**Length** (mm)
Ibuprofen							
PFR 1 (IBB→$\mathbf{2_A}$)	150	31.41	41.58	91	5.0	6.392	326
PFR 2 ($\mathbf{2_A}$→$\mathbf{3_A}$)	50	2732.3	115.77	98	5.0	1.997	102
PFR 3 ($\mathbf{3_A}$→API)	65	15.57	306.90	99	5.0	28.912	1472
Artemisinin							
PFR 1 (DHAA→$\mathbf{3_B}$)	-20	39.12	109.86	98	5.0	10.442	532
PFR 2 ($\mathbf{3_B}$→API)	25	2.91	109.86	79	5.0	55.685	2836
($\mathbf{4_B}$→$\mathbf{6_B}$)	25	1.78	109.86	61	5.0	55.685	2836

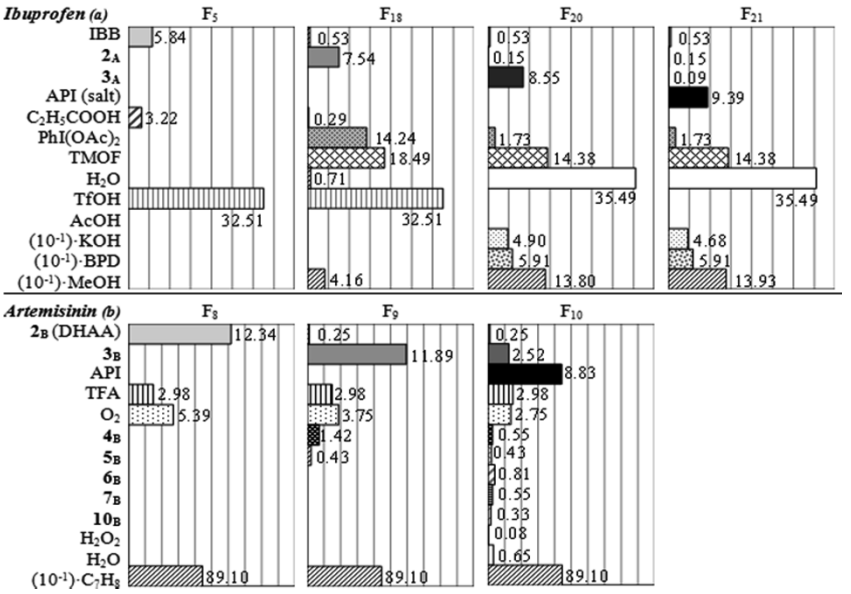

Figure 4. Mass balances for streams of both CPM designs (units: 5 g hr^{-1}/a, 2 g hr^{-1}/b).

4. Separation design

Separation design entails the analysis of candidate solvents and operating conditions: for ibuprofen production, liquid-liquid extraction (LLE) has been considered as a viable choice, to achieve high API recovery before crystallisation and downstream processing. Six solvents (acetonitrile, ethanol, methyl acetate, ethyl acetate, n-hexane, toluene) have been evaluated to assess performance and environmental impact (Alfonsi et al, 2008). Solvent-to-feed mass ratios ($S:F_{21}$) ranging from 0.25 to 5 have been considered for the ones yielding phase split (n-hexane, toluene), at 25 °C (ambient) and 65 °C (PFR3). Stream F_{21} is approximated as a H_2O-MeOH mixture; solubility and phase equilibria modelling enables computation of effluent compositions (Jolliffe & Gerogiorgis, 2015).

The recommended choice is toluene, at a $S:F_{21}$ ratio of 0.75 at 25 °C, resulting in 81.7% final ibuprofen recovery: operation at higher temperature (65 °C) gives higher recovery, but is less preferable due to heating cost and off-gassing (Jolliffe & Gerogiorgis, 2015). While n-hexane performs better in many instances of $S:F_{21}$ ratios and temperatures, it has a grave environmental impact and is not a desirable solvent (Alfonsi et al, 2008). The other solvents considered are unsuitable for this LLE case due to full miscibility. Purification design must consider seamless downstream (e.g. ethanol-based) processing.

Kopetzki et al. (2013) used acetonitrile to dissolve artemisinin, allowing the removal of poorly-soluble DCA by filtration: the latter is followed by two crystallisation stages, both of which use a cyclohexane-ethanol (9:1 v/v) solvent mixture to obtain solid API. The published organic flow synthesis pathway produces artemisinin at a yield of 65%; the subsequent sequential crystallisations achieve respective yields of 57% and 46%, corresponding to an overall API recovery of 70.8%: this can also be improved further to increase CPM efficiency, by means of multicomponent equilibria and solubility models.

5. Environmental impact: the E-factor

The environmental factor (E-factor) is a green engineering metric of process impact: in its simplest form, it is defined as the ratio of waste to product mass (Sheldon, 2012). Highly efficient continuous (e.g. petrochemical) industries have typical E-factors of 0.1, while pharmaceutical industries frequently reach values of 200 or higher (Ritter, 2013). E-factors have been calculated for both CPM designs considered: a very attractively low low E-factor of 25.4 has been calculated for ibuprofen (Jolliffe & Gerogiorgis, 2015), indicating that CPM implementation is a viable option even without solvent integration. The corresponding E-factor of 33.5 for artemisinin is equally appealing (albeit slightly higher): the total mass of material input considers both feedstocks as well as solvent (cyclohexane-ethanol) requirements for both crystallisation stages and API production. The comparable and similar E-factor values underline the importance of systematic environmental impact evaluation, while also illustrating that there is indeed clear scope for improving the efficiency of artemisinin recovery by continuous separation design.

6. Economic evaluation

Economic CPM performance has been analysed using established economic metrics, Net Present Value (NPV), Return on Investment (ROI), and Payback period (PBP); for these, the plant lifetime, τ (20 yr), and the discount rate, r (variable) are key parameters. Prices are taken as £538/kg and £229/kg for ibuprofen and artemisinin, respectively. For CapEx calculations, all equipment costs have been sourced from vendor databases. For ibuprofen, unit prices of all expensive equipment as listed by Bogdan et al. (2009) have been considered and scaled up accordingly; for artemisinin production, a literature figure for equipment cost of similar capacity has been used (Extance, 2012). Assumptions include: equipment delivery cost 5% of price, working capital 3.5% of annual sales, contingency 20% of the battery-limits installed cost (BLIC, i.e. equipment plus delivery) (Schaber et al., 2011); total CapEx is the sum of BLIC and contingency. For OpEx calculations, waste disposal costs £0.33 and £1.98 per litre of water and of solvent have been considered, respectively; utility cost is £0.96 per kg of input material (Schaber et al., 2011). Labour, material handling, tax and quality control have not been considered, but are essential components of a more detailed technoeconomic analysis. Annual operation is set at 7728 and 8000 hr for ibuprofen and artemisinin, respectively. Economic performance indices for CPM design evaluation are summarised in Table .

Table 2. Economic performance comparison for CPM production of both APIs analysed (r =5%).

	Ibuprofen	**Artemisinin**
NPV	£73,500	£108,300
ROI (%)	33.95	82.60
PBP (years)	3.27	1.28
BEP (kg API/year)	7.37	3.03

Artemisinin has a stronger economic potential (higher NPV and ROI), reaching payback (positive NPV) in less than half the time (Fig. 5). Nevertheless, both CPM designs are clearly viable, even if Table values are only useful in preliminary economic evaluation (implementation requires a comprehensive analysis of all equipment and cost factors). The CPM of artemisinin is very attractive as it uses as feedstock waste material from the current artemisinin extraction process: great added value is attainable by implementing this CPM design to address demand. The CPM of ibuprofen is also promising, but a strong competitive advantage is essential to demonstrate in case of no patent protection.

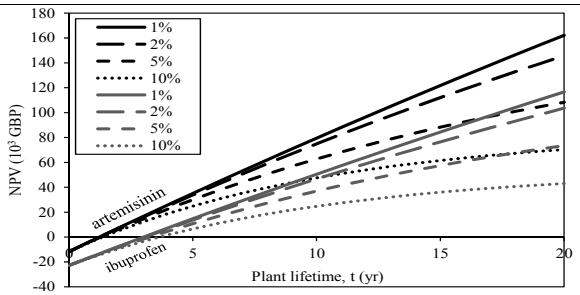

Figure 5. Comparison of projected Net Present Values (NPV) for a wide range of discount rates.

7. Conclusions

Continuous Pharmaceutical Manufacturing (CPM) has great potential to deliver strong cost and efficiency benefits for two APIs (ibuprofen and artemisinin) at a 50 kg/yr scale. Computed PFR volumes range from 2÷55 mL, illustrating CPM applicability benefits, with a positive environmental impact outlook (E-factors of 25.4 and 33.5, respectively), and the enormous sustainability benefit of using batch process waste as CPM feedstock. Both designs thus hold high economic promise (NPV: £73,500 and £108,300, ROI: 34% and 83%, PBP: 3.3 yr and 1.3 yr, respectively) toward CPM pilot plant implementation.

Abstract

A grain comminution process is based on a gradual size reduction approach, through repeated milling and sieving units that increase the flour yield. In this study we use latent variable modeling techniques to link process parameters and grain properties to the final product quality. Using experimental data, it is shown how the use of models in their direct form allows one to improve process understanding and to predict the product quality from the process settings and grain properties. Additionally, it is shown that, by inverting the latent variable models, the optimal combination of process parameters and grain properties leading to a desired product quality can be determined.

Keywords: grain comminution, latent variable model, process understanding, product design

1. Introduction

Through direct consumption and indirectly via animal feed, cereals supply more than half of global food consumption. Around 2 billion tons of cereals are produced annually, with wheat contributing around 600 million tons, from which 123 million tons of flour are produced from medium and large mills (Campbell, 2007). The aim of wheat milling is to break open the kernel and to separate its structural components (endosperm, bran and germ) in such a way as to recover endosperm in maximum quantity at minimum contamination (with bran and germ), and at a minimum cost. A wheat milling process typically comprises up to five break stages and a dozen reduction stages, arranged in a complex configuration (Campbell, 2007). Flour milling uses repeated size reduction steps (by roller milling) and repeated separation steps (by sifting) to achieve an effective separation of endosperm from bran and germ, and an appropriate reduction of the endosperm into flour. This gradual reduction approach greatly increases the flour recovery (with minimum bran contamination), but needs profound process understanding to be operated. This is also due to the origin of wheat that, as a natural product, shows a high intrinsic variability. Therefore, the millers' main challenge is to produce flour of consistent uniform quality, in the face of a changing feedstock. Nowadays the process operation is mostly based on the operators' experience. This study focuses on the second break stage of a wheat milling process. The second break is one of the most important passages of the entire process, and only few studies have been reported about this passage. Yuan et al. (2003) considered second break milling in their systematic analysis of the entire break subsystem. Al-Mogahwi

and Baker (2005) included the second break passage in their study of both break and reduction milling.

There is a great interest in finding systematic approaches that can be used to improve process understanding, to support the process operation by predicting the product quality, and to optimize the process operating conditions by suggesting how the process parameters should be set to counteract the changing characteristics of the input materials, as well as to ensure a consistent product quality. Modeling the process by first principles is still a very challenging and unresolved issue. A data-based modeling approach, namely partial least-squares regression (PLS; Wold et al., 2001) is used in this study to analyze the second break process, given the multivariate nature of the process and the correlation showed by the process parameters, wheat properties and product quality.

2. Materials and methods

2.1. Experiments and available data

The dataset used in this study was obtained from an experimental campaign carried out in a pilot-scale roller mill fed with material entering the second break stage of an industrial-scale mill. Experiments were designed following a central composite face-centered design of experiments (DoE) strategy applied to the most important parameters of the process: wheat kernel moisture content (MC), mass flow (MF) to the roller mill and milling gap (MG). The ranges for MC, MF and MG were chosen in such a way as to match typical industrial ranges. In addition, for each experiment, ambient humidity (MC_e) and ambient temperature (T_e) were measured and included in the dataset. Each experiment was repeated at least twice and average values are used in this study. Some other parameters affect the milling operation. These comprise process and equipment parameters (such as roll speed, roll speed differential, roll fluting) and wheat properties (such as hardness of the wheat kernel). Roll speed, speed differential, and fluting were fixed as in the industrial second break roller mill, whereas the kernel hardness was not considered in this study.

The experimental data were organized in a regressor matrix **X** [15×5] and in a response matrix **Y** [15×37]. The **X** matrix included 5 variables referring to process parameters (MF and MG), wheat properties (MC) and ambient conditions (MC_e and T_e) for 15 different averaged observations. The **Y** matrix included 37 variables, where each y_i variable represents the range of diameters of the output particle size distribution (PSD) within bin i; namely, y_1 corresponds to the smallest particle diameter range (0-4 μm), whereas y_{37} represents the biggest diameter range (5958-7399 μm). The value taken by each y_i variable refers to the volume fraction of particles whose diameter is within the diameter range of bin i. The PSDs were measured with the image analysis sensor QICPIC (Sympatec GmbH, Germany). Note that the particle diameter range does not change linearly across the PSD bins (see later on Figure 1b).

2.2. Mathematical methods

PLS (Wold et al., 2001) is a latent variable regression modeling technique that relates input variables (e.g., process parameters and wheat properties) and response matrices (e.g., product PSD) by projecting them onto a space of uncorrelated latent variables (LVs). The LVs explain the major sources of the variability of the inputs that are most correlated to the variability of the response variables. After appropriate data pretreatment (namely, autoscaling; Wold et al., 2001), PLS is applied to the **X** [I×N] and **Y** [I×M] matrices:

$$\mathbf{X} = \mathbf{T}\mathbf{P}^{\mathrm{T}} + \mathbf{E}_{\mathbf{X}} \tag{1}$$

$$\mathbf{Y} = \mathbf{T}\mathbf{Q}^{\mathrm{T}} + \mathbf{E}_{\mathbf{Y}} \tag{2}$$

$$\mathbf{T} = \mathbf{X}\mathbf{W}^{*} \quad , \tag{3}$$

where $\mathbf{T}$ [$I \times A$] is the score matrix, $\mathbf{P}$ [$N \times A$] and $\mathbf{Q}$ [$M \times A$] are the loading matrices and $\mathbf{W}^*$ [$N \times A$] is the weight matrix. $\mathbf{E}_{\mathbf{X}}$ [$I \times N$] and $\mathbf{E}_{\mathbf{Y}}$ [$I \times M$] are the residual matrices accounting for the model mismatch. A represents the number of significant LVs chosen to build the model, i.e. it corresponds to the dimensions of the latent space that should be appropriately selected (Picard and Cook, 1984).

A PLS model correlating $\mathbf{X}$ and $\mathbf{Y}$ explains the systematic variability in the process settings and wheat properties that are related to the variability in the product PSD. This model can be exploited to identify the main driving forces acting on the system. To this purpose, a loading analysis is used. Loading plots are very useful to understand and quantify the correlation between input variables and product characteristics; namely, they allow one to understand the effects of input process parameters on the output PSD.

PLS models can be used in their direct form for predictive purposes (e.g., to predict the PSD from process parameters and wheat properties). On the other hand, PLS model inversion (Jaeckle and MacGregor, 2000) can be exploited to calculate the combination $\mathbf{x}_{\mathrm{NEW}}$ of input conditions (e.g., process parameters and wheat properties) that lead to desired product quality $\mathbf{y}_{\mathrm{DES}}$.

Letting $R_{\mathbf{X}}$=rank($\mathbf{X}$) and $R_{\mathbf{Y}}$=rank($\mathbf{Y}$), if $R_{\mathbf{X}} = R_{\mathbf{Y}}$ (namely, the effective dimension of $\mathbf{X}$ is the same as that of $\mathbf{Y}$) direct model inversion can be done and $\mathbf{x}_{\mathrm{NEW}}$ can be calculated as:

$$\mathbf{x}_{\mathrm{NEW}} = \mathbf{t}_{\mathrm{DES}}\mathbf{P}^{\mathrm{T}} \quad , \tag{4}$$

where:

$$\mathbf{t}_{\mathrm{DES}}^{\mathrm{T}} = (\mathbf{Q}\mathbf{Q}^{\mathrm{T}})^{-1}\mathbf{Q}^{\mathrm{T}}\mathbf{y}_{\mathrm{DES}}^{\mathrm{T}} \quad . \tag{5}$$

Note that the designed input set $\mathbf{x}_{\mathrm{NEW}}$ belongs to the model space and has the same covariance structure of historical data used for PLS model building.

3. Results and discussion

A PLS model using 3 LVs explains a large amount of variability (86.9 % of explained variance) of the $\mathbf{X}$ matrix. Since MF, MC and MG were varied according to a DoE plan, they are uncorrelated, and each LV essentially describes the variability of each input. The 3 LVs describe a large fraction (88.6 %) also of the $\mathbf{Y}$ variability, with the first LV explaining as much as 83.2 % of the variance. This means that the variables describing the PSD are strongly correlated, and one LV is enough to describe almost the entire variability of $\mathbf{Y}$. Hence, the second and the third LVs are mainly used to describe the variability of $\mathbf{X}$. Note that describing a sufficiently large fraction of the $\mathbf{X}$ variability is important for model inversion.

The PLS model is used to: *i*) improve process understanding, by studying the correlation between the input parameters and the output PSD from the second break stage; *ii*) predict the product quality profile (PSD), and *iii*) to identify (by model inversion) the process parameters and wheat properties that are required to obtain a product with desired quality specifications.

3.1. Process understanding

Figure 1 shows the plots of the **P** (Figure 1a) and **Q** (Figure 1b) loadings of the PLS model; each loading is weighted for the explained variance of the relevant LV.

The first latent variable (top plot of Figure 1a) is dominated by the MG. The effects of MG can be understood by comparing the top plot of Figure 1a with the top plot of Figure 1b, which is the loading plot of first LV of matrix **Y**. By looking at the top plot of Figure 1b, it can be seen that the MG has a strong effect on the whole PSD. Namely, when the MG increases, the quantity of particles with a diameter lower than 751 μm decreases (refer to the bars that have a negative value in the top plot of Figure 1b), whereas bigger particles increase. This behavior is meaningful from a physical point of view: when the MG decreases, the possibility of obtaining smaller particles increases. The threshold particle diameter is ~751 μm: a reduction of the particle diameter by MG reduction can be achieved for particles smaller than this threshold, and this is obtained at the expense of the fraction of particles with larger diameters. In fact, the number of particles with diameter larger than the threshold descreases as the MG decreases. Since first LV explains about 83 % of data variability of the output PSD, it can be concluded that nearly the whole data variability in the PSDs is due to the variability of the MG.

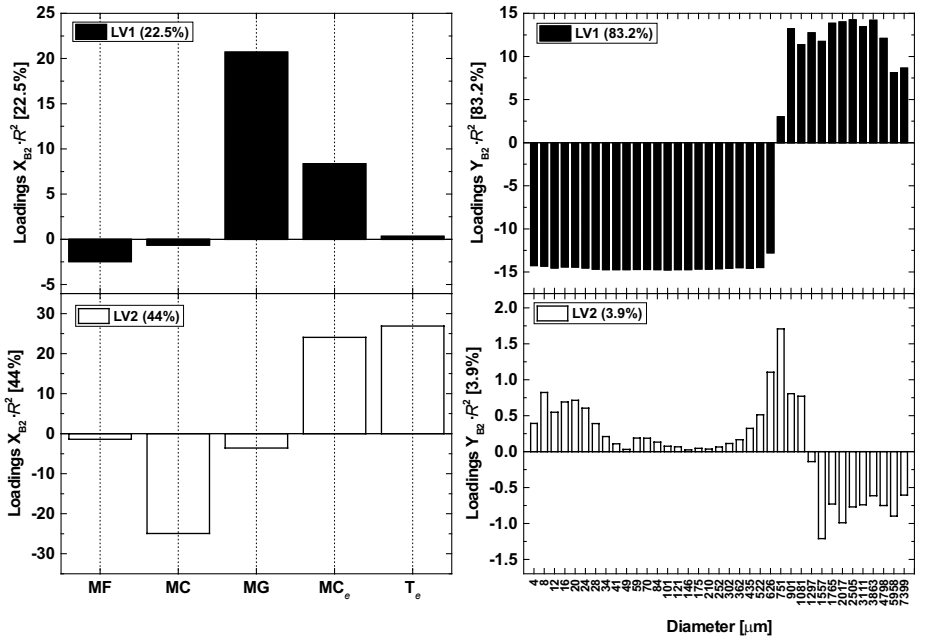
The second LV (lower plot of Figure 1a) is dominated by the MC. MC exhibits a negative correlation with MC_e and T_e (which are positively correlated). This correlation is not representative of the process, but simply illustrates the ambient conditions in the days when the experimentation was carried out. MC has a strong effect on particles whose diameter lays in the range 626-751 μm (tallest bar in the lower plot of Figure 1b). MC has a considerable influence also on particles that are bigger than 1081 μm (bars with negative values in the lower plot of Figure 1b). When MC increases, also the amount of these particles increases. This behavior can be explained physically by noticing that particles with diameter bigger than 1081 μm are identified as bran. The bran breakage behavior is highly dependent on the MC: a higher wheat kernel MC has the effect of hardening the bran, with the result that it breaks in larger particles.

The loading plots for third LV are not reported because, even though this LV is explaining a reasonably large amount of data variability for matrix **X** (20.4 %, due to the variability of MF), it explains a very low percentage of explained variance for **Y** (only 1.5 %), meaning that the effects of MF on the output PSDs are negligible.

It is interesting to notice that a threshold diameter range exists around 751-1081 μm, where all PSDs show an "inversion" pattern (namely, the relevant loadings change sign). The physical explanation for this behavior is the difference in the shape of the milled particles. Particles bigger than 1081 μm are identified as bran and are characterized by flat large particles (two-dimensional particles); smaller particles are made of endosperm and have a more spherical shape (three-dimensional particles). In fact, the difference in shape can explain why the PSD bins behave differently when a process parameter is changed.

3.2. Product quality prediction

In this subsection the main idea is to evaluate how the product quality can be predicted once process parameters, wheat properties and ambient conditions are known. A jackknife approach was used (Miller, 1964). Namely, one of the available observations was removed from the database and it was used to validate the model built on the remaining observations. The procedure was then iterated by including that observation in the dataset and removing a different one, until each observation was removed once. Eventually, the results were averaged through all iterations.



(a) (b)

Figure 1. Loading plots of the PLS model: (a) loadings of matrix **X** and (b) loadings of matrix **Y**.

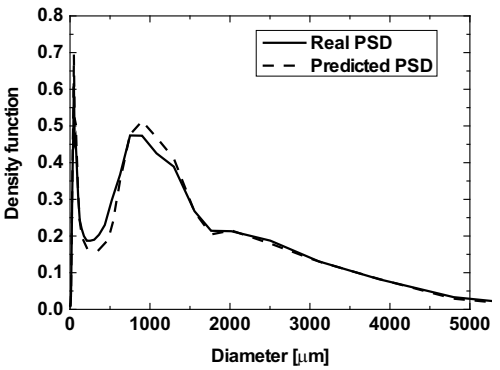


Figure 2. Example of prediction of output PSD from roller mill for the second break step.

Figure 2 shows that the predictions are very good for all observations. The average root mean square error (RMSE) for all predictions is 0.0338 (that corresponds to an average correlation coefficient R^2 of 0.9755); the average RMSE is lower than the average variability of the PSDs (0.1042). The prediction error is usually larger at the distribution peaks (i.e., where the PSD variability increases).

3.3. Milling product design

PLS model inversion can be used to calculate the best combination of process parameters and wheat properties that are needed to obtain a product with assigned PSD. As an illustrating example, the observation related to a product with desired PSD ($\mathbf{y}_{DES}$) was removed from the dataset, and the input combination (MG, MC and MF) required to obtain $\mathbf{y}_{DES}$ was estimated by direct model inversion. The calculated input set is

reported in Table 2 together with the true input set leading to $\mathbf{y}_{DES}$. Unfortunately, a validating experiment was not possible due to a problem in the experimental apparatus. Nevertheless, the calculated and true input sets are in fair agreement, indicating that the model inversion approach has the potential for the design of the optimal operating conditions.

Table 2. Example of product design for the second break step.

	MG [µm]	MC [%]	MF [kg/h]
Input set estimated by model inversion	275	17.22	316.58
True input set	300	14.89	300.00

4. Conclusions

In this study, how PLS modeling can be used in different ways to support the operation of the second break step in a wheat milling process has been discussed.

A loadings analysis improved process understanding, by studying and quantifying the correlation between process parameter, wheat properties and product PSD. The study supported the evidence that the product PSD is mostly affected by the milling gap, but it was found that the correlation between input parameters and output PSD depends on how the different constituents distribute in the milled product, as endosperm and bran have different breakage behavior. The range of particle diameters separating different breakage behavior was found to be around 751-1081 µm.

Latent variables models have been used to predict the product PSD with very promising results. This kind of prediction can greatly support process optimization, allowing one to predict product quality profile reducing costly and time expensive experimental campaigns. Furthermore, it was shown how the same models can be inverted and used to calculate the best combination of input parameters (milling gap, moisture content and wheat mass flow) that leads to a desired PSD. Although this study concentrated on the second break stage, it can be extended to other break and reduction passages.

Abstract

A simple steady state model of a milk drying process was built to help process understanding. It involves a spray chamber and also internal/external fluid beds. The model was subjected to a statistical analysis for quality assurance using sensitivity analysis (SA) of inputs/parameters, identifiability analysis (IA) of parameters, and uncertainty analysis (UA) to estimate confidence intervals on parameters and in model predictions. A local method was used for SA, IA was based in the delta mean square and collinearity index calculation, and Maximum Likelihood Estimation was used as the main UA technique. SA results provide evidence towards over-parameterization in the model, and the chamber inlet dry bulb air temperature was the variable (input) with the highest sensitivity. IA results indicated that at most 4 parameters are identifiable: two from spray chamber and one from each fluid bed dryer. Moreover, the confidence intervals obtained for identifiable parameters were reasonable, although two parameters were found significantly correlated. The obtained confidence intervals for model predictions reflect a low uncertainty for the outputs. The rigorously analyzed model is expected to contribute to model-based decision making for process operation and optimization.

Keywords: Sensitivity analysis, Identifiability analysis, Uncertainty analysis, Milk drying process.

1. Introduction

The most widely used technique for dehydration of dairy products is spray drying. It can preserve food properties as it doesn't involve severe heat treatments since drying occurs within a few seconds (Schuck et al., 2008). The standard process has three sequential stages: spray chamber, internal and external fluid beds as it is shown in Figure 1. There are two fundamental approaches to modeling drying processes: lumped and distributed formulations. The main difference is that the distributed models can include second order terms (diffusion) for air stream and also inside each particle being dried. The lumped models involve the concept of the reaction engineering approach (process kinetics) using a characteristic drying curve (Wang and Langrish, 2009). In this study a simple steady state lumped model for production scale of three stage dryer (not shown due to space restrictions) is built to help process understanding and guide optimization efforts. It is based on a simultaneous convective heat/mass transfer between the mean particle/air trajectories. Figure 1 shows this model and Table 1 exposes the involved variables and parameters. In this work the model is subjected to a comprehensive statistical analysis for quality assurance.The following methods are used: (i) sensitivity

analysis (SA) of inputs/parameters, (ii) identifiability analysis (IA) of parameters for parameter estimation (PE), and (iii) uncertainty analysis (UA) to estimate confidence interval on the identifiable parameter subset and also in model predictions.

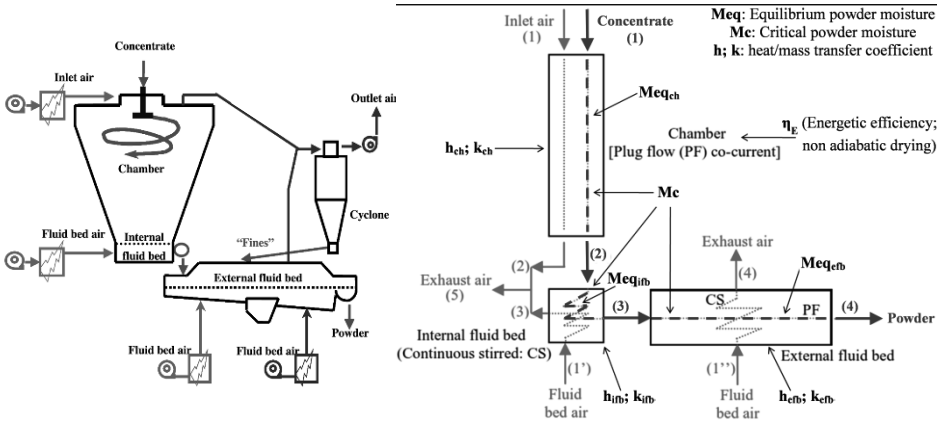

Figure 1. Left: physical system of three stage dryer scheme; right: process model.

Table 1. Description of model variables and parameters

Symbol	Name	Dimension
Inputs		
$W_{P,1}$	Concentrate mass flow rate	$kg_{total}.h^{-1}$
$M_{P,1}$	Concentrate moisture	$kg_{water}.kg_{total}^{-1}$
$T_{P,1}$	Concentrate temperature	K
$Q_{A,1}$	Chamber inlet air volumetric flow rate	$m^3.h^{-1}$
$H_{A,1}$	Chamber inlet air humidity	$kg_{water}.kg_{dry\ air}^{-1}$
$T_{A,1}$	Chamber inlet dry bulb air temperature	K
$Q_{A,1}'$; $Q_{A,1}''$	Internal/external fluid bed inlet air volumetric flow rate	$m^3.h^{-1}$
$H_{A,1}'$; $H_{A,1}''$	Internal/external fluid bed inlet air humidity	$kg_{water}.kg_{dry\ air}^{-1}$
$T_{A,1}'$; $T_{A,1}''$	Internal/external fluid bed inlet dry bulb air temperature	K
Outputs		
$M_{P,2}$; $M_{P,3}$ and $M_{P,4}$	Powder moisture	$kg_{water}.kg_{total}^{-1}$
$T_{P,2}$; $T_{P,3}$ and $T_{P,4}$	Powder temperature	K
$H_{A,2}$; $H_{A,3}$; $H_{A,4}$ and $H_{A,5}$	Exhaust air humidity	$kg_{water}.kg_{dry\ air}^{-1}$
$T_{A,2}$; $T_{A,3}$; $T_{A,4}$ and $T_{A,5}$	Exhaust dry bulb air temperature	K
Parameters		
M_C	Critical dry basis powder moisture	$kg_{water}.kg_{dry\ solids}^{-1}$
Meq_{ch}; Meq_{ifb}; Meq_{efb}	Equilibrium dry basis powder moisture for the chamber, internal fluid bed and external fluid bed	$kg_{water}.kg_{dry\ solids}^{-1}$
h_{ch}; h_{ifb}; h_{efb}	Heat transfer coefficient for the chamber, internal fluid bed and external fluid bed	$kcal.h^{-1}.K^{-1}.m_{axial}^{-1}$
k_{ch}; k_{ifb}; k_{efb}	Mass transfer coefficient for the chamber, internal fluid bed and external fluid bed	$kg_{water}.h^{-1}.(kg_{water}.kg_{dry\ air}^{-1})^{-1}.m_{axial}^{-1}$
η_E	Energetic efficiency for chamber [$0 < \eta_E < 1$]	Dimensionless

2. Materials and methods

2.1. Data

Figure 2 shows the outputs used in this work which are derived from a full scale process (feed concentration: 48% total solids; throughput: 6 ton/h final powder; actual plant) (**Mp**: product moisture; **HA**: air humidity; **Tp/TA**: product/air temperature). The data also agree with profiles showed by Kieviet (1997) and Birchal and Passos (2005).

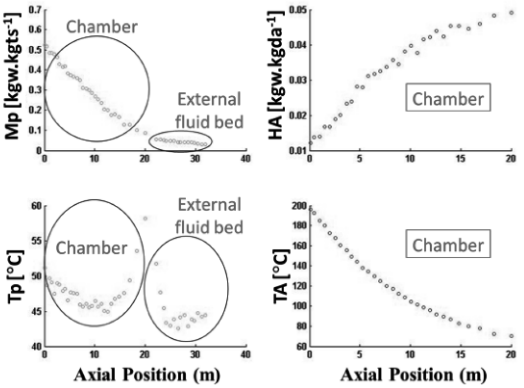

Figure 2. Process data; "axial position": reference independent variable representing the virtual straight way for mean trajectories; kgw = kg_{water}, kgts = $kg_{total\ solids}$, kgda = $kg_{dry\ air}$.

2.2. Sensitivity, identifiability and uncertainty analysis

A differential local SA was implemented. Each input or parameter is perturbed in turn (around a nominal point), and the effect on the outputs is measured by Eq. (1).

$$s_{ij} = \left(\frac{\partial y_i}{\partial \theta_j} \right) \cdot \frac{\theta_j^{\,0}}{y_i^{\,0}} \tag{1}$$

Where **s** is the dimensionless sensitivity; **y** and $\mathbf{y^0}$, the output and its reference value; $\boldsymbol{\theta}$ and $\boldsymbol{\theta^0}$, the input (or parameter) and its nominal value; **i**, an output index; and **j,** an input (or parameter) index.

IA implementation was based in the delta mean square and collinearity index calculation (Sin et al., 2010). It is based in the local SA of the outputs to the parameters, sensitivities that are then used to rank the parameter significance through a measure called $\boldsymbol{\delta^{msqr}}$. Then, parameter subsets are analyzed and the linear correlation between parameters is evaluated through a new measure called collinearity index ($\boldsymbol{\gamma}$). As higher the $\boldsymbol{\gamma}$ value, means more correlation between the parameters. The analysis is used to find the largest size identifiable subset assuming a threshold $\boldsymbol{\gamma}$ value for the identifiability. Table 2 summarizes the steps involved in this IA.

Table 2. Sequential steps for identifiability analysis

Steps	Formulation	
Absolute sensitivity(*)	$S_a = \{s_{a,ij}\}$	$s_{a,ij} = \partial y_i / \partial \theta_j .$
Dimensionless sensitivity	$S_{nd} = \{s_{nd,ij}\}$	$s_{nd,ij} = s_{ij}$ [see Eq. (1)]
Normalized sensitivity	$S_{norm} = \{s_{norm,ij}\}$	$s_{norm,ij} = s_{nd,ij} / \left\| s_{nd,ij} \right\|$
Parameter significance	$\partial_j^{\,msqr} = \sqrt{\frac{1}{N} \cdot \sum_{i=1}^{N} (s_{nd,ij})^2}$	
Collinearity index(*)	$\gamma_K = \frac{1}{\sqrt{\min(\lambda_K)}}$	$\lambda_K = eigen\,(S_{norm,K}{}^T S_{norm,K})$

(*) - **i**, **j** and **K**, refers to an index for outputs, parameters, and parameter subsets respectively.

In order to rank subsets with the same $\boldsymbol{\gamma}$ value, it is used a new measure called subset sensitivity index (**SSI**) which is defined by Eq.(2).

$$SSI = mean(\partial_0^{\,msqr}, \partial_1^{\,msqr}, ...\partial_j^{\,msqr}) \qquad \text{j} = \text{each parameter of the subset} \tag{2}$$

Maximum Likelihood Estimation (MLE) was used as the main UA technique for the estimation of an identifiable parameter subset and output predictions. In this work PE was solved through a least squares method which represents a special case of MLE (Seber and Wild, 1989). Confidence interval of parameters ($\boldsymbol{\theta_{1-\alpha}}$) are estimated in accordance to Eq. (3) and (4).

$$COV(\theta) = \frac{J(\theta)}{N-p}.\left[\left(\frac{\partial y}{\partial \theta}\right)^T Q_m^{-1}\left(\frac{\partial y}{\partial \theta}\right)\right] \quad \text{Covariance matrix of parameter estimators} \tag{3}$$

Where $\mathbf{J(\theta)}$ is the sum of squared errors from least squares method; $\mathbf{(\delta y/\delta \theta)}$, a sensitivity matrix; $\mathbf{Q_m}$, the covariance matrix of errors; and **N** and **p**, the total number of measurements and parameters. All functions are evaluated at the estimated values of the parameter set.

$$\theta_{1-\alpha} = \hat{\theta} \pm \sqrt{diag[COV(\hat{\theta})]}.t\left(N-p, \frac{\alpha}{2}\right) \tag{4}$$

Where $\mathbf{t(N\text{-}p,\alpha/2)}$ is the upper $\boldsymbol{\alpha/2}$ quantile of t-distribution with **N-p** degrees of freedom. The correlation matrix between two estimators [$\mathbf{COR(\theta_l,\theta_u)}$] is given by Eq. (5) and the confidence interval of predictions ($\mathbf{y_{1-\alpha}}$) is estimated using Eq. (6) and (7).

$$COR(\theta_l, \theta_u) = \frac{COV(\theta_l, \theta_u)}{\sqrt{\sigma_{\theta_l}^2 . \sigma_{\theta_u}^2}} \tag{5}$$

$$COV(y) = \left(\frac{\partial y}{\partial \theta}\right) COV(\hat{\theta}) \left(\frac{\partial y}{\partial \theta}\right)^T \quad \text{Covariance matrix of predictions} \tag{6}$$

$$y_{1-\alpha} = y(\hat{\theta}) \pm \sqrt{diag[COV(y)]}.t\left(N-p, \frac{\alpha}{2}\right) \tag{7}$$

Modelling and algorithms for SA, IA and UA were implemented in Matlab 7 (R2010a).

3. Results and discussion

3.1. Sensitivity and identifiability analysis

SA results are shown in Figure 3 where y-axis indicates the local dimensionless sensitivity of an input/parameter to a measured output and x-axis is the location of the measured data points. The results provide evidence about model over-parameterization, which are revealed by the low sensitivity values and close similarity of some sensitivity profiles indicating correlation between the parameters. These could represent difficulties in order to obtain unique estimates for parameters (Sin et al., 2010). Hence, identifiability analysis becomes necessary to identify a parameter subset for PE. The chamber inlet dry bulb air temperature ($\mathbf{T_{A1}}$) was found the variable with major sensitivity as it is showed in Figure 3.

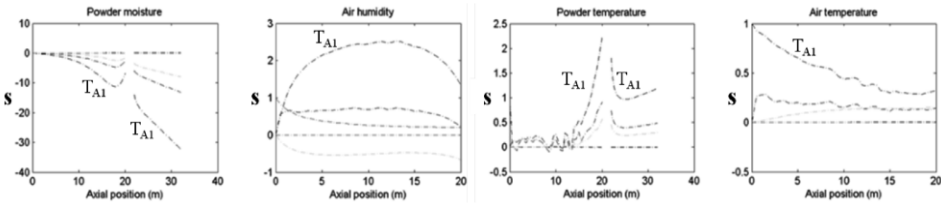

Figure 3. Example of SA results; comparison between sensitivity respect to $\mathbf{T_{A1}}$ and other variables.

With respect to IA results, Figure 4 and Table 3 show the most sensitive parameters ($\boldsymbol{\delta^{msqr}}$) and the ranking of largest size identifiable subsets. Identifiability threshold for collinearity index was assumed 5. The results indicated that identifiable subsets represent a 4.4 % of total subsets and at most 4 parameters are identifiable. These are

two parameters from spray chamber and one parameter from each of fluid bed models. This reflects the major significance of the spray drying process in the model overall. Another observation is that mass and heat transfer coefficients from the same unit are not identifiable simultaneously.

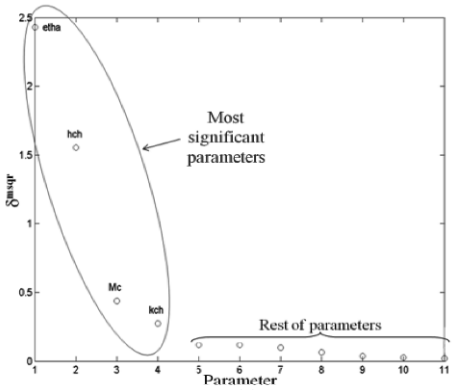

Figure 4. Most sensitive parameters.

Table 3. Ranking of largest size identifiable subsets

Largest size identifiable parameter subsets				Collinearity index	SSI
Meq_{ch}	Meq_{ifb}	h_{ch}	k_{efb}	4.387	0.463
Meq_{ch}	h_{ch}	k_{ifb}	k_{efb}	4.387	0.458
Meq_{ch}	Meq_{ifb}	h_{ch}	h_{efb}	4.602	0.443
Meq_{ch}	Meq_{ifb}	Meq_{efb}	h_{ch}	4.475	0.438
Meq_{ch}	h_{ch}	h_{efb}	k_{ifb}	4.602	0.438
Meq_{ch}	Meq_{efb}	h_{ch}	k_{ifb}	4.475	0.433
Meq_{ch}	Meq_{ifb}	k_{ch}	k_{efb}	4.215	0.143
Meq_{ch}	k_{ch}	k_{ifb}	k_{efb}	4.215	0.138
Meq_{ch}	Meq_{ifb}	h_{efb}	k_{ch}	4.417	0.123
Meq_{ch}	Meq_{ifb}	Meq_{efb}	k_{ch}	4.298	0.119
Meq_{ch}	h_{efb}	k_{ch}	k_{ifb}	4.417	0.118
Meq_{ch}	Meq_{efb}	k_{ch}	k_{ifb}	4.298	0.113
Meq_{ch}	h_{ifb}	h_{efb}	k_{ch}	4.989	0.100

This is reasonable because both phenomena are linked by system fluid-dynamics.

3.2. Uncertainty analysis

The identifiable subset for PE was chosen from a maximum **SSI** point of view, since the minimum collinearity index value of most subsets were close to each other. The selected subset is **{Meq_{ch}, Meq_{ifb}, h_{ch}, k_{efb}}**. The optimization problem was solved using the "lsqnonlin" function with the "trust-region reflective" algorithm. Table 4 summarizes main PE results. Despite confidence intervals for parameters present a reasonable extension, some correlation between h_{ch} and Meq_{ifb} is observed (correlation coefficient: 0.85). Parameters Meq_{ch} and Meq_{ifb} seem to also have a pseudo correlation (coefficient: -0.55). Figures 5 and 6 show the model fit to the data and the posterior simulations. Good fit and low model predictions uncertainties were obtained.

Table 4. PE results ([Meq_{ch}, Meq_{ifb}]: $kg_{water}.kg_{dry\ solids}^{-1}$; [$h_{ch}$]: $kcal.h^{-1}.K^{-1}.m_{axial}^{-1}$; [$k_{efb}$]: $kg_{water}.h^{-1}.(kg_{water}.kg_{dry\ air}^{-1})^{-1}.m_{axial}^{-1}$)

	Meq_{ch}	Meq_{ifb}	h_{ch}	k_{efb}
Mean	0.081	0.031	2126	1889
Conf. interval (95%)	[0.074 - 0.087]	[0.026 - 0.036]	[2103 - 2149]	[1740 - 2038]
		Correlation matrix		
Meq_{ch}	1	-0.55	-0.41	0.17
Meq_{ifb}	-0.55	1	0.85	0.37
h_{ch}	-0.41	0.85	1	0.15
k_{efb}	0.17	0.37	0.15	1

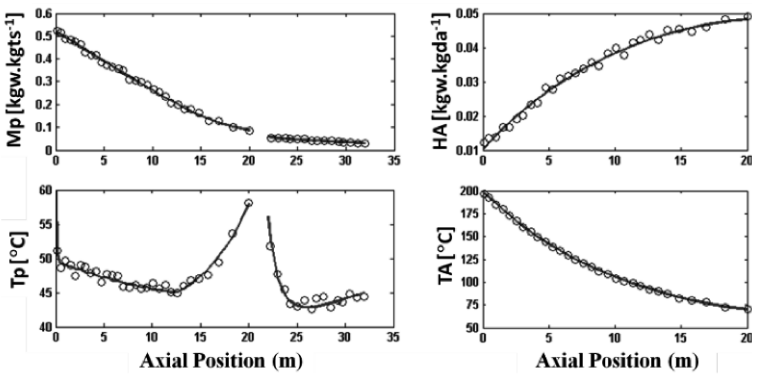

Figure 5. MLE fitting (data: dotted; model: line).

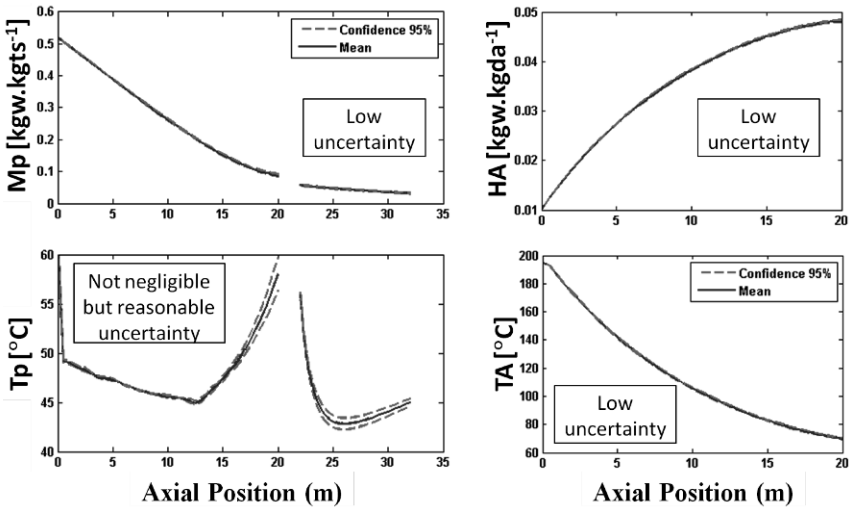

Figure 6. Error propagation in output predictions.

4. Concluding Remarks

A simple steady state model for milk spray and fluid bed drying was developed and implemented in Matlab. The results indicate the presence of some degree of over-parameterization and thus suggesting a potential for model reduction which is a future challenge. As chamber inlet dry bulb air temperature was the variable with major local sensitivity, this point to energy optimization potential since air heating represents the main energy consumption in the system. IA implementation indicated that maximum 4 parameters are identifiable: two from spray and one from each fluid bed. Despite PE was carried out for the best identifiable subset, it was found some degree of correlation between two of the parameters. To reduce this correlation, it is suggested to improve the quality/quantity of available experimental data by means of design of experiments. As posterior simulations present low uncertainty (95% confidence), the developed model is expected to be a robust tool for a model-based decision-making at industrial scale.

Abstract

As in other segments of the food industry, the ice-cream industry has its own features that influence the production management of its processes. Amongst these we identify: changeover tasks, products shelf-life, raw-materials (RM) perishability and, multiple deliveries during the planning horizon. These aspects have been often left out when studying the production planning and scheduling within the batch food industries. Thus, the aim of this work is to define an optimal planning and scheduling model based on the Resource Task Network, where the profit maximization is performed taking into account the cost trade-off between the approach based on the perishable RM inventory for the planning horizon versus the just-in-time RM delivery policy. The study is motivated by a Portuguese artisanal ice-cream industry.

Keywords: Production Scheduling, Batch process, RTN, Perishability, Raw-material Inventory Management.

1. Introduction

The food industry has been growing throughout the years. This growth has been driven by the increase of new market competitors, as well as by an increase on the consumers' demand and requirements. These factors combined have changed the trends in the industry and, production optimization is nowadays a need. In this context the production scheduling became an important activity for companies, allowing them to determine when, where and how a set of products should be produced considering the operational aspects. Thus, the scheduling activity has an important role for performance improvement while adjusting the resources consumption/production to demand needs through an accurate allocation. In the ice-cream industry, mainly artisanal ice-creams production, the major challenge is related to the raw-materials (RM) quality aspects as the final products' qualities/freshness is deeply dependent on these characteristics. In this context it is extremely important to address this aspect on the production at the scheduling level.

Nowadays, a wide range of methodologies and techniques to deal with the production planning and scheduling is available in the literature. However, the artisanal ice-cream industry is a food industry niche and the literature regarding this subject is very scarce.

Nevertheless, some research has been made considering the perishable inventory management, such as the work developed by Goyal (1994) and Soman et al.

(2004) based on the application of the Economic Lot Size Problem (ESLP). However, the ESLP has in its base assumptions that are unrealistic for the ice-cream industry. Beyond that, another research stream has been explored considering products shelf-life aspects. Kallrath (2005) presented a MILP formulation for design and planning problems considering products shelf-life limitation at the planning level. Accordingly in these cases limitations on the final products' shelf-life require records control to trace time stamps of products. Entrup et al. (2005) have developed a MILP formulation considering shelf-life restrictions for the final products applied to the yoghurt industry. This aspect was accounted in the objective function, which aims to maximize the margin contribution. Considering the segment of seafood products, Cai et al. (2008) proposed a formulation that takes into account the RM perishability, considering three type of decisions: i) the type of products to be produced, ii) the processing time of resources to be allocated to each type of product, and finally, iii) the sequence of products production . The authors stated that this model can be applied to any system that has limitations in terms of RM and uncertainty in the delivery dates. Amorim et al. (2011) have also presented a MILP formulation exploring two cases; i) a make-to-order and; ii) a hybrid make-to-order /make-to-stock strategy.

Notwithstanding, the research on production planning and scheduling in the ice-cream industry with perishable goods is still at its beginning. Exploring this gap, the present work develops a mathematical formulation for the artisanal ice-cream batch multipurpose and multi-product process. The aim of the model is to explore the characteristics of the artisanal ice-cream industry, accounting for RM perishability, changeover tasks and multiple deliveries simultaneously with the planning and process scheduling.

2. Description of Ice-cream Production Process

The ice-cream industry has different types of ice-creams production, which are often classified into four different categories according to their main ingredient, as it is shown in Figure 1. The ice-cream is classified based on: vanilla, cream, yoghurt and fruits/sorbets. However, when considering the production process of these products they are mainly divided in two categories: sorbets and other types of ice-creams production. Both categories differ in its production process until frozen task is reached.

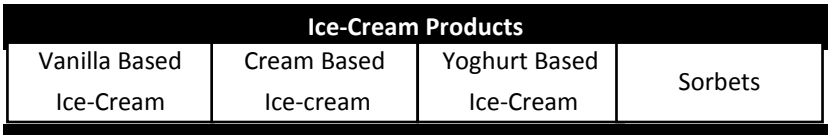

Figure 1 – Classification of the types of ice-creams.

For confidentiality reasons a generic ice-cream production process is characterized in Figure 2, followed by its description.

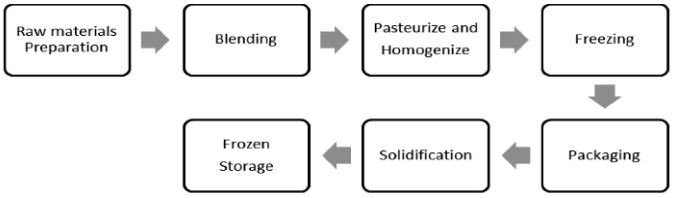

Figure 2 - Generic diagram of the ice-cream production process.

Raw-Materials Preparation: Each product requires a different RM according to its flavor. All RM must have good quality to avoid quality problems in the final products. According to each RM, its chemical characteristics and properties, different types of storage are used: dry, frozen and ambient temperature.

Blending: The blending phase comprises the mix of products according to each recipe of ice-cream. In this phase the ingredients are mixed for the production of a uniform liquid product.

Pasteurization/Homogenization: During pasteurization all the pathogens agents are removed. This task must be performed in a pre-defined temperature and duration. It is also during this phase that the product is homogenized, and particles are diminished in order to create uniform product with the desired consistency.

Freezing: In this phase the product that is in a liquid state is transformed into a mousse.

Packaging: The ice-cream is packaged in tubes to guarantee the safety, integrity and quality of the final product.

Solidification: The tubes go to an area with lower temperature than freezing to perform the solidification task. This task is performed in appropriate solidification equipment.

Frozen Storage: After performed all the phases mentioned before, the ice-creams are stored in a very low temperature environment to maximize the products quality.

3. Problem Statement

This work addresses the scheduling problem in an artisanal ice-cream production line of a multiproduct dairy batch plant. The optimal scheduling of production can be obtained by solving the following problem:

Given:

- Process description, through a Resource Tasks Network representation;
- The maximum amount of each type of resource available (equipment and manpower);
- Resource characteristics and capacities;
- Time horizon of planning;
- Task and resources operating data;
- Raw-material and products shelf-life;
- Spoilage, purchase and storage costs;
- Changeover costs;
- Quantities contracted of raw-material supplies;
- Selling price of ice-creams and sorbets;
- Demand deliveries along the planning horizon.

Determine:

- The amount of each resource used;
- The optimal scheduling satisfying not only the multi-deliveries along the horizon, but also, the demand at the end of the horizon;
- Raw-materials planning for the time horizon.

Based on the problem described, a formulation was developed using the RTN representation proposed by Pantelides (1994) considering a discrete time representation. This formulation was applied under two cases. The first case considers the existence of the current contracts with the RM suppliers, taking advantage of economies of scale, but requiring RM inventory control. Only the RM with shelf-life within the production time horizon are used in the production process. Otherwise, the RM are discarded at the end of the planning horizon and opportunity costs are considered. The second case explores a new policy, where a just-in-time approach is used. The inventory levels diminish but RM acquisition costs increases. A changeover task is required whenever the production between two different products changes.
The two cases were solved with an optimality margin of 0%. A computer with Intel 2.16 GHz processor and RAM memory of 4 GB and GAMS 24.2.2 software package with CPLEX solver were used.

4. Example

The scheduling of an artisanal ice-cream industry is explored considering the profit maximization. The production schedule of six products: 500 l of A- Strawberry, 250 l of B- Mango, 250 l of C- Limon, 200 l of D – Hazelnut, 600 l of E –Chocolate and 300 l of F – Vanilla is to be performed considering an aggregate set of specific RM to produce each flavor. For instance, Amp, Bmp, Cmp, Dmp, Emp and Fmp define the set of RM used to produce A, B, C, D, and F, respectively. For confidentiality reasons, it is not possible to explicitly state each recipe. Along the process, intermediated storage for working-in-process products is considered and a make-to-order strategy is followed. For simplicity, the processing time horizon is two working days with an 8h shift/day. This example is explored for two different cases: a) define the scheduling and perishable RM inventory, taking advantage of economy of scale in its purchase price and b) define the scheduling based on a just-in-time strategy associated to the RM supplies. A cost-benefit analysis of those cases is performed. The present suppliers contracts verify a delivery of 2600 l of RM, at a pre-defined price every second day, the JIT strategy follows the market price, which reflects an average increase of 50% monetary units over the pre-define price for each RM. The two cases differ in purchase costs. The other costs are only considered in case a), such as: storage and opportunity costs that are penalized, in case the RM is spoiled. Two time-windows are considered where the final products can be delivered.

The results obtained are shown in Figures 3 to 5. The RM consumption profile is shown in Figure 3. Case a) is based on the present contracts with the RM suppliers, the RM availability to fulfil the total demand is shown furthermore, the RM spoilage is penalized and discarded in the final of the planning horizon. Analyzing case b) using JIT strategy, the RM purchase is exactly the required to satisfy the order demand, avoid RM spoilage.

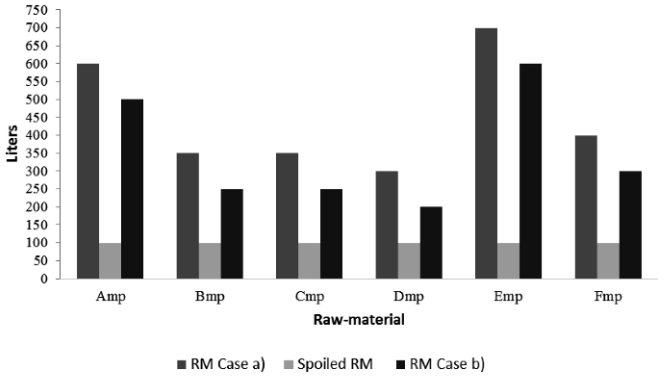

Figure 3 – Raw materials consumption/spoiled.

The production scheduling shown in Figure 4, illustrates only four working hours day –in the morning period. The production is aggregated not only by product, taking into account the change-over tasks, but also its set of equipment, where some are shared. The production starts with product A, followed by E, C, E, A, C, F, A and D till t=4, where 200 l of products A and E are delivered. During the time horizon two time-windows for each product are defined, allowing as many deliveries as necessary to fulfil the demand.

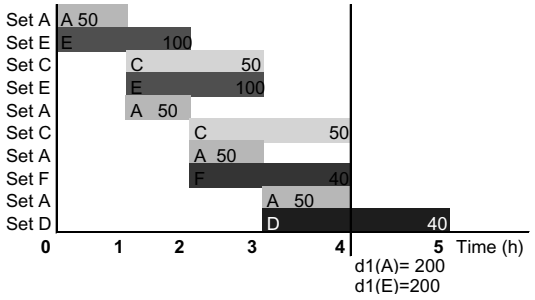

Figure 4 – Schedule Results.

In Figure 5 is shown the final product deliveries profile. Product E has five deliveries, in a total of 600 l and products C and D only one, with 250 l and 200 l, respectively. Product A has four deliveries, two of 200 l (shown in Figure 4) and two of 50 l later on, fulfilling the total demand.

The JIT strategy followed in case b) presented an increase of 25 % of profit over case a). This result is derived mainly from the reduction of RM storage and spoilage costs, despite the increase of RM purchase price of this strategy. Additionally, JIT strategy has a major importance qualitative aspect, which is the RM quality/ freshness that is reflected into the final product quality. As disadvantages is the dependence on the RM deliveries and the suppliers' difficulties to implement it.

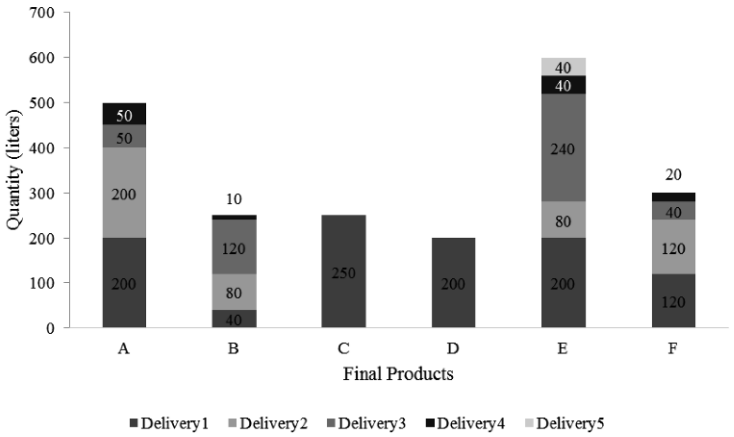

Figure 5 – Final products deliveries profiles.

5. Conclusions

In the present work, the production scheduling problem of a real ice-cream facility and RM inventory management are discussed. A process characterization of the artisanal ice-cream industry is presented. A MILP formulation is developed considering its own industry characteristics and two strategies over the RM inventory management are analysed. Results seem to indicate that the supplier strategy JIT is better to be applied in this type of food industry. Not only it presents better economic results, but also allows better final products quality. The extension of the present work will explore the other main characteristics of this industry, such as changeovers.

Abstract

Developing advanced conversion ways for fossil fuels and renewable energy sources to electricity or other total or partial decarbonised energy vectors (e.g. hydrogen, heat, synthetic fuels) is of paramount importance in modern energy sector. In addition, the development of carbon capture, utilisation and storage (CCUS) technologies is equally important for transition to low carbon economy. This paper evaluates various integration aspects of energy vectors poly-generation (focussing on power, hydrogen and synthetic fuels) based on chemical looping systems using syngas produced from solid fuel gasification. As illustrative examples, iron-based and calcium-based chemical looping systems were assessed in conjunction with coal gasification plants.

The paper presents in details the evaluated plant configurations, focussing especially on operational and mass & energy integration issues. The plant designs were modelled and simulated using process flow modelling software, the results being used to assess the overall performance indicators. For energy integration analysis, pinch method was used to evaluate in details and to find the best energy integration options of available heat generated in the chemical looping unit into overall steam cycle of the power block. Other mass and energy integration aspects, e.g. air flow mass integration between the air separation unit and the gas turbine, plant flexibility in terms of changing generated energy vectors vs. time, were evaluated as well to assess their influence on overall plant energy efficiency. As the results show, the chemical looping-based conversion systems exhibit both higher energy efficiency and carbon capture rate than current state of the art gasification plants with gas-liquid absorption for carbon capture (benchmark case).

Keywords: Energy vectors poly-generation; Chemical looping; Energy integration; Carbon capture, utilisation and storage (CCUS).

1. Introduction

Chemical looping is an emerging carbon capture method suitable to be applied in advanced energy conversion processes because CO_2 is inherently separated and no significant energy duty is required (Fan, 2010). This technology is attractive for reducing energy and cost penalties associated with carbon capture. Most of the looping systems are applied to gaseous fuels (e.g. natural gas, syngas) due to the fact that no ash contamination of the oxygen carrier occurs. From various energy conversion technologies, gasification has one of the highest potential for CO_2 capture with low penalties in energy and cost due to high partial pressure of carbon species (mainly CO) in the syngas to be treated for carbon capture. In addition, when energy vector poly-generation is targeted, hydrogen production from gasification seems the obvious choice.

The chemical looping with hydrogen production is based on three interconnected fluidized bed reactors, fuel, steam and air reactors, with an oxygen carrier circulating between them (Adanez et al., 2012). For example, the reactions for iron lopping are:
- Fuel reactor:

$$2Fe_2O_3 + 3CO + 3H_2 \rightarrow 4Fe + 3H_2O + 3CO_2 \quad (1)$$

- Steam reactor:

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2 \quad (2)$$

- Air reactor:

$$4Fe_3O_4 + O_2 \rightarrow 6Fe_2O_3 \quad (3)$$

A special looping cycle is based on calcium sorbents to push the water gas reaction equilibrium towards hydrogen (Sorbent Enhanced Water Gas Shift - SEWGS). The formed $CaCO_3$ is then regenerated in a separate reactor and the CaO is recycled back:
- SEWGS reactor:

$$CaO + CO + H_2O \rightarrow H_2 + CaCO_3 \quad (4)$$

- Calcination reactor:

$$CaCO_3 \rightarrow CaO + CO_2 \quad (5)$$

As illustrative syngas-based looping systems for energy vectors poly-generation, plant designs with about 400 - 600 MW net power and a flexible hydrogen output (0 to 200 MW_{th} based on lower heating value) were assessed. The product flexibility (the capability to change the generated energy vectors according to timely demand from the grid) is an important aspect for integration in modern energy conversion systems. The carbon capture rate of evaluated energy conversion concepts is almost total (>95%).

2. Description of plant configurations and key model assumptions

Figures 1 and 2 present hydrogen and power co-generation concepts using syngas-based iron and calcium looping cycles. As illustrative gasifier, Shell reactor was used.

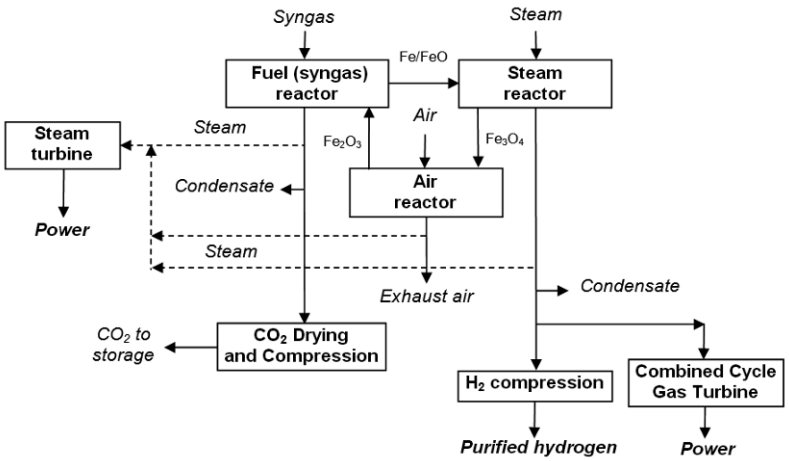

Figure 1. Hydrogen and power co-generation using syngas-based iron looping cycle (Case 1)

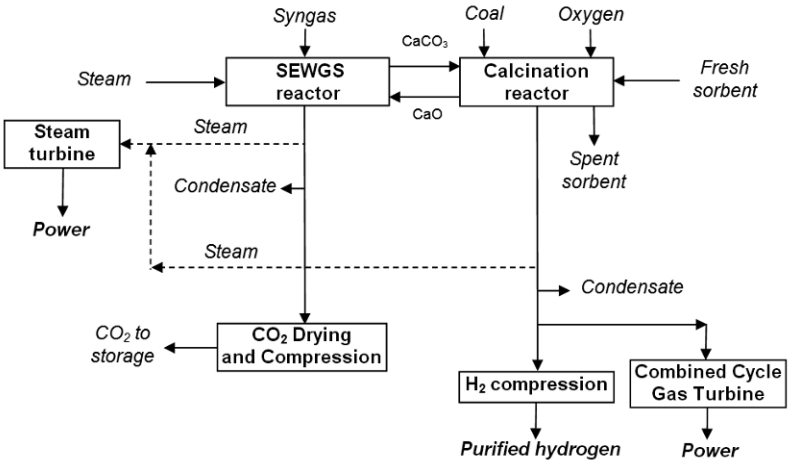

Figure 2. Hydrogen and power co-generation using syngas-based calcium looping cycle (Case 2)

All plant configurations consider a standard Shell-based coal gasification island with Selexol® process for syngas desulphurization (gas-liquid absorption). The main plant sub-systems of investigated plant concepts and theirs design assumptions used in the modelling are presented in Table 1 (Cormos et al., 2013; Tong et al., 2014).

Table 1. Main design assumptions

Unit	Parameters
Air separation unit (ASU)	O_2 purity: 95 % (vol.) Power consumption: 225 kWh/ton O_2
Gasifier (Shell)	Pressure: 40 bar; Temperature: >1400°C Pressure drop: 1.5 bar; Gas quench configuration
Acid gas removal (AGR)	Solvent: Selexol® for H_2S capture
Iron looping cycle (Case 1)	Oxygen carrier: ilmenite ($FeTiO_3$) Fuel reactor parameters: 30 bar / 700 - 750 °C Steam reactor parameters: 28 bar / 700 - 800 °C Air reactor parameters: 26 bar / 850 - 1,000 °C Gibbs free energy minimization model Pressure drop fuel and steam reactors: 1 bar / reactor
Calcium looping cycle (Case 2)	Sorbent: calcium-based ($CaO/CaCO_3$) SEWGS reactor parameters: 30 bar / 650 – 700 °C Calcination reactor parameters: 28 bar / 900 – 950 °C Gibbs free energy minimization model Pressure drop fuel and steam reactors: 1 bar / reactor
CO_2 compression and drying	Delivery pressure: 120 bar Solvent for CO_2 drying: TEG (Tri-ethylene-glycol) Captured CO_2 specification (vol. %): >95 % CO_2; <2,000 ppm CO; <500 ppm H_2O; <100 ppm H_2S
H_2 compression	Delivery pressure: 60 bar Compressor efficiency: 85 %
Gas turbine	Gas turbine type: M701G2 (MHI) Net power output: 334 MW; Net efficiency: 39.5 %
Heat recovery steam generation (HRSG) and steam cycle	Pressure levels: 120 bar / 34 bar / 3 bar & MP reheat Steam turbine isoentropic efficiency: 85 % Steam wetness ex. steam turbine: max. 10 %
Heat exchangers	$\Delta T_{min.}$ = 10 °C; Pressure drop: 3 - 5 % of inlet pressure

3. Results and discussions

Both chemical looping pre-combustion capture coal gasification-based concepts were modelled and simulated using ChemCAD and Thermoflex software. By simulation all required data to evaluate the key performances of investigated concepts are generated. The designs were optimized by performing heat and power integration analysis (using pinch technique) for maximization of power generation (Cormos, 2010). Steam flows generated in the gasification island, syngas conditioning line and chemical looping units were integrated in the steam (Rankine) cycle of the combined cycle. As minimum approach temperature between hot and cold streams, 10 ^{o}C was considered.

Figures 3 presents the hot and cold composite curves (HCC and CCC) for gasification island and iron looping cycle (Case 1). Similarly for the same case, Figure 4 presents the hot and cold composite curves for hydrogen-fuelled combined cycle gas turbine.

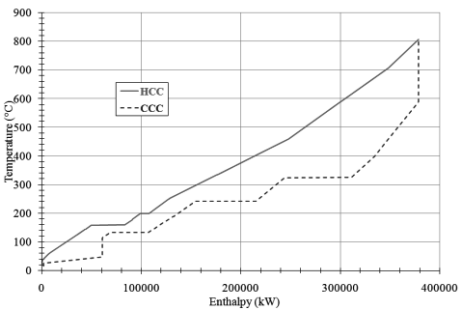

Figure 3. Composite curves for gasification island and iron looping cycle

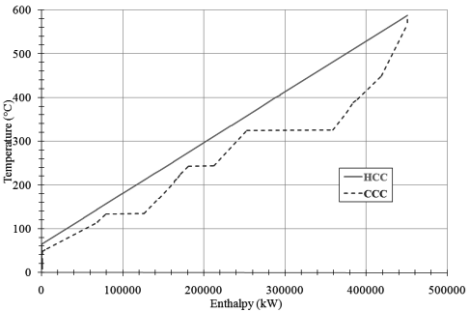

Figure 4. Composite curves for hydrogen-fuelled combined cycle gas turbine

For Case 2, Figure 5 presents the hot and cold composite curves for SEWGS calcium looping cycle. The composite curves for the hydrogen-fuelled combined cycle gas turbine are similar with the one presented in Figure 4 for Case 1.

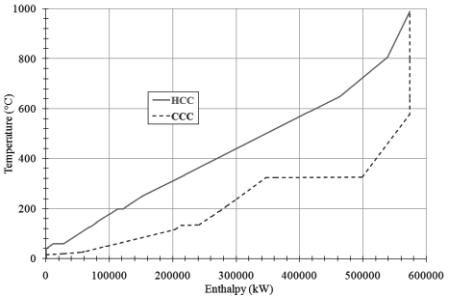

Figure 5. Composite curves for gasification island and calcium looping cycle (SEWGS)

As can be noticed from Figures 3 and 5, the calcium looping case (Case 2) has a higher heat recovery potential than Case 1 (574 MW_{th} vs. 378 MW_{th}) due to the additional coal stream and higher operation temperature (about 1,000 ^{o}C) in the calcination reactor. The good energy integration of plant sub-systems leads to optimum plant energy efficiency.

The first operation scenario was based on power generation only. As can be expected this scenario is susceptible of the greatest importance due to the significance of electricity in overall energy sector. Table 2 presents the main performance indicators for both iron and calcium looping options. As benchmark case (noted as Case 3), an IGCC design based on Shell gasifier fitted with a pre-combustion capture unit using gas-liquid absorption (Selexol®) was considered (Cormos, 2010; Ozcan and Dincer, 2014).

Table 2. Main performance indicators (power generation only)

Main Plant Data	Units	Case 1	Case 2	Case 3
Coal flowrate	t/h	167.21	226.71	165.70
Coal lower heating value (LHV)	MJ/kg		25.353	
Coal thermal energy (A)	MW_{th}	1,177.57	1,596.64	1,166.98
Gas turbine output	MW_e	334.00	334.00	334.00
Steam turbine output	MW_e	205.43	410.49	210.84
Air expander power output	MW_e	3.54	1.40	0.78
Gross electric power output (B)	MW_e	542.97	745.89	545.62
Air separation unit consumption	MW_e	45.13	70.74	44.73
Fuel processing consumption	MW_e	15.52	9.68	9.12
Carbon capture + CO_2 drying & compression	MW_e	15.63	52.35	39.81
Power island consumption	MW_e	21.80	21.97	18.78
Total ancillary power consumption (C)	MW_e	98.08	154.74	112.44
Net power output (D = B - C)	MW_e	444.89	591.15	433.18
Gross electrical efficiency (B/A * 100)	%	46.61	46.71	46.75
Net electrical efficiency (D/A * 100)	%	37.78	37.02	37.11
Carbon capture rate	%	99.71	95.94	90.79
CO_2 specific emissions	kg/MWh	3.88	32.89	86.92

The net power efficiency has the highest value for Case 1 (iron looping); the calcium looping (Case 2) has a lower net efficiency with about 0.8 percentage points. Case 1 has a bit higher net power efficiency than the benchmark case (~0.7 net percentage points) since Case 2 is about the same as the benchmark case. One important aspect to be mentioned is the higher decarbonisation rate of both looping cases (almost total for Case 1). This aspect underlines the good potential of chemical looping options to deliver higher energy efficiency simultaneously with an almost total carbon capture rate.

Any modern power plant has to have the capability to timely adjust the generating load according to the grid demand. The chemical looping cases have the capability of reducing power output by producing high purity hydrogen (mass integration). Figure 6 presents the variation of plant efficiencies vs. hydrogen output for Case 1 (iron looping). As can be noticed the overall plant efficiency is increasing with hydrogen output.

Other potential mass integration option to further increase the energy efficiency by poly-generation would be for instance power and substitute natural gas co-generation (Ozcan and Dincer, 2014). For this option part of the syngas / captured CO_2 is reacted with hydrogen to produce methane. As an illustrative example for Case 1 (iron looping), the energy efficiency is about 70 % and the carbon capture rate is about 60 - 65 %.

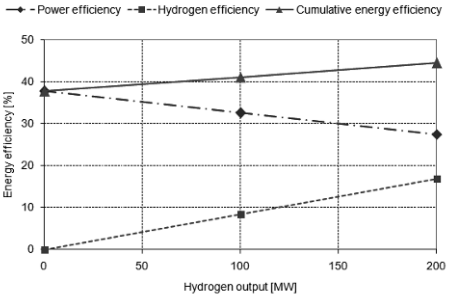

Figure 6. Variation of plant energy efficiency vs. hydrogen output (Case 1)

To increase further the efficiency, an option would be to integrate the air separation unit with the gas turbine compressor (Cormos, 2010). An air bleed from the GT compressor can supply the air required by the ASU. The degree of air mass integration is defined as the percentage of the total ASU air required coming from the GT compressor. Figure 7 presents the variation of plant energy efficiency vs. air integration degree for Case 1.

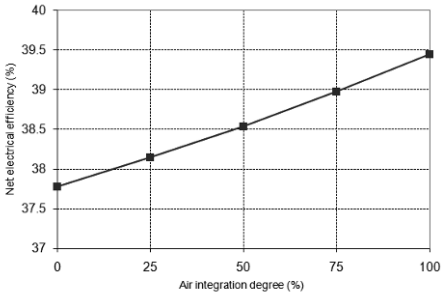

Figure 7. Variation of plant energy efficiency vs. ASU-GT air integration degree (Case 1)

As can be noticed from Figure 7, the ASU-GT air flow (mass) integration lead to an energy efficiency increase and net power output up to 1.7 percentage points and about 20 MW net power for a total air integration compared to non-integration case. Also, the tight energy integration leads to reduction of plant cooling duty (water consumption).

4. Conclusions

The paper evaluates two syngas-based chemical looping configurations for hydrogen and power co-generation. The designs were evaluated in various conditions to assess the energy integration aspects. Both looping cases show superior carbon capture rate compared to the benchmark case. In addition, the iron looping case exhibits superior energy efficiency and the calcium looping case has comparable efficiency.

Abstract

Trigeneration systems produce heat, power and cooling simultaneously from a single fuel source. With such efficient use of fuel, installing trigeneration systems on-site would be beneficial as it reduces the requirement of external power and fuel, reduces emissions, and improves local power reliability. On the other hand, trigeneration systems need to have a reliable network of component process units, since the high level of integration increases the likelihood of cascading failures. Each unit may not always be available to function because it may require preventive or corrective maintenance during the course of operations. Traditionally, this issue is handled by installing additional process units based on heuristics. This approach, however, may not be able to address complex decisions on whether to purchase a single additional unit with larger capacity or multiple smaller capacity units. Additionally, the decision becomes increasingly complex when seasonal variations in operations are considered. If not addressed appropriately, such decisions may result in excessive capital and/or maintenance costs. To address these issues, this work presents a systematic procedure for the grassroots design of a trigeneration system considering equipment redundancy for variations in raw material and energy demand. To illustrate the proposed approach, a simple case study on designing a grassroots steam turbine configuration for a biomass-based trigeneration system (BTS) is presented.

Keywords: Trigeneration; Reliability; Redundancy Allocation.

1. Introduction

Trigeneration systems are energy (or utility) systems which produce heat, power and cooling simultaneously from a single fuel source. In this respect, installing a trigeneration system on site would be able to reduce the importation of power and fuel (from large distances), reduce environmental impact, and improve local power reliability (Stoijkov et al., 2011). However, such benefits may not be realized if a trigeneration system is not sufficiently equipped to cope with an event of failure (e.g., preventive maintenance, equipment breakdown). Since typical energy systems contain a network of interconnected equipment, an event of failure would disrupt the overall system performance. As such, it is arguable whether an energy system design is suitable for keeping a desired level of reliability in meeting energy demands. In this respect, reliability is defined as the probability that a system will perform a required function at a given point in time, when operated under specific conditions (Ebeling, 1997). It is a quantitative measure (e.g., percentage) of non-failure operation over a given

(operational) time period. Since no equipment in an energy system is fully (100%) reliable, it is necessary to account for the possible failures during its design. A common way of addressing such issue is by implementing redundancy allocation (Kuo and Zhu, 2012). Redundancy allocation is a strategy of employing additional number of equipment connected in parallel to perform the same function, with the intention of achieving higher system reliability. Traditionally, redundancy cases were considered by means of heuristics. The $n + 2$ rule is an exemplary heuristic applied where two extra units are added to an initial design, n (where redundancy was not considered). Besides implementing additional units, safety factors have been used to oversize equipment.

Besides heuristics, optimization studies have been employed to address redundancy allocation in energy systems. For instance, Olsommer et al. (1999a; b) proposed a methodology to optimize the design and operation of a co-generation system subject to different operating scenarios. The methodology also performs a reliability analysis via an automated program and determines all the possible failure modes upon defining the optimal system. Frangopoulos and Dimopoulos (2004) then extended the previous work, by using the same steps but all within one optimization procedure. In their contribution, a search subroutine using genetic algorithm first proposes a design for which reliability analysis is carried out, generating all possible failure scenarios and calculating penalties whenever the demands are not fully met. The corresponding investment and operating costs are then compared with the designs automatically generated from the search, until a near-optimal solution is found. Besides, Aguilar et al. (2008) presented a framework to address reliability issues in the design and operation of a utility system. In their work, a robust optimization framework was presented to handle both grassroots and retrofit problems. In addition, the framework determines the redundancy allocation for the system based on different time horizons and failure scenarios. Recently, Voll et al. (2012) presented a framework on automated superstructure generation and optimization of a trigeneration system based on different demands, available technologies, equipment redundancy and topological constraints.

Based on the aforementioned contributions, it can be seen that there are several opportunities to further explore and improve systematic approaches on redundancy allocation for an energy system. For instance, there is a need for less labor and computationally intensive approaches to address redundancy allocation issues in energy systems. Apart from that, a more comprehensive systematic approach is required to address complex decisions such as whether to install additional large capacity units or multiple smaller capacity units. This is because each option is unique in terms of equipment reliability. Besides, redundancy allocation decisions become increasingly complex when seasonal variations in raw material supply and energy demand are also be factored in. If such decisions are not addressed appropriately, an energy system may perform sub-optimally in certain operational periods and incur unnecessary or excessive capital and maintenance costs. To address such opportunities, this work introduces an alternative approach to tackle redundancy allocation of technological units during the grassroots design of a biomass-based tri-generation system (BTS). This alternative approach adapts the *k*-out-of-*m* system modeling, an approach previously used for reliability optimization of existing systems with pre-defined redundancy (Coit and Liu, 2000). In this work however, *k*-out-of-*m* system modeling is adapted to develop an optimization model to determine the required redundancy allocation for a particular technology in a BTS based on a minimum reliability level. The minimum reliability level is defined using chance-constraint programming. Chance-constraint programming

is an approach that considers the probabilistic level of constraint satisfaction (Charnes and Cooper, 1959). Following this, the developed model is solved via multi-period optimization. In multi-period optimization, the variations in raw material supply and energy demand are discretized into multiple intervals such that each individual interval represents a scenario with an approximated discrete distribution. As such, this approach provides a unique solution that is feasible for the given set of anticipated supply and demand scenarios. To illustrate the proposed approach, a simple grassroots design case study on steam turbines in a BTS is solved.

2. Problem Statement

As various established technologies are available in the market, the grassroots design of a reliable tri-generation system can be a complex problem. The grassroots design problem addressed in this work is stated as follows: Raw material *i* can be converted to product $p \in P$ through technology $j \in J$. The objective of this work is to develop a systematic approach for the grassroots design of a reliable BTS configuration with maximum economic performance while considering multiple supply and demand scenarios, $s \in S$. In each considered scenario, various design capacities $n \in N$ are available for selection within technologies *j*. Based on the aforementioned problem, a mathematical model is formulated for each scenario. The formulated model consists of material and energy balances, and economic correlations for all considered alternatives. Following this, each scenario is represented by a fraction of occurrence, α_s and the required redundancy allocation is determined via *k*-out-of-*m* system modeling and chance-constraint programming as shown in the next section.

3. Mathematical Formulation

The mathematical formulation for this work is shown in Eq.(1 – 6). As shown, F_{jp}^{I} is the flow rate of product *p* in technology *j* while $\mathrm{F}_{jn}^{\mathrm{Design}}$ is the fixed design capacity *n* available for purchase in technology *j*. Meanwhile, z_{jn} and m_{jn} are positive integers which represent the number of operating and installed units with design capacity *n* selected in technology *j* respectively. Besides, P_{jn} is the reliability of design capacity *n* performing its function in technology *j* while R_{jn} $(m_{jn} \geq z_{jn})$ represents the reliability of design capacity *n* in technology *j* whereby at least z_{jn} out of m_{jn} number of units are operational. *C* is the binomial coefficient. R_j is overall reliability of technology *j*. I_{jn} is a binary integer variable which denotes the presence of a selected technology *j* with design capacity *n* in the configuration for each scenario *s*. $\mathrm{R}_{jn}^{\mathrm{Min}}$ is the minimum reliability level of design capacity *n* in technology *j*. *EP,* AOT, C_p and CRF are the economic performance, annual operating time, product selling price and capital recovery factor respectively. Meanwhile, *CAP* and *MAC* are the total capital and maintenance costs respectively. *CAP* and *MAC* are both determined based on m_{jn} units to achieve the specified minimum reliability level.

$$\sum_{n=1}^{N}\left(z_{jn}\right)_s \mathrm{F}_{jn}^{\mathrm{Design}} \geq \left(\sum_{p=1}^{P} F_{jp}^{\mathrm{I}}\right)_s \qquad \forall j \forall s \qquad (1)$$

$$\left(R_{jn}\left(m_{jn} \geq z_{jn}\right)\right)_s = \sum_{k=(z_{jn})_s}^{m_{jn}} {}^{m_{jn}}C_k \left(\mathrm{P}_{jn}\right)^k \left(1-\mathrm{P}_{jn}\right)^{m_{jn}-k} \qquad \forall j \forall n \forall s \qquad (2)$$

$$\left(R_j\right)_s = \left(\sum_{n=1}^{N} R_{jn} I_{jn}\right)_s \qquad \forall j \forall s \quad (3)$$

$$\left(z_{jn}\right)_s \le \left(\mathrm{M} \times I_{jn}\right)_s \qquad \forall j \forall n \forall s \quad (4)$$

$$\left(R_j\right)_s \ge \left(\sum_{n=1}^{N} \mathrm{R}_{jn}^{\mathrm{Min}} I_{jn}\right)_s \qquad \forall j \forall s \quad (5)$$

$$EP = \sum_{s} \alpha_s \left[\mathrm{AOT} \times \left(\sum_{p=1}^{P} F_{jp}^{\mathrm{I}} \mathrm{C}_p \right)_s \right] - \mathrm{CRF} \times CAP - MAC \quad (6)$$

To illustrate this approach, a simple grassroots design case study of a steam turbine configuration for a BTS is presented. In the case study, a mixed integer non-linear programming (MINLP) model consisting of 46 continuous variables, 27 integer variables and 62 constraints is formulated based on Eq. (1 – 5). The developed model is then solved via multi-period optimization in LINGO v14 Global Solver in Dell Vostro 3400 with Intel Core i5 (2.40GHz) and 4GB DDR3 RAM in an average time of 0.1s of CPU time.

4. Case Study

In this case study, it is assumed that the owner of a BTS is interested to design a reliable steam turbine configuration with maximum economic performance. The steam turbine configuration is required to deliver output power based on the seasonal requirements shown in Table 1 (assuming the boiler is able to supply steam at fixed rate). In addition, Table 1 also shows the fraction of occurrence for each respective season. Table 2 shows the design capacity options available for purchase and their respective reliabilities while Table 3 summarizes other economic parameters used for this case study. Besides, the steam turbine configuration is expected to operate on a minimum reliability level of 95%. Subsequently, a simple superstructure is developed to include all considered turbine options (as shown in Figure 1). Note that although only one unit is shown for each option in the superstructure, it is possible to have several pieces in the case where units with small design capacities are selected as described in Eq.(1 – 5). The mass, energy and economic calculations for these options are then mathematically modeled, allowing quantitative analysis and optimization. Following this, the developed model for this case study is solved by maximizing Eq.(6) to determine a reliable steam turbine configuration.

Table 1: Fraction of Occurrence and Power Demand for Seasons 1, 2 and 3

Season	Power Demand (kW)	Fraction of Occurrence, α_s
1	489	$\alpha_1 = 0.417$
2	225	$\alpha_2 = 0.333$
3	289	$\alpha_3 = 0.250$

Table 2: Available Design Capacity Options

Design Capacity Options	Capital Costs (USD)	Maintenance Costs (USD)	Reliability
250 kW	90,549	5,000	0.90
500 kW	122,380	10,000	0.91
1 MW	165,395	20,000	0.92

Table 3: Economic Parameters for Case Study

Operational Hours, AOT	5000/year
Operation Lifespan	15 years
Capital Recovery Factor, CRF	0.13/year
Price of Power Sold, C_p	0.09 USD/ kWh

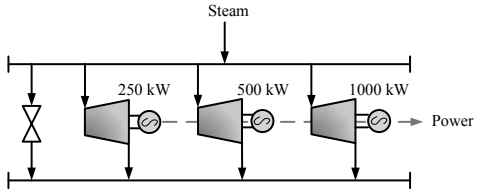

Figure 1: Superstructure of Steam Turbine Options for Case Study

The resulting grassroots steam turbine configuration is shown in Figure 2. As shown, the configuration consists of three 250 kW steam turbine units. Based on the optimized result, the *EP*, *CAP* and *MAC* are determined as 111,187 USD/year, 279,646 USD and 15,000 USD/year respectively. Meanwhile, Table 4 shows the reliability level achieved with this configuration are 0.972, 0.999 and 0.972 for Seasons 1 – 3 respectively. Moreover, Table 4 shows the status (e.g., operational or standby) of the steam turbines in each season. As shown, Season 1 has two operating turbines while the remaining one will be placed on standby. Since one turbine is available on standby in Season 1, the synthesized configuration would still be able to meet demands if one of the operational turbines fails. In Season 2, only one turbine would be operational while the remaining two would be on standby mode. If the turbine in operation experiences failure, two standby turbines are available to meet power requirements. Therefore, a higher reliability value is obtained in Season 2 compared to Season 1. Similar to Season 1, two out of the three turbines would be operating in Season 3. If one of the turbines in operation fails, the remaining turbine on standby is still available and capable to resume operations.

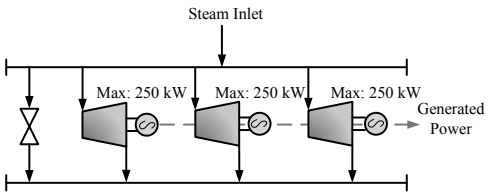

Figure 2: Synthesized Grassroots Design of Steam Turbine configuration

Table 4: Equipment Status for each Season

Season	Status		Reliability
	Operational, $(z_{jn})_s$	Standby	
1	2	1	0.972
2	1	2	0.999
3	2	1	0.972

5. Conclusions

A systematic approach was presented to design a reliable grassroots steam turbine configuration for a BTS with reliability aspects. In this approach, an alternative reliability modeling approach, based on *k*-out-of-*m* system modeling, is adapted to determine the required redundancy allocation for a particular technology in a system. The required redundancy allocation is then determined based on a minimum reliability level specified via chance-constrained programming. The developed model is solved via multi-period optimization. The presented approach is used to determine whether to install a large capacity equipment unit or multiple smaller capacity units based on their unique reliabilities. The proposed approach is illustrated using a simple case study on designing a reliable grassroots steam turbine configuration for a BTS.

Abstract

The ambient temperature strongly influences the demand of heat and electricity in Finland. In order to study a potential expansion of the gas distribution network and the use of new gas sources, a mathematical model for the pipeline network was formulated. The model considers daily variations in the energy demand at the consumers, the gas flow rates and pressures in the pipes, as well as compressor duties. Using the model, the present natural gas system was simulated for a reference year. This gave a basic understanding about the gas flow rates and pressures in the pipes, as well as compressor duties for every day. The possibilities to extend the pipeline to other cities was also studied, and the implications for additional gas supply, using alternative sources, on the system was analysed, revealing an extra need of compression as well as information about the feasibility of the system at these new states. The pipeline network expansion problem was stated and solved as a nonlinear programming cost minimization problem, yielding information about an optimal operation of the network. Finally, an attempt was made to optimize the integration of a new LNG terminal from which regasified natural could be supplied to the pipeline.

Keywords: Natural gas pipeline, nonlinear programming, compression, mass flow.

1. Introduction

In Finland natural gas (NG) is today distributed to the southern parts of the country with a pipeline from Russia (Figure 1). The gas is mainly used for electricity and heat production, and in 2013 about 33.2 TWh of natural gas was delivered to customers in Finland. The extension of the distribution pipeline network to other cities has been considered. Further possibilities to provide natural gas to the users would be to connect regasification facilities from liquid natural gas (LNG) terminals or sites with biogas production to the pipeline. The construction of LNG terminals and storages is seen a means to increase the independence of Finland on the energy deliveries while the use of biogas will lower the emissions considerably.

The problem of an efficient pipeline operation depends to a large extent on the components and size of the distribution network. In order to provide a delivery of gas of sufficient amount and pressure, adequate pressure for the transmission of the gas has to be maintained everywhere in the system. Compression stations built in regular intervals along the pipeline serve this purpose. Work to solve the problem of an efficient pipeline operation, utilising methods such as dynamic programming, was presented already in the 1960's, e.g. Wong and Larson (1968). A dynamic programming approach is also discussed in a more recent article by Borraz-Sanchéz and Haugland (2011).

Other methods, such as an extended simplex algorithm by De Wolf and Smeers (2000) or MINLP formulation by Cobos-Zaletta and Ríos-Mercado (2002) have been presented in the literature. As an alternative solution, meta-heuristic methods such as ant colony optimization have been proposed by, e.g., Chebouba et al. (2009). In the present approach sequential quadratic programming was used to tackle the problem, as the resulting formulation can handle nonlinearities, is flexible and efficient for the studied system.

Figure 1. Present gas distribution network (Kaasuyhdistys 2014)

2. Mathematical Model

The current configuration of the model is designed for simulation of the distribution of natural gas in a NG transmission network in Finland. The simulation is based on the information provided by the Finnish gas company Gasum Oy and their web pages (Gasum Oy 2014a, Gasum Oy 2014b). There are three compression stations placed before Imatra, after Kouvola and after Mäntsälä, which are used to increase the natural gas pressure to a level suitable for the transmission. In the model, the following cities are included as nodes for the base case study (with node numbers reported in parentheses): Imatra (1), Kouvola (2), Orimattila (3), Kotka (4), Lahti (5), Mäntsälä (6) Tampere (7), Helsinki (8), Lohja (9), Porvoo (10), and Hamina (11). As potential extension nodes in the test scenarios, Pori (12) and Turku (13) are considered. In Pori, which has a large port, plans to build an LNG terminal have recently been announced. In the present work, it is assumed that a regasification unit at this terminal would make it possible to supply NG to the network, but gas will also be consumed by the city and local industry. Thus, Pori is at the same time a consumer and a supply point to the gas network, while Turku is assumed to be an additional demand point in the network. All nodes included in the simplified pipeline model are illustrated in Figure 2.

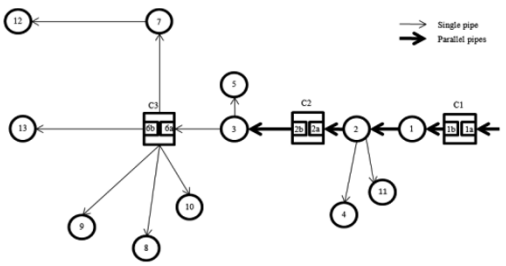

Figure 2. Scheme of nodes and pipes included in the simulation

The pressure and mass flows through the nodes should be determined in an optimal way. The existence of pipelines between the nodes is determined prior to the simulation together with the pipe diameters. There is a double pipe from Russia trough Imatra (node 1) and further to Orimattila (node 3). The pressure of the NG at the Russian-Finnish border is assumed to be known (p_0). Three compression stations are located before Imatra, after Kouvola and after Mäntsälä. Both the inlet pressure and discharge pressure of those compression stations are optimised. The inlet pressure is limited to be at least $p_{c,\mathrm{in}}$ and the discharge pressure to be no larger than $p_{c,\mathrm{out}}$. For the sake of simplicity, the temperature in the pipe is assumed to be proportional to the ambient temperature T_0 and inclination of the pipe is assumed to be negligible.

Mass flows of gas, $m_{i,j}$, between the nodes are balanced based on a balance between the inflows/supply and outflows/demands of the nodes. Assuming static conditions, the mass balances can be expressed as linear equality constraints

$$\sum_j m_{i,j} + D_i = \sum_j m_{j,i} + S_i \quad \forall\, i \quad i \neq j \tag{1}$$

where D_i and S_i are the demand and supply, respectively, at node i. The pressure, p_i, at each node is bounded by minimum and maximum values

$$p_{\min} \leq p_i \leq p_{\max} \quad \forall i. \tag{2}$$

Furthermore, the pressure at (some) demand nodes should fulfil the condition

$$p_i \geq p_{\mathrm{D},i} \tag{3}$$

For the calculation of NG density, it was assumed that the temperature of the gas in the pipe assumes the temperature of the surrounding and that the ideal gas law holds, i.e.,

$$\rho_i = \frac{p_i M}{R T_0} \quad \forall i. \tag{4}$$

where M is the molar mass of the NG. Pressures at the nodes are calculated with the equation for pressure drop in a pipe with a flow of a compressible gas

$$\frac{p_i^2 - p_j^2}{2p_i} = \frac{1}{2} f \frac{l_{i,j}}{d_{i,j}} \rho_i m_{i,j} \left| m_{i,j} \right| \left(\frac{n}{4} \rho_i \pi d_{i,j} \right)^{-2} \quad \forall j \; \forall i \; i \neq j \tag{5}$$

where n is the number for parallel pipes. This general equation also applies if the direction of the mass flow changes. The length of each pipe between nodes i and j, l_{ij}, is determined as in Euclidean distance calculation. The Darcy friction factor, f, is given by the Colebrook-White equation. The average velocity in the pipe is given by

$$w_i = \frac{4 m_{i,j}}{\rho_i \pi {d_{i,j}}^2} \quad \forall i \in I. \tag{6}$$

The cost of the compression depends on the difference between the temperature of the gas and the temperature of the surrounding, assuming that the NG is cooled down after each compression to the ambient temperature. The temperature after an ideal compression stage, $T_{i,\mathrm{id}}$, was determined considering the possible reverse flow by nonlinear inequality constraints, Eqs. (7a,b). The real temperature after the compression, T_i, was the obtained from Eq. (7c) by considering the efficiency factor (η_{ad}) of the compressor

$$T_{i,\mathrm{id}} \geq T_0 \left(\frac{p_{ib}}{p_{ia}} \right)^{\frac{R}{MC_p}} \qquad T_{i,\mathrm{id}} \geq T_0 \left(\frac{p_{ia}}{p_{ib}} \right)^{\frac{R}{M}} \qquad T_i = T_0 + \frac{T_{i,\mathrm{id}} - T_0}{\eta_{\mathrm{ad}}} \qquad \forall i \in I_{\mathrm{cmp}} \tag{7a,b,c}$$

where the set of compressors for the base case is I_{cmp}={1,2,6}. The objective to be minimized is the total energy demand for compression, i.e.,

$$E_1 = \left(m_{1,2}(T_1 - T_0) + m_{2,3}(T_2 - T_0) + m_{3,6}(T_6 - T_0)\right) c_p t \quad (8)$$

where t is the time period. The task is a constrained non-linear programming problem which has been solved using `fmincon` in Matlab [1], employing the sequential quadratic programming algorithm.

3. Results and Discussion

The model developed was applied to optimize the Finnish NG system. The energy demand during the year was estimated based on the information about the average daily consumption during 2009-2011. The total demand was proportionally distributed between the end nodes 4, 5, 7, 8, 9, 10 and 11 for the base case according to the assumed number of consumers in the nodes (roughly yielding the shares 5 %, 5 %, 20 %, 45 %, 5 %, 15 % and 5 %). The demand at every node with a consumer was approximated to follow the outdoor temperature by a linear function adapted to some known consumption in the network. The NG pressure in the network was taken to be bounded (cf. Eq. (2)) by p_{min} = 30 bar and p_{max} = 52 bar. As for the demand pressures, inequalities (cf. Eq. (3)) were imposed for four nodes (Kotka, Tampere, Lohja and Porvoo) with $p_{D,4}$ = 30.5 bar, $p_{D,7}$ = $p_{D,9}$ = 30.0 bar and $p_{D,710}$ = 31.5 bar, while p_0 = 35 bar for the NG entering Finland. For the flow to and from the compressors (cf. Eq. (7)) the pressure limits applied are $p_{c,in}$ = 32 bar and $p_{c,out}$ = 52 bar. For the compressors, an efficiency of η_{ad} = 75 % was assumed. No other costs were included in the objective function as they would only cause an increase in the objective function value, without any real impact on the final result as, in this case, all pipeline connections are defined prior to the simulation.

Each day was separately optimized, with t = 24 h in Eq. (8). The results are illustrated by reporting the pressures at the compressors along the year and the mass flows and for three days corresponding clearly different temperatures: The first is the coldest day (–19.4 °C), the second is the warmest day (28.3 °C) and the third is one which has the median temperature (7.7 °C).

3.1 Base Case

The base case scenario includes nodes 1-11, i.e., the existing NG network in Finland. The left part of Figure 3 illustrates the resulting discharge pressures from the three compressors over the year, with the three reference days indicated by vertical lines. The corresponding total compression power requirement is depicted by a dark line in the right part of Fig. 3. The total compression requirement over a year was for the base case 69.2 GWh. The mass flow rates in the pipes during the reference days for the base case (B) are reported in the Table 1 and the pressures in Table 2. As expected, the temperature has an influence both on the demand and on the density of the gas in the pipeline, thus influences also the gas behavior in the pipe. Therefore, the largest mass flow and compression power requirement can be found during the coldest day.

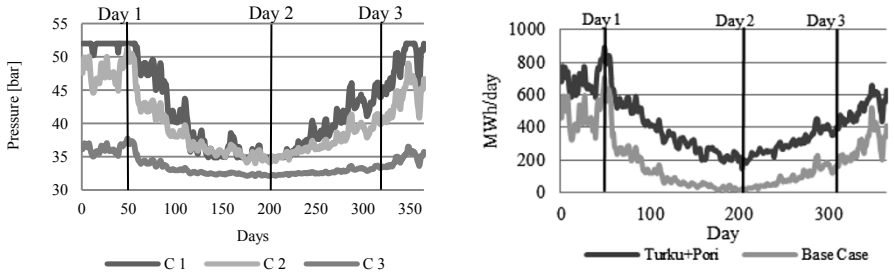

Figure 3. Left: Discharge pressures for base case. Right: Power demand of compression

3.2 Extension Scenario

In an extension scenario, nodes 12 (Pori) and 13 (Turku) are added, with maximum demands of 400 MW and 800 MW, respectively, during the coldest day. A yearly NG supply about 2 TWh from an LNG terminal in Pori into the network is assumed and the supply and demand are both distributed along the year based on the outdoor temperatures. In case the demand in Pori is less than the supply from the LNG terminal, the gas surplus can be compressed into the NG network. The compression of the gasified LNG was taken to occur in N steps with equal pressure ratios, $(p_{12}/1\ \mathrm{bar})^{1/N}$, yielding a revised objective function

$$E_2 = E_1 + N\left|m_{7,12}\right|(T_{12} - T_0)c_p t \qquad m_{7,12} \leq 0 \tag{9}$$

where T_{12} is the NG temperature after each compression step. Assuming a six-step compression (N = 6), the power demand in the optimized extension (E) scenario is illustrated by the gray line in the right panel of Figure 3. Table 1 reports the mass flow rates, where negative values indicate reversed direction of the flows in the pipe between nodes 7 and 12. The mass flow rates in the pipes during the three days are reported in Table 1 and the pressures in Table 2. The cost of the compression increases in the extension scenario, as the compression power demand increases by about 10 MW, but it should be stressed that the added demand in Turku and Pori could not be satisfied by the original network setup: Without a supply in Pori, the maximum delivery of NG to Turku and Pori (during the coldest day) would be 400 MWh and 250 MWh, respectively. The total yearly power requirement was 152.2 GWh.

4. Conclusions

The natural gas pipeline in Finland has been studied numerically by simulation and optimization. The results show a possibility to evaluate the reversion of the gas flow in the pipeline, addition of new pipeline extensions, and increase of the demand and addition of new sources to the network. The model is able to cover the nonlinearities caused by the compressibility of the gas in the pipe and also the effect of temperature and demand changes during the year. By the model, extension options of the current pipeline network can be studied. In future work, the model will be expanded to an MINLP model to optimize the network considering several potential new demand and source sites, also considering investment costs and energy efficiency aspects.

Abstract

An increasing concern in the supply chain management field is the determination of policies aiming at improving the performance of the whole system while preserving an adequate reward for each partaker. The work presented here deals with this critical issue applying the Nash game theory to the development of bioenergy systems. The supply chain planning problem was formulated as a Mixed Integer Linear Programming (MILP) model using a linearized Nash-type objective function. The approach was demonstrated through a case study concerning the bioethanol production in Northern Italy. Result show significant improvements in the mechanisms of transfer price formation towards a fair profit allocation between partakers in bioenergy systems.

Keywords: Multi-enterprise supply chain, Bioethanol, Transfer pricing, Game theory.

1. Introduction

In recent years, energy production from biomass has become increasingly important, both for energy security and climate change concerns (Höök and Tang, 2013). Biofuels, corn-based ethanol in particular, have generated quite a lot of interest in the transport sector as alternative substitutes to fossils. Since the economics of first generation bioethanol strongly depends on the feedstock supply costs (Solomon and Johnson, 2009), the presence of suitable market mechanisms for a fair profit allocation among the main partakers involved, i.e. feedstock suppliers and biofuel producers, is crucial.

Game theory (GT) approaches have been widely used as mathematical and logical tools to study the interactions between the 'players' or 'agents' who are involved in a business (von Neumann and Morgenstern, 1944). However, the integration of profit allocation mechanisms with the optimization of operational decisions along a SC might require sophisticated solution algorithms (Aplak and Sogut, 2013; Zhang et al., 2013). Gjerdrum et al. (2002) proposed a mixed-integer nonlinear programming (MINLP) model based on the game-theory Nash bargaining solution approach for a two-enterprise SCs and formulated a spatial branch-and-bound solution algorithm.

There has been a general lack of focus on the multi-enterprise SC optimization for biofuel systems and only recently, Yue and You (2014) applied game-theory as a solution approach through revenue sharing policy to the arbitrary allocation of the total profit and to align the interests of individual participants in a non-cooperative biofuel SC. In this work, we aim at incorporating a game-theoretical Nash-type model approach within a Mixed Integer Linear Programming (MILP) framework in order to optimize a fair profit distribution between members of multi-enterprise SCs. The modelling framework proposed in Giarola et al. (2011) and Ortiz-Gutiérrez et al. (2013) is

extended to include GT principles and study the effects on the dynamic evolution of a bioethanol SC driven by the fulfilment of an increasing biofuel demand. Model decision variables include the biomass production per site and its supply strategy, the location and capacity of biorefineries as well as the transport logistics of the product. The transfer price policy, an efficient method to create a fair, optimized profit distribution in the biofuel SC using GT, is used as powerful tool in the decision making.

2. Problem Description

The emerging biomass-based ethanol production in Northern Italy was assessed as a real world case study to illustrate the applicability and capabilities of the proposed approach in steering the strategic design and planning of systems such as biofuels supply networks. All the assumptions concerning the case study formulation (i.e. territory discretization, logistics, biomass availability, biomass and energy market characteristics as well as technology definition) are in the work by Ortiz-Gutiérrez et al. (2013). Here, we will mainly focus on the changes applied to both the mathematical formulation and the case study in order to include a GT analysis.

The design process was conceived as an optimization problem for two-enterprise bioethanol SCs. One enterprise was devoted to growth and sale of biomass to a biorefinery (the second enterprise) in order to produce bioethanol and byproducts for their onward sale to external customers. The system is capable of meeting the bioethanol demand as defined by European Directive 2009/28 (EC, 2009). The overall timeframe of 15-years was divided into five time intervals (t) of each three-year long in order to reduce the computational burden. Northern Italy was discretized into 59 square cells, considering an additional one for biomass import. The biorefinery was described using three alternative corn-based bioethanol production technologies: (i) dry-grind process (DGP), which is the standard corn-based ethanol process; (ii) DGP-CHP plants, where the DGP byproducts are burnt to cogenerate electricity and heat; and (iii) the fermentation of the thin stillage (considering natural gas supplement for energy needs) enabling production of both electricity and DDGS (DGP-TSNG) (Ortiz-Gutiérrez et al., 2013). Three price levels have been taken into consideration for the corn purchased from the local market within a range of 100-175 €/ton, which is aligned to market price variation in the last decade. Biomass imported from foreign suppliers was supplied at a constant price of 110 €/ton. Price levels were not fixed to a certain amount of biomass supplied by farmers.

3. Mathematical Features

According to Gjerdrum et al. (2001) the Nash-type objective function, ϕ, for a two-echelon SC could be formulated as follows :

$$\varphi = \left(\Pi_{farmers} - \Pi^{L}_{farmers}\right)\left(\Pi_{biorefinery} - \Pi^{L}_{biorefinery}\right) \tag{1}$$

where Π represents the profit of each enterprise (i.e. farmer, biorefinery) which is subject to meet a minimum profit requirement (Π^{L}) as stated below.

$$\Pi_{farmers} \geq \Pi^{L}_{farmers} \;;\; \Pi_{biorefinery} \geq \Pi^{L}_{biorefinery} \tag{2}$$

Eq.(1) was linearized using a separable programming approach based on logarithmic differentiation to obtain a MILP model (Gjerdrum et al., 2001). Accordingly,

$$\hat{\phi} = \sum_{s}^{n} \lambda_{f(s)} \ln\left(\Pi_{farmers(s)} - \Pi^{L}_{farmers}\right) + \sum_{s}^{n} \lambda_{b(s)} \ln\left(\Pi_{biorefinery(s)} - \Pi^{L}_{biorefinery}\right) \quad (3)$$

$$\sum_{s}^{n} \lambda_{f(s)} \Pi_{farmers(s)} + \sum_{s}^{n} \lambda_{b(s)} \Pi_{biorefinery(s)} = \Pi_{farmers(s)} + \Pi_{biorefinery(s)} \quad (4)$$

$$\sum_{s}^{n} \lambda_{f(s)} \ , \ \sum_{s}^{n} \lambda_{b(s)} = 1 \quad (5)$$

$$\lambda_{f(s)} \ , \ \lambda_{b(s)} \geq 0 \quad (6)$$

Eq. (3) represents the new objective function ($\hat{\phi}$) where the enterprise profits were approximated as piecewise linear functions using $s \in S = [1, n]$ transfer price levels and introducing the continuous variables as the intervals $\lambda_{f(s)}$ and $\lambda_{b(s)}$ for farmers and the biorefinery, respectively. While Eq.(4)is the convexity requirement, Eq.(5) and (6) guarantee that two adjacent nodes take non zero values, using n grid points.
The overall profit of biomass growers (TFP [€]) was calculated as follows:

$$\Pi_{farmers(s)} = -TFP \quad (7)$$

$$TFP = \sum_{i} \sum_{g} \sum_{t} FR_{(i,g,t)} \varepsilon_{CF(t)} \quad (8)$$

$$FR_{(i,g,t)} = \sum_{s} Pbl_{(i,g,s,t)} Lvs_{(i,g,s)} - TOC_{(i,g,t)} \quad (9)$$

$$Pb_{(i,g,t)} \geq Pb_{(i,g,t-1)} \quad (10)$$

where $\varepsilon_{CF(t)}$ is discount factor related to time period t specific for $FR_{(i,g,t)}$ representing the incomes from biomass sale, which is evaluated by multiplying the linearized quantity, $Pbl_{(i,g,s,t)}$, of biomass i from the farmer in cell g at time t of the s available levels by the corresponding variable for biomass selling prices for each level ($Lvs_{(i,g,s)}$), $TOC_{(i,g,t)}$ stands for the farmers' total operating cost and accounts for biomass i production and transport cost at time period t. Eq. (10) constraints the farmers to long-term contracts with the biorefinery.
The mathematical model describing the biorefinery company was based on the work by Giarola et al. (2011) to which we refer for the mathematical details. The overall profit of the biorefinery represented as the NPV was calculated by summing up the discounted annual cash flows [CF_t (€/period)] for each period t minus the capital investment [TCI_t (€)] for establishing or enlarging a production facility to meet a minimum profit requirement (Π_L) as stated below.

$$\Pi_{biorefinery} = -NPV \quad (11)$$

$$NPV = \sum_{t} \left(CF_t \cdot dfCF_t - TCI_t \cdot dfTCI_t\right) \quad (12)$$

where $dfCF_t$ and $dfTCI_t$ represent the discounting factors for cash flows and capital costs, respectively. The biomass procurement costs, as part of the CF_t definition have been modified compared to the original model to include the transfer prices.

4. Results and Discussion

The optimization problem for a fair profit allocation in a 2-enterprise corn-based ethanol SC was solved by means of the CPLEX solver in the GAMS® modelling tool.
In order to apply the linearization procedure, minimum profit requirements at different transfer prices were determined solving the optimization problem described in Ortiz-Gutiérrez et al. (2013) for a single enterprise at a time (i.e. farmers and biorefinery). Table 1 reports the minimum profit values for the two enterprises at the chosen.

Table 1. Corn price levels and corresponding minimum profit for farmers and biorefinery.

Level (S)	Price (€/ton)	$\Pi_{farmers}$ (€)	$\Pi_{biorefinery}$ (€)
1	100	2.20E+08	1.00E+06
2	145	6.90E+08	3.19E+08
3	175	1.16E+09	6.37E+08

Once the minimum profit requirements were established we proceeded with the maximization of the enterprise profits ($Max\ \hat{\Phi}$). The outcome of the optimization procedure for each enterprise implementing the linearized Nash objective function, were 2.971 €/GJ_{EtOH} for the biomass growers ($\Pi_{farmers}$) and 1.034 €/GJ_{EtOH} for the biorefinery consortium. The λ multipliers used for the linear approximation took values for $\lambda_{f(1)}\lambda_{f(2)} = 0.982$, and $\lambda_{b(2)} = 1$.
Fig. (1) compares the results obtained for a two enterprise SC with and without the inclusion of a Nash GT approach. The first stacked bars were obtained when the optimized problem aimed at the maximization of an overall profit ($\Pi_G = \Pi_{biorefinery} + \Pi_{farmers}$). The second ones were obtained after the Nash optimization. As is clear in Fig. (1) the proposed approach ensures a more equal profit-split between the two enterprises involved in the SC.

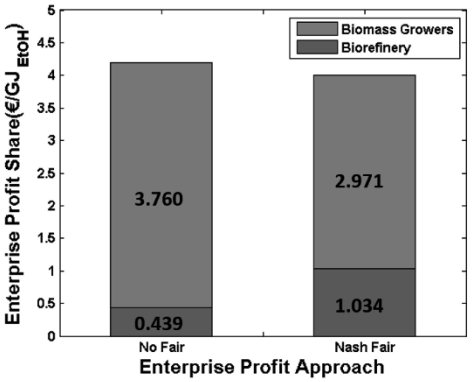

Figure 1. Profit share before and after Nash supply chain optimization and the overall improvement after fair split.

It is interesting to note that the introduction of a Nash-type approach allows the farmers to choose different price levels along the time horizon. The overall system profit embedding a Nash approach matches very close the value obtained from a pure optimization of the enterprise profit summation, which results in a better economic performance of the supply chain as a whole.
In terms of design and planning, the SC configuration at the final period is represented in Fig. (2). The optimal solution involves the establishment of four DGP bioethanol production plants operating at full capacity (over 250 kton/year). One facility is located on the coastline, although the system also relies on biomass importation. At the end of time period 5, the observed amount of imported biomass was about 42%, which reduced significantly the biomass supply costs, due to the lower price of the imported corn.

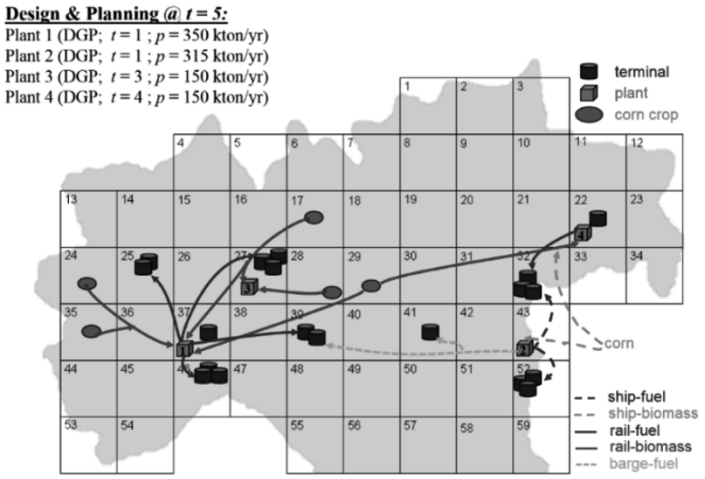

Figure 2. Design and planning strategy at time period t = 5 under Nash optimization supply chain.

Furthermore, an analysis within the Nash modelling framework was performed by fixing the price levels over the time horizon (Table (2)). It has been necessary to increase the original first corn price level (which was set to 100 €/ton) to 130 €/ton, since prices below 130 €/ton so not allow the system to reach the minimum profits established according to the Nash optimization.

Table 2. Enterprise profit under fixed price.

Fixed Price	$\Pi_{farmers}$ (€/GJ_{EtOH})	$\Pi_{biorefinery}$ (€/GJ_{EtOH})
Low (130€/ton)	2.319	1.442
Average (145 €/ton)	2.799	1.130
High (175 €/ton)	2.904	1.034

From the results, it emerges that the fairest split of the profit is obtained at the lowest corn price, where the biorefinery consortium receives about 40% of the total and the farmers' enterprise holds the 60%.

5. Final Remarks

A modelling framework which utilizes a separable programming approach to implement the game theoretical concepts developed by Nash was proposed. The purpose was to guarantee fair profit allocation in the design and planning of a two-enterprise biofuel supply chain. The proposed method guarantees fair profit levels of the separate enterprises while an optimum total profit of the entire supply chain is achieved. The transfer prices for biomass selling-acquirement which allow a fair split of the profits between the two enterprises are mostly located in the higher price level (i.e. 175 €/ton). However, when the proposed method guaranteed that even at a low corn price over the time horizon (130 €/ton) better economic performance were achieved.

The integration of GT aspects in SC optimization tools could support the decision-making among the stakeholders involved in the planning of bioenergy systems. As a matter of fact, these tools could enable the definition of planning strategies from which every single enterprise could benefit. This would facilitate the bargaining among the stakeholders as well as help the planning of bioenergy system capable achieve a better overall performance when a fair profit split is guaranteed.

Optimal integration of the year-round operation for methane production from CO_2 and water using wind, solar and biomass

Mariano Martín, William Davis

Department of Chemical Engineering. University of Salamanca, Plz. Caídos 1-5, 37008, Salamanca, Spain

Abstract

In this paper we integrate the use of biomass, wind and solar energy for the constant production of synthetic methane over a year to determine the optimal combination of renewable energy to maintain a production level and to store it in a ready to use and practical form. Biomass is used for the production of power and/or hydrogen. Photovoltaic solar and wind energy are used to obtain power. The power is used to split water through electrolysis to generate oxygen, which is used to process the biomass and hydrogen, that is used to synthesize methane together with CO_2. The optimal operation of the facility involves the use of biomass for the production of power, while hydrogen is to be produced from water electrolysis. The investment and production costs are 175 M€ and 0.38€/Nm^3 respectively. A sensitive analysis shows that biomass is used when its price is lower than 50€/t and for investment rates below 1500€/kW. Solar energy is used for power when the price of biomass is high and only if the solar incidence is above 1200 kWh/m^2 yr. The use of wind is recommended where there is a low solar incidence and wind velocities above 9 m/s.

Keywords: Synthetic methane, CO_2, Process integration, Renewable energy

1. Introduction

Most sustainable sources of energy, namely biomass, wind and solar, present variable availability with time, seasonality and day-long variability, with the weather and the region, which results in the fact that storage systems, supplementary sources of energy or a combination of some of them (Yuand and Chen, 2012) are needed to maintain the production capacity and to meet the demand. While solar and wind energy are very volatile sources, biomass can be stored for a certain period of time and can be used to supply the need for energy during periods of lower availability of wind and solar. The availability of the different sources is also inversely correlated. For example: high intense solar areas typically have low availability of biomass and water.

In this work we evaluate the production of synthetic methane as an energy carrier to store renewable energy. The idea is to avoid idle units within the facility over a year time. The reagents used are renewable hydrogen, produced either from water electrolysis or from biomass gasification, and CO_2 from flue gases is the selected carbon source. The electricity to split the water comes from either a Brayton cycle using syngas generated out of the biomass, or from wind turbines or solar photovoltaic panels.

2. Process description

The process is divided in three zones: biomass processing for syngas production, which is further used for hydrogen or electricity production; water electrolysis that produces hydrogen and the oxygen needed in direct gasification; and methane synthesis from CO_2 and hydrogen. Water is also produced and can be recycled back to the electrolyzer.

2.1. Biomass processing

The biomass is washed and milled before the gasification, producing raw syngas. Two alternatives are considered: The Renugas gasifier operates at medium pressure using oxygen and produces a gas rich in CO_2. The light hydrocarbons generated can be further reformed to hydrogen and CO. High pressure gasification allows a large throughput per reactor volume, and reduces the need for a downstream pressurization, reducing therefore the overall power needed. However, the efficiency of the gasifier is lower, and a large amount of steam and pure oxygen are needed to avoid syngas dilution and reduce the size of the gasifier (Eggeman, 2005). The low pressure gasifier, Battelle Columbus (Ferco), is indirectly heated. The system consists of two chambers, a gasifer and a combustor. Sand, olivine, provides the energy for gasification by being heated up in the combustor with the energy released in the combustion of char. This type of gasifier produces a gas with low CO_2 content, but contains heavier hydrocarbons. The reactor is fast fluidized, allowing throughputs equal to those of the bubbling fluidized Renugas gasifier despite the nearly atmospheric operation. Working at a lower pressure decreases the operating cost (Phillips, 2007). Subsequently, the syngas is reformed to remove the hydrocarbons. Steam reforming is an endothermic reaction but provides a higher concentration of hydrogen in the syngas. Partial oxidation is exothermic but its yield to hydrogen is lower. Finally, the raw syngas is cleaned. Two steps are proposed. Cold cleaning by means of a scrubber for low pressure gasification or a ceramic filter operating at high temperature for high pressure gasification is the first one. The second step consists of a multibed PSA system, used to remove the last traces of hydrocarbons, H_2S and CO_2 in that order. Once the syngas is purified, we can use it for the production of hydrogen, via water gas shift reaction, or for the production of power using a Brayton cycle.

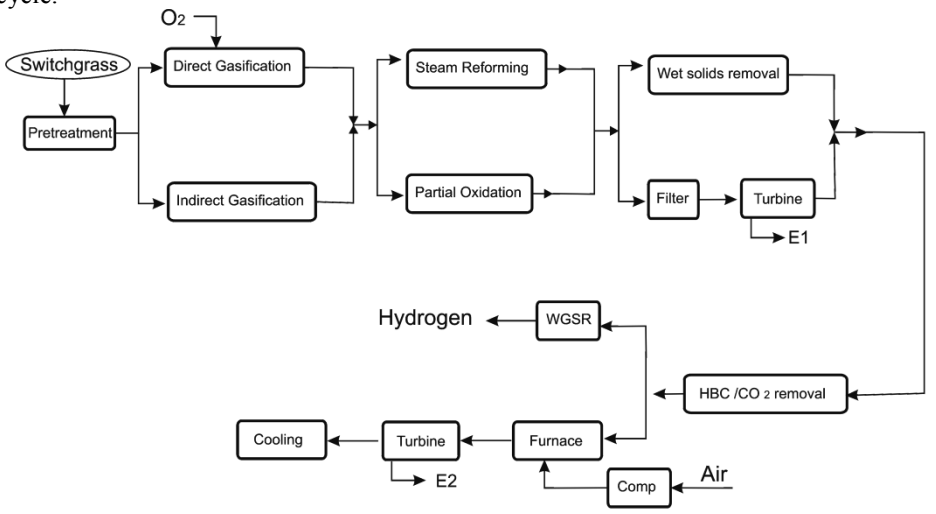

Figure 1.- Biomass processing superstructure

2.2. Water electrolysis

The second section of the facility corresponds to water electrolysis (NEL, 2012). It uses energy from the Brayton cycle, from the wind farm and/or the solar field. On the one hand, we have the line of oxygen that carries water vapor and traces of hydrogen. This water is condensed and the resulting stream is dehydrated using a zeolite adsorber, before compressing and storing the oxygen. This oxygen can be used in the direct gasifier and/or the partial oxidation section of the biomass processing process. On the other hand, we have the stream of hydrogen containing traces of oxygen and water vapor, most of which is separated by condensation. The oxygen represents a challenge for further synthetic stages, so it is eliminated by using a deoxygenation reactor where water is produced. Next, a zeolite is used to dehydrate the stream. Figure 2 shows a scheme of this section.

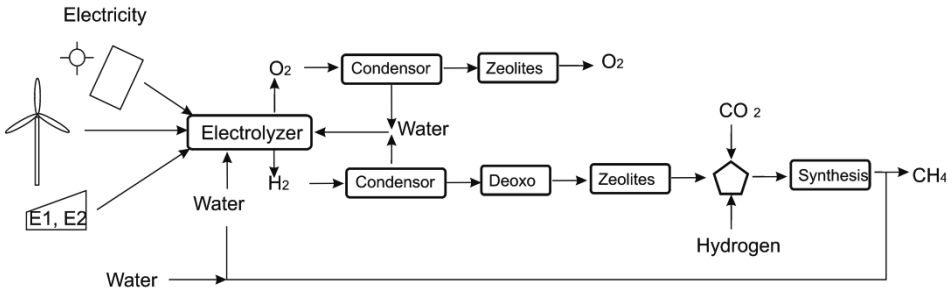

Figure 2.- Water electrolysis and methane synthesis

2.3. Methane synthesis

At this point, hydrogen is mixed with the CO_2. In order to avoid carbon deposition, the proper composition and conditions of the feed are required. Methane is produced through methanation. One important characteristic to reduce water consumption in this process consists of recycling the water produced together with the methane. Thus, the water is condensed, separated, and recycled. The gas produced, mainly methane but also containing CO, CO_2 and unreacted H_2 must meet the constraints related to composition so that the gas phase can be fed to the network that currently supplies natural gas. Figure 2also shows the scheme of this section of the flowsheet.

3. Solution procedure

3.1. Modelling approach

The different units are modelled using first principles, mass and energy balances, such as the case of heat exchangers, compressors, Brayton cycle; first principles combined with experimental data for conversions, i.e. gas reforming or species equilibrium for the WGSR and the methanation reactor (Davies & Lihou, 1971); experimental correlations define the gas composition produced form the gasifiers (Eggemann, 2005, Phillips et al., 2007); rules of thumb for the adsorbent beds or small parameter estimation problems for the performance of the wind turbines (Davis & Martín, 2014). We formulate the model for the superstructure as an MINLP problem in GAMS. The original allocation for

analysis is the Gulf of Cádiz, so that the results are comparable to previous work. (Davis & Martín, 2014).

3.2. Solution procedure

We first evaluate the operation of the facility on a monthly basis to determine the best biomass processing technology. By default, the number of wind turbines and the number of electrolyzers are considered as continuous variable. It is important to notice that their cost is given per kW of energy produced and, thus, the actual number has not a large impact on the investment cost. For each month we solve four problems, NLP's, corresponding to each of the gasifier and reforming models to determine the optimal topology. For each period, the model consists of 3000 equations and 4100 variables. The objective function is given as eqs. (1)-(4) adding a constant, 2, so that Figure 3 is more clear and easier to follow:

$$Z = 2 + F_{CH4} + C_{O2} \cdot F_{O2} - cost\_stw \cdot F_{Biomass} - wind\_t - solar\_t - bio\_t - steam\_t \quad (1)$$

$$wind\_t = \frac{1}{3} \cdot \frac{Wind_{Invest} \cdot P_{nominal} \cdot n_{wind\_turbine}}{time} + Op\_cost_{wind} \cdot P_{nominal} \cdot n_{wind\_turbine}; \quad (2)$$

$$solar\_t = \frac{1}{3 \cdot time} \cdot n_{panel} \cdot \left(P_{panel} \cdot c_{panel} + A_{pannel} \cdot c_{area} \right); \quad (3)$$

$$bio\_t = \frac{1}{3 \cdot time} \cdot cost_{bio} \cdot \left(-W(BraytonTurbine) \right); \quad (4)$$

The investment cost per kW when produced from wind is 1600 €, with an operating cost of 0.015 €/kWh. For PV panels, 2300 €/kWp for PV panels with a cost for area preparation of 5.5 €/m^2 (IRENA 2012). Finally, we use 1100 €/kW (IEA 2013) as the basic price for the energy produced from biomass using the Ferco gasifier, partial oxidation and the correction factors as function of their efficiency in producing electricity for a certain amount of fed biomass are 1.04, 1.19 and 1.24 for Ferco-Steam reforming, Renugas-Partial oxidation and Renugas-Steam Refoming, respectively.

Next, we use a multiperiod optimization formulation for the optimal operation of the selected topology over a year. Finally, we evaluate the selection of the different technologies as a function of the energy availability and cost.

4. Results

4.1. Plant topology

The optimal integration of technologies for the production of methane selects the use of the Ferco gasifier followed by steam reforming to meet the demand, fixed to be 1 kg/s of CH_4. Furthermore, solar is the preferred technology during summer time and no biomass needs to be used, see Figure 3.

4.2. Plant optimal operation

For the year long operation of the plant we assume that, if solar panels, biomass processing units or wind turbines are used at any point during the year, they need to be

bought. The excess of energy produced out of them when it is not needed for methane production can be sold to the grid. The objective function for the multiperiod optimization problem is given by eq. (5):

$$Z = 2 - \text{cost\_stw} \cdot F_{\text{Biomass}} + F_{CH4} + C_{O2} \cdot F_{O2} - \text{wind\_t} - \text{solar\_t} - \text{bio\_t} - \text{steam\_t} + \frac{C_{electro}}{12} \sum_{j \in \{months\}} Power_{generated,j} - Power_{consumed,j} \quad (5)$$

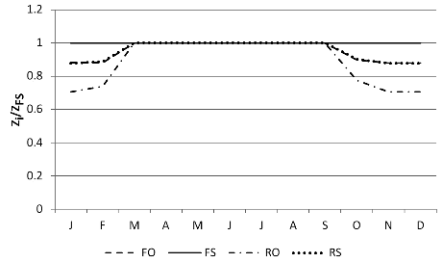

Figure 3. Biomass processing technology selection
F: Ferco; R: Renugas; S:Steam Ref.; O: Partial Oxid.

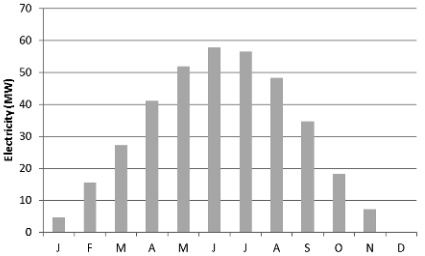

Figure 4. Excess of energy produced over a year

The biomass section operates at a constant capacity of up to 20 kg/s of biomass, resulting in the need for 42,400 panels for the operation of the plant. We produce 4.95 kg/s of oxygen as a byproduct of the electrolysis. There is a certain excess of electricity produced every month but for December, see Figure 4.

This facility requires an investment of 175 M€, 64% of which corresponds to the solar field. The production cost adds up to 46.4 M€/yr and, apart from methane, we produce oxygen and electricity. If both of them are considered as credit, at 98.8 €/t and 0.06 €/kWh respectively, the production cost of synthetic natural gas results in 0.38€/Nm^3 or 10.57€/MMBTU. Although the production cost is higher to that of the current cost of natural gas, this facility requires only one half of the investment compared to solar or wind based facilities for similar production capacity.

4.3. Sensitivity analysis

We consider an availability of up to 1700 t/d of biomass, up to 100 wind turbines, and 100,000 panels of 1kWp each with an assumed efficiency of 75% at a base cost 2300 €/kWp for solar panels and 1600€/kW for wind turbines. The biomass cost is assumed to be within 30-100€/kg, and the cost of the biomass based technology to produce electricity, 1140-2250 €/kW. Figure 5 presents a scheme of the use of the different renewable resources for meeting the methane demand as a function of the solar and wind availability and the price of the biomass.

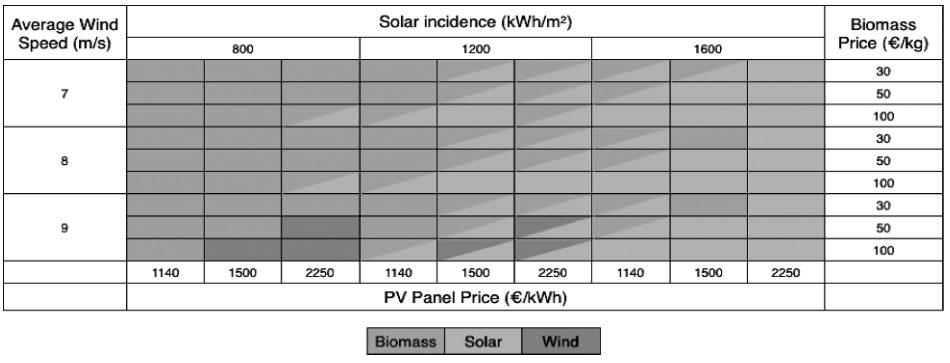

Figure 5. Selection of renewable energy source for different scenarios

Wind energy is only recommended for high wind velocities, above 9m/s, low solar irradiance, below 800 kWh/m^2 and high costs of biomass, above 50 €/t and 1500 €/kW. Solar energy is recommended above 1600 kWh/m^2 of incidence for medium to high cost of biomass. If the cost of biomass is high (above 50€/t) and the wind availability is above 9 m/s, wind turbines complement the production of energy. Otherwise, solar complements the biomass as source of energy.

5. Conclusions

In this work we have developed a mathematical formulation for the integrated use of renewable resources – biomass, wind and solar – for the constant production capacity of a chemical, based on a mathematical optimization framework.

Biomass was processed via gasification, reforming and syngas purification before it was used for either hydrogen synthesis or power production using a Brayton cycle. Wind and photovoltaic solar energies were used for power production. The power was later used in water electrolysis producing hydrogen and oxygen. While the oxygen was sold, the total amount of hydrogen, either from biomass or water electrolysis, was used together with CO_2 from flue gas for the production of methane.

The optimal operating conditions determined the use of biomass indirect gasification and steam reforming if the cost of investment and that of the biomass was low, below 1500€/kW and 50€/t respectively. Solar is the preferred complement as long as the biomass cost is high and we wish to maintain constant production capacity, while the use of wind energy is only recommended for wind velocities above 9m/s, low solar incidence and high costs of biomass. However, the large area required for the solar fields and their actual geographical allocation may favor the use of wind.

Abstract

The idea of cryogenic energy storage (CES), which is to store energy in the form of liquefied gas, has gained increased interest in recent years. Although CES at an industrial scale is a relatively new approach, the technology used for CES is well-known and essentially part of any cryogenic air separation unit (ASU). In this work, we assess the operational benefits of adding CES to an existing air separation plant. Three potential new opportunities are investigated: (1) increasing the plant's flexibility for load shifting, (2) storing purchased energy and selling it back to the market during higher-price periods, (3) creating additional revenue by providing operating reserve capacity. We develop a mixed-integer linear programming (MILP) scheduling model for an ASU-CES plant and apply a robust optimization approach to model the uncertainty in reserve demand. Results from an industrial case study show that the amount of wasted products can be considerably reduced and significant cost savings can be achieved by utilizing the CES.

Keywords: cryogenic energy storage, demand side management, robust optimization

1. Introduction

The concept of cryogenic energy storage (CES) is to store energy in the form of liquefied gas. When energy is needed at a later time, the liquid gas is pumped to high pressure and vaporized; the high-pressure gas can then be used to drive a turbine to generate electricity. The CES technology is being pioneered in the UK (Chen et al., 2008; Harrabin, 2012) where the company Highview Power Storage has been running a liquid air energy storage (LAES) pilot plant since 2011.

Interestingly, although CES at an industrial scale is a relatively new approach, the technology used for CES is well-known and essentially part of every air separation unit (ASU) that utilizes cryogenic separation. In cryogenic air separation, air is separated into its individual components at low temperatures, and typically, large amounts of oxygen and nitrogen are liquefied. Before being distributed to the customers, the liquid products are stored in large tanks. Hence, by adding a few pieces of equipment, namely pump, heat exchanger, and turbine, one is able to vaporize the stored liquid products and generate electricity, which by definition makes it a CES system.

This raises the following question: What are the potential benefits of an air separation plant with added CES capability? Here, we see three immediate opportunities for such an integrated ASU-CES system: (1) In general, an ASU has a limited range of oxygen to nitrogen ratio at which

it can efficiently operate. This often leads to overproduction of one product, which is typically vented and therefore wasted. With CES, instead of venting overproduced products, we can store them and recover energy from them to increase the plant's flexibility for load shifting. (2) Power generated from the CES system can be sold to the electricity market. (3) Similarly, the plant can gain additional revenue by providing operating reserve capacities which can be dispatched upon request. Operating reserves are required when the real-time electricity demand in the grid is higher than the supply, e.g. due to unexpected load increase or generator failures.

In the spirit of industrial Demand Side Management (Samad and Kiliccote, 2012; Merkert et al., 2014), we develop a scheduling model to assess the potential benefits of an integrated ASU-CES plant. In the proposed framework, robust optimization techniques are applied to model the uncertainty in operating reserve demand. This paper complements the work by Zhang et al. (2015) with a more involved industrial case study that provides additional insights into the interactions between gas and liquid production in such a plant.

2. Integrated ASU-CES Model

We consider an air separation plant that consumes air and electricity to produce gaseous oxygen (GO2), gaseous nitrogen (GN2) as well as liquid oxygen (LO2), liquid nitrogen (LN2), and liquid argon (LAr). To this existing plant, we add a CES system that can generate electricity by vaporizing LO2 or LN2. The energy drawn from the CES can be used internally to power the ASU, or we can sell it to the electricity market. Furthermore, operating reserve capacity can be provided and sold to the reserve market.

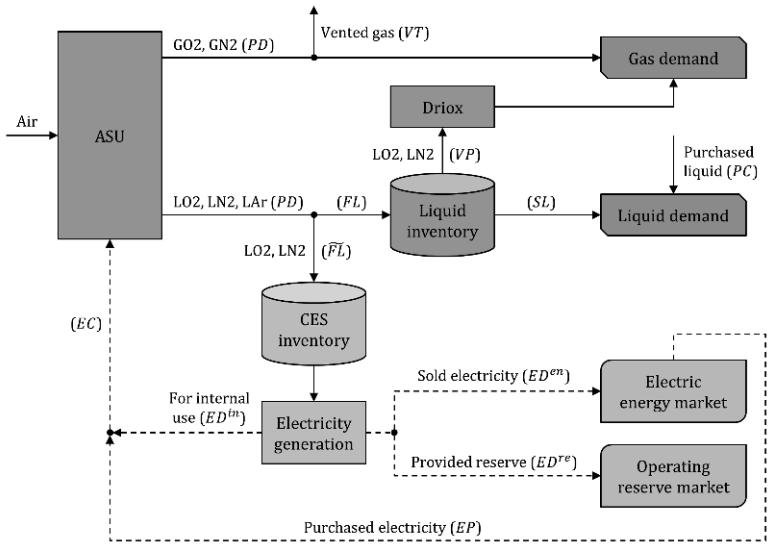

Figure 1: The flowsheet shows the integrated ASU-CES environment. The mass and power flows are depicted by solid and dashed lines, respectively. Flow variable names are shown in parentheses.

Figure 1 shows the mass and power flows in an integrated ASU-CES system. The plant has to satisfy product demand, which can be specified on an hourly basis. Gaseous product customers are connected to the plant via pipelines. We assume that there is no capacity for storing GO2 and GN2. However, there is the possibility of vaporizing LO2 and LN2 to feed the pipelines in case GO2 and GN2 production from the ASU alone is too low to satisfy the demand; in the air

separation industry, this process is referred to as *driox*. LO2 and LN2 are stored in inventory tanks and distributed to the customers when required. Alternatively, liquid products can be purchased from third-party suppliers.

The objective is to find a schedule for the integrated ASU-CES plant over a given scheduling horizon (typically a week) that minimizes the total operating cost minus the revenue from selling power and reserve capacity. This problem can be formulated as an MILP for which the complete formulation is given in Zhang et al. (2015). In the following, we highlight the main features of the proposed model:

- A common-grid discrete-time representation is applied.
- We assume that the ASU can operate in different operating modes. Each mode corresponds to a particular configuration or state of the ASU, e.g. "off", "on", or "startup". At any point in time, the ASU has to run in exactly one of the possible operating modes.
- Each operating mode is defined by a Convex Region Surrogate (CRS) model (Zhang et al., 2014), in which the feasible region is approximated by a union of convex regions in the form of polytopes. For each convex region, a linear power consumption function with respect to to the production rates is given. In this way, nonlinearities and nonconvexities are implicitly taken into account while retaining an MILP formulation.
- The formulation proposed by Mitra et al. (2013) is applied to model mode-to-mode transition constraints. These constraints include enforcing a minimum stay time in a particular mode after transitioning to it from another mode, and fixing the stay time in a mode that represents a certain process that takes a known amount of time, e.g. the startup process.

3. Robust Model with Reserve Demand Uncertainty

Selling reserve capacity is attractive because the reserve provider is rewarded even when no actual generation of power is required. In other words, the reserve provider is selling its mere capability of dispatching power upon request. However, one does not know in advance when reserve will be required. Since noncompliance would result in extremely high penalties, reserve providers have to operate in a way such that dispatch of the committed reserve capacities can be guaranteed.

We apply robust optimization techniques to account for the uncertainty in reserve demand, which is denoted ED_t^{re} for time period t. ED_t^{re} is bounded above by the reserve capacity provided in time period t, RC_t, which is a variable. The uncertainty is specified in terms of an uncertainty set from which any point is a possible realization of the uncertainty. The robust model is then formulated such that the optimal solution is feasible for all possible realizations of the uncertainty and minimizes the objective function. However, if the uncertainty is simply defined as

$$U(RC) = \left\{ \left[ED_1^{re}, \ldots, ED_{|\overline{T}|}^{re} \right]^{\mathrm{T}} : 0 \le ED_t^{re} \le RC_t \ \ \forall t \in \overline{T} \right\} \tag{1}$$

with $\overline{T}$ being the set of time periods in the scheduling horizon, the solution will have to be feasible for the maximum dispatch case in which $ED_t^{re} = RC_t \ \forall t \in \overline{T}$, which is an extremely conservative and also extremely unlikely case. Hence, in order to be able to realistically characterize the uncertainty and to adjust the level of conservatism in the model, we adopt the "budget of uncertainty" approach introduced by Bertsimas and Sim (2004). By defining the normalized reserve demand $w_t = ED_t^{re}/RC_t$, we can restrict the size of the uncertainty set by defining it as follows:

$$U(RC) = \left\{ \left[w_1, \ldots, w_{|\overline{T}|} \right]^{\mathrm{T}} : ED_t^{re} = RC_t\, w_t,\ 0 \le w_k \le 1 \ \ \forall k \le t,\ \sum_{k=1}^{t} w_k \le \Gamma_t \ \ \forall t \in \overline{T} \right\} \tag{2}$$

where the budget parameter, Γ_t, defines the maximum number of time periods in which maximum reserve dispatch can occur up to time t.

The uncertainty set given in Eq. (2) is used to formulate the robust counterpart. Here, we show the derivation for the main constraints involving reserve demand uncertainty, which are the CES inventory constraints:

$$\widetilde{IV}_t = \widetilde{IV}_0 + \sum_{k=1}^{t} u_k - \frac{1}{\eta}\sum_{k=1}^{t} RC_k w_k \qquad \forall t \in \overline{T} \tag{3a}$$

$$\widetilde{IV}^l \le \widetilde{IV}_t \le \widetilde{IV}^u \qquad \forall t \in \overline{T} \tag{3b}$$

where $\widetilde{IV}_t$ is the CES inventory level at time t, u_t is the net flow into the CES tank in time period t, and η is a conversion factor given in unit power per unit mass of liquid. Eq. (3b) sets bounds on the CES inventory levels. By substituting $\widetilde{IV}_t$ in Eq. (3b) and applying the "worst case" with respect to the given uncertainty set to each constraint, we obtain:

$$\widetilde{IV}_0 + \sum_{k=1}^{t} u_k - \frac{1}{\eta}\min_{w\in U(RC)}\left\{\sum_{k=1}^{t} RC_k w_k\right\} \le \widetilde{IV}^u \qquad \forall t \in \overline{T} \tag{4a}$$

$$-\widetilde{IV}_0 - \sum_{k=1}^{t} u_k + \frac{1}{\eta}\max_{w\in U(RC)}\left\{\sum_{k=1}^{t} RC_k w_k\right\} \le -\widetilde{IV}^l \qquad \forall t \in \overline{T} \tag{4b}$$

We can simply drop the term $\min\limits_{w\in U(RC)}\left\{\sum\limits_{k=1}^{t} RC_k w_k\right\}$ in Eq. (4a) since it always takes the value zero. To reformulate Eq. (4b), we introduce the following auxiliary problem for each $t \in \overline{T}$:

$$\max \sum_{k=1}^{t} RC_k w_k \quad \text{s.t.} \quad \sum_{k=1}^{t} w_k \le \Gamma_t, \quad 0 \le w_k \le 1 \ \ \forall k \le t \tag{5}$$

of which the dual is

$$\min \Gamma_t q_t + \sum_{k=1}^{t} s_{tk} \quad \text{s.t.} \quad q_t + s_{tk} \ge RC_k \ \ \forall k \le t, \quad q_t \ge 0, \quad s_{tk} \ge 0 \ \ \forall k \le t. \tag{6}$$

By strong duality, since Problem (5) is feasible and bounded for all $\Gamma_t \in [0,t]$, the dual problem (6) is also feasible and bounded, and moreover, (5) and (6) have the same optimal objective function value. Since Problem (6) is a minimization problem and every feasible solution will yield an objective function value equal to or greater than the minimum, we can substitute (6) for (5) in the robust counterpart formulation. The optimization will automatically drive the objective function value of (6) to its minimum, which coincides with the solution to Problem (5). Hence, we arrive at the following robust counterpart formulation for Eqs. (3):

$$\widetilde{IV}_0 + \sum_{k=1}^{t} u_k \le \widetilde{IV}^u \qquad \forall t \in \overline{T} \tag{7a}$$

$$-\widetilde{IV}_0 - \sum_{k=1}^{t} u_k + \frac{1}{\eta}\left(\Gamma_t q_t + \sum_{k=1}^{t} s_{tk}\right) \le -\widetilde{IV}^l \qquad \forall t \in \overline{T} \tag{7b}$$

$$q_t + s_{tk} \ge RC_k \qquad \forall t \in \overline{T}, k \le t \tag{7c}$$

$$q_t \ge 0,\ s_{tk} \ge 0 \qquad \forall t \in \overline{T}, k \le t \tag{7d}$$

4. Industrial Case Study

We now apply the proposed model to a real-world industrial case study for which the data are provided by Praxair. Given is an existing air separation plant that has to satisfy GO2, GN2, LO2, and LN2 demand. It is important to note that we consider an "oxygen-limited" plant, i.e. the production is driven by the oxygen demand; at such a plant, the nitrogen production often exceeds the demand, which makes venting of GN2 necessary. The scheduling horizon is one week to which we apply an hourly time discretization resulting in 168 time periods.

Assuming an overall CES efficiency of 70 %, we consider the following four cases: *Case 1* – only existing ASU; *Case 2* – existing ASU with added CES, but without reserve market participation; *Case 3* – ASU and CES with reserve market participation and budget parameter $\Gamma_t = 1 \; \forall t \in \overline{T}$; *Case 4* – ASU and CES with reserve market participation and budget parameter $\Gamma_t = 1$ for $t = [1,48]$, $\Gamma_t = 2$ for $t = [49,96]$, $\Gamma_t = 3$ for $t = [97,168]$. Case 3 and Case 4 differ in their levels of conservatism. While Case 3 represents a more realistic but maybe slightly risky uncertainty assumption, Case 4 is highly conservative and leads to very robust solutions.

Figure 2 shows the power consumption profiles for all four cases. One can observe that more power is consumed in an integrated ASU-CES plant, which indicates that the plant is utilizing more of its production capacity to benefit from the added CES capability.

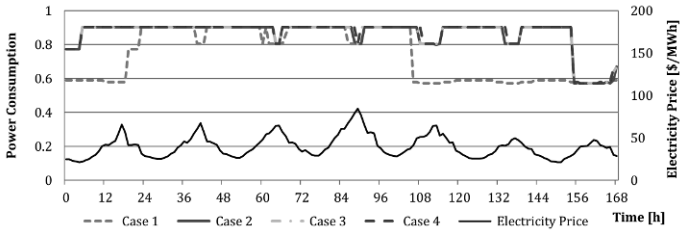

Figure 2: The power consumption profiles for the cases involving CES (Cases 2, 3, and 4) are almost identical, but differ significantly from the ASU-only Case 1.

The significant difference in the production schedules mainly stems from the handling of the produced GN2. In the ASU-only case, the GN2 production exceeds the GN2 demand by a considerable amount, of which a large portion is simply vented. As shown in Table 1, the ASU-CES plant liquefies a large amount of GN2 and uses it for energy storage instead of venting it. In this way, the amount of vented GN2 is reduced to up to 80 %.

Table 1: The normalized results from the four cases show the potential cost savings achieved by an integrated ASU-CES plant. Note that cost of purchasing products and driox cost are not listed.

	Case 1	**Case 2**	**Case 3**	**Case 4**
GN2 Vented	1	0.221	0.205	0.200
LN2 Produced	1	1.172	1.174	1.175
Electricity Cost	0.965	0.933	0.948	0.962
Revenue from Electricity Sales		0.027	0.022	0.018
Revenue from Providing Reserve			0.062	0.062
Total Net Operating Cost	1	0.935	0.894	0.911

The results given in Table 1 further show that by using power recovered from the CES to run the ASU or sell electricity to the grid, the total net operating cost can be reduced by 6.5 %. The cost

savings are even higher if we also participate in the reserve market, namely 10.6 % in Case 3 and 8.9 % in the more conservative Case 4. For Case 4, Figure 3 shows the flows into and out of the CES tank as well as the CES inventory profile resulting from the particular scenario in which no reserve power is dispatched. In each time period in which reserve capacity is provided, the CES inventory level ensures that the maximum amount of reserve can be dispatched. Since for the given budget parameter, maximum dispatch can occur up to three times, the final CES inventory level depicted here is not zero but instead three times as high as the provided reserve capacity.

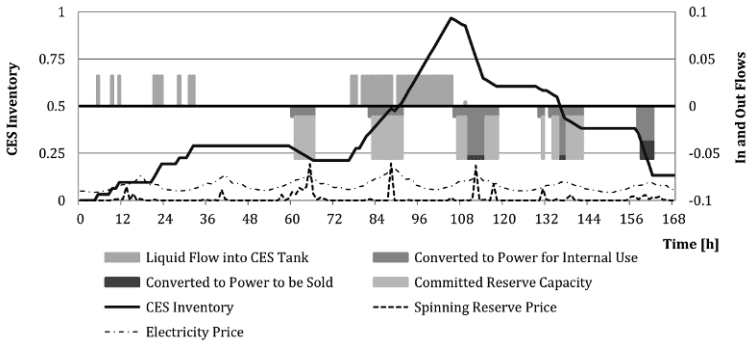

Figure 3: The CES inventory profile is shown for Case 4 for the scenario in which no reserve power is dispatched, resulting in a nonzero final CES inventory level.

5. Conclusions

This work has assessed at an operational level the economic benefits of adding a CES system to an existing cryogenic air separation plant. The proposed MILP scheduling model for an integrated ASU-CES plant incorporates the possibility of recovering energy from CES for internal use or for being sold to the electricity market. Using a robust optimization approach, this model has been further extended to consider uncertainty in operating reserve demand, which results in solutions that guarantee reserve dispatch feasibility under the committed reserve capacity. Furthermore, budget parameters are used to adjust the level of conservatism in the solution.

The proposed model has been applied to a real-world industrial case study. The results yield relative cost savings of approximately 10 % under relatively conservative uncertainty assumptions, which highlights the potential economic benefits of an integrated ASU-CES plant.

An Integrated Unit Commitment and Generation Expansion Planning Model

Nikolaos E. Koltsaklis[a], Michael C. Georgiadis[a,*]

[a]*Department of Chemical Engineering, Aristotle University of Thessaloniki, University Campus, Thessaloniki, 54124, Greece*
mgeorg@auth.gr

Abstract

This work presents a generic mixed integer linear programming (MILP) model that integrates the unit commitment problem (UCP) (daily energy planning) within the long-term generation expansion planning (GEP) framework. The model has been tested on an illustrative case study of the Greek power system. Our approach aims to provide useful insights into the strategic and challenging decisions to be determined by investors and/or policy makers at a national and/or regional level by providing the optimal energy roadmap according to specific assumptions and projections (e.g., electricity demand, fuel prices, and investment costs).

Keywords: Energy policy, Power sector, UCP, GEP, System marginal price.

1. Introduction

For decades, traditional long-term GEP models are based on simplifications with regard to operational costs and issues ignoring technical details such as start-up and shut-down related decisions, ramp rates and operating reserves. However, due to the intermittency and high fluctuations of rapidly penetrated renewable energy technologies (RES) (e.g., wind and solar), the net load required to be met by the hydrothermal power plants is characterized by higher uncertainty and has faster time dynamics (Palmintier and Webster, 2011). As a result, the incorporation of short-term decisions (UCP) into the long-term planning framework (GEP problem) can enhance the accuracy of the decisions to be made and guarantees power networks' stability. There are several works in the literature that have separately addressed the UCP (Simoglou et al., 2010, Marcovecchio et al., 2011) and the GEP problem (Koltsaklis et al., 2014, Cheng et al., 2015). A generic MILP model has been developed in this work integrating the UCP within the long-term GEP framework. Typical daily constraints at an hourly level such as start-up and shut-down related decisions, ramping limits, system reserves requirements are combined with representative yearly constraints such as power capacity additions, power generation bounds of each unit, peak reserve requirements, and energy policy issues (RES penetration limits, CO_2 emission cap). For modelling purposes, a representative day (24 hours) of each month over a number of years has been employed in order to determine the optimal capacity additions, system marginal prices (SMP), and daily operational planning of the studied power system.

2. Problem Statement and Mathematical Formulation

This work deals with the combined long-term GEP and UCP of a power system at a national and/or regional level. The problem under consideration is defined according to the following: The studied power system is divided into a number of sectors $s \in S$. Each

sector $s \in S$ is further divided into a set of zones $z \in Z$.The whole planning horizon is split into sets of years $y \in Y$, months $m \in M$, and hours $t \in T$. A set of power generating units $i \in I$ is available for the solution of the combined UCP and GEP problem. These units are further divided into hydrothermal $i \in I^{HT}$, thermal $i \in I^{TH}$, renewables $i \in I^{RES}$, existing $i \in I^{EX}$, and new units $i \in I^{NEW}$. A set of permissible power plants' start-up types $a \in A$ (hot, warm, and cold start-up) is taken into consideration for each hydrothermal power unit $i \in I^{HT}$. Power capacities of both hydrothermal plants and electricity imports interconnections $nc \in NC^{IMP}$, as well as exports interconnections $nc \in NC^{EXP}$, are split into a number of operational blocks $bl \in BL$ in order to represent more realistically their operational characteristics. The objective function to be optimized concerns the minimization of the total discounted cost for the development and operation of the power system, as described by Eq.(1).

$$\boldsymbol{Min\ Cost} = \overbrace{Fuel\ cost + Variable\ operating\ and\ maintenance\ cost + CO2\ emissions\ cost}^{Marginal\ cost} + \overbrace{Electricity\ imports\ cost\ - Electricity\ exports\ revenues}^{Net\ electricity\ trade\ cost} + \overbrace{Shut\ down\ cost + Start-up\ cost}^{Other\ operating\ costs} + Reserves\ provision\ cost + New\ units'\ capital\ cost + Fixed\ operating\ and\ maintenance\ cost\ of\ RES \quad (1)$$

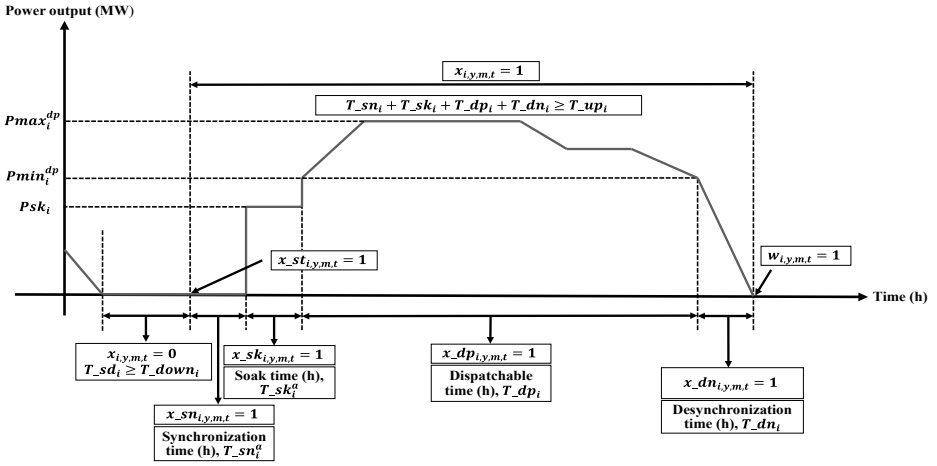

Figure 1. Operating stages of a hydrothermal unit in the UCP

All the possible operating modes of a hydrothermal unit $i \in I^{HT}$ in the UCP including start-up, synchronization, soak, desynchronization, as well as minimum up and down time constraints, are illustrated in Figure 1. More specifically: after being shut-down ($x_{i,y,m,t} = 0$) for T_sd_i hours (T_sd_i must be greater than or equal to the minimum down time of each unit $i \in I^{HT}$, T_down_i), and according to the amount of that time, T_sd_i, the unit $i \in I^{HT}$ starts-up ($x\_st_{i,y,m,t} = 1$). Note that a hydrothermal unit $i \in I^{HT}$ is able to start-up with only one start-up type $a \in A$ at each time period ($\sum_{a \in A} x\_st^a_{i,ym,t} = x\_st_{i,y,m,t} \leq 1$), depending on the value of T_sd_i. Once the appropriate start-up decision is taken ($x\_st^a_{i,ym,t} = x\_st_{i,y,m,t} = 1$ for a certain $a \in A$), the hydrothermal unit enters the synchronization operational stage ($x\_sn^a_{i,ym,t} = x\_sn_{i,y,m,t} = 1$ for a certain $a \in A$) having a duration of $T\_sn_i^a$ hours. Note that the

power output of each unit during the synchronization phase is zero. After completing the synchronization stage, the unit $i \in I^{HT}$ enters the soak operating stage ($x\_sk^{a}_{i,ym,t} = x\_sk_{i,y,m,t} = 1$ for a specific $a \in A$), having a duration of $T\_sk_i^a$ hours and during which unit's power output equals a fixed value, Psk_i. The next operational stage of each unit $i \in I^{HT}$ is that of dispatchable stage ($x\_dp_{i,y,m,t} = 1$), with a duration of T_dp_i hours and during which unit's power output is able to range from its technical minimum, $Pmin_i^{dp}$, to its maximum, $Pmax_i^{dp}$, subject to technical up and down ramp rates (RR_up_i and RR_down_i correspondingly) contributing to the power demand satisfaction, $Dem_{s,y,m,t}$, and to reserve requirements, if selected. Finally, the last possible operational stage of a unit $i \in I^{HT}$ is that of desynchronization, having a duration of T_dn_i hours. During that stage ($x\_dn_{i,y,m,t} = 1$), unit's power output decreases with a particular power sequence. Note that a shut-down decision ($w_{i,y,m,t} = 1$) cannot be taken unless $T\_sn_i + T\_sk_i + T\_dp_i + T\_dn_i \geq T\_up_i$, i.e., unit $i \in I^{HT}$ remains operational during hour $t \in T$ if it has started-up the previous ($T\_up_i - 1$) hours. Constraints (2) ensure that unit $i \in I^{HT}$ can only be at one of the possible operating states when committed. Constraints (3) and (4) model the start-up ($x\_st_{i,y,m,t}$) and shut-down ($w_{i,y,m,t}$) decision of each unit $i \in I^{HT}$ during each time period. Constraints (5) correlate design and operational decisions, i.e., a unit $i \in I^{NEW}$ is not operationally available unless the decision for its construction has been taken ($cn_{i,y} = 1$) and its installation has been completed, requiring T_con_i years. Constraints (6)-(8) specify the power output limits of each unit $i \in I^{HT}$ in each operating stage. The first three terms on the right-hand side of these constraints define unit's power output during synchronization, soak and desynchronization phases. Non-negative continuous variables $r1^{up}_{i,y,m,t}$, $r2^{up}_{i,y,m,t}$, $r2^{down}_{i,y,m,t}$, $r3^{sp}_{i,y,m,t}$ represent the contribution of each unit $i \in I^{HT}$ in primary-up, secondary-up, secondary-down, and tertiary spinning reserve type in each time period. Binary variable $x\_sc_{i,y,m,t}$ denotes if the unit $i \in I^{HT}$ contributes or not to secondary reserve in each time period. Constraints (9) and (10) describe the ramp-up and ramp-down limits of each unit $i \in I^{HT}$. Parameter RR_sec_i represents the ramp rates of each unit $i \in I^{HT}$ when providing secondary reserve ($x\_sc_{i,y,m,t} = 1$). Moreover, equations (11) describe the demand balance of the power system. More specifically, net power injection from all the installed power units ($\sum_{i \in I^s} p\_inj_{i,y,m,t}$) plus net electricity flow rates ($\sum_{s' \in S^s} cf_{s',s,y,m,t} - \sum_{s' \in S^s} cf_{s,s',y,m,t}$) and net electricity imports ($\sum_{nc \in NC^s} im\_inj_{nc,y,m,t} - \sum_{nc \in NC^s} exp_{nc,y,m,t}$) to each sector, must be equal to the sector's electricity demand $Dem_{s,y,m,t}$. Other UCP related model constraints concern: (i) reserve upper and lower bounds (primary-up, secondary-up and down, tertiary spinning and non-spinning reserves), (ii) hourly power output constraints taking into account capacity and zonal availability factors for thermal and RES units correspondingly, (iii) diversification of power output into fixed (non-priced) component including RES power injection, mandatory hydro injection and power injection from units being under commissioning status, and that of priced component based on the energy offer per power capacity block of each unit, and (iv) power system's requirements for all reserve types. An additional series of constraints concerns the GEP decisions. Constraints (12) and (13) define the additional capacity limits. Non-negative continuous variable $nc_{i,y}$ represents the newly-built capacity of unit $i \in I^{NEW}$ in year $y \in Y$ being available for the first time after T_con_i years from the decision taken for its construction ($cn_{i,y} = 1$). Parameter $IC_{i,y}$ represents the installed capacity of unit $i \in I^{EX}$ in year $y \in Y$. Other GEP related constraints of the model refer to: (i) reserve margin constraints, i.e., the

installed capacity being available in each time period plus the available imports must be adequate enough to meet the projected load plus an allowance above that level for security reasons, (ii) annual generation bounds of each unit and annual bounds on imports and exports, (iii) maximum allowable RES penetration rates, (iv) annual RES penetration targets in the power mix, and (v) maximum allowable bound of CO_2 emissions produced by all units.

$$x_{i,y,m,t} = x\_sn_{i,y,m,t} + x\_sk_{i,y,m,t} + x\_dp_{i,y,m,t} + x\_dn_{i,y,m,t} \quad \forall\, i \in I^{HT}, y \in Y, m \in M, t \in T \tag{2}$$

$$x\_st_{i,y,m,t} - w_{i,y,m,t} = x_{i,y,m,t} - x_{i,y,m,t-1} \quad \forall\, i \in I^{HT}, y \in Y, m \in M, t \in T \tag{3}$$

$$x\_st_{i,y,m,t} + w_{i,y,m,t} \leq 1 \quad \forall\, i \in I^{HT}, y \in Y, m \in M, t \in T \tag{4}$$

$$x_{i,y,m,t} \leq \sum_{y' \leq y} cn_{i,y'-T\_con_i} \quad \forall i \in I^{NEW}, y \in Y, m \in M, t \in T \tag{5}$$

$$p_{i,y,m,t} - r2^{down}_{i,y,m,t} \geq 0 \cdot x\_sn_{i,y,m,t} + p\_sk_{i,y,m,t} + p\_dn_{i,y,m,t} +$$

$$\sum_{s' \in S^s} cf_{s,s',y,m,t} + \sum_{nc \in NC^s} exp_{nc,y,m,t} + Dem_{s,y,m,t} \quad \forall\, s \in S, y \in Y, m \in M, t \in T \tag{11}$$

$$nc_{i,y+T\_con_i} = Pmax_i^{dp} \cdot cn_{i,y} \quad \forall\, i \in I^{NEW}, y \in Y \tag{12}$$

$$c_{i,y} = IC_{i,y} + \sum_{y' \leq y} nc_{i,y'} \quad \forall\, i \in I, y \in Y \tag{13}$$

3. Case study description

The proposed model has been tested on the Greek power system having a total installed capacity of 16,192 MW, of which lignite accounts for 27 % of the total, natural gas makes up 26.3 %, hydro has a share of 19.8 % and followed by photovoltaics (PV) with 15 %, wind with 9.5 %, and other RES with 2.5 %. The examined period is that between

2014 and 2020. The candidate units for installation include new lignite, coal, natural gas, wind, and PV units. Typical marginal costs for lignite units range from 36 to 58 €/MWh, depending on each unit's power capacity block, time period (due to different fuel and carbon price evolution), as well as on the characteristics of each unit (e.g., age). The corresponding ones for natural gas units vary from 66 to 96 €/MWh, and for candidate coal units between 36 and 43 €/MWh. RES power generation and mandatory hydro injection (based on detailed estimations of their availability factors in each zone, month, and hour) have zero cost. Regarding electricity demand, an annual increase of 1 % is assumed, from 51.5 to 54.7 TWh. A gradual decrease in RES investment cost is also assumed, reflecting the fact that they gradually constitute mature technologies.

4. Results and Discussion

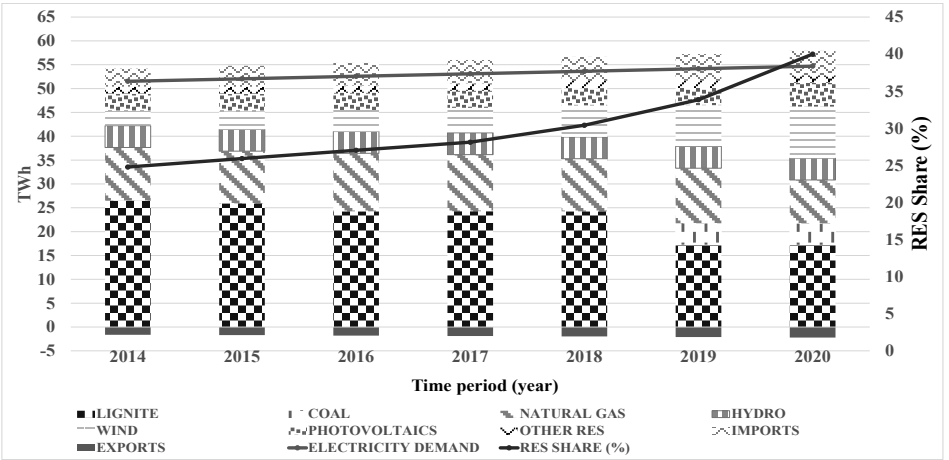

Figure 2. Power generation mix (TWh) and RES share (%) in each time period (year)

As depicted in Figure 2, the results indicate a decrease of 35 % in the projected lignite-fired power generation between 2014 and 2020. This is due to the fact that a significant proportion of them constitute old power stations and as a consequence, they have lost part of their relative competitiveness. In addition, the incorporation of energy policy measures in the mathematical model, i.e., 40 % of the electricity demand should be met by RES by 2020, and the introduction of a CO2 emission cap, contributes also to the gradual decrease of the lignite-fired electricity production. It is also worth mentioning that part of the lost thermal power generation (in favor of RES) is replaced by the installation of a new advanced coal unit, and thus, total thermal power generation (lignite and coal) decreases only by 18 % between 2014 and 2020, from 26.5 to 21.7 TWh. Natural gas production is relatively constant during the whole planning horizon with a small decrease in 2020 due to the high penetration of wind turbines to reach the 2020 RES target. The marked impact of energy policy measures is reflected in the total RES power generation, rising by 71.4 % between 2014 and 2020, from 12.7 TWh to 21.9 TWh. Wind turbines play the dominant role in that evolution accounting for 49.4 % of the total RES generation in 2020 and followed by PVs with 22.8 %, hydro with 20.8 %, and other RES (biomass, small hydro, etc.) with 6.9 %. An increasing trend is also observed in both imports and exports providing more flexibility to the power demand satisfaction. In total, 3400 MW of wind turbines and 857 MW of PV enter the system, the majority of which (1857.1 MW) in 2020 to reach the 2020 RES target, as shown in Table 1. A new coal unit is also installed in 2019 to support thermal power

generation. With regard to SMP (price to be paid to all electricity producers), the results highlight a gradual fall in its value, from 57.64 €/MWh in 2014 to 42.28 €/MWh in 2020 (a decrease of 26.7 %). This fall in SMP (annual weighted average value) can be mainly attributed to the fact that a continuously increasing share of power demand is satisfied from RES (zero marginal cost and their contribution is mandatory), and the introduction of the relatively low marginal cost coal unit into the system, since it comprises the marginal unit for several hours of its operation.

Table 1. SMP evolution (€/MWh) and capacity additions per technology, zone and year (MW)

	2014	2015	2016	2017	2018	2019	2020
New_Coal_Zone_3	-	-	-	-	-	600	-
WIND_Zone1	-	-	-	-	-	300	300
WIND_Zone2	-	-	-	-	300	300	300
WIND_Zone3	-	300	300	300	300	300	300
WIND_Zone4	-	-	-	-	-	-	100
PV_Zone3	-	-	-	-	-	-	257.1
PV_Zone4	-	-	-	-	-	-	300
PV_Zone5	-	-	-	-	-	-	300
System Marginal Price	57.64	56.75	54	51.06	48.1	45.99	42.28

5. Conclusions

An integrated GEP and UCP model has been developed in this work. The planning framework has been extended up to hourly level to better reflect the operational characteristics of thermal units along with the fluctuations arising from the intermittent nature and rapid penetration of RES into the system. The model outputs include optimal investment plan of the power sector and the SMP development. The applicability of the model has been tested on the Greek power system illustrating the impacts that energy policy measures have on the development path of the country's power system.

Abstract

This work investigates the possibility of off-grid energy generation and storage for large scale continuous processes located in remote areas, such as mines. In this paper, a superstructure containing two solar energy generation alternatives (Solar panels and Central receiver system) and three energy storage alternatives is optimized to meet the hourly electrical and thermal demands of a Chile-based mine. A cost-based MINLP formulation for energy generation, storage and supply is developed from first principles and implemented in GAMS. The model determines the optimal configuration of the superstructure and design capacities of the selected alternatives. The daily and seasonal behaviour of the selected storage alternatives are also discussed.

Keywords: Energy Storage, Mining, MINLP, Systems Modelling

1. Introduction

The mining industry accounts for a significant portion of industrial energy demand. The rising demand for metals around the world, coupled with the depletion of readily accessible ore deposits, has led to mining operations moving to more remote locations. Mining operations located in remote regions face significant energy problems, since grid electricity is not usually available. Such mines typically resort to the use of diesel generators, leading to a significant increase in emissions and overall mining cost. These challenges, along with the ever-rising fossil fuel costs, have driven mining operations to seek alternative sources of energy. Renewable energy is considered to be the most promising solution to the mining industry energy problem due to the low operating cost of renewable systems and the possibility of earning tax credits (Paraszczak and Fytas, 2012). However, problems of variability and reliability have limited its use in large-scale operations.

Energy storage may enhance the viability of renewable energy generation systems. Integration of storage alternatives, such as batteries and pumped hydro systems, with renewable energy sources has been considered (Yang et al., 2009; Ma et al., 2014). However, most of the focus has been on the integration of single storage options into small-scale hybrid grid-PV-wind systems. Little consideration has been given to the integration of multiple storage systems, particularly for large-scale off-grid continuous operations. This work investigates the possibility of operating remote mines using renewable energy with a variety of energy storage schemes. A model which determines the cost-optimal energy system design for mining processes is presented. The daily and seasonal behaviours of the selected generation and storage alternatives are investigated. The novel combination of generation and storage alternatives presented in this work allows for the exploration of energy system designs best suited to large scale continuous operations.

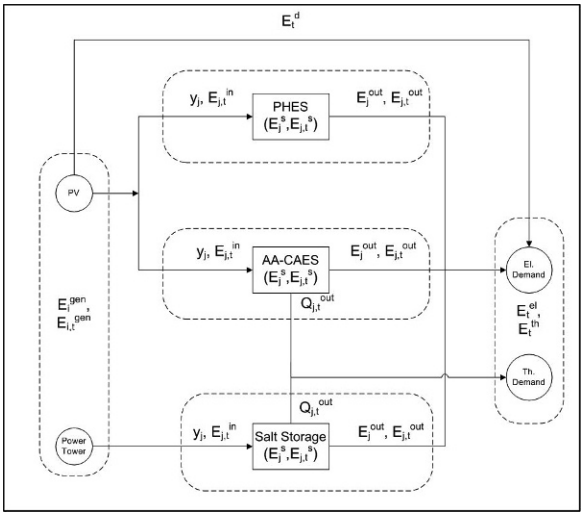

Figure 1: Superstructure for off-grid energy supply for a mine

2. Problem Statement

An off-grid plant located in a remote region with abundant solar radiation for most of the year is considered. Two solar energy collection options are available: electricity generation via photovoltaic cells and thermal energy collection in a molten salt via solar towers (concentrated solar power). Three energy storage alternatives are available. Two for electrical energy (Pumped Hydraulic Energy Storage [PHES] and Advanced Adiabatic Compressed Air Storage [AA-CAES]), while the third stores thermal energy (molten salt storage). Heated molten salt may be used for electricity generation through heating of steam for a turbine.

Figure 1 shows a schematic representation of the superstructure. In the superstructure, i represents the available energy generation options (PV =1; solar tower = 2), j the storage/delivery options (PHES =1; AA-CAES =2; salt storage = 3), while t is an index into discrete time periods of duration Δt, $t > 0$. y_j is a binary variable which determines whether a storage option within the superstructure is selected. $E_{i,t}^{gen}$ refers to the amount of energy generated by unit during time period t; E_t^d is the electrical energy generated by the panels sent directly to the process after DC/AC conversion; $E_{j,t}^{in}$ refers to the energy sent to storage option j; $E_{j,t}^s$ refers to the energy stored; $E_{j,t}^{out}$ refers to the electricity supplied delivered from a storage option; and $Q_{j,t}^{out}$ refers to the heat taken out of a storage unit to meet heat demands.

Given the hourly thermal and electrical demands of the plant (E_t^{th}, E_t^{el}), the total daily solar radiation for the plant location (H_d), and efficiencies for all mechanical units (compressors, turbines, motors, generators and pumps), we choose the optimal capacities of the energy generation units (E_i^{gen}), storage units (E_j^s) and delivery units (E_j^{out}) required to meet the given demands so as to minimize the overall capital cost, CC, of the energy system:

$$CC = \sum_{i=1}^{2} U_i^{gen} E_i^{gen} + \sum_{j=1}^{3} y_j \left(U_j^s E_j^s + U_j^{out} E_j^{out} \right) \tag{1}$$

where U_i^{gen}, U_j^s, and U_j^{out} are the unit costs of generation, storage and electricity supply respectively. The model is subject to generation, storage and process demand constraints as detailed

in the next section. The total energy supplied to the process must meet the process demands at all times. The electrical demands may be met by any storage method or directly from the solar panels, while the thermal demands are met from either the AA-CAES or molten salt systems. The capacities of the generation (delivery) units are calculated from the maximum amount of electricity generated (supplied) by the unit over the time period. The solution of the model provides energy generation ($E^{gen}_{i,t}$), storage ($E^{s}_{j,t}$) and delivery ($E^{out}_{j,t}$) profiles for all active units within the optimized superstructure.

3. Energy system models

The differential equations describing material and energy balances around the generation and storage units were discretized using Euler's method which is suitable due to the slow dynamics expected. Data from literature were used for properties which are not easily modelled, such as the mechanical efficiencies of units. The hourly global radiation (G^{tot}_t) was estimated from the total daily solar radiation using the CPRG model (Gueymard, 2000). The hourly direct normal radiation intercepted by the power tower (G^{DNI}_t) was estimated as outlined in Duffie and Beckman (2013).

3.1. Generation Models

The electricity generated in a time interval from the PV array is

$$E^{gen}_{1,t} = \eta_{1,t}\eta^{inv}G^{tot}_t A_{panel} \qquad t \geq 0 \tag{2}$$

where $\eta_{i,t}$ and η^{inv} are PV and inverter efficiencies (Evans, 1981) and A_{panel} is the total area $[m^2]$ of PV installed. Thermal energy from the power tower heats molten salt flowing through a collector:

$$E^{gen}_{2,t} = E^{in}_{3,t} = \left(\alpha\eta_{hel}A_c G^{DNI}_t\right) - Q^{conv}_t - Q^{rad}_t \qquad t \geq 0 \tag{3}$$

where Q^{conv}_t and Q^{rad}_t are the convective and radiative heat losses from the receiver [Wh]; A_c is the total collector area $[m^2]$; α is the heliostat absorptivity; and η_{hel} the heliostat efficiency.

3.2. Storage Models

For the PHES system, a material balance was carried out around the reservoir. The energy accumulated within the PHES system is given by the potential energy equation $E^{s}_{1,t} = \rho V_{1,t} g H$. Mechanical losses from the turbine and pump were incorporated as efficiencies.

The AA-CAES system stores energy in two forms: potential energy as high pressure air and thermal energy. The model incorporates two-stage compression and expansion with inter-stage cooling and heating during the charging and discharging phases and is based on a material balance around the cavern and an energy balance around the heat store. For a given stored mass of air, $m^{s}_{2,t}$, the energy accumulated within the system is estimated as:

$$E^{s}_{2,t} = m^{s}_{2,t} R_a \sum_{N} \Delta T^{tur}_t \qquad t \geq 0 \tag{4}$$

where N is the number of expansion turbines, R_a the specific gas constant for air (287 J kg^{-1} K^{-1}), and ΔT^{tur}_t is the difference in inlet and outlet operating temperatures of the turbines [K]. Expressions for the mechanical losses incurred during the air compression (compressor and motor losses) and expansion (turbine and generator losses) stages, as well as thermal losses from the thermal energy store (TES), were incorporated in the model.

In the molten salt system, energy is stored in the form of sensible heat. Enthalpy balances were carried out around the storage tanks, with the heat loss term accounting for both temperature and fill level. The minimum capacities of the storage units may be estimated from the maximum energies accumulated within them over the entire time period. The system is constrained to operate between the salt solidification and decomposition temperatures as given in Zaversky et al. (2013).

Steady state is enforced by ensuring that the initial and final states of the storage systems are the same. For PHES, the state is defined by the stored mass. For the AA-CAES and molten salt systems, the state is defined by both the mass and temperatures within the system.

4. Case Study

The case study considers the demands of Collahuasi mine, located in Chile, investigating both steady-state daily and seasonal behaviours. For the daily storage, we model two consecutive days in July. The seasonal storage considers four days, each representative of a season. Historical climate data is summarised in Table 1. The electrical data used correspond to data for power consumption for the mine in July 2013 as recorded by the Chilean electrical supply authorities (CDEC-SING, 2014). The hourly electrical demand varies between 163.9 and 177.4 MWh, with slightly higher energy demands during the day. Thermal demands are assumed to be 10 % of the electrical demands (Pellegrino et al., 2004).

For the PHES system, the reservoir height was set at 700 m (Deane et al., 2010), while the pump and turbine efficiencies are set based on Barnes and Levine (2011). The mechanical efficiencies of units within the AA-CAES system were set based on data from Hartmann et al. (2012). An insulated concrete block was selected as the TES, with thermal oil selected as the heat transfer fluid due to the operating temperature range of the TES (Laing et al., 2009). The heliostat efficiency and absorptivity were obtained from Li et al. (2010). The efficiency of the power block of the molten salt system was based on Garcia et al. (2011).

The proposed daily model, containing 5,684 variables and 8,570 equations, was implemented on GAMS 24.2 (GAMS, 2013) and solved using Baron 12.7.3 (Tawarmalani and Sahinidis, 2005). For an optimality gap of 1%, a solution was obtained after 19 minutes and is shown in Table 2. The AA-CAES system is not selected. Electricity is supplied by the PHES when solar irradiation is unavailable and the molten salt system is used for thermal demands. The unit costs for PHES and AA-CAES are similar but the latter incurs larger mechanical and thermal losses. The low efficiency of thermal-to-electrical energy conversion in the power block (approx. 40 %) makes the molten salt system less favourable for electricity generation. The comparably lower unit costs and higher storage efficiency of the molten salt system drive its choice over AA-CAES for thermal energy supply. Accounting for the turbine efficiency, the PHES system can supply almost 2500 MWh of electricity when fully charged, translating to 14 h of electricity at maximum capacity.

Figure 2 shows the behaviour of the PHES system. The plant operates in two distinct phases: charging and discharging. The charging phase lasts for 9 hours, during which direct supply of electricity from the PV system occurs. The pumping capacity is approximately three times the discharge capacity. As expected, the behaviour of the plant is cyclic (Figure 3). For the molten salt system, the partial charging phase lasts 9 h and the discharge phase for 13 h. The maximum

Table 1: Solar Availability Data (Departamento de Geofísica de la Universidad de Chile, 2012)

	Summer	Autumn	Winter	Spring
Representative day	Jan 15	April 15	July 15	October 15
H_d(MJ.m^{-2} per day)	32.40	23.04	18.36	31.32

Table 2: Optimal Solution for Daily Storage

	Unit	Description
Generation	PV System	776.74 MW_e capacity; 9,498,100 m^2 panels
	Power Tower	46.59 MW_{th} capacity; 79,457 m^2 collectors
Storage	PHES	2,729.77 MWh storage; 174.50 MW_e capacity
	Tank Storage	222.97 MWh storage,17.80 MW_{th} capacity

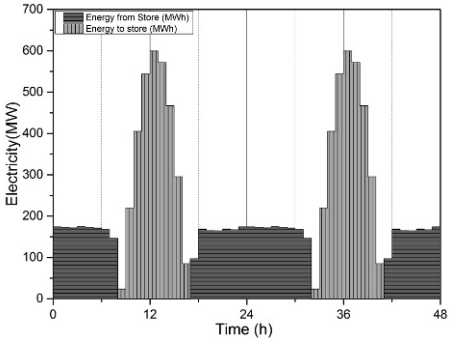

Figure 2: Daily PHES Behaviour

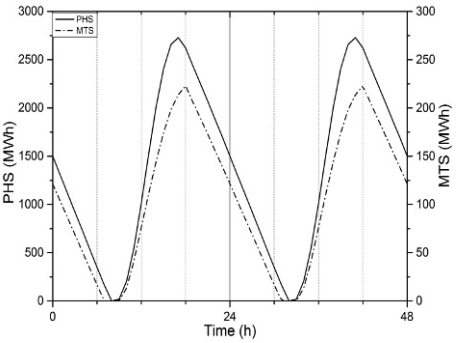

Figure 3: Energy Accumulation Profiles

heat loss from the thermal store (hot tank) is 115 kWh, representing 0.05% of the stored energy.

The seasonal model, with 17,987 equations and 10,617 variables, had a solution time of 188 minutes. Figure 5 shows the effect of seasonal solar radiation variability. The capacities of the generation and storage systems are determined by the season with the lowest solar availability (winter). The total energy generated to meet the demands for each season decreases with increasing solar radiation. Most of the process demands are met directly with PV generation for seasons with higher solar radiation (Table 3), with solar radiation available for longer periods. As a result, less electricity needs to be generated since storage losses are incurred less often. The fraction of the storage capacity required varies from 12 h during summer to 14 h during winter. The annual efficiencies of the storage systems, defined as the ratio of total output to input energy for each storage system, were estimated to be 0.764 and 0.993 for the PHES and molten salt systems respectively.

5. Conclusion

This work demonstrates the systems integration of renewable energy generation and storage techniques for off-grid continuous operations and highlights the importance of storage. The fundamental principles are applicable to other renewable energy resources. One current limitation is that daily variability, beyond the seasonal changes, of solar irradiation has not been considered.

Table 3: Analysis of Seasonal Behaviour of Electrical system

	Summer	Autumn	Winter	Spring
Total Generation (MWh)	4764.26	4832.71	4858.72	4797.05
Fraction of daily electrical demand met from Storage	0.52	0.58	0.60	0.54

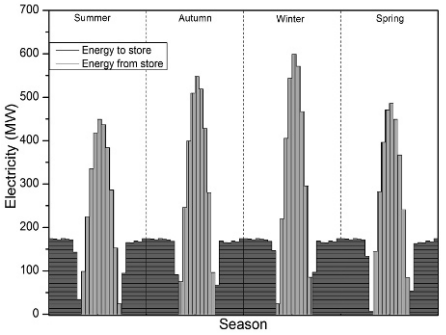

Figure 4: Seasonal PHES Behaviour

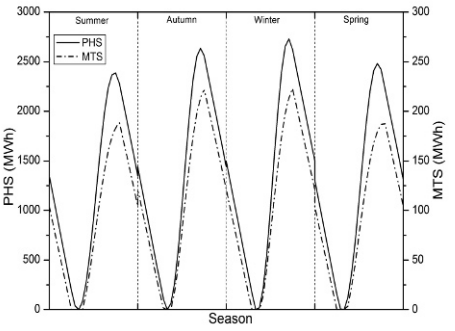

Figure 5: Seasonal Accumulation Profiles

One possible solution to the challenge which is currently being explored is the representation of renewables input with probability distribution functions generated from historical solar radiation data. A stochastic approach to renewables modelling would account for variability in the prediction of the optimal design and extend the applicability of the work, particularly to wind power.

Energy assessment of different configurations for the ethanol production process from lignocellulosic biomass

Cristian F. Triana, Eric S. Fraga and Eva Sorensen
Centre for Process Systems Engineering, Department of Chemical Engineering, UCL, Torrington Place, London WC1E 7JE, UK

Abstract

This work presents an evaluation of the energy requirements for the production of ethanol from corn stover for three different arrangements of the separation stage. The first configuration comprises two distillation columns and a hydrophilic membrane system. The second configuration considers a novel organophlic membrane system, one distillation column and a hydrophilic membrane system. The third approach is similar to the second, but includes a recycle of the retentate stream from the organophilic membrane system to the fermentation reactor to further the production of ethanol. For each arrangement, the overall energy demand is evaluated in order to identify the optimal heat source distribution within the process. The results show that the inclusion of the organophilic membrane system reduces the overall energy consumption significantly and also represents a reduction in the size of the plant. Recycling the retentate from the organophilic membrane increases the conversion of substrate into ethanol during the fermentation and thereby reduces the overall energy demand by reducing the energy consumption in the distillation column.

Keywords: Bioethanol, lignocellulosic, energy, membrane, distillation

1. Introduction

The production of biofuels has increased significantly in the last decades as a growing world population is demanding more energy. In countries like Brazil and the US, the production of ethanol from sugar cane bagasse and corn has been implemented into the main market of fuels resulting in an attractive option for industrial applications with low emissions of "greenhouse" gases (Karlsson et al., 2014).

However, one of the main challenges of the production of ethanol from lignocellulosic biomass is the high energy requirements leading to high operating costs. The main energy requirement is usually related to the recovery of ethanol in the separation section. Current research is focusing on the development of new technologies that allow a reduction in the energy demand in some of the separation units of the process (Triana et al., 2011; Roth et al., 2013).

Hybrid separation processes, consisting of a membrane-based system coupled with a conventional separation method, have emerged as an alternative technique to traditional separation by distillation, with high separation rates and lower energy consumption (Kreis and Górak, 2013). The separation of an ethanol/water mixture by distillation is restricted by the presence of an azeotrope. High levels of energy are required in order to achieve high concentrations of ethanol close to the azeotropic point (Fan et al., 2013).

Membrane-based operations, such as pervaporation, can dehydrate the ethanol/water mixture beyond the azeotropic concentration (Koch and Górak, 2014). This work presents three different configurations of the separation stage of the production of ethanol from corn stover. The overall energy demand for each configuration is considered, and an optimal distribution of the energy sources within the process is proposed.

2. Process description

The ethanol production process consists of four main stages:

- **Pretreatment:** The lignocellulosic material, which mainly consists of cellulose hemicellulose and lignin, is treated with dilute acid at high temperatures and pressure to degrade the lignin and to convert the hemicellulose into xylose and by-products (e.g furfural, HMF and organic acids) (Esteghlalian et al., 1997; Nigam et al., 2011).
- **Overliming:** The liquid fraction from the pretreatment stage is treated with $Ca(OH)_2$ to reduce the concentration of the by-products produced during the pretreatment that can diminish the performance of the fermenting microorganisms (Purwadi et al., 2004; Nigam et al., 2011).
- **Simultaneous saccharification and co-fermentation (SSCF):** Cellulose, which did not react in the pretreatment stage, is treated with cellulases to produce glucose and cellobiose through enzymatic hydrolysis (Moreno et al., 2013). Glucose and cellobiose, along with the xylose obtained during the pretreatment stage, are converted into ethanol and other by-products (acetic acid, CO_2, etc.). In this work, the simultaneous saccharification and co-fermentation (SSCF) using *Zymomonas mobilis ZM4(pZB5)* is considered (Morales-Rodriguez et al., 2011).
- **Separation:** Distillation is one of the most commonly used separation methods to purify ethanol produced via fermentation. The maximum concentration of ethanol achievable by this technique is 93% w/w (concentration of the minimum-boiling-point azeotrope). The separation can also be achieved using membranes, for instance, as in this work by using an novel organophilic membrane system with which ethanol is removed from the fermentation broth in the permeate (Koch and Górak, 2014), before a distillation column followed by a hydrophilic membrane system after the column which allows the dehydration of ethanol up to biofuel standard concentrations (>99% wt.) (Gaykawad et al., 2013).

3. Process alternatives

The ethanol production process considered in this work comprises two main sections, a fed-batch section and a continuous section.

3.1. Fed-Batch section

The fed-batch section consists of the pretreatment reactor, an evaporator, the overliming reactor, a mixing tank and the SSCF reactor. The pretreatment reactor is fed with the raw material until reaching the required operating volume. Once the reaction has finished, the content of the reactor is transferred to the evaporator where the concentration of reducing sugars is increased. The concentrated hydrolysates from the evaporation are treated with $Ca(OH)_2$ in the overliming reactor to degrade residual by-products from the pretreatment. The solid fraction of the pretreatment reactor, and the

detoxified hydrolysates from the overliming reactor, are mixed and sent to the SSCF stage where the reducing sugars are converted into ethanol. The output from the SSCF unit is collected in a storage tank. As soon as the material has left the pretreatment reactor, a second batch is started etc, and each batch is collected in the storage tank. The storage tank acts as the feed tank to the next main section, the separation section, which is operated continuously.

3.2. Continuous section

The continuous section comprises distillation columns and the pervaporation modules. The storage tank is the link between the fed-batch section and the continuous section as it collects the ethanol produced during the fermentation and constantly feeds the separation units. Three different configurations of the continuous section are considered in this work and are described as follows:

- **Configuration 1:** This configuration (see Figure 1) consists of two distillation columns and a pervaporation system with a hydrophilic membrane (in this work a PAN-B5 membrane) that dehydrates ethanol beyond the azeotropic point. This configuration is the most commonly used in industry (Morales-Rodriguez et al., 2011).
- **Configuration 2:** Using the same fed-batch section as Configuration 1, this arrangement introduces a new set of pervaporation modules before the distillation column. The new pervaporation system includes an organophilic membrane (in this work a PERVAP 4060 membrane). Ethanol is removed in the permeate stream and fed to the distillation column (see Figure 2).
- **Configuration 3:** The pervaporation system with the organophilic membrane becomes part of the fed-batch process as it removes the ethanol from the fermentation broth and recycles the unreacted substrate back to the SSCF reactor. This configuration increases the conversion of all the available substrate in the process and the overall amount of ethanol produced during the fermentation (see Figure 3).

4. Results

The mass and energy balances and other equations used in this work are solved using the commercial software gPROMS (PSE, 2014). As mentioned in Section 3, each configuration is divided into two main subsections: the fed-batch section and the continuous section. The batch section in every configuration runs three times in order to keep the storage tank full so it can keep on supplying the continuous section. Figures 1 to 3 show the flowsheet of each configuration and the concentration of ethanol throughout the process.

Figure 4 presents the minimum heat duty in the reboiler as a function of the number of trays. In the case of configuration 1, the energy requirement is the sum of the heat duties of both columns, assuming that both columns have the same number of trays. As shown in Figure 4, the energy requirement in the reboiler decreases with the number of trays in the column. For configuration 1, the minimum number of trays required is taken to be 10 for each column. For configurations 2 and 3 the minimum number of trays in the single column is taken to be 14 trays.

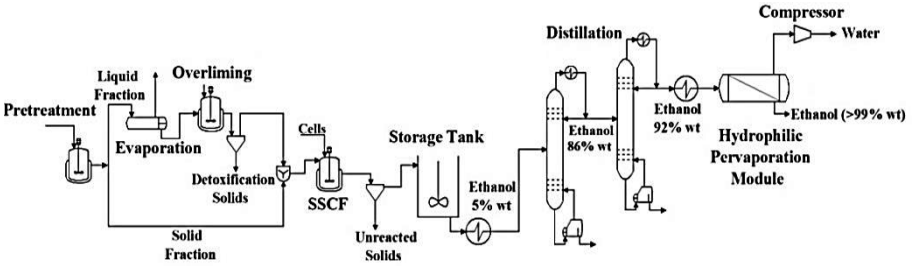

Figure 1: Configuration 1 with two distillation columns followed by a hydrophilic pervaporation system

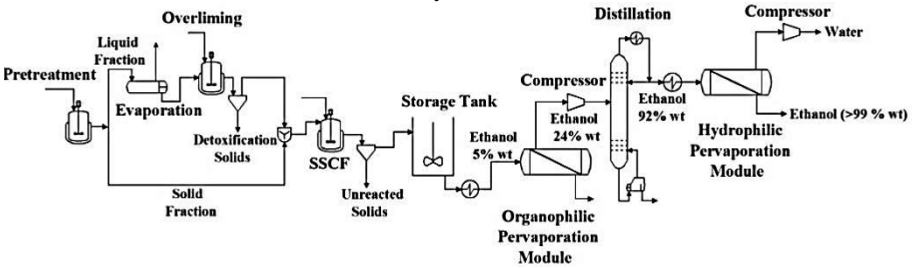

Figure 2: Configuration 2 with an organophilic system followed by one distillation column and a hydrophilic pervaporation system

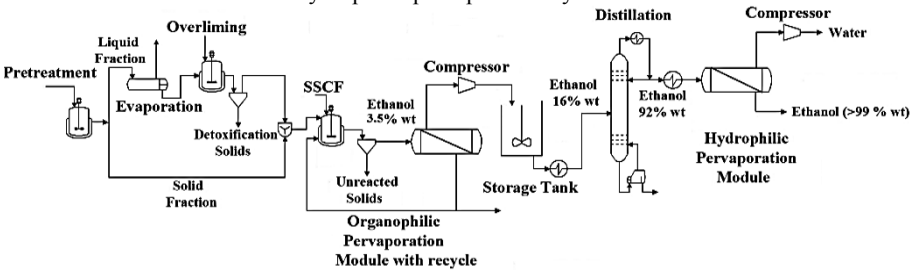

Figure 3: Configuration 3 with an organophilic system followed by one distillation column and a hydrophilic pervaporation system and with recycle of the retentate to the SSCF reactor

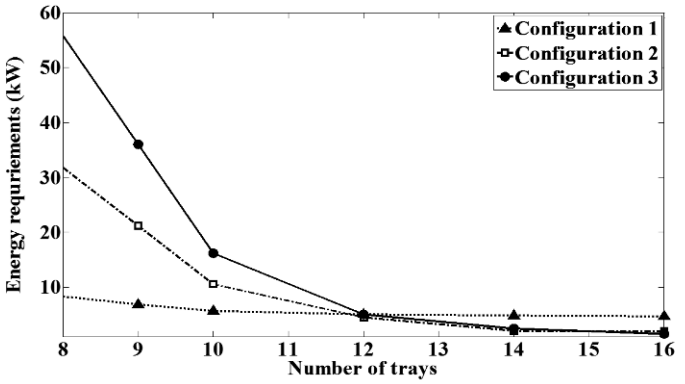

Figure 4: Minimum heat duty in the reboiler as a function of the number of trays

The area for the organophilic membrane module is determined as the area required to obtain a concentration of ethanol in the retentate $W_{Ethanol} < 0.001$. For the hydrophilic membrane system, the required area is calculated for a concentration of water in the retentate $W_{Water} < 0.001$. Table 1 summarises the parameters used in the simulation

for an annual production of 15 million litres. For the reactors, the parameters are taken from literature. For the distillation columns and the membrane systems, the parameters are obtained via optimisation using gPROMS. For the distillation columns, the optimisation consists of finding the reflux ratio that minimises the heat duty in the reboiler(s). For the membrane systems, the optimisation consists of finding the area that minimises the concentration of ethanol (in the organophilic membrane) and water (in the hydrophilic membrane) on the retentate side.

Table 1: Parameters used in the simulation of the ethanol production process from lignocellulosic biomass for three different configurations

	Configuration 1	**Configuration 2**	**Configuration 3**
Pretreatment	Acid concentration: 10% wt ; Raw material/acid solution ratio : 1:10 Temperature: 120 ^{0}C; Reaction time: 30 minutes (Esteghlalian et al., 1997; Nigam et al., 2011).		
Overliming	Acid hydrolysates are treated with $Ca(OH)_2$ for 80 minutes at 30 ^{0}C (Purwadi et al., 2004).		
SSCF	Enzymes concentration: 45 g/g of substrate; *Z. mobilis* concentration: 2.5 g/L; Temperature: 50 ^{0}C; Reaction time: 36 hours (Morales-Rodriguez et al., 2011)		
Organophilic membrane	-	Permeate pressure: 4 mbar Temperature: 50 ^{0}C Area: 3950 m^2	Permeate pressure: 4 mbar Temperature: 50 ^{0}C Area: 4100 m^2
Distillation col. 1	Reflux ratio: 3.7 Number of stages:10 Feed stage: 5	Reflux ratio: 6.3 Number of stages:14 Feed stage: 7	Reflux ratio: 8 Number of stages:14 Feed stage: 7
Distillation col. 2	Reflux ratio: 1.3 Number of stages:10 Feed stage: 5	-	-
Hydrophilic membrane	Permeate pressure: 1 mbar, Temperature: 70 ^{0}C, Area: 600 m^2		

Figure 5 shows the evaluation of the energy consumption of the whole process for each configuration. The results show a reduction of 72% on the energy consumption of the process when an organophilic membrane system is implemented. When a recycle stream, which consists mainly of unreacted reducing sugars and water, is returned to the SSCF reactor, then the operating volume increases and the concentration of ethanol decreases even if the amount of ethanol increases. Hence, the reduction in energy consumption in configuration 3 is 66%.

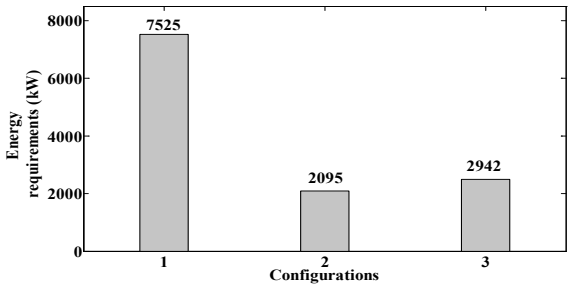

Figure 5: Overall energy consumption for each configuration

5. Conclusions

The production of biofuels from biomass aims to find new approaches and technologies with which biofuels can be obtained not only efficiently but profitably for sustainable energy generation. The results show that the implementation of an organophilic membrane contributes to the reduction of the overall energy consumption in the process by up to 72%. When the retentate stream from the organophilic membrane system is recycled to the SSCF, the amount of ethanol produced increases since all the available substrate is converted. Recycling the retentate also contributes to the reduction in the consumption of energy within the process (66%), making this configuration an attractive alternative for a successful implementation of ethanol production from biomass into industry. However, recycling streams not only increases the size of some units of the process but also presents additional operational requirements.

Abstract

In this study, we introduce a novel solar thermal (ST) hydrogen and electricity coproduction process, which integrates a new solar water power (SWP) cycle and ST hydrogen production techniques. SWP cycle has a potential to generate electricity with efficiencies greater than 40 % for solar heat collection temperatures above 1250 K. Higher solar heat collection temperatures enable the integration of SWP cycle with ST hydrogen production techniques to coproduce hydrogen and oxygen. When solar energy is unavailable, we propose a turbine based hydrogen water power cycle. For a 100 MW continuous power supply plant, the overall efficiency of the proposed integrated process is estimated to be greater than 34 % in spite of the assumed 20 % solar energy loss in the solar collector system. Furthermore, the coproduced hydrogen and oxygen can be used for various applications other than energy storage to create a sustainable economy.
Keywords: solar, electricity, hydrogen, water power cycle, sustainability.

1. Introduction

Diminishing fossil fuel reserves and increasing environmental concerns urge to utilize renewable energy sources to meet energy needs. Development of renewable power production technologies is important since electric power is the largest consumer of primary energy resources and it has the highest growth rate among alternate energy use sectors. Solar energy is a prominent source due to its abundance. Yet intermittencies and land availability constraints for solar energy collection are the grand challenges for solar power generation and demand an efficient continuous solar power generation solution.

Here, we meet these challenges by introducing a novel and highly efficient solar thermal (ST) power and hydrogen coproduction process, which includes; (i) solar water power cycle, (ii) ST hydrogen production process, and (iii) turbine based hydrogen power cycle (Agrawal et al., 2014). Solar water power cycle has a potential to generate electricity with sun-to-electricity (STE) efficiencies greater than 30 % at low solar heat collection temperatures (~750 K). The cycle also promises STE efficiencies greater than 40 % for the high solar heat collection temperatures (>1250 K). For higher solar heat collection temperatures, the ST power cycle is integrated with the hydrogen production process to coproduce hydrogen and oxygen for chemical storage of solar energy. When solar energy is not available, the coproduced hydrogen is utilized to generate electricity for grid distribution around the clock. The overall STE efficiency of a 24 hour cycle is estimated to be greater than 34 %, which is comparable to batteries integrated with solar water power cycle and the storage energy density is comparable to carbon storage cycles (Gençer et al., 2014). Coproduced hydrogen can also be used as a feedstock for production of other chemicals or other applications. The process design and simulation has been

conducted using an integrated Matlab and Aspen environment. We have performed sensitivity analysis and optimization using genetic algorithm to determine key process parameters. Simulation strategy and details of an example process design are presented in the following sections.

2. Solar Thermal Hydrogen and Electricity Coproduction Strategy

Temperatures higher than ~1000 K enable water splitting reaction to form H_2, O_2 and OH. This phenomenon creates an opportunity to produce hydrogen using concentrated solar energy with high solar heat collection temperatures (Mallapragada and Agrawal, 2014). Analysis of theoretical and achievable sun-to-hydrogen efficiency for ST hydrogen production revealed that the ST hydrogen production has a grand potential to efficiently produce hydrogen (Mallapragada and Agrawal, 2014). ST hydrogen production mainly involves pressurizing, heating, vaporization and superheating of water, compression and collection of hydrogen and oxygen. The energy requirement for the water heating is likely to be supplied from solar energy and partially from the heat released due to the cooling of products prior to compression. This step is exergetically inefficient due to the use of high temperature ST energy to heat up and vaporize pumped water at low temperature. The second step of compression of products consumes electricity, which can be supplied from solar electricity produced via concentrated solar power plants or photovoltaic systems. There are mainly two routes for thermochemical hydrogen production; (i) single step membrane reactor, (ii) two step metal oxide cycle (Mallapragada and Agrawal, 2014). Two step hydrogen production involves the cyclic oxidation and reduction of a metal; for this study we considered the cyclic transformation of FeO and Fe_3O_4 that is given by Eqs. (1) and (2). Oxidation reaction (Eq. (1)) partially converts H_2O to H_2, and reduction reaction (Eq. (2)) releases O_2 using high temperature heat. FeO and Fe_3O_4 are circulated between the two reactors.

$$3FeO + H_2O \rightarrow Fe_3O_4 + H_2 \quad (1)$$

$$Fe_3O_4 \rightarrow 3FeO + 0.5O_2 \quad (2)$$

ST electricity production, involves a solar heat collection unit that contains solar concentrators, solar receiver and heat exchanger and a Rankine-type power cycle that utilizes solar heat as heat source (Siva, et al. 2013). ST hydrogen production and electricity production can be synergistically integrated to increase the overall production efficiency by minimizing the exergy losses due to utilization of high temperature heat with large temperature differences and supplying high efficiency electricity for compression of hydrogen and oxygen. An example integrated process for ST coproduction of hydrogen and electricity is depicted in Figure 1. Water is the working fluid of the ST power production unit for the integrated process. ST hydrogen and power production units are integrated, allowing mass exchange and heat exchange, *i.e.*, the entire water superheating step can be a part of the power production unit and a portion of the pressurized superheated water can be directed to hydrogen production unit. Depending on the pressure level, the unconverted water stream can be sent to power production unit to be cooled down against a process stream in the power production unit. Furthermore, depending on the utilization of coproduced hydrogen more process integration is possible.

3. Efficient Solar Thermal Hydrogen and Electricity Coproduction

Solar water hydrogen power (SWH_2P) cycle shown in Figure 1 is a novel efficient hydrogen and electricity coproduction process integrating solar water power cycle with two step ST hydrogen production process using FeO/Fe_3O_4 cycle.

3.1. Solar Water Power (SWP) Cycle

SWP is derived from a Rankine power cycle and is developed to operate at a range of solar heat collection temperatures with maximum power generation at high temperatures while minimizing exergy losses. SWP with 1-solar reheating (SWP-1) cycle, shown with solid lines in Figure 1, has eight processing steps: (i) water is pumped to a high pressure (~200 bar), (ii) pressurized water is preheated and partially vaporized against process streams, (iii) pressurized water is fully vaporized and superheated in the solar receiver, (iv) a portion of the stream is sent to high pressure turbine (HPT), (v) the expanded stream to a medium pressure is reheated to a high temperature (solar heat collection temperature for the base case), (vi) reheated stream is further expanded in a medium pressure turbine (MPT) and the discharge of the last MPT is cooled against the pressurized liquid water, (vii) the cooled stream is further expanded and partially condensed in a condensing turbine (CT), (viii) the partially condensed water is fully condensed and recycled.

m (kg/s)	82	116	116	34	34	34	34	82	82	40	40	5	42	82

Figure 1 Simplified process flowsheet of solar water hydrogen power cycle with two step hydrogen production. HPT, MPT, CT: high pressure, medium pressure and condensing turbine. Details of SWH_2P cycle at solar heat collection temperature of 1600 K, 200 bar operating pressure and 1 % CT condensation for 100 MW power supply with 30.9 % OSTE efficiency is given in the table.

3.2. Solar Thermal Hydrogen Production

Solar thermal hydrogen production with FeO/Fe_3O_4 cycle has nine processing steps: (i) water is pumped to a high pressure (~200 bar), (ii) pressurized water is preheated and partially vaporized against process streams, (iii) pressurized water is fully vaporized and superheated in the solar receiver, (iv) a portion of the stream is sent to HPT and expanded to the water-splitting reactor pressure, (v) the temperature of the stream is adjusted against a pressurized water stream and sent to water-splitting reactor, (vi) water is partially converted to hydrogen and hydrogen-water mixture is expanded in a turbine and cooled against pressurized water stream, (vii) the oxidized metal is fed to the solar reactor and it is reduced using ST energy and recycled to the water splitting reactor. (viii) the hydrogen-water mixture is separated, hydrogen is collected as gas and water is collected as liquid, (ix) hydrogen and oxygen are brought to their storage conditions, water is mixed with

fresh water feed and pumped to the high pressure. For continuous constant rate power supply hydrogen is stored as compressed hydrogen and oxygen is stored as liquid oxygen.

3.3. Hydrogen Water Power (H_2WP) Cycle

For continuous power supply, the electricity is produced from the stored hydrogen and oxygen when the solar energy is not available. To efficiently generate electricity and avoid shut-off of the power generation equipment (turbines, CT, etc.), we propose using a novel turbine based hydrogen power cycle, which is a modified configuration of SWP-1 cycle replacing solar thermal heating with direct hydrogen oxy-combustion.

4. Process Simulation and Determination of Operating Conditions

Detailed process simulations are performed in an integrated Aspen Plus v8.0 and Matlab environment. A Matlab script is developed to ensure the two way communication between Aspen Plus simulation files and Matlab scripts. The simplified integrated simulation flow diagram is shown in Figure 2, the dotted box is not enabled for the regular runs and sensitivity analyses but only utilized to optimize the parameters. Core Communication Script (CCS) is developed in Matlab to transfer data between different models. Transferring data between different models enables integration of various models for design and optimization of complex flowsheets (Tock and Maréchal, 2012).

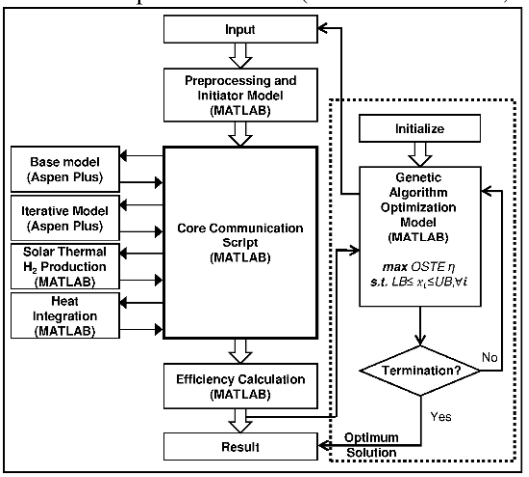

Figure 2 Integrated Aspen Plus and Matlab simulation and optimization strategy.

4.1. Process simulation models

Various Aspen and Matlab models are developed for the simulation, i.e. Preprocessing and Initiator model, Base model, Iterative model, Solar Thermal H_2 Production model and Heat Integration model, are briefly described below. The material flows for both power and hydrogen production processes are calculated via Base model, which contains all the process units, e.g. turbines, reactors, heat exchangers, etc. Detailed calculations for hydrogen production via FeO/Fe_3O_4 based thermochemical cycle are carried out in Matlab (Solar Thermal H_2 Production model) using HSC Chemistry thermodynamic data. For multiple reheating stages the Iterative model is developed and integrated with the Base model through CCS. The minimum solar heat and cooling requirement for the process is calculated from the overall process heat balance using heat cascade principle of the pinch analysis method (Duran and Grossmann, 1986), which is implemented in the Heat Integration model. The Predictive Redlich-Kwong-Soave equation of state,

NBS/NRC steam tables and HSC Chemistry database are used to retrieve the relevant thermodynamic properties for the calculations.

4.2. Process parameters and simulation initialization

Key processing parameters such as solar heat collection temperature, pressure ratio across turbines, number of reheating stages, etc. are identified and implemented as variables that can be controlled via CCS. To initiate a simulation some of the variables to be specified are solar heat collection temperature, number of reheating stages, CT allowable wetness that is a limitation for the maximum condensation in the outlet of CT. Preprocessing and Initiator model generates the initial set of specifications. For example, once the solar heat collection temperature is set the same temperature is used for all superheating and reheating heat exchangers and for the solar reactor used during hydrogen production. Similarly, the number of reheating stage determines the pressure ratio across each turbine, assuming equal pressure ratio across all turbines. The initial set of specifications is then applied to the corresponding models via CCS and the simulation starts.

4.3. Performance metrics

Two metrics of interest are sun-to-electricity (STE) efficiency given by Eq. 3 and overall sun-to-electricity (OSTE) efficiency, the former refers to the fraction of incident solar energy that is directly recovered as the net electricity output and the latter refers to the fraction of incident solar energy recovered as electricity a constant power delivery round-the-clock, i.e. over the average 24 hour production accounting for energy storage and delivery of the stored energy while solar energy is unavailable. In Eq. 3, W_{net} is the net electricity output, Q_{in} is the heat requirement of the process, Φ is the solar factor, Ω_{opt} is the optical efficiency of solar collectors, σ is the Stefan-Boltzmann constant, T is the solar heat collection temperature, I (1000 W/m^2) is the solar intensity and C is the solar concentration ratio. The expression in the denominator of Eq. 3 refers to the solar heat required for the process. Note that Eq. 3 doesn't account for the intermittency and variability associated with solar energy.

$$\text{STE efficiency} = \frac{W_{net}}{Q_{in} \cdot \Phi^{-1}} \times 100, \text{ where } \Phi = \Omega_{opt}\left(1 - \frac{\sigma T^4}{I \cdot C}\right) \tag{3}$$

4.4. Sensitivity analysis and optimization

The operating conditions of various units and topological structure are determined using sensitivity analysis and optimization. The objective function is to maximize the STE and OSTE efficiency for SWP cycle and SWH_2P cycle, respectively. The OSTE efficiency is calculated using the process information for the H_2WP cycle at the given operating temperature and pressure. The effects of solar heat collection temperature (650 K $\leq$ T $\leq$ 2300 K), operating pressure (100 bar $\leq$ P $\leq$ 1000 bar), solar energy availability (2.4 hr $\leq$ t $\leq$ 8.4 hr), etc. have been investigated by sensitivity analysis. An outer loop is introduced for the manipulated variable(s) and the simulation is performed as described in Section 4.2 for multiple initial sets. The exercised simulation strategy allows various studies, which are impractical using only a process simulation software, e.g. adding 100 reheating stages. SWH_2P cycle has been optimized using genetic algorithm to determine the process design and process parameters with maximum OSTE efficiency for a given solar heat collection temperature and water-splitting reactor temperature. Pressure ratio of turbines, CT inlet temperature and hydrogen production pressure are some of the optimized parameters. For example the optimized CT inlet temperatures are 523 K and 385 K for 1 % and 10 % CT wetness, respectively. This study revealed that the process topology is highly sensitive to the water-splitting reactor temperature and maximum OSTE efficiency may require different hydrogen production pressures for different settings.

5. Results

For all STE and OSTE estimations, efficiency of the solar concentrator system has been assumed to be 80 %. SWP-1 cycle achieves STE efficiency of greater than 30 % at relatively low solar heat collection temperature of 750 K. For solar heat collection temperature greater than 1250 K, STE efficiency of SWP-1 cycle is greater than 40 %. The maximum STE efficiency of 42.6 % is achieved at 1850 K. The sensitivity analysis on the number of solar reheating showed that the first reheating improves STE efficiency by 1 – 3 % depending on the solar heat collection temperature. Additional reheating stages have a diminishing effect on STE efficiency improvement. For uninterrupted electricity supply to the grid using an integrated process, for a scenario of 4.8 h of solar availability and 24 h of 100 MW power supply, OSTE is calculated to be greater than 34 % at 1600 K solar heat collection temperature. This efficiency compares well with best possible integrations of existing technologies for solar power generation and energy storage. For example, OSTE of an integrated molten salt solar thermal power plant with thermal storage is 20.2 %, of a single-junction PV plant integrated with Li-ion batteries is 26.7 % and of a concentrated four-junction PV integrated with Na/S batteries is 35.3 %.

6. Conclusions

In this study we have developed a solar water power cycle, a hydrogen water power cycle and an integrated solar thermal hydrogen and power coproduction process. Solar water cycles and hydrogen power cycles have potential to operate at very high efficiencies, greater than 40 % STE efficiency and greater than 64 % hydrogen-to-electricity efficiency, respectively. The integrated coproduction process provides a synergistic process that minimizes exergetic losses and increases production efficiency. Efficient coproduction of hydrogen and electricity presents a continuous power supply solution that can exceed 34 % OSTE efficiency when combined with the H_2WP cycle and also creates other opportunities because hydrogen has numerous uses in chemical industry, biofuel production, and transportation sector.

Abstract

The energy planning problem becomes increasingly important during the recent years mainly due to the pressing needs that need to be taken into account in terms of economic, environmental and social aspects. At the same time, technology supports many options and alternative solutions in the design of energy and fuel supply chains (SCs), based on more holistic approaches that have their origin in the production management. Considering the introduction of an integrated framework of evaluation for alternative energy supply options, the present work applies a RTN (Resource Task Network) based representation of the Energy SCs (ESCs) along with a mathematical programming optimisation model in order to analyse and model a location specific energy planning problem. Special emphasis is given to fuel mix optimisation in terms of maximising the economic, social and environmental performance of ESCs. Furthermore, the interaction between aspects and implications under the existing limitations both in the design and technical characteristics of the system as well as in the environmental / air quality limitations, will be also revealed.
On top of the results obtained, the present work's added value relates to the development of the proposed model for the analysis of various energy planning scenarios, comprising in this way a very useful decision making tool.
Keywords: energy supply chains, energy planning, energy systems optimisation.

1. Introduction

Energy planning involves the identification of different criteria, stakeholders and goals in an interacting environment. Traditional energy planning problems which were made on the basis of single criteria approach, aiming at identifying the optimum ESC configuration under techno-economic considerations seem to be gradually abandoned, as environmental concerns and social implications need to be accounted as well. Striving for a transition towards a sustainable energy sector, policy makers must gradually balance the trade-offs between energy production and minimum environmental impacts whilst providing the opportunity at any level of production (local/regional, country/national, global (Thery and Zarate, 2009)) to mobilise the social and economic activities.

That is the reason that aided-decision making with the use of methods and tools (multicriteria decision making, modeling approaches, expert systems and multiobjective optimisation (Cai et al., 2009, Papageorgiou, 2009, Pohekar and Ramachandran, 2004)) have gained significant attention seeking to provide a supportive framework of assorted decisions under an environment of uncertainty: conflicting goals and preferences expressed by parameters and indexes, with many of them being present in an intangible basis.

To this end, modeling of ESCs and especially electricity SCs has been recently extended to include on top of economic criteria environmental and social aspects by mobilising optimisation methods and tools coupled with lifecycle considerations (Akgul et al., 2014, Papapostolou et al., 2014, Pinto et al., 2012, Vance et al., 2014, Yue and You, 2014). To this type of problems emphasis is given not only to the selection of the optimisation method and the assorted evaluation indicators but also to the representation and sustainable design: homogenous and simple framework formulations are adopted and used in order to solve large scheduling problems in the chemical process industry (State-Task Network (Kondili et al., 1993) and the Resource-Task Network (RTN) (Pantelides, 1994)).

Seeking to describe the problem of energy planning and of alternative energy and fuels SCs along the environmental and social aspects beyond the techno-economic ones, the present work will introduce the concept of energy planning optimisation under the perspective of sustainable development. To this end, based on the RTN representation of the alternative energy supply options developed in previous works of the authors, the developed MILP model will be tested for a detailed time frame of one day (24h) and one month accordingly (720h) for a wind, diesel and storage energy supply option. Model results include the adaptability of the optimisation criterion under different set of priorities considered and provide operational data for the configuration under utilisation.

2. Modeling approach

The present modeling approach is formed on the basis of maximising the total value of the optimised ESC configuration. In respect to that, all the criteria and the assorted indexes were selected and quantified appropriately. The overall value of the ESC(s) is estimated by employing three distinctive groups of criteria (on top of a set of weights applied in each value): economic, environmental and social. All parameters are expressed in €/kWh or in €/kW. More precisely, in the Economic Value the real or implied revenues minus the total costs of the electricity generation are considered i.e. investment, maintenance and operational costs. Accordingly the Environmental Value reflects the positive environmental impact of the ESCs on a Life Cycle Analysis basis compared to a– non friendly fossil based ESC (i.e. wind Vs diesel SC) in tn of CO_2 eq /kWh, all being monetised by the current price of CO_2 (in €/tn). Finally the Social Value accounts for the social benefits at the micro (employment yield €/ kWh per selected technological option) and the macro level (contribution of the selected ESC in the energy security of area investigated, with no limitations of the level being examined: local/region, country, transnational/global. With respect to that, fossil based ESCs are penalised (-1), if being selected by decision makers. Finally the weights being applied in each value (all summing up to 1, with 1 being the most important and 0 being the least important), reflect the relative importance of each criterion based on the type of initiated policy.

3. Model development

The developed mathematical model is formulated as a Mixed Integer Linear Programming (MILP) problem, seeking to combine both discrete types of decisions (to make an investment for a new energy infrastructure project or not) and continuous ones (to demonstrate the best fuel mix utilisation option under the set of existing resources). However there are no conceptual limitations to include both non-linear functions as well. In the present work a detailed operational electricity supply problem is modelled and approached as a LP mathematical model. Under the provisions of sustainable dimensions incorporation (Economic, Environmental and Social), the optimisation criterion seeks to express the maximisation of the total value of the ESCs' configuration for a preset time horizon H, for a set of resources R, storage stations S, interconnection options I and a set of users U to be satisfied::

$$Max = \sum \left\{ a_1 \times ECONV_{r,s,i} + a_2 \times ENVV_{r,s,i} + a_3 \times SOCV_{r,s,i} \right\} \quad (1)$$

Where, a_1, a_2, a_3 correspond to appropriately weighted normalisation (overall summing at 1.0) factors of the different dimensions considered. At this point one may note that the weighted factors are location-specific and case study dependent on the basis of the priorities set by the decision makers, if real energy planning problems are approached. However if future projects are considered, the weighted factors may result from a consensus / experts' based methodology i.e. a Delphi approach (Kaldellis et al., 2013).

The economic value considers the real or implied Revenues and the Total Costs of the electricity generation (Investment, Maintenance and Operational Costs) (TC) (€)

$$ECONV_{r,s,i} = REV_{r,s,i} - TC_{r,s,i} \quad \forall r,s,i \in R,S,I \quad (2)$$

In case there are no revenues, the economic value is the negative value the Total Costs.
The environmental value considers the environmental positive impact of the ESC in Life Cycle Analysis compared to an environmental – non friendly fossil based ESC with a "typical-average" impact on the environment (for example a moderate case is the Diesel SC) (€). For each time –step that we have:

$$ENVV = (ENVF_r \times EG_r + ENVF_{r,s} \times ES_{r,s} + ENVF_i \times EIN_i) \times PCO_2 \quad \forall r,s,i \in R,S,I \quad (3)$$

Where PCO_2 is the current price of CO_2 (€/kWh), $LCREF$ the reference ESC environmental value and $LCENVF_{r,s,i}$ is the environmental footprint (in LCA terms) of each ESC.
Finally the Social value of the ESC considers micro and macro – economic benefits from the implementation and operation of the different ESC configurations (€):

$$SOCV = MiSOCV + MaSOCV \quad (4)$$

$$MaSOC = (SEC_r \times EG_r + SEC_{r,s} \times ES_{r,s} + SEC_i \times EIN_i) \times PEX \quad (5)$$

Model constraints reflect the technical and physical limitations of the system. Thus for each time-step t we have:

- Energy production plants capacity limitations for each supply resource r
- Storage stations capacity limitations
- Capacity limitations of the interconnection supply sources

- Storage balance-rate of charge of the storage stations
- Land availability limitations
- Environmental impacts (in $CO2_{eq}$) from each supply resource in terms of Life Cycle Analysis.

4. Case study: Typical Greek island

Under a pre-set geographical area (typical Greek island in Cyclades complex), for a set of available energy supply options (wind, diesel, energy storage) and for a discrete time-step (hourly based load and demand profile) the present work will try to identify the optimum energy/fuel mix utilisation. Modeling is carried out under the timeframe of a single day and of a month, under different optimisation targets (economic versus social) acknowledging the differentiations that may appear in energy decision making under a cross sectional approach. Diesel and storage act as base loads with min capacities 1000 kW per hour correspondingly whilst the remaining demand has to be met a) in techno-economic terms (a_1=1, a_2=0, a_3=0) by the combination of their optimal operation for a single day (always under the very discrete time step of one hour (Figure 1) or b) just accounting for the maximum energy security (MaSOC) -(a_1=0, a_2=0, a_3=1), (Figure 2) or c) equally accounting both economic and Macro-Social implications (a_1=0.5, a_2=0, a_3=0.5) (Figure 3) in a longer time period- one month. Some preliminary parameters considered for model testing are cited in Table 1.

Table 1: Parameters considered for model optimisation

$CAP_r^{\max}$	Maximum capacity of each electricity production plant r (MW)	Wind:10, Diesel: 10
$CAP_r^{\max}$	Minimum capacity of each electricity production plant r (MW)	Diesel: 1
$ESS_s^{\max}$	Maximum capacity of the storage station (MWh)	Energy storage: 10
$ESS_s^{\min}$	Minimum capacity of the storage station (MWh)	Energy storage: 1
$OPER_{r,s,i}$	Operational cost of the selected resource, storage station or interconnection option (€/ kWh)	Wind: -0.02, Diesel: -0.03, Energy storage: -0.01
EMF_r	Direct emission factor from each energy resource r, s (in kg CO_2 eq / kWh)	Wind: 0.0, Diesel: 0.8, Energy storage: 0.0
$EMF_{ceiling}$	Emissions ceiling factor for the electricity generated (in kg CO_2 eq / kWh)	Natural gas: 0.78
PEX	Exchange losses from imported energy (and resources) (€/kWh)	0.078
PCO_2	Current commercialization price of CO_2 (€/kWh)	15

5. Results and discussion

Model simulation was undertaken with an open-source optimiser OpenSolver 2.6, 8.10.14 (Mayson, 2012) with no technical limitations in the number of variables and constraints. Results concerning the operational characteristics of an existing set of ESCs for a typical winter day and month, with low available energy production and for a corresponding winter month are illustrated as follows (Figures 1,2,3).

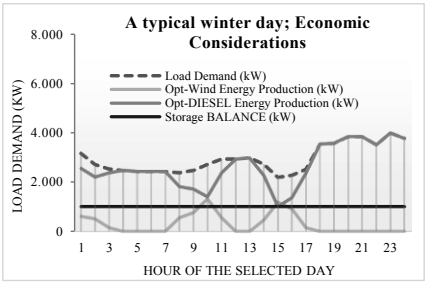

Figure 1. Optimisation results- daily load- Economic Considerations (a_1=1, a_2=0, a_3=0)

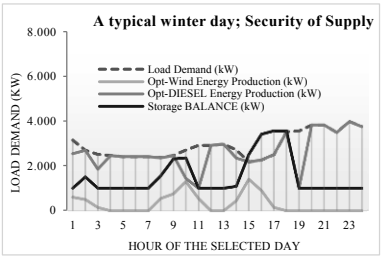

Figure 2. Optimisation results- daily load- Social/ Security of Supply Considerations (a_1=0, a_2=0, a_3=1)

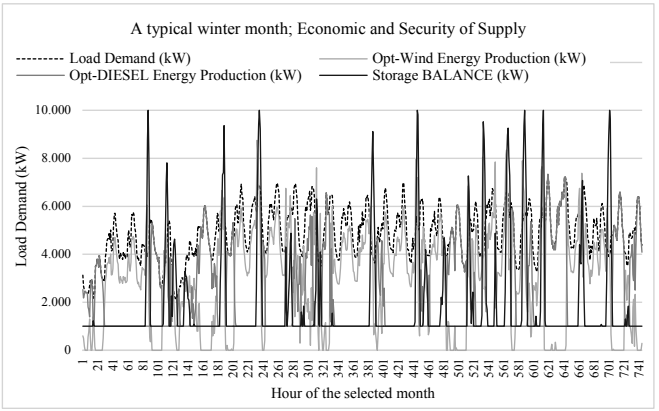

Figure 3. Optimisation results- monthly load- Economic and Macro-Social Considerations (a_1=0.5, a_2=0, a_3=0.5)

Results obtained evidence that different criteria under different set of priorities (optimisation criteria) may result to diverse ESCs configurations. One may notice that if considering the long term aspect of energy planning -especially in large scale / state level problems- the security of energy supply may be of greater importance than the minimisation of the total operational cost of the existing energy production plants. However according to the proposed modeling approach cited in the present work a temporal and local optimum may be obtained according to the location specific criteria set, in each case study under examination.

6. Conclusions

In the present work the developed mathematical model for the optimisation of alternative ESCs, formulated as a LP has been cited. Through a simple case-study the hybrid character of the model i.e. to adapt to different optimisation targets based on the policy-makers' needs was revealed. Furthermore the model also provides the possibility of being treated as a decision support tool when holistic considerations, mainly applicable at large energy planning problems occur. Decisions to be supported by model implementation include energy fuel mix diversification possibilities, local security of

energy supply, sustainability of energy supply schemes, adaptability of the energy decision making process and scheme to incorporate emerging issues and parameters in the problem under consideration. The proposed methodology due to its generic nature may equally be applied to other types of energy problems i.e. heat and water resources energy optimisation.

Abstract

The research in the field of microalgae-based biofuels and chemicals is in early phase of the development, and therefore a wide range of uncertainties exist due to inconsistencies among and shortage of technical information. In order to handle and address these uncertainties to ensure robust decision making, we propose a systematic framework for the synthesis and optimal design of microalgae-based processing network under uncertainty. By incorporating major uncertainties into the biorefinery superstructure model we developed previously, a stochastic mixed integer nonlinear programming (sMINLP) problem is formulated for determining the optimal biorefinery structure under given parameter uncertainties modelled as sampled scenarios. The solution to the sMINLP problem determines the optimal decisions with respect to processing technologies, material flows, and product portfolio in the presence of uncertain parameters. The developed framework is implemented and tested on a specific case study, to identify the promising processing pathway for the production of biofuels from microalgae while accounting for modelled uncertainties.

Keywords: Uncertainty analysis, Stochastic mixed integer nonlinear programming (sMINLP), Microalgal biorefinery.

1. Introduction

Under the broad concept of microalgal biorefinery, microalgae is cultivated and processed to produce a wide range of products such as biofuels, chemicals, animal feed, pigments, power/heat, etc. (Yen et., 2013; Rawat et al., 2013). Despite the various benefits associated with the development of microalgae based biorefinery (such as potentially significant improvements in the overall economics of biofuels), there are many challenges yet to overcome and to be addressed systematically. These challenges include (1) existence of a number of potential processing pathways for biorefinery development, and (2) inconsistency and shortage in the process information available in the literature because the idea of utilizing microalgae as a renewable feedstock for the production of biofuels and chemicals is relatively new and involved processing technologies are still at a nascent stage. Potential development of additional technologies as well as the likely future improvements may further increase the uncertainty one faces at a preliminary assessment phase. Consequently, the optimal biorefinery configuration determined based on uncertain parameters can prove to be highly suboptimal later due to discrepancies among the assumed and actually realized parameter values. Stochastic programming/optimization is a widely used tool to

determine the optimal design under stochastic uncertainty, and this approach has been used in many studies (Karuppiah and Grossmann, 2008; Quaglia et al., 2013).

In this paper, we propose a systematic modelling framework to determine the promising processing pathway for the production of biofuels from microalgae by considering the effect of uncertainty present in microalgal biorefinery design. The problem of finding the promising biorefinery configuration under uncertainty is formulated as a sMINLP problem which is solved in the software package GAMS.

2. Modelling framework

In an earlier work (Rizwan et al., 2013), we addressed the problem of determining the promising pathways for the production of biodiesel from microalgal biomass by developing a superstructure based optimization model. Later the model was extended to locate the promising biorefiney configurations by coupling the utilization of microalgae residue along with the biodiesel production. In this contribution, we have incorporated the major uncertainties into the biorefinery superstructure model which results in the formulation of a stochastic optimization problem.

2.1. Problem definition

In the first step, the problem scope is defined by identifying and selecting the objective function with respect to the techno-economic constraints considering the uncertainties in the sensitive model parameters. A general problem statement is given as follows.

Given is a microalgal biorefinery superstructure (Figure 1) which consists of available potential technological alternatives/options for the various processing steps involved in the microalgal biorefinery such as cultivation of microalgae, harvesting of microalgal biomass, pre-treatment step including drying and cell disruption of harvested biomass, lipid extraction, transesterification, post-transesterfication purification, pre-treatment of microalgae residue, and conversion of residue into the useful products. The optimization problem is defined as to determine the optimal processing network(s) under uncertainty for the production of biofuels from microalgae. When the uncertainties are expressed as distributions in the parameter space or discrete scenarios sampled from it, it leads to the formulation of a sMINLP problem. The objective function chosen is to maximize the expected value of gross operating margin over the uncertain space. Use of other risk-sensitive measures is also possible but not examined in this paper.

2.2. Data collection and superstructure development

We have developed a biorefinery superstructure for the production of biodiesel from the lipid contents of microalgae and the simultaneous conversion of microalgae residue into the useful products. It includes all the major processing steps/stages for the production of biofuels from *Chlorella vulgaris*, and at each processing step various potential technological alternatives/options are considered. As shown in Figure 1, each option included in the superstructure is represented by two indices; the first index represents the option number and the subsequent second index represents the processing stage. The list of technological options included in the biorefinery superstructure model is given in Table 1. The empty boxes represent the bypassing of certain processing stages, e.g., to accommodate wet lipid extraction, in-situ transesterification, etc. The detailed description of the problem data and superstructure development can be found in our previous study (Rizwan et al., 2013).

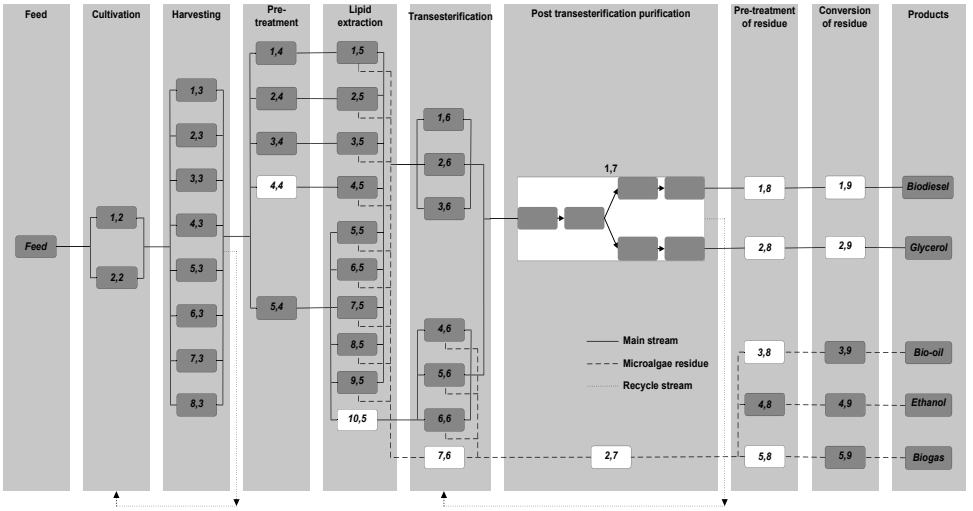

Figure 1. Biorefinery superstructure for the production of biofuels from microalgae

Table 1. Option/technological alternatives

1,1	Feed	10,5	Empty
1,2	Open pond system	1,6	Base catalyzed transesterification
2,2	Photobioreactor	2,6	Acid catalyzed transesterification
1,3	Flocculation with poly electrolyte	3,6	Enzymatic transesterification
2,3	Flocculation with NaOH	4,6	Alkaline in-situ transesterification
3,3	Flocculation with PGA	5,6	Acidic in-situ transesterification
4,3	Flocculation with chitosan acid solution	6,6	Enzymatic in-situ transesterification
5,3	Bioflocculation + Centrifugation	7,6	Empty
6,3	Centrifugation	1,7	Post transesterification purification
7,3	Auto flocculation (induced by high pH)	2,7	Empty
8,3	Microfiltration + Centrifugation	1,8	Empty
1,4	Grinding in liquid nitrogen	2,8	Empty
2,4	Drying + Ultrasound	3,8	Empty
3,4	Drying+Grinding+Microwave+Ultrasound	4,8	Enzymatic hydrolysis
4,4	Empty	5,8	Empty
5,4	Drying	1,9	Empty
1,5	Grinding assisted lipid extraction	2,9	Empty
2,5	Ultrasound assisted Extraction by [Bmim][MeSO4]	3,9	Fast pyrolysis
3,5	Ultrasound & microwave assisted lipid extraction	4,9	Fermentation
4,5	Wet lipid extraction	5,9	Anaerobic digestion
5,5	Solvent extraction (Bligh & Dyer Method)	1,10	Biodiesel
6,5	Extraction by Mod. Bligh & Dyer Method	2,10	Glycerol
7,5	Supercritical fluid extraction	3,10	Bio-oil
8,5	Extraction by ionic liquid mixture	4,10	Bioethanol
9,5	Extraction by [Bmim][MeSO4]	5,10	Biogas

2.3. Uncertainty characterization

In this step, the uncertain parameters are identified and characterized in terms of distributions. Based on the approach described in Brun et al., 2002 and Sin et al., 2009,

three classes of uncertainties such as low, medium and high are defined which correspond to 5 %, 25 % and 50 % variations around the mean value, respectively. The uncertain parameters and their class of uncertainty are given in Table 2. In this study, these classes are defined on the basis of available information or data in the literature. For example, the fractional conversion of lipids into biodiesel via base catalysed transesterification is known with good accuracy; hence, it is classified as a parameter of low uncertainty. The available information about the fractional conversion of lipids into biodiesel via in-situ transesterification, CO_2 conversion, lipid yield for wet lipid extraction method, and cost of feed are not consistent in the literature; therefore, these are classified as having medium uncertainty. The same is true for the lipid contents but with a very large range of variations; therefore, it is put in the category of high uncertainty. Even less and highly inconsistent information is available for the conversion of microalgae residue (for bioethanol and biogas production), and therefore it is also placed in the class of high uncertainty.

From the uncertain parameters space, we have generated the future scenarios with equal probability of realizations of the uncertain parameters by using Latin Hypercube Sampling (LHS) method. LHS is a well know probabilistic sampling technique for the sampling of uncertain space (Mckay et al., 1979). A good uniform coverage of the sampling space can be obtained with this technique (Sin et al., 2009). Uniform probability distribution of uncertain data is assumed in this study for scenarios generation. 200 samples are generated from the distribution to be used as scenarios.

Table 2. Uncertain parameters and their class of uncertainty

Parameters	Uncertainty class	Variations (%)
Fractional conversion of lipids (for base catalysed transesterification	Low	5
Fractional conversion of lipids (for acidic in-situ transesterification)	Medium	25
CO_2 conversion/fixation		
Lipid yield (for wet lipid extraction)		
Cost of feed		
Lipid contents	High	50
Fractional conversion of residue (for bioethanol and biogas production)		

2.4. Deterministic problem formulation

In this step, a deterministic optimization problem is formulated and solved to find the optimal processing network in the nominal conditions by disregarding the uncertainties in the model parameters. The deterministic problem results in the formulation of MINLP model. The results obtained in this step locate the deterministic optimal processing pathway for the production of biofuels from microalgae.

2.5. Decision making under uncertainty: Stochastic formulation

In this step, a stochastic optimization problem is formulated to find the optimal processing pathway under uncertainty which is solved via sample average approximation (Birge and Louveaux, 1999). The objective function is to maximize the expected value of gross operating margin over the uncertain space, which is sampled to generate 200 future scenarios. The stochastic problem is formulated and solved in the software package GAMS with DICOPT solver using a database built in Excel.

3. Case study

The developed modelling framework is implemented on a case study to determine the optimal processing pathway under uncertainty for the production of biofuels from microalgae.

The biorefinery superstructure is developed for the production of biofuels form microalgae as shown in Figure 1, and briefly described in section 2.2. The optimization problem is defined as to determine the optimal processing pathway under uncertainty. The objective function chosen is to maximize expected value of gross operating margin which is defined as the difference between total sales of products and the operating cost.

4. Results and discussion

The obtained optimization results are given in Table 3. Figure 2 represents the optimal processing pathway (for the maximization of gross operating margin) obtained by solving the stochastic programming problem, which consists of open pond cultivation, harvesting of microalgal biomass by flocculation using poly electrolyte as a flocculent, wet lipid extraction, base catalysed transesterification followed by the purification step, and anaerobic digestion for the conversion of microalgae residue into biogas.

Table 3. Optimization results obtained by solving deterministic and stochastic models

	GOM ($)	Yield biodiesel (GGEs)	Yield glycerol (GGEs)	Yield biogas (GGEs)
Nominal value for det. solution	-46.493	8.814	0.468	4.912
	Pathway: 1,1 1,2 1,3 5,4 10,5 5,6 1,7 2,7 1,8 2,8 5,8 1,9 2,9 5,9 1,10 2,10 5,10			
Exp. value for det. solution	-53.488	7.855	0.417	4.899
Exp. value for stoch. solution	-47.748	8.031	0.427	4.900
	Pathway: 1,1 1,2 1,3 4,4 4,5 1,6 7,6 1,7 2,7 1,8 2,8 5,8 1,9 2,9 5,9 1,10 2,10 5,10			

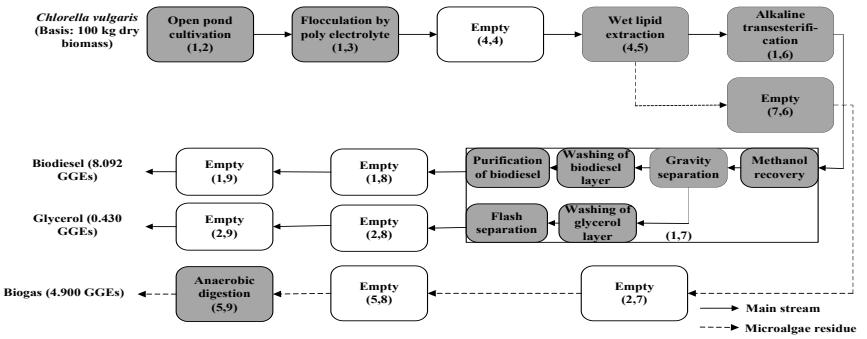

Figure 2. Optimal processing pathway obtained by solving stochastic model

By modelling the uncertainties in the parameters, the selected processing pathway by the stochastic solution maximizing the expected value of gross operating margin is different from the deterministic solution obtained in step 4. In contrast to the deterministic solution, here the biodiesel production is described by wet lipid extraction method followed by base catalyzed transesterification. The expected value of gross operating margin is found to be $-47.748, which is slightly lower than the value achieved based on the nominal parameters due to the uncertainties but higher than the expected value for the deterministic solution that did not consider them. In other words,

by solving a more elaborate stochastic program considering the uncertainties, the expected value of gross operating margin is increased by more than 10 %. These findings highlight that the uncertainties in the problem dataset have significant effect on the optimal structure of microalgal biorefinery.

5. Conclusions

In this paper, we have developed a stochastic optimization model to assess the impact of major uncertainties in the model parameters on the design of optimal processing network for the production of biofuels from microalgae. The previously developed superstructure based modelling framework was extended to formulate sMINLP problem by incorporating major uncertainties in the model parameters as a large number of sampled scenarios. The developed framework was applied to a specific case study which is based on microalgal biorefinery, to highlight the implementation and applicability of the methodology and the impact of uncertainty on the optimal design as well as on the achieved gross operating margin.

The optimization results showed that the uncertainty in the problem dataset has an impact on the optimal biorefinery configuration. As future work, the modelling framework will be extended to consider a more diverse set of objective functions that reflect risk aversion strategies.

Effect of feed natural gas conditions on the performance of mixed refrigerant LNG process

Mengyu Wang, Rajab Khalilpour, Ali Abbas*

School of Chemical and Biomolecular Engineering, The University of Sydney, NSW 2006, Australia
ali.abbas@sydney.edu.au

Abstract

The natural gas wellhead conditions vary over the life of a production well. These variations affect the performance, production and product quality of liquefied natural gas (LNG) plant. This study, through a simulation-based sensitivity analysis, highlights the significance of the effects imparted by the feed natural gas conditions on process performance of a propane precooled mixed refrigerant (C3MR) LNG process. The results show that the specific shaft work and thus OPEX is sensitive to the feed composition, flowrate, and pressure. For instance, as LNG production decreases from its design capacity of 3.0 MTPA to 2.4 MTPA over time, the specific OPEX increases from $128/t-LNG to $154/t-LNG.

1. Introduction

For many countries around the world, natural gas is recognized as an important energy source from economic and environmental perspectives. Natural gas liquefaction process is a key step in the natural gas supply chain however it is an energy intensive process. The design and operation optimization of LNG plants has received significant industrial and research attention driven by the significant demand for natural gas and the sheer scale of the natural gas market. Many researchers studied optimization of LNG liquefaction process aiming at reducing energy consumption and improving energy efficiency. Lee et al. (2002) conducted a systematic method on the optimal design of a PRICO cycle seeking optimal operating conditions. Jensen et al. (2007) and Jacobsen et al. (2013) worked on operation optimization of a single mixed refrigerant (SMR) cycle. Nogal et al. (2008) presented an optimal design methodology for a SMR cycle to reduce the compression work. Aspelund et al. (2010) developed a non-deterministic search method for optimization of PRICO cycle. Khan et al. (2012) optimized a SMR process with non-linear programming along with exergy efficiency analysis. Wang et al. (2013) and Wang et al. (2014) studied the impact of numerous key variables including mixed refrigerant (MR) composition on the performance of a LNG plant. The optimization studies of natural gas liquefaction processes are reviewed by Lim et al. (2012).

In addition, efficient design and operation of LNG plants require optimal process responses to various factors including feed conditions, economics, and climate of LNG plant. These factors at a given supply source influence process performance and product quality over time. Castillo et al. (2013) evaluated performance of different LNG precooling cycles in cold and warm climates. Their results showed that a three-stage propane precooled MR cycle is more suitable for warm climates while a two-stage MR cycle is the most efficient technology for cold climates. Clementino et al. (2014) studied

sensitivity analysis of C3MR to investigate the specific shaft work required at different temperature and pressure of feed natural gas. Our literature reviews showed that less attention has been given to addressing the impact of variations in feed natural gas composition and flowrate on process performance. This study is focused on understanding, through sensitivity analysis, the effects of different feed natural gas conditions including composition, flowrate, pressure, and temperature on process performance and LNG product of a C3MR process.

2. Process description

Figure 1 shows the flow diagram of C3MR process. C3MR process consists of precooling cycle and subcooling cycle. The treated natural gas and MR is partially cooled to around -35 °C in a propane precooling cycle. The precooled MR is then separated into gaseous stream and liquid stream to provide the cooling for natural gas in main cryogenic heat exchanger (MCHE) to around -161 °C at atmospheric pressure. After that, MR is completely vaporized from the exit of MCHE and then compressed by a series of compressors to its initial inlet conditions.

3. Sensitivity analysis

The modelling package HYSYS® (Aspentech, USA) was used to model the LNG plant, shown in Figure 1, and to assess its performance under the following sensitivity analysis:

1) The effect of natural gas composition at a constant temperature of 25 °C and pressure of 5000 kPa is studied. Six different compositions of natural gas are conducted as listed in Table 1. The mole fraction of methane in natural gas is adjusted from its base value of 96.92 % to 84.55 % with 10 % decrements of component mole flow of methane while keeping the mole flow of remaining components constant.
2) The temperature of feed gas is varied within the range of 10 °C and 50 °C.
3) The pressure of feed gas is varied within the range of 3000 kPa and 5000 kPa.
4) The flowrate of feed gas is varied within the range of ±20 % of its design value.

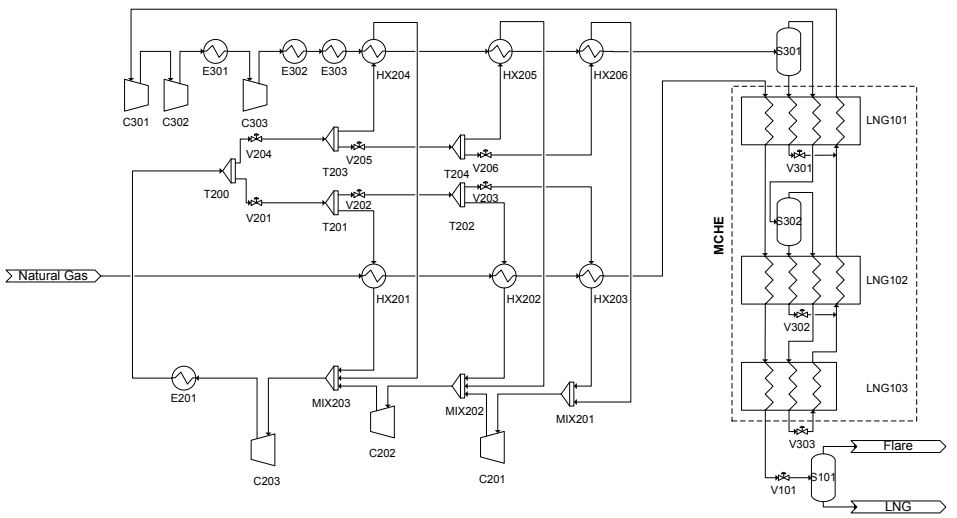

Figure 1. The flow diagram of C3MR process.

Table 1. Feed natural gas composition (in unit of mole fraction).

Feed composition case	Methane	Ethane	Propane	n-butane	Nitrogen
Base case*	96.92	2.94	0.06	0.01	0.07
NG1	96.70	3.15	0.06	0.01	0.07
NG2	96.31	3.53	0.07	0.01	0.08
NG3	94.80	4.96	0.10	0.02	0.12
NG4	91.63	7.99	0.16	0.03	0.19
NG5	84.55	14.75	0.30	0.05	0.35

*Refer to Wang et al. (2013)

3.1. Assumptions

C3MR process is modelled and simulated with the following input conditions and assumptions.

1) The feed natural gas is dry and sweet prior to entering the liquefaction process.
2) The feed gas is at T=25 °C and P=5000 kPa to produce 3.0 MTPA of LNG.
3) Natural gas is composed of 96.92 % methane, 2.94 % ethane, 0.06 % propane, 0.01 % n-butane and 0.07 % nitrogen (Wang et al., 2013).
4) The overall heat transfer coefficient and area (UA) of MCHE is fixed at design value of 16.39 MW/°C (Wang et al., 2013).
5) The prices of electricity and cooling water are $10.99/GJ and $0.40/GJ respectively (Turton et al., 2009). The price of feed natural gas is $2/mmBTU.

3.2. Performance equations

The following equations are used for calculating the total power consumption and variable operating cost of the C3MR process. Total shaft work is expressed by Eq. (1) in which W_i is the shaft work used at compressor C_i.

$$W_{Total} = \sum_{i=1}^{n} W_i \tag{1}$$

Operating expenditure (OPEX) includes electricity, water and feed natural gas. It is represented as Eq. (2).

$$OPEX = \frac{P_{Elec}\sum_{i=1}^{n} W_i + P_{Water}\sum_{j=1}^{m} Q_j + P_{NG}F_{NG}}{F_{LNG}} \tag{2}$$

where, P_{Elec} is electricity price, P_{Water} is cooling water price, P_{NG} is the price of feed natural gas.

4. Changes in natural gas conditions

The results in Figure 2 indicate that for a given amount of feed gas, the decrease of 12.37 mol% in methane concentration results in the reduction of specific shaft work by 5.17 %, while it only increases the LNG production by 0.76%. This is because methane reduction increases the molecular weight of natural gas mixture. A feed natural gas with

lower methane content which has lower dew point requires less refrigeration capacity; consequently produces more LNG products. In accordance with Clementino et al. (2014), plant operation and LNG production are also sensitive to pressure, temperature, and flowrate variation of feed natural gas. Three scenarios are carried out: change in feed flowrate, change in feed pressure, and change in feed temperature. In each scenario, feed gas composition varies is based on Table 1.

Scenario 1: Variation in natural gas composition with different feed flowrate

This scenario examined variation in natural gas composition with different feed natural gas flowrate. The specific shaft work is shown in Figure 3, along with the specific OPEX. It is obvious that decline in natural gas flowrate with a constant composition requires less cooling duty provided by C3MR process at fixed UA, which is in an agreement with Wang et al. (2013). This shows the significant impact of plant feed capacity on process operational costs.

As natural gas flowrate decreases from 4.788×10^5 kg/h to 3.129×10^5 kg/h, the base case natural gas with highest methane content shows the maximum effect on cooling duty. It results in the largest decrease of specific shaft work by 7.08% for base case and the smallest decrease by 1.34 % for NG5. However, specific OPEX increases since natural gas flowrate decreases at fixed UA. Specific OPEX for base case natural gas composition increases from \$113.3/t-LNG to \$153.6/t-LNG. Similar trend is observed for the other four feed gas compositions.

Scenario 2: Variation in natural gas composition with different feed pressure

The feed pressure of a natural gas well will decline over time. This scenario examines the effect of supplying natural gas with different composition and pressure on specific shaft work at a constant temperature of 25 °C as shown in Figure 4. The reference specific shaft work is obtained at a feed pressure of 5000 kPa. It is evident from Figure 4 that with reduction in feed gas pressure, a given amount of natural gas requires higher specific power to liquefy resulting in higher specific OPEX. This shows the influence of upstream feed pressure on the process economics, an important variable for the operator to consider as the gas well ages.

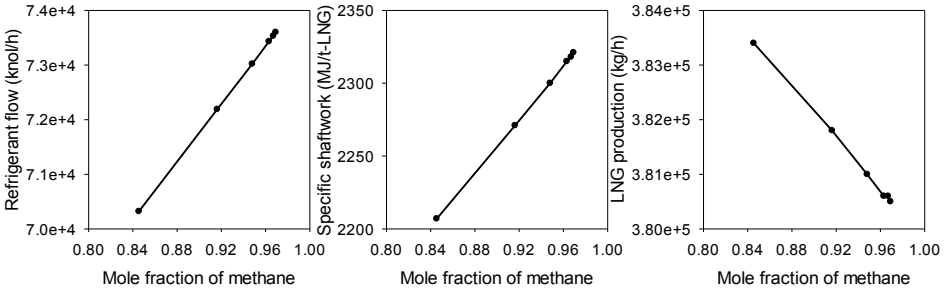

Figure 2. The effect of feed natural gas compositions change on refrigerant flow, specific shaft work and LNG production (T= 25 °C and P=5000 kPa).

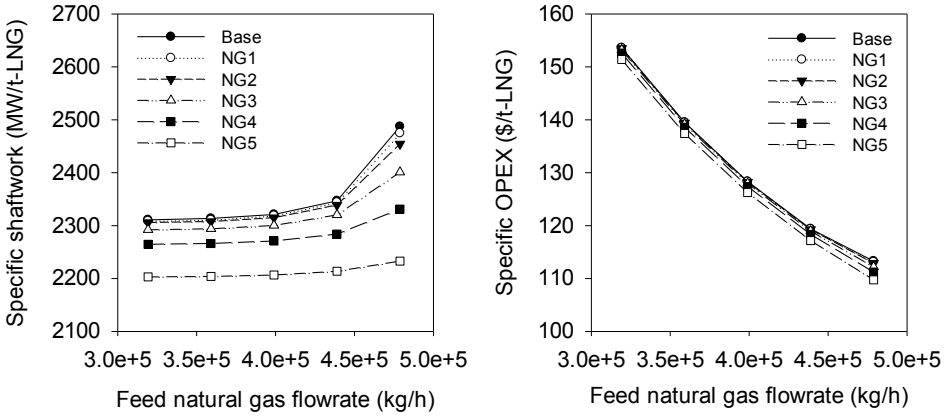

Figure 3. The effect of feed natural gas flowrate change on specific shaft work and specific OPEX (T= 25 °C and P=5000 kPa).

Scenario 3: Variation in natural gas composition with different feed temperature

Figure 5 shows the effect of natural gas temperature variation on specific shaft work at a constant feed pressure of 5000 kPa. The temperature variation of natural gas is in a range of 10 °C and 50 °C. It is evident from the figure that temperature variation of feed natural gas has a trivial effect on specific power consumption. At a constant pressure, the specific power increases by 0.73 % for base case and 0.76 % for NG5 when feed natural gas temperature increase by 40 °C increase. For the base case, natural gas containing more methane than other cases requires more compression work to produce the same amount of LNG.

5. Conclusions

This work investigated the effects of varying the inlet natural gas conditions for an existing LNG plant (i.e. with a constant UA). The findings from this study show that variations in feed natural gas composition, pressure, and flowrate have more refrigeration effect than feed temperature for given feed flowrate. With reduction in feed gas flowrate over a well's life time, the overall shaft work declines. However, the specific energy requirement per unit weight of LNG product increases translating to higher production costs.

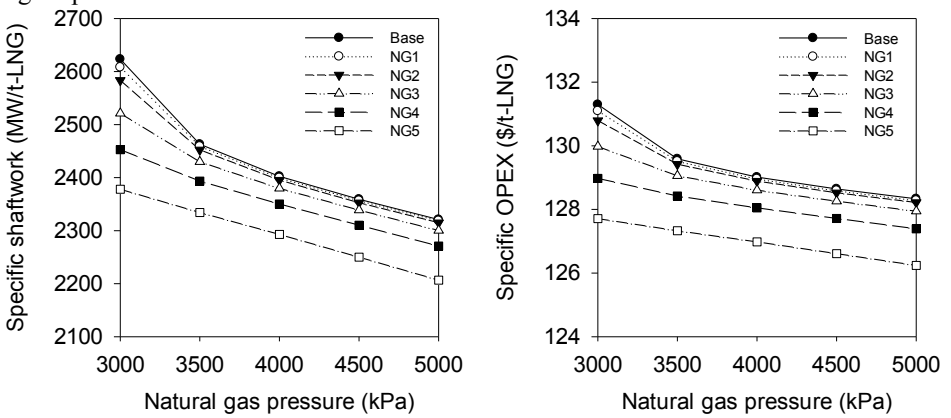

Figure 4. The effect of feed natural gas pressure change on specific shaft work and specific OPEX (T= 25 °C).

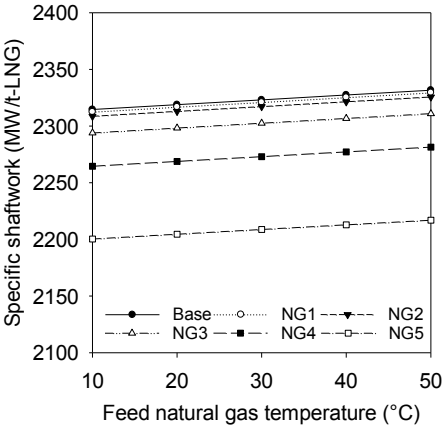

Figure 5. The effect of feed natural gas temperature change on specific shaft work (P=5000 kPa).

A Spatial Decomposition Procedure for Efficient Solution of Two-Dimensional Energy Distribution Problems

Carl Haikarainen[a], Frank Pettersson[a], Henrik Saxén[a]

[a]*Thermal and Flow Engineering Laboratory, Åbo Akademi University, Biskopsgatan 8, FI-20500 Åbo, Finland*

Abstract

As more and more technologies emerge in the energy sector, there is a possibility that structures of energy systems and networks will move towards a more distributed, decentralised structure, with multiple smaller power plants and energy supplier units providing the energy previously commonly supplied by a large centralised plant. If well planned, these distributed structures are anticipated to increase the efficiency, flexibility and security of energy systems. Many mathematical models have been formulated for aiding the design process and analysis of distributed energy systems such as district heating systems. A search for optimal structures and multi-period operational schemes of district heating networks consisting of supplier, consumer and storage nodes connected via pipelines can be formulated as a mixed-integer linear program and solved using standard algorithms, but as the problem sizes increase, the solution times become too long for practical use. For this reason, a procedure for decomposing such an optimization problem in order to reduce the required computational time is proposed. The procedure is based on dividing the geographical area of the energy system into separate sectors which are treated as nodes in a simplified network. During consecutive iterations, the number of sectors, along with the detail level of the simplified network, is increased. Each iteration reduces the search space of the original problem, thus reducing the time needed for the solution. While reaching global optima cannot be guaranteed, examples are given where the procedure finds better solutions than standard algorithms could find within any reasonable, or even relatively unreasonable, time limits.

Keywords: Distributed energy systems, Optimization, District heating

1. Introduction

One glance at a review paper by Keirstead et al. (2012) reveals the multitude of approaches taken to modelling urban energy systems. Together with the overall increase in energy use of human societies, much of this use is more and more concentrated to urban areas and other distributed energy systems. Thus, it is motivated to put more research effort into developing models that could aid in finding ways to restrain or even reduce the negative impacts of this energy use. One category of such models concerns the optimization of district heating systems providing heat from centralized plants to consumers via pipelines in the form of hot water. Some models deal with the operational optimization of the networks and the power plants, which in itself contains several problematic aspects (Vesterlund and Dahl, 2015). Then there is also the question of combining operational and structural optimization. Structural optimization has been

performed on relatively small networks (Omu et al., 2013), but some tested models come to a halt when facing larger networks, i.e. networks with more than just tens of nodes (Haikarainen et al., 2014). As a real heating network usually has hundreds or thousands of consumer nodes, it becomes necessary to develop a model that is able to handle larger networks. While Fazlollahi et al. (2014) represented urban areas as sets of "integrated zones", the method presented in this article features a sequence of similar clustered representations aimed at finding solutions for the original, non-clustered, network representation, with its complete selection of pipelines, suppliers and storages.

2. Model Description

The mathematical model which the work in this article is based on is described in detail by Haikarainen et al. (2014). In essence, it paints a picture of a network of consumer nodes with a certain demand of heat and electricity, and a set of supplier nodes which represent power plants and other energy supply units in place to satisfy the consumer demands. This is formulated as a mixed-integer linear programming (MILP) problem. The consumers may or may not be connected to the pipeline network. If not connected, consumers may also have their demands served through heat pumps or other local forms of heating. With continuous variables representing supplier capacities, enthalpy flows, water velocities, power required for pumping, etc., and binary variables representing the existence of network components and various discrete decisions, the optimization gives suggestions on which new components to build (new power plants, heat storages, or pipelines) and of which kind (fuel types, maximum capacities, pipe diameters), as well as schemes for running the entire network over multiple periods. Plausible objective functions can for instance be minimization of costs or emissions.

3. Decomposition method

The biggest issue in the original model is the large number of binary variables involved, so a decomposition procedure for reducing the number of significant binary variables, working as a pre-solver, was devised. The basic idea can be thought of as dividing the geographical area under scrutiny into separate sectors and treating the sectors as nodes in a simplified network. Starting by keeping the number of sectors small, the process is repeated increasing the number of sectors (i.e. the level of detail) with each iteration, as illustrated in Figure 1. If some network components have been deemed unfavourable in the previous iteration, they are left out in the subsequent iterations. Thus, when reaching the full level of detail of the original problem, a number of binary variables can be left out from the problem – unless every possible component is considered beneficial in the optimal solution.

Division of the geographical area into sectors is in this case essentially the same as arranging all the nodes (consumers, suppliers, storages and transition nodes) into suitable clusters. This was done using k-means clustering, which groups nodes in a way that their distances to the centres of the clusters they belong to are minimized (MacKay, 2003). Naturally, other clustering methods could be feasible as well. The decomposition was also tested as a simple division of the geographical area into equal-sized squares. This worked adequately, but a k-means clustering approach evaded any awkward situations with empty sectors.

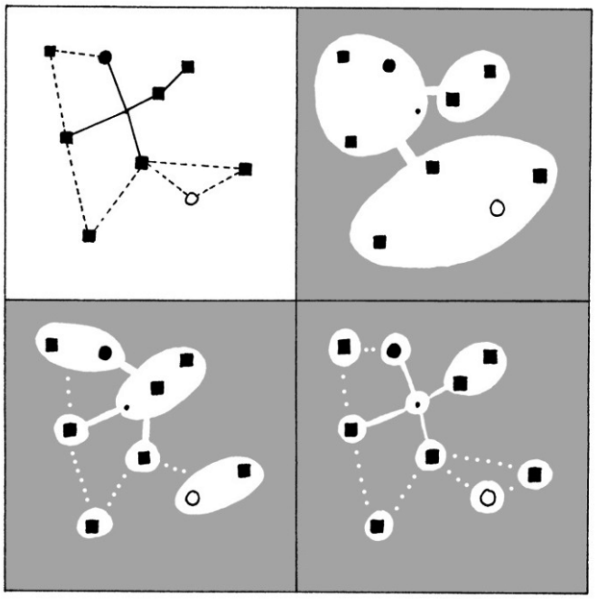

Figure 1. The network in the top-left corner is divided into 3, 6 and 9 sectors. Circles represent suppliers, squares consumers.

Each sector is treated as a node with heat and electricity demands equalling the sum of the demands of the consumer nodes it contains. Each sector can supply energy according to the supplier nodes it contains, distinguishing between known capacity from pre-existing supplier nodes and new capacity that can be built within the sector. The same goes for storage capacity. If a sector contains several possible new supplier nodes, the information of all of them is treated within the same new supplier element of the sector.

The connections between sectors accumulate information from several pipelines in the original problem. Most importantly, the 'lengths' of the connections between two sectors are calculated as the average of the length of all pipelines connecting the sectors, plus, in the case that the pipelines end at a transfer node, the average distances between the end points of the pipelines and each non-transfer node within the sectors containing said end points. To account for new pipelines within a sector, an internal cost proportional to the sector heat demand satisfied by district heating is added to the objective function:

$$C_{internal,N} = K \cdot c(l_{internal,N}) \frac{\sum_p (\dot{H}_{S,N,p} + \dot{H}_{in,N,p} - \dot{H}_{out,N,p}) t_p}{Q_{C,N}} \quad (1)$$

In Eq. (1), subscript N is the sector number and p is the period number, $C_{internal,N}$ is the approximated investment cost of pipelines within a sector, K is a model coefficient, $c(l_{internal,N})$ is the total cost of all pipelines within a sector with a total pipeline length of $l_{internal,N}$. This total pipeline length is calculated as the minimum spanning tree connecting all nodes within the sector. Furthermore, $\dot{H}_{S,N,p}$ is the enthalpy flow from supplier nodes within a sector, $\dot{H}_{in,N,p}$ and $\dot{H}_{out,N,p}$ are the enthalpy flows into and out

from a sector, t_p is the timespan of a period and $Q_{C,N}$ is the total consumer heat demand in a sector. Every optimization step solves an MILP problem, implemented in Matlab using CPLEX as a solver (IBM 2014).

4. Examples

To demonstrate the functionality of the decomposition procedure, with its strengths and weaknesses, three examples in the form of imaginary test cases will be shown. Cases of differing complexities and solution qualities were chosen, to give examples of how the method performs. The initial structures of the test cases are on display in Figure 2, with some basic data arranged in Table 1. As in Figure 1, circles represent suppliers, squares consumers, and additionally, diamonds represent storage nodes. Network components in grey are not pre-existing, but could potentially be built. All the test cases are optimized for a data set of one year divided into twelve periods, representing averages over two-month intervals with days and nights as separate periods (Haikarainen et al., 2014). Heat demands vary between seasons, and between day and night as well. Electricity demands on the other hand were chosen to be constant between seasons, for the sake of simplicity. Some characteristics of the cases are presented in Table 2.

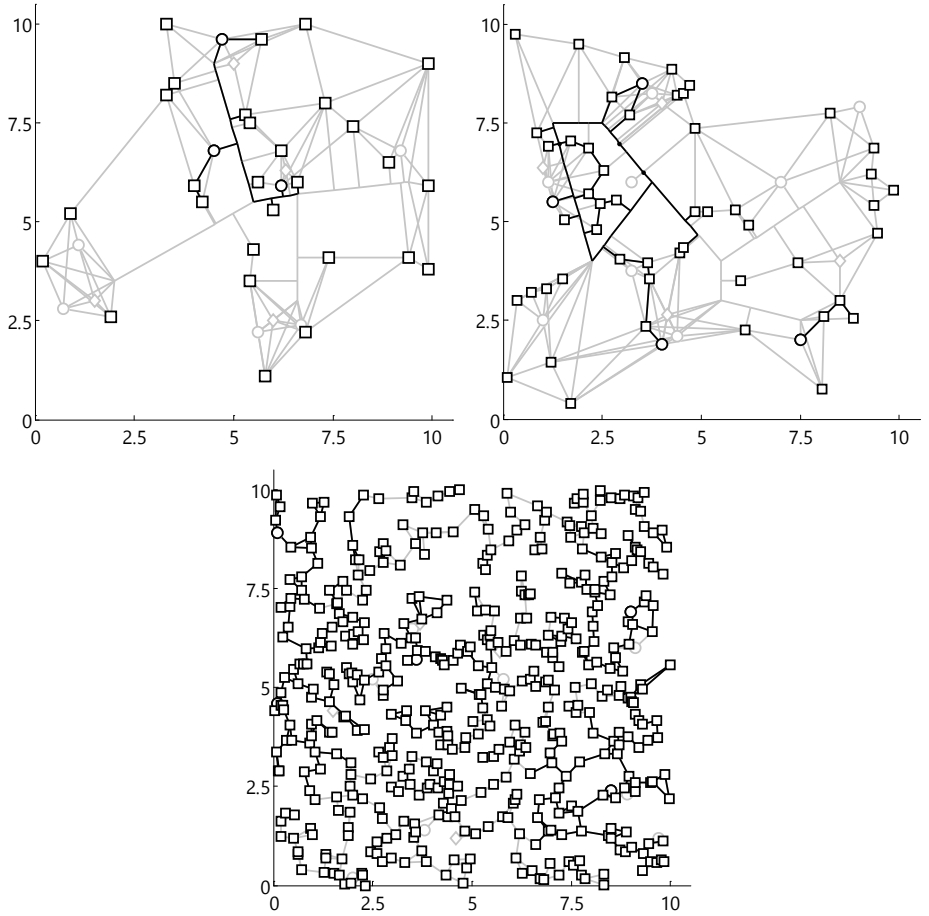

Figure 2. Three test cases are of varying complexity. Units in km.

Table 1. Basic data for the three test cases

Case	Suppliers	Consumers	Storages	Pipelines	Continuous variables	Binary variables
1	8 (3)	28	4 (0)	147 (24)	12,320	954
2	12 (4)	50	4 (0)	243 (62)	23,482	1,573
3	12 (5)	500	4 (0)	704 (332)	140,236	4,789

Numbers in brackets refer to pre-existing components.

Table 2. Variation in total consumer demands in the three test cases

Case	Max heat demand [MW]	Min heat demand [MW]	Total annual heat demand [GWh]	Electricity demand [MW]	Total annual electricity demand [GWh]
1	53	7	242	24	208
2	105	26	478	51	449
3	364	46	1,662	220	1,928

Even the simplest of the cases, despite its less than immense number of nodes, has such a structure that verifying the global optimum with the original model requires too much time, so they are all in need of some sort of alternative treatment, such as this proposed decomposition. The results of the optimization runs are assembled in Table 3. Each test case was first solved with the decomposition method with seven iterations starting with k-means clustering into 9 sectors, ending at 81 sectors, followed by a finalization run. They were then solved with the original model, limiting the solution times to the times used by the decomposition method. Each test case has quite a different behaviour with the decomposition method. In the first case, a good value is found quickly, the original model is far from securing an optimal solution, which is seen from the large optimality gap remaining, and the objective does not reach the value found by the decomposition method. This value is found after 23,679 s, but the optimality gap is still 12.56 % at that point. The same solution is still the best one after 60,000 seconds, with an optimality gap of 2.60 %, but verifying whether or not this is the global optimum would require much more time. So, in the first case, the decomposition method is very successful.

The second case is less spectacular, as it takes a much longer time to solve, and the original model finds a better solution than the decomposition method is able to find. This is a case where the structure of the network is such that the decomposition method surely cannot find the global optimum. Despite attempts with different decomposition formulations and coefficient values, better solutions were not yet found.

In the third case, the solution time is very long even with the decomposition. The solution time for the seven decomposed iterations was still a reasonable 5,419 seconds, but the finalization was slow enough to be interrupted at an, admittedly small, optimality gap of 0.46 %. Despite the generous solution time provided to the original model, CPLEX could not even get past the initial root node processing steps before hitting the time limit, at an objective value far greater than the one found by the decomposition method. This third case represents a situation where the decomposition method can at least find some solution to the problem when the original model has trouble even getting to a start due to the complexity of the problem. This is the type of problem size that the decomposition approach was developed for, so the results show promise for future implementations of the method.

Table 3. Optimized objective values and solution times of the three test cases

		Decomposition method		Original model	
Case	Solution time [s]	Objective value [M€]	Optimality gap [%]	Objective value [M€]	Optimality gap [%]
1	389	19.2	-	20.2	89.65
2	7,276	38.1	-	37.3	90.62
3	66,852	153.4	0.46	158.65	96.80

5. Conclusions

A decomposition method for solving complex distributed energy system optimization problems was developed and tested. The test cases described in this article show how the strength of the method is heavily dependent on the case being analysed. Sometimes, the method can aid in finding a near-optimal solution relatively quickly, but it is not possible to be sure of the quality of the solution. So in its current form, the method can be useful in the case that a problem is too hard to solve with the original model, as there is a possibility that the method can find a better solution within a relatively short solution time. But by itself, a good solution cannot be guaranteed. Without certainty of the solutions of either the original model or the decomposition model, there is still need for further development of reliable methods for optimizing complex distributed energy systems.

Abstract

This work proposes a discrete-time Mixed Integer Linear Programming (MILP) formulation based on a combined rolling horizon and stochastic programming approach for the simultaneous management of energy supply and demand in microgrids, considering flexible demand profiles, which allows delays in the nominal energy demands by applying penalty costs. This mathematical formulation uses a scenario-based stochastic programming approach, which considers different scenarios associated to internal variations in the duration of the energy consumptions, to contemplate all possible scenarios related to the energy demand. However, the high complexity related the estimate the weather forecast with a high degree of precision makes unaffordable the consideration of all possible external scenarios, thereby updating input data is needed to ensure the adequate quality in the obtained results. Hence, the proactive MILP stochastic programming formulation is introduced into a rolling horizon approach.

Keywords: rolling horizon; stochastic programming; scheduling; mathematical programming; microgrid.

1. Introduction

The development of sustainable energy supply chains has led to advances in the area of Energy Systems Engineering. One example is the exploitation of renewable energy sources in microgrids, which are decentralized networks able to integrate several heat/power generation systems of low/medium capacity, with the main purpose of distributing the generated energy locally so as to reduce energy losses and improve the responsiveness to energy demand fluctuations. Several mathematical models have been developed in order to manage the energy production (Kopanos et al., 2013), energy demand (Della Vedova and Facchinetti, 2012) and the production and demand in a sequential way (Hadera et al., 2014).

One of the main drawbacks associated to managing a microgrid is the presence of uncertainty, which must be considered to ensure the operability and the reliability of the system, since the optimal solution obtained under deterministic conditions can easily be infeasible or even suboptimal in practice. The main sources of uncertainty in microgrids are associated to the external weather conditions, which affects the availability and production capacity of renewable energy generation units (i.e. wind turbines) as well as

the energy demand variations, given by the variations related to the duration of the energy consumption. Approaches under uncertainty can be classified into reactive and proactive. Typically, reactive approaches modify a nominal plan to adjust it to the updated system data. The rolling horizon approach is a reactive method that solves iteratively the deterministic problem by moving forward the optimization horizon in each iteration, assuming that the status of the system is updated as soon as the different uncertain or not accurate enough parameters became to be known. This approach considers a prediction horizon, where the uncertain parameters related to this time horizon are assumed to be known with certainty and a control horizon, where the decisions of the optimization are taken. A preliminary rolling horizon approach for the simultaneous energy production and demand management was presented by Silvente et al. (2014). Proactive approaches generate a plan that satisfies all considered scenarios. Proactive scheduling has the advantage that the solution found will be feasible for all scenarios; however it may be too conservative. Hence, a typical two-stage stochastic problem is based in first-stage variables, which does not depend on the scenario, and second-stage variables, which will be different according to each scenario. Although energy production management has been studied broadly, the scheduling of a microgrid taking into account the simultaneous management of energy production and energy demand has received limited attention, and involves a challenge in this research field. In this work, a mathematical formulation is presented to cope with the uncertainty through a rolling horizon stochastic programming approach to optimally manage a microgrid.

2. Problem statement

The problem formulation takes into account the production and storage levels to be managed by the microgrid, energy sales to the main power grid and the possibility to modify the timing of the energy consumption, in order to maximize the profit of the microgrid. The mathematical model includes the energy balance constraints required to describe the energy flows and constraints associated to the equipment and technologies involved in the microgrid. The problem under study is described in terms of these terms:

(i) A given planning horizon, which is divided into a set of equal-size time intervals $t \in T$. Also, a given Prediction Horizon (PH) and a given Control Horizon (CH).
(ii) A set of scenarios $n \in N$.
(iii) A set of energy generators $i \in I$, characterized by a minimum and maximum energy generation capacity, $P_{i,t}^{min}$ and $P_{i,t}^{max}$, and a given operational cost.
(iv) A set of energy storage systems $k \in K$, having a minimum and a maximum energy storage capacity, $SE_{k,t}^{min}$ and $SE_{k,t}^{max}$, and cost.
(v) A given energy demand, given by the amount of energy required by a set of energy consuming tasks j, f, n, where $f \in F_j$ denotes the f^h time that the consumer j is active in each scenario n. For any energy consuming task, its duration $U_{j,f,n}$ and a target starting time $Ts_{j,f}^{min}$ are established, although tasks can be delayed within certain limits $Ts_{j,f}^{max}$ generating a penalty cost. All tasks which might be active during each iteration of the rolling horizon approach are included in the dynamic set $F_j RH$.
(vi) A given set of power grids $r \in R$, which can buy the excessive energy produced, or sell additional energy if required.

The proposed rolling horizon stochastic formulation is solved iteratively, which allows to update all inputs parameters, and includes the presence of first and second stage variables through the stochastic formulation, in which different scenarios for the duration of

different consumption tasks has been considered. In this formulation, *first stage* variables are related to the decision of produce/purchase energy each energy generator i in each period of time t, whereas the main decisions associated to *second stage* variables are:

(i) The amount of power $P_{i,n,t}$ to be supplied by generator i at time interval t in each scenario n.
(ii) The energy storage $SE_{k,n,t}$ at the end of each time interval *t* in each scenario n.
(iii) The nominal time $Ts_{j,f,n}$ to execute an energy consuming task in each scenario n.

The main equations of the proposed Mixed Integer Linear Programming (MILP) are briefly described (Silvente et al., 2013). Energy production bounds for every energy generator are specified by eq 1, where $X_{i,t}$ indicates if generator i is being used or not. Eq. 2 represents the link among energy flows at a specific storage system and time in each scenario k, n, t, taking into account the storage level $SE_{k,n,t}$, the energy requirements covered by the storage $SP_{k,n,t}$, the supply flows arriving to the storage $L_{k,n,t}$ and the efficiency of the energy storage system η. The energy required by each consumption task in each scenario j, f, n is calculated with eq. 3, while eq. 4 establishes the overall energy balance of the microgrid, considering the production, the consumption, the charge and discharge of the storage unit, and the energy sales to external power grids in each scenario. Also, eq. 5 gives the bounds for the starting times $Ts_{j,f,n}$, of each energy consumption.

$$P_{i,t}{}^{min} \cdot X_{i,t} \leq P_{i,n,t} \leq P_{i,t}{}^{max} \cdot X_{i,t} \qquad \forall i, n, t \in TRH \quad (1)$$

$$SE_{k,n,t} = SE_{k,n,t-1} + \eta_k^{in} \cdot L_{k,n,t} - \frac{SP_{k,n,t}}{\eta_k^{out}} \qquad \forall k, n, t \in TRH \quad (2)$$

$$D_{n,t} = \sum_{j}^{J} \sum_{f}^{F_j} Cons_{j,f} \cdot \left[W_{j,f,n,t} \cdot DT - Z_{j,f,n,t} \cdot \left(T_{t+1} - \left(Ts_{j,f} + U_{j,f,n} \right) \right) \right] \qquad \forall n, t \in TRH \quad (3)$$

$$\sum_{i=1}^{I} P_{i,n,t} \cdot DT - D_{n,t} + \sum_{k=1}^{K} SP_{k,n,t} - \sum_{k=1}^{K} L_{k,n,t} - \sum_{r=1}^{R} S_{r,n,t} \cdot DT = 0 \qquad \forall n, t \in TRH \quad (4)$$

$$Ts_{j,f}{}^{min} \leq Ts_{j,f,n} \leq Ts_{j,f}{}^{max} \qquad \forall j, f \in F_j RH, n \quad (5)$$

The expected profit of the microgrid, which is the objective function to be maximized, is calculated considering incomes and costs for each scenario n in eq. 6, subject to the previous constraints. Each considered scenario in the proposed stochastic programming has associated a probability, Pr_n, which is taken into account to calculate the expected profit. Note that production and storage costs depend on the use of the different available energy production/storage systems, and the penalization cost is determined by the delay in satisfying each energy demand.

$$Profit = \sum_{n} Pr_n \cdot [Incomes_n - CostProduction_n - CostStock_n - CostPenalty_n] \quad (6)$$

In order to use the proposed model in a rolling horizon scheme, the following set of variables and equations are used to link past decisions with the current prediction horizon:

$$\hat{Y}_{j,f,n} + \sum_{t \in RH} Y_{j,f,n,t} = 1 \qquad \forall j, f \in F_j, n, t \quad (7)$$

$$Ts_{j,f}{}^{min} = Ts_{init}{}_{j,f}^{min} - CH \cdot it \qquad \forall j, f \in F_j, n \quad (8)$$

$$Ts_{j,f}{}^{max} = Ts_{init}{}_{j,f}^{max} - CH \cdot it \qquad \forall j, f \in F_j, n \quad (9)$$

$$Dur_{j,f,n} = Dur_{init\,j,f} - \left(CH \cdot it - Ts_{j,f,n}\right) \cdot \hat{Y}_{j,f,n} \qquad \forall j, f \in F_j, n \qquad (10)$$

$$SE_{k,n,t-1} = \widehat{SE}_{k,n,t'} \qquad \forall k, n, t, t' \in TRH, t' = T_t \cdot DT \qquad (11)$$

Binary variable $\hat{Y}_{j,f,n}$ indicates if the consumption task j, f, n has started before the beginning of the current prediction horizon, so eq. 7 establishes that all consumption tasks must start in the scheduling horizon. Minimum and maximum starting times and duration of consumptions are upload by eq. 8, 9 and 10, considering information from previous iterations. Finally, eq. 11 links the energy storage level of the previous control horizon to the initial energy storage level of the current prediction horizon. Then, the rolling horizon algorithm can be applied as follows (Kopanos and Pistikopoulos, 2014):

- Initially, set the initial conditions of the system and set the length of the scheduling, prediction and control horizons.
- Next, for the first scheduling period solve the scheduling problem.
- Update the state of the system as well as the values of the uncertain parameters and solve the scheduling problem, after moving a time step equal to the control horizon.
- Then, if this re-scheduling corresponds to the last period of time, stop. Otherwise, fix the values obtained in the optimization problem for that iteration, re-schedule and update the period of time until the last planning period is reached.

Notice that although the solution obtained in each prediction horizon is optimal for this period of time, the solution of the overall problem could be suboptimal, since future information outside the current prediction horizon is not considered. So, the length of the prediction horizon must be appropriate to guarantee the quality of the obtained results.

3. Illustrative example

The microgrid under study (Silvente et al., 2013) consists of a photovoltaic panel, a wind turbine, an energy storage system and the connection to the external power grid. The scheduling horizon considered is 24 h, and the duration of each time interval is 15 min. In order to study how the length of the PH affects the optimal solution, PHs of 5, 10, 20, and 30 time intervals have been considered. Energy consumption tasks related to two energy consumers and associated to each scenario j, f, n are considered and a limited starting time delay is allowed subject to a penalty cost. It has been considered that all input data (i.e., energy demands, weather conditions) can be updated at the beginning of every time interval. The control horizon has been established as 15 min. This allows to update uncertain parameters, what is very important in order to be able to react in front of unexpected scenario changes from the nominal plan, including for example variations in the power availability or in the duration of the consumptions. Three different durations have been assigned to five consumption tasks, which involves the presence of 3^5=243 different scenarios. Also, each scenario has an associated occurrence probability.

3.1. Results and discussion

The MILP problem has been solved in GAMS/CPLEX 12. Figure 1 displays the obtained daily schedule for energy production and consumption tasks for a PH=20 time intervals within the stochastic approach for one scenario. The energy demand has been managed by the delayed of some consumption tasks. Figure 2 shows the expected profit for the rolling horizon approach under different prediction horizons within the stochastic approach in comparison with the stochastic model (PH=96 under uncertainty) and the perfect information case (PH=96 without uncertainty). Not surprisingly, as the length of

the prediction horizon increases and the input parameters are revealed, the total objective is improved and closes the gap from the solution of perfect information.

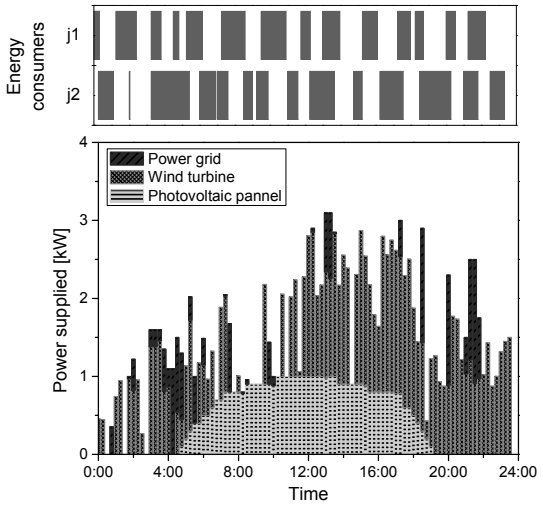

Figure 1. Daily schedule for energy production and consumption tasks (PH=20 for one of the considered scenarios).

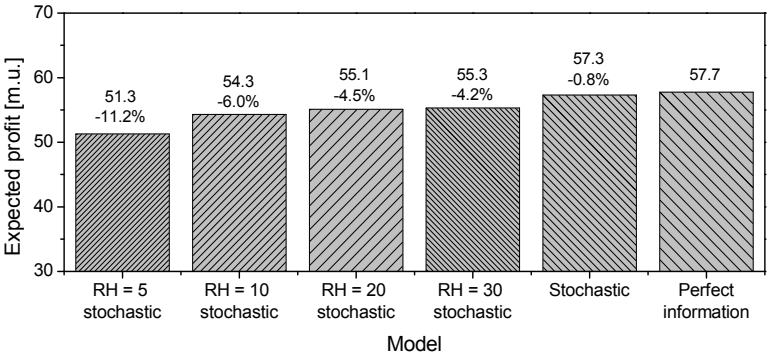

Figure 2. Expected objective value for different PHs through the rolling horizon stochastic approach and the perfect information case.

But, in spite of this obvious conclusion, what is very important is to be able to react in front of unexpected scenario changes. This reactive and proactive approach allows updating input parameters, in order to react to variations from the nominal/initial plan, including alterations in the power availability or in the duration of energy consumptions. The second situation analyses the optimization procedure if a change over the initial weather conditions (i.e. reduction in the solar and wind forecast) and in the duration of some consumptions (considered in the demand scenarios) suddenly appears.

Without the implementation of the rolling horizon approach, there is no possibility to modify the initial demand schedule, since all decisions have been taken previously. Thanks to the rolling horizon approach, it is possible to react to this alterations from the initial conditions. Figure 3 compares the obtained results for the simultaneous energy supply and demand management, for different lengths of PH and the perfect information

case. According to the results, the use of the rolling horizon approach have allows the benefit to be more than 0.9 % high compared with the perfect information case.

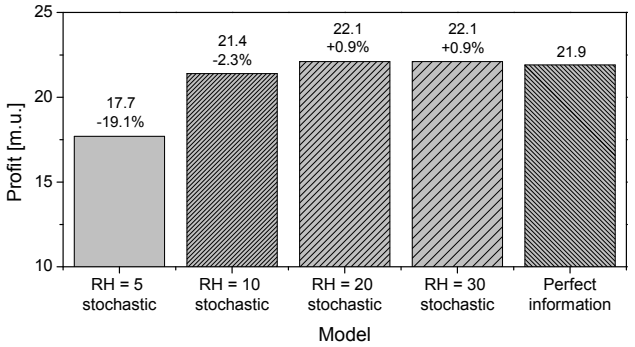

Figure 3. Objective value for different *PH*s under unexpected conditions.

4. Conclusions

A rolling horizon stochastic MILP approach has been developed for the simultaneous management of energy production and demand in microgrids, in order to optimize its profit. A combination of reactive and proactive approaches has been used to deal with the uncertainty associated to the energy production and energy demand. This approach allows updating input parameters, in order to react to variations from the nominal plan, which allows to adapt energy production and energy demand to upload parameters.

Abstract

This work presents the design and development of a supervisory control methodology for the management of energy decisions in a hybrid powered system. More specifically the methodology implements an energy management strategy (EMS) which is applied in a fuel cell – battery system for vehicular applications and explores the behaviour of the system under a realistic operation scenario. The EMS relies on a Hybrid Timed Automaton (HTA) combined with propositional rules and formalizes the operation of the system as it thoroughly describes the dynamic transitions between each operating state. A sensitivity analysis reveals the influence of the power distribution between the two energy sources and an optimization study determines the values of the selected operating parameters. Finally the response of the Fuel Cell Electric Vehicle (FCEV) system is assessed through a combined urban and high-way driving cycle.

Keywords: hybrid systems, power management strategy, fuel cell battery vehicle

1. Introduction

Hybrid energy systems consisting of fuel cells and battery have recently emerged as a potential alternative to the conventional battery powered vehicles. A challenging issue that arises when integrating a fuel cell and a battery stack is the handling of the dynamics that arise by their use (Krewer et al., 2014). Also the management of the various decisions that are applied in order for the integrated system to operate in an optimum way, while fulfilling the frequently and rapidly changing load demand (Degliuomini et al., 2014). In that context the resulting hybrid system should be complemented by a control system that will be able to handle the complex dynamics and the discrete decisions of the overall system. At the core of the considered control system an EMS is necessary that will dictate the appropriate decisions for each subsystem at various operating conditions. The field of energy management of hybrid energy systems is of increasing importance due to the necessity for optimum operation of the various interconnected subsystems that constitute the integrated system.

2. System Description

The design and development of an efficient and modular EMS is motivated by a system that consists of a battery stack, a fuel cell system and an electric motor. The main energy provider is the fuel cell and the secondary is the battery. More specifically the subsystems of the FCEV and their specifications are:

· Polymer Electrolyte Membrane (PEM) fuel cell stack: provides the main source of power and it is rated at 85 kW nominal power and 100 kW maximum power. The nominal voltage is 288 Vdc and its average efficiency is 58 %. The fuel cell operates at 75 °C and 3 bar pressure. The nominal utilization of hydrogen and oxidant is 95 % and 50 % and the nominal consumption of fuel and air is 374 lpm and 1698 lpm.

· Hydrogen tank: The vehicle autonomy is 350 km which is equivalent to 3.5 kg of hydrogen. The consumption is considered at 100 km/kg of hydrogen.

· Lithium-ion Battery: 20 Ah, 288 Vdc, 25 kW.

· Permanent Magnet Synchronous Motor (PMSM): The output motor power is 100 kW and the maximum torque is 256 Nm.

· Power electronics: average value buck DC/DC converter with a current regulator (95% efficiency) and a 3-phase DC/AC inverter.

Figure 1 shows of three subsystems which are: the fuel cell, the electrical and the motor subsystem. The supervisory controller is responsible for the power split between the two main power sources. A set of low level controllers exist at each subsystem that translates the supervisory level actions to device specific commands. The objective of the motor subsystem is to determine the power demand of the electric motor to achieve a certain driving cycle. A dynamic mathematical model for the fuel cell (Njoya et al., 2009) and the battery (Tremblay and Dessaint, 2009) are used in order to simulate the FCEV's response and performance under the proposed supervisory EMS.

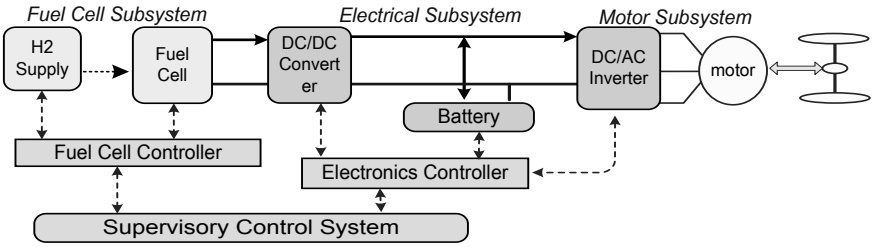

Figure 1 Topology and main components of the FCEV

3. Energy Management Framework

The exploitation of the hybrid nature of the aforementioned system requires a well-designed energy management strategy (EMS) that determines how the demanded by the load (motor) power is distributed between the two energy sources while satisfying design and operation requirements such. Thus, the purpose of the EMS is twofold, to supervise the status of each subsystem and to be able to adjust to system operational modes (Ziogou et al., 2013). During start-up, normal driving or acceleration, both the fuel cell, through the DC/DC converter and the battery deliver electrical energy to the inverter, which then drives the electric motor and subsequently the wheels via the transmission as shown at Figure 1. The PMSM can be operated in either a generator or a motor mode, determined by the mechanic torque. When the torque is positive it is the motor mode and when the torque is negative then it is the generator mode. During

deceleration, the electric motor acts as a generator which transforms the kinetic energy of the wheels into electricity which is stored at the battery. Also to avoid frequent start/stops of the fuel cell the produced power is used to charge the battery during deceleration. More specifically the State of Charge (SOC) of the battery and the available hydrogen (state of energy - SOE) at the storage tanks are the main parameters that drive the operating decisions combined with the power demand from the motor.

3.1. Hybrid Timed Automaton

The interaction between discrete and continuous operating states motivates the use of the hybrid approach and thus a Hybrid Timed Automaton or Automata (HTA) appears as a suitable formulation that includes the semantics for the realization of a generic EMS while the system requirements are translated into propositional based logic representing a set of operating rules. A hybrid automaton H is a collection $H=(Q,X,f,Init,D,E,G,R)$, where Q is a set of discrete states, X is a set of continuous states, $f:Q\times X\rightarrow X$ is a vector field, $Init\subset Q\times X$ is a set of initial states, $E\subset Q\times Q$ is a set of edges, $D:Q\rightarrow P(X)$ is a domain (invariant set), $G:E\rightarrow P(X)$ is a guard condition, $R:E\times X\rightarrow P(X)$ is a reset map. The HTA is used to define possible evolutions for their state H which is defined as $(q,x)\in Q\times X$. Starting from an initial value $(q_0,x_0)\in Init$, the continuous state x flows according to the vector field $f(q_0,\cdot)$, while the discrete state q remains constant. The continuous evolution can go on as long as x remains in $D(q_0)$. If at some point x reaches a guard $G(q_0,q_1)$, for some $(q_0,q_1)\in E$, the discrete state may change value to q_1. At the same time the continuous state gets reset to some value in $R(q_0,q_1,x)$. After this discrete transition, continuous evolution resumes and the whole process is repeated. The collection of these two maps (q, x) is denoted an execution, run or hybrid trajectory of the hybrid automaton (Lygeros, 2003). Hybrid automata are often depicted as directed graphs (Q,E) with vertices Q and edges E representing transitions between them. To each vertex $q\in Q$, a set of initial states are associated $Init_q=\{x\in X:(q,x)\in Init\}$, a vector field $f(q,\cdot)$ and a domain $D(q)$. With each edge $e\in E$ a guard $G(e)$ and a reset map $R(e,\cdot)$ is associated.

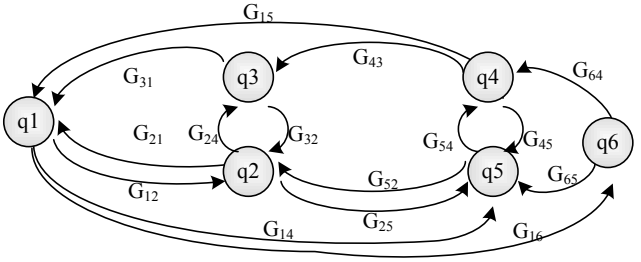
3.2. Propositional Logic used for the transition definition (guards)

The guards of the HTA are described using propositional-based logic rules which are derived by the knowledge of the operation of the system combined with information about the objectives of its operation. The status of each subsystem (BAT, FC, H2, MOT), the user requested action, pedal acceleration, which is translated to the power demand (P_{dem}) and the decision variables, SOC and SOE, define a set of Boolean variables. Each subsystem is related to one or more Boolean variables. For each guard of the HTA a logical rule is defined. More specifically the every logical function is expressed as a combination of the logical operations ($AND:\wedge, OR:\vee, NOT:!$) and the status of each subsystem or the level of stored energy is subsequently compared to the respective level or to each other using the respective operand. Furthermore a hysteresis band is used in the boundary limits of the accumulator to avoid irregular operation (reduction of frequent start-ups and shut-downs of the fuel cell). For example when only power from the battery is provided to the motor and the power demand increases beyond the predefined level (P_{dem}>50 kW) then the fuel cell is activated (P_{FC}=50 kW) and the remaining power is provided by the battery ($P_{Bat}=P_{dem}-P_{FC}$). Table 1 presents the analysis of a guard (G_{25}) that describes the use of both the fuel cell and the battery.

Table 1 Propositional rule for a Guard definition

Guard	Analysis
$G_{2,5}(q_2,q_5)=$ $(\delta_{Pow} \wedge \delta_{H2}) \vee ! \delta_{BAT}$	δ_{Pow} represents the increased power demand, P_{dem}>50 kW
	δ_{BAT} represents the status of the battery, SOC > SOC_{min}
	δ_{H2} represents the availability of hydrogen, SOE> SOE_{min}

The hybrid automaton model of the fuel cell – battery dynamical system is depicted in Figure 2. The vertices of the graph are the discrete states ($q_0,..,q_6$) representing the possible switch positions between the operation modes of the system with respect to the usage of the fuel cell and the battery for the fulfillment of the power demand.



q1: Standby
q2: Battery discharge
q3: Battery charge
q4: Battery charge, FC_{on}
q5: Battery discharge, FC_{on}
q6: Start fuel cell operation (FC_{on})

Figure 2 Hybrid automaton for fuel cell – battery system

When the battery is discharged it means that the demanded power is drawn entirely from the battery (q2) or partially (q5). The battery is charged when the vehicle decelerates and part of the motor power is directed to the battery and from the fuel cell power to avoid frequent start stops.

4. System Operation

The overall objective of this study is to evaluate the effect of the hybrid storage system on the performance of the FCEV. Therefore, besides the fulfilment of the load demand, the EMS should consider the optimal use of the available hydrogen, the protection of the battery's lifetime and the preservation of the fuel cell's durability.

4.1. Parametric Sensitivity Analysis

A parametric sensitivity analysis is performed that involves mainly the battery and the fuel cell subsystem in order to determine the effect that main parameters have to the behavior and response of the integrated system.

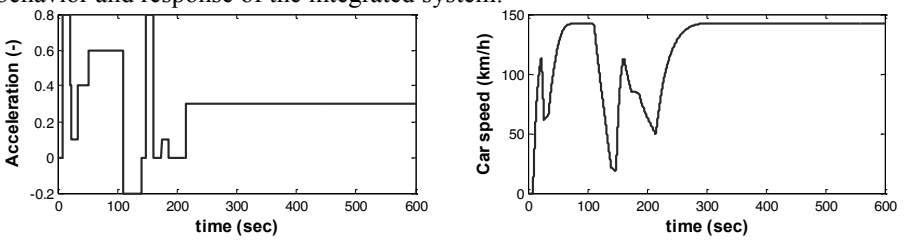


Figure 3 a) Acceleration profile, b) FCEV speed (km/h)

Figure 3 shows the acceleration profile and the resulting vehicle speed which is a combination of an urban drive cycle (first 3min) with a high-way drive cycle (next 7min). A set of simulated driving cycles where performed with different values for three main parameters related to the operation boundaries of the fuel cell ($P_{FC,min}$,$P_{FC,max}$) and

the battery ($P_{BAT,max}$) that influence the Depth of Discharge (DOD), the remaining driving distance and the overall hydrogen consumption (Table 2).

Table 2 Propositional rule for a Guard definition

Parameter	Range	DOD	Tot. H2 consumption	Driving distance (init:350km)	Power split (BAT/FC)
$P_{FC,max}$	50-100 kW	8.2 %	983-1506 lt	344-331 km	17 %/83 %
$P_{FC,min}$	2-6 kW	9.5 %	781-795 lt	345 km	19 %/81 %
$P_{BAT,max}$	21-25 kW	11.2 %	777-778 lt	344-342 km	24 %/76 %

4.2. Optimization

After the sensitivity analysis a deterministic optimization problem is formulated in order to determine the optimal values for the selected parameters. The utilization pattern of the battery and the fuel cell determines the frequency of equipment replacement and maintenance and therefore the operating costs, over the lifespan of the overall system. Thus, the optimization problem focuses on these operation parameters, the DOD for the battery and the SOE for the fuel cell. A constrained medium-scaled optimization problem is formulated, utilizing a deterministic optimization method as the subsystems are described by deterministic, non-linear models. The feasible area that the optimizer explores is determined by the variables' bounds and the operational constraints of each subsystem. The optimization was performed for a combined driving cycle, urban and high-way, and the resulting values of the decision variables are $P_{BAT,max}$*=23.7kW,* $P_{FC,min}$*=2kW,* $P_{FC,max}$*=82.5kW*.

5. Analysis Results and Behaviour Assessment

The proposed EMS is evaluated on a case study regarding the optimal operation of the system. A driving cycle (highway with traffic, 4min) was applied to explore the response of the system and the power distribution between the fuel cell and the battery. Figure 4 shows the requested acceleration and the resulted vehicle speed and the power distribution combined with the battery SOC.

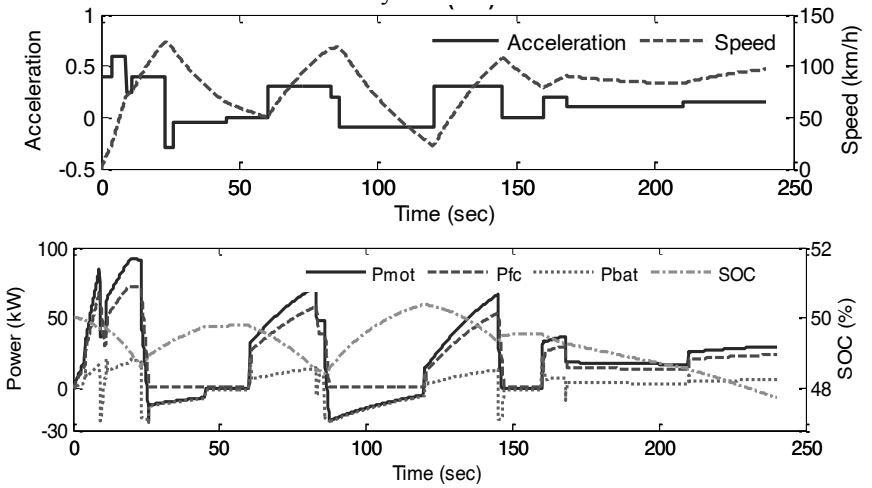

Figure 4 a) Acceleration profile & FCEV speed (km/h), b) Power distribution and SOC

The error between the requested power and the provided is <1% and the hybrid power system is able to provide the requested power. Overall the demanded power was served at a ratio of 91/9% from the fuel call and the battery, the maximum DOD was 2.65%, the fuel cell operated with an average efficiency of 43%. The fuel cell provided 96% to the motor and 4% was used to charge the battery. The power from motor (during braking) that was stored to the battery was 3.4% and the non-absorbed power was 1.8% due to the maximum charging rate of the battery. The selected case study reveals the potential of developed EMS, explores the synergy among the various subsystems and demonstrates the response of the integrated system.

6. Conclusions

An integrated model-based EMS for a FCEV was designed that implements an efficient Supervisory Algorithm based on SOC and SOE. Overall the operation results reveal the potential of the proposed EMS that explores the synergy among the various subsystems and demonstrate the response of the integrated system. The FCEV has successfully followed the driving cycle while the EMS was able to provide the requested power.
Although the methodology was developed for a FCEV vehicle it is not limited to the specific application. Since it relies on a generic formulation, due to the modular nature of the hybrid automaton and the propositional rules, the proposed approach can be used to other systems, such as hybrid renewable power generation stations, where hybrid operation is required and other applications such as stationary fuel cell systems. Also it can be parameterized to include different subsystems, such as an ultra capacitor for small-scale energy storage. Finally the proposed EMS was developed with implementation considerations in mind. Since it relies on simple propositional based logic, it is equally suitable for use at simulation environments (to study the behaviour of the system) as well as for deployment to automation systems for proof of concept (such as Supervisory Control and Data Acquisition (SCADA) systems) and embedded platforms or PLCs for validation in the relevant environment.

Abstract

In this work, an optimization framework to support the planning of the development of shale gas resources is proposed. Financial aspects are taken into account through the integration of financing options, such as own capital, and external sources, short and long term bank credit lines. The model also includes the design of well-pads in terms of total number of wells, and length and number of hydraulic fractures completed at each well. In addition, different capacities and locations are considered for compressor stations, gas separation plants, and water treatment plants. A case study involving two alternative financing strategies was conducted to demonstrate the capabilities of the model. It is found that external financing can play an important role in the development of a shale gas field, achieving an increase in net profit of almost 65 % when compared to a scenario where only own capital is considered.

Keywords: supply chain, optimization, financial aspects, shale gas.

1. Introduction

According to the BP Energy Outlook (BP, 2014), world primary energy consumption is expected to increase roughly 41 % from 2012 to 2035, with an average annual growth rate of 1.5 %. Fossil fuels will remain as the major source of energy, with a share of 81 % in 2035. Among fossil fuels, gas consumption will increase the most at 1.9 % per year. Nearly half of the growth in global gas supply will be provided by shale gas, which is projected to grow at 6.5 % per year.

The development of shale gas resources can play an important role in the expansion of chemicals production and electricity generation (Jenner and Lamadrid, 2013; Siirola, 2014). On the other hand, the production of shale gas is commonly regarded as challenging due to the petrophysical characteristics of shale formations, which have very low permeability when compared to conventional plays. These conditions require the use of advanced production technologies that can give rise to negative environmental impacts if not properly managed. All those factors are reflected in high capital investments. For example, the U.S. Energy Information Administration, in 2012 (EIA, 2012), reported that total average cost, drilling and completion expenses, per horizontal well in Bakken, Eagle Ford, and Marcellus formations varies between approximately $6.5 million and $9 million. Nonetheless because of favourable market conditions, investments in shale gas development in United States totalled $133.7 billion between 2008 and 2012. Given the high cost and volatility in market prices, careful analysis of alternative investment strategies which include choices between

using own capital or external financing such as short or long term bank credit lines is essential. In this work, we proposed an optimization approach as a decision support tool for guiding the investment in the development of shale gas resources which includes aspects such as water availability constraints, capital and operating costs and financing aspects (Laínez et. al, 2007 and Laínez et. al, 2009). The Mixed Integer Linear Programming (MILP) model presented incorporates selection of the design of well-pads in terms of total number of wells, and length and number of hydraulic fractures completed at each well. Different capacities and locations are considered for compressor stations, gas separation plants, and water treatment plants. The formulation also takes into account financial components such as short and long term bank credit lines.
Finally, the capabilities of the proposed model are shown through a case study where two scenarios are evaluated. In the first scenario, external financing is not considered and only limited amounts of own capital can be invested. In the second scenario we include financing options in order to allow more flexibility in the timing of the development plan, reflecting the most common situations in the oil and gas business.

2. Problem Statement and Mathematical Formulation

The development of shale gas resources involve many strategic and operational decisions such as selection of sources of water for fracking processes, selection of well-pad locations and designs, the design of gas and liquid pipeline networks, technology, location, and capacity for waste water treatment plants, and the location and design of gas processing plants. A general shale gas supply chain superstructure is shown in Figure 1.

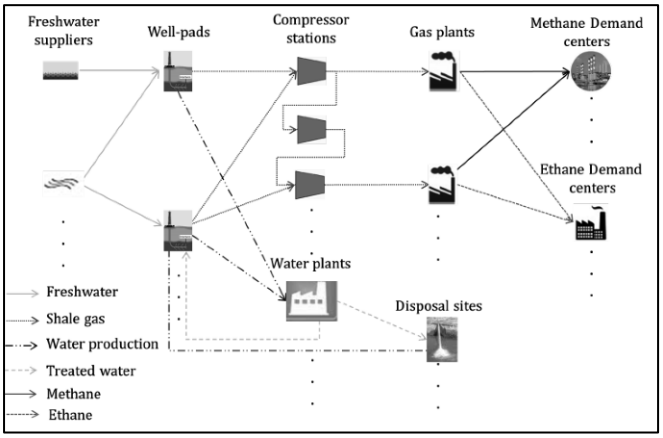

Figure 1. General superstructure for shale gas supply chain.

The features of this superstructure can be summarized as follows:

Given:

- Potential well-pad locations that allow vertical and horizontal wells to be drilled and hydraulically fractured.
- Alternative well-pad designs for each potential location and corresponding production profiles
- Water demand for drilling and fracturing according to the Well-pad designs
- Fresh water availability at potential suppliers (rivers, lakes, etc.)

- Transport and processing infrastructures for water and gas
- Gas and liquid product demands at different locations
- Investment budget and/or financing parameters

To determine:

- Drilling scheme
- Well-pad design in terms of the number of wells, length and number of stage fractures for each well
- Location, capacities, technologies, CAPEX and OPEX for water and gas treatment plants
- Total water consumption, recycled water and disposal
- Gas and water transport network

The objective function is to maximize the Net Present Value (NPV), defined as the cash flow $CashFlow(t)$ minus capital expenditures $Capex(t)$, associated with the design of the shale gas supply chain. In this work, well-pad design, location, and timing are considered the most important decisions in shale gas site development. These decisions are integrated into the binary variable $WellDes(d,w,t)$. This variable is equal to one if the well-pad design d is selected for potential well-pad w during period t, the variable is equal to zero otherwise. This variable is used to determine gas production, water consumption, water production, and capital expenses associated with the drilling operations. Salvage value SV is also included to account for the value of the assets at the end of the time horizon. In addition, the total debt due to borrowings $TotalDebt(T)$ is required to be repaid when the project finishes. Thus, the objective function used in this work is shown in Eq. (1).

$$max \quad NPV = \sum_t \frac{CashFlow(t) - Capex(t)}{(1+wacc)^{t-1}} + \frac{SV}{(1+wacc)^{T-1}} - \frac{TotalDebt(T)}{(1+wacc)^{T-1}} \tag{1}$$

where the weighted average capital cost $(wacc)$ represents the interest rate per period t and it is calculated based on the fractions of own invested capital and borrowed money from external financing sources. The total required investments $Capex(t)$ can be fulfilled with capital internal to the corporation and funds borrowed from banks $BorrowLT(t)$ through long term debt as showed in Eq. (2)

$$Capex(t) \; = \; BorrowLT(t) + \; Capital(t) \tag{2}$$

Additional equations related to long term debt are necessary to keep track of the current debt $DebLT(t)$, net transactions between borrowings and payments $NetLTC(t)$ and how much is paid in every period $RepayLT(t)$. A long term credit is subject to an interest rate $irLT(t)$ defined by an agreement stablished with the bank. This can be done by including Eq. (3)-(5).

$$DebLT(t) = (1 \; + \; irLT(t)) * DebLT(t-1) + \; BorrowLT(t) - RepayLT(t) \tag{3}$$

$$NetLTC(t) = BorrowLT(t) - RepayLT(t) \tag{4}$$

$$RepayLT(t) \geq irLT(t) * DebLT(t-1) \tag{5}$$

A similar formulation is included for short term credit lines, which are used to keep liquidity in a company in case the cash flow reaches a minimum value. A short term credit ensures there is sufficient working capital to cover short term expenditures such as transport costs, operating costs, etc. The financial model is coupled with the formulation developed for the shale gas supply chain shown in Figure 1. The integration of these models allows decision makers to establish the best options regarding strategic decisions for the shale gas supply chain development and simultaneously to optimize the financial implications of these decisions.

3. Case study

3.1. Description

A case study is implemented to demonstrate the capabilities of the optimization model for shale gas supply chain management described in the previous section of this paper. The case study has the following scope: 10 year time horizon (40 quarters), 15 potential well-pad locations, 2 freshwater suppliers , 2 compressor stations (2 sizes), 2 water treatment plants (3 sizes), 2 gas processing plants (2 sizes), 2 disposal sites, and 2 demand centers. Three different configurations for well-pads designs are included as follows: “ShortFew” with 1500 ft length for horizontal wells and 3 fracture stages, “base” with horizontal length of 3000 ft and 8 fracture stages, and “LongMany” with horizontal length of 5000 ft and 20 fracture stages, each well-pad design is composed of 5 horizontal wells. In addition, gas composition is considered to be constant. Two scenarios are studied differing in their financial aspects. In the first scenario (base case), only the use of internal capital is considered, therefore a constraint on maximum capital budget available for new investment is included. In the second scenario (financing case), in addition to own capital, long and short term credit lines are included in order to support investments and operating costs, respectively. The characteristics of the developed models are summarized in Table 1.

Table 1. Model statistics for both case studies

	Base case	Financing case
Constraints	8,777	9,141
Continuous variables	8,241	8,602
Binary variables	5,400	5,400
Non zero elements	174,065	175,306

The statistics reported in Table 1 show that the financing case contains additional equations and continuous variables which are related to the integration of the financial formulation and the shale gas supply chain optimization model. In this study, an annual interest rate of 15 % and 10 % was considered for the short and long term credit line, accordingly.

3.2. Results and discussion

The results regarding the optimal solutions for both cases are discussed in this section. The optimization problems were solved in GAMS (version 24.3.1) with CPLEX (version 12.6.0.1) as the MILP solver using an Intel i-7 @ 2.40 GHz processor with 8 GB RAM, running 64-bit Windows 8.1. The relative optimality gap was set to 3 % for both cases. For the base case, after 24.5 h the algorithm was interrupted resulting in a

candidate solution with an optimality gap of 9.2 %. The CPU time for solving the financing case was 3.1 h with a relative optimality gap of 1.04 %. These differences in CPU time and gap may be due to a tighter LP sub-problem in the financing case. The cumulative net cash flows for the two scenarios are presented in Figure 2. For the base case, the optimal net present value is determined to be around $341.3 Million and the investment for shale gas infrastructure starts in the 11th quarter when the gas price is about 5,753 US$/MMSCF. On the other hand, when external financing options are incorporated, the NPV increases up to $565.3 Million, an increment of about 65.6 % with respect to the base case. In addition, for this case it is economically feasible to invest when the gas price is around 4,143 US$/MMSCF.

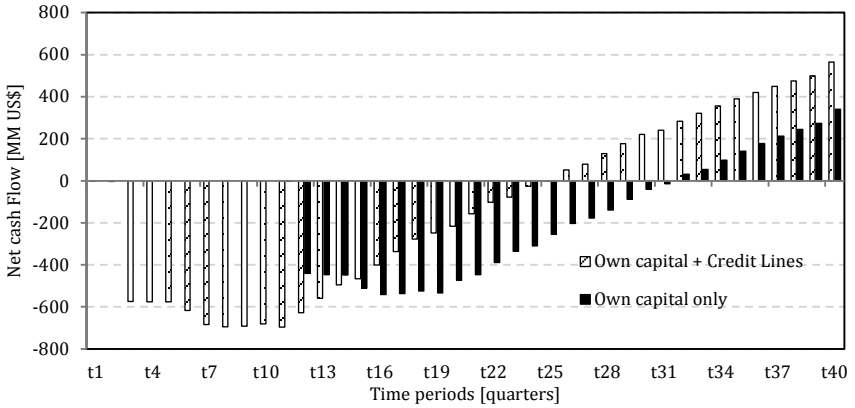

Figure 2. Accumulated net cash flow.

It is worth of mention that under capital investment restrictions (base case), the investment plan is postponed in order to take advantage of higher methane prices at the end of the time horizon, as shown in Figure 3. By contrast, when external financing resources are considered, the investment plan is selected in such a way that gas production starts earlier than in the base case, despite the relatively lower gas prices at the beginning of the time horizon. In this case, the lower gas prices are compensated by higher total gas production, which is estimated to be 281.9 billion SCF and 368.9 billion SCF for the base case and financial case models, respectively.

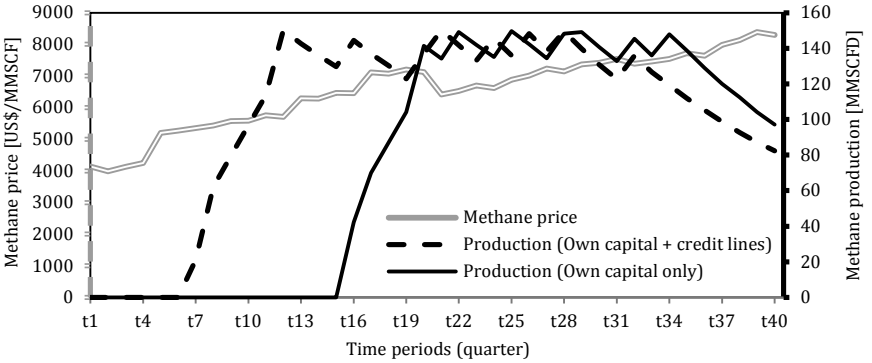

Figure 3. Methane production and gas prices.

With respect to the optimal drilling strategy, 14 well-pads (2 “base” and 12 “LongMany” designs) were chosen for the base case. Total fresh water use is about 448.7 million gallons and water reuse, defined as a % of total water production, is 60.3 %. The cumulative gas production for the 14 well-pads is approximately 281.9 billion SCF. By comparison, for the financing case, 15 well-pads with only “LongMany” designs were chosen. In this case, the total fresh water consumption for drilling and fracturing operations is about 462.7 million gallons and water reuse is 76.1 %. This increase in water reuse is due to a higher demand of water and limitations on disposal capacities, which leads to greater water treatment volumes. Finally, the cumulative gas production for the 15 well-pads is approximately 368.9 billion SCF. It is important to note that both financing and drilling strategies could be affected by the uncertainty associated to water availability, natural gas prices and production profiles.

4. Concluding Remarks and Future Work

This paper has addressed the integration of financing aspects into the optimization models for the development of shale gas resources. It was shown that the financing through external resources, such as short and long credit lines, could be appropriate for the development of shale gas resources. It was also shown that financing strategies have an important impact on the optimal drilling plan as well as the water use and management. Directions for future work include the implementation of case studies considering variations in shale gas composition over the life of the well. Additionally, since the economy of shale gas depends strongly on the market conditions, the financing strategies can be affected by this variability, therefore the development of stochastic optimization models in order to take into account the uncertainties in gas prices, water availability, and gas production profiles will be addressed.

Abstract

Adsorption-based energy systems can provide environmentally friendly heating and cooling energy as they can be driven by low-grade heat, such as solar or waste heat. However, solar and often also waste heat are fluctuating over time. Thus, an optimal operation policy has to be identified to run adsorption-based energy systems efficiently. This work therefore presents a method to determine the optimal control for dynamic adsorption-based energy systems. To determine the optimal control, a two-step approach is used: First, the original non-linear dynamic model is approximated by a set of linear ordinary differential equations connected by Heaviside functions. In a second step, an optimal control problem is formulated and optimized for a set of control variables using a gradient method. The derived model predictive control is tested for a non-linear adsorption chiller model. The MPC shows good performance for both efficiency and specific power as objective functions.

Keywords: adsorption chiller, adsorption chiller model, adsorption heat pump, optimal control, optimal cycle time, model predictive control (MPC)

1. Introduction

Adsorption based energy systems can provide cooling or heating using heat as driving power. Heat-driven adsorption chillers or heat pumps thus enable the use of solar or waste heat (Chan et al., 2013). Adsorption-based systems operate cyclic by switching between adsorption and desorption phase. Controlling such a system means determining the duration of each phase, which has great impact on system performance. For adsorption chillers, a trade-off exists: Long cycles promote a high coefficient of performance (COP), whereas short cycles promote high specific cooling power (SCP) (Chua et al., 1999, 2004). Whether COP or SCP should be the objective function for control depends strongly on the heat source: a limited heat source requires a high COP, an unlimited heat source a high SCP (Alam et al., 2003).

Current control strategies used for adsorption-based energy systems can be clustered into three groups: (1) predefined cycle times; (2) cycle times based on physical states measured during operation; (3) model predictive control.

Predefined cycle times need knowledge of the optimal cycle times for all operating conditions, such as temperature levels, cooling and heating power, as well as system characteristics. Thus, a high amount of a priori knowledge is needed and adaption during operation is hardly possible.

Cycle times based on physical states measured during operation use, for example, the cold water temperature to determine the optimal switching point (Schicktanz, 2011). These controls are typically based on heuristics and experience. Gräber proposed a control based on the average measured cooling power for which he proved optimality regarding SCP when the heat source is unlimited (Gräber, 2013).

The third control strategy is model predictive control (MPC). MPC calculates the feedback law online, by successively solving finite–horizon optimal control (open–loop) problems, see also Morari et al. (1993). Since an accurate model of the problem is needed and an optimal control problem is solved online, MPC is the most complex control strategy described. This complexity is compensated by a high amount of flexibility regarding the optimized objective function and the adaption to changing operating conditions.

This work is structured as follows: First, a non-linear process model of an adsorption chiller is described (Section 2.1) and an MPC procedure for this class of models is derived (Section 2.2). In Section 3, the control is tested for two different objective functions (SCP and COP) using the adsorption chiller model described and a fluctuating input temperature.

2. Model predictive control

2.1. Non-linear process model

The model predictive control presented in this paper is applied to a two-bed adsorption chiller model shown in Figure 1. The chiller model is a dynamic model written in Modelica, an object-oriented, equation-based modeling language. The model is built using the adsorption energy systems library developed at RWTH Aachen University (Bau et al., 2014). The model was experimentally validated by Lanzerath et al. (2014). The chiller model consists of two adsorber beds, an evaporator and a condenser. These components are connected to heat exchangers via heat resistance models. The adsorber beds are connected to the evaporator and the condenser by valve models, describing the mass transfer. Heat losses for all components are modeled using a constant heat transfer coefficient. As model inputs, inflow temperatures and volume flow rates into the four heat exchanger are used. We define the inflow temperature levels: $T_0 < T_{\mathrm{mid}} < T_{\mathrm{high}}$.

2.1.1. Operation of adsorption chiller

The operation of each adsorber bed is divided into four phases: (1) precooling; (2) adsorption; (3) preheating and (4) desorption. During adsorption, the actual cooling power is produced by evaporating water at a low temperature level T_0. This water vapor flows to the adsorber and is adsorbed at T_{mid}. When the adsorber reaches its maximum capacity, the process is reversed by heating the adsorber to T_{high} and condensing the released water in the condenser at medium temperature T_{mid}. To close the circuit, the liquid water from the condenser returns to the evaporator. Precooling and preheating are transition phases between adsorption and desorption to change the temperatures of the adsorber beds. For the considered 2-bed system, symmetry requires equal times for precooling and preheating and for adsorption and desorption. The duration of each phase has to be determined by a controller.

2.1.2. Modeling approach

Adsorber (A), evaporator (E) and condenser (C) have the same model structure: They are modeled as dynamic lumped models with a uniform temperature T. All of them contain a media model. For evaporator and condenser, a two-phase model for saturated water is used. In the adsorber, a

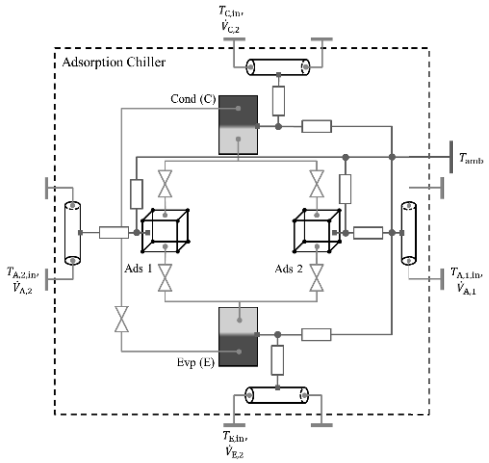

Figure 1: Structure of the adsorption chiller model: two adsorber beds (Ads 1 and Ads 2), an evaporator (E) and a condenser (C) are connected via mass transfer models (blue valve symbols). Connection to heat exchangers (tube models) via heat transfer models (red boxes). Heat losses are implemented via heat transfer resistances coupled to a heat sink at T_{amb}. (Color online)

media model describing the equilibrium data of the sorbent is used. Our adsorption energy systems library (Bau et al., 2014), contains many sorbent media models, allowing for fast changes of the sorbent material. In this work, silica gel 123 is used, described by the Dubinin model (Dubinin, 1967) with a characteristic function measured by Schawe (2001). Exemplary for all components, the mass balance of the adsorber is shown here

$$m_{\mathrm{sor}} \frac{\mathrm{d}x}{\mathrm{d}t} = \frac{\mathrm{d}m_{\mathrm{ad}}}{\mathrm{d}t} = \dot{m}_{\mathrm{E}} - \dot{m}_{\mathrm{C}} \,, \tag{1}$$

where m_{sor} is the mass of the sorbent material and m_{ad} is the mass of adsorbed water. $\dot{m}_{\mathrm{E}}$ describes the mass flow from the evaporator, $\dot{m}_{\mathrm{C}}$ the one to the condenser. The energy balance reads

$$\frac{\mathrm{d}U_{\mathrm{A}}}{\mathrm{d}t} = u_{\mathrm{ad}} \frac{\mathrm{d}m_{\mathrm{ad}}}{\mathrm{d}t} + \left(m_{\mathrm{ad}} c_{\mathrm{ad}} + m_{\mathrm{sor}} c_{\mathrm{sor}}\right) \frac{\mathrm{d}T_{\mathrm{A}}}{\mathrm{d}t} = \dot{m}_{\mathrm{E}} h_{\mathrm{E}}^{\mathrm{v}} - \dot{m}_{\mathrm{C}} h_{\mathrm{A}}^{\mathrm{v}} + \dot{Q}_{\mathrm{A}} \,. \tag{2}$$

The internal energy of the adsorber (U_{A}) is described by the specific internal energy of the adsorbed water (u_{ad}) and the temperature of the adsorber (T_{A}) multiplied by the total heat capacity ($m_{\mathrm{ad}} c_{\mathrm{ad}} + m_{\mathrm{sor}} c_{\mathrm{sor}}$). The internal energy is changed by the enthalpy flows from the evaporator and to the condenser and by a heat flow. The heat flow

$$\dot{Q}_{\mathrm{A}} = \left(\alpha A\right)_{\mathrm{A}} \left(T_{\mathrm{A}} - T_{\mathrm{A,hx}}\right) \tag{3}$$

between sorbent and the outer heat exchanger surface is described with a constant heat transfer coefficient $\left(\alpha A\right)_{\mathrm{A}}$.

Considering the mass and energy balances also for the other components (evaporator, condenser and heat exchangers), we get a coupled system of differential and algebraic equations. In general terms, the resulting system may be written as

$$\frac{\mathrm{d}}{\mathrm{d}t} x(t) = F_i(x(t)) \quad \text{for } t \in (0, t_4) \,, \tag{4}$$

where $i = 1, \ldots, 4$, denotes the current phase. The vector x contains the state variables $x \in \mathscr{C}^1([0,t_4], \mathbb{R}^{16})$ describing the physical quantities.

2.2. Controller design

To control an adsorption system, we propose a model predictive control (MPC) strategy, also called receding horizon control (Rawlings and Muske, 1993). A MPC solves an optimal control problem for a defined time horizon in the future. The obtained optimal control is then used to steer the system. After a certain time, the optimal control problem is updated by the current system state to close the feedback loop (see Figure 2).

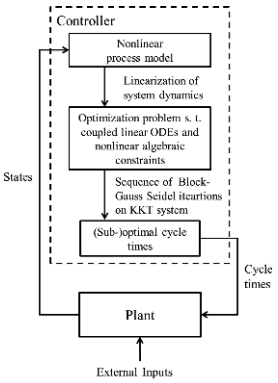

Figure 2: Scheme of the used control strategy: Controller inputs are the current system states, controller outputs are the cycle times used for the next interval. The nonlinear process model is linearized at the given states resulting in an optimization problem with linear ODEs and nonlinear algeabric constraints. This KKT system is than solved by a sequence of Block-Gauss Seidel iterations to get (sub-)optimal cycle times for the next interval.

Due to the strong nonlinearities in F_i with respect to the states x, a direct inversion for controller design is computationally expensive. Similarly, an MPC based on equation (4) leads to a large–scale nonlinear optimization problem which is again computationally challenging to solve. Therefore, we propose the design of the controller for a linearization of F_i at a given state $x(\tilde{t})$, which leads to the following system of ODEs

$$\dot{x}(t) = A_i x(t) + b_i, \quad \text{for } t \in (t_{i-1}, t_i) \tag{5}$$

with $A_i \in \mathbb{R}^{16\times 16}$, $b_i \in \mathbb{R}^{16}$ for $i = 1,\dots,4$ and where A_i and b_i, depend on $x(\tilde{t})$.

This problem is still difficult to solve due to the possible discontinuity in the right–hand side of the ODE at phase switching times between the phases. We therefore combine the ODEs (5) for all phases using a smoothed version of the indicator function.

We parameterize $[0,t_4]$ with $t = t(\tau) = t_4\tau$, $\tau \in [0,1]$ and obtain the final MPC problem for determining optimal cycle times as

$$\begin{aligned} &\min_{x,h} \int_0^1 -\dot{Q}_0(\tau,x) \quad \text{or} \quad \min_{x,h} \int_0^1 -\frac{\dot{Q}_0(\tau,x)}{\dot{Q}_{\text{in}}(\tau,x)} \\ &\text{s.t.} \quad \dot{x}(\tau) = A(\tau,h)x(\tau) + b(\tau,h), \quad \text{for } \tau \in (0,1), \\ &\qquad x(0) = x_0, \\ &\qquad h \geq 0 \end{aligned} \tag{6}$$

with

$$A(\tau,h) := \left(\sum_{k=1}^{4} h_k\right)\tilde{A}\left(\tau\sum_{k=1}^{4} h_k, h\right) \quad \text{and} \quad b(\tau,h) := \left(\sum_{k=1}^{4} h_k\right)\tilde{b}\left(\tau\sum_{k=1}^{4} h_k, h\right).$$

The first objective function in (6) maximizes the cooling power of the system, the second one maximizes the coefficient of performance (COP). The objective function should be chosen according to the available driving power: If driving power is freely available, high cooling power is desired to built compact devices; if not, a high COP is desired to use the available input power as efficient as possible.

From the Lagrange function, we derive the formal necessary optimality conditions for a cycle time h^*, a corresponding state x^* and multiplier $\lambda = \lambda(t)$ and $\mu \in \mathbb{R}^4$. The resulting system is fully coupled and linear in x and λ. We exploit the structure of the equations in the numerical method. This leads to the following iterative solution strategy for the system: Given an initial control h_{old}, we determine a new control h_{new} by first solving the system

$$\dot{x}(t) = A(t, h_{\text{old}})x(t) + b(t, h_{\text{old}}) \quad \text{for } t \in (0,1), \qquad x(0) = x_0$$

for $x(\cdot, h_{\text{old}})$, then solving the system

$$-\dot{\lambda}(t) = A(t, h_{\text{old}})^\top \lambda(t) + \nabla_x - \dot{Q}_0(\tau, x) \quad \text{for } t \in (0,1), \qquad \lambda(1) = 0$$

for $\lambda(\cdot)$. Finally, we obtain

$$h_{\text{new}} = \max\left\{ h_{\text{old}} - \sigma \left[\int_0^1 \left(\frac{\mathrm{d}}{\mathrm{d}h} \left[A(t, h_{\text{old}}) x(t) \right] \right)^\top \lambda(t) + \left(\frac{\mathrm{d}}{\mathrm{d}h} b(t, h_{\text{old}}) \right)^\top \lambda(t) \, \mathrm{d}t \right], 0 \right\} \quad (7)$$

where $\sigma > 0$ is chosen such that the integral of the chosen objective function enjoys descent. The procedure can be repeated with the new h_{old} being h_{new} until no change in the control appears; indicating optimality. A complete derivation of the control strategy including robustness tests for the different parameters of the method, such as linearization points and intervals or the smoothing parameter of the indicator function can be found in Bau et al. (2015).

3. Numerical results

In this section, the controller is applied to an adsorption chiller using different objective functions. We use the non-linear chiller model presented in Section 2.1. To represent fluctuating weather conditions, we vary the input temperature $T_{\text{high}} = 75\left(1 + 0.2 \sin {}^1\!/_{1800\,\text{s}^{-1}}\, \pi t\right)$ °C. The other temperatures are kept constant. The system is simulated with the derived MPC using both objective functions: maximum cooling power and maximum COP. The obtained solutions are compared to a controller based on the average measured cooling power (Gräber, 2013), which maximizes cooling power.

Figure 3 shows the results for the three investigated controls. The top graph shows the phase times of ad- and desorption ($h_2 = h_4$). The two bar graphs below show the obtained average cooling power and the average COP of the system. For an objective function maximizing cooling power, the derived MPC and the controller of Gräber achieve similar results, regarding cooling power and COP. This behavior is expected as Gräber's controller was derived for this case. In terms of phase times, the MPC uses slightly longer times than Gräber's control for low input temperatures (around 45, 105 and 165min), but with almost no effect on the obtained objective function. When the objective function is changed, the MPC computes significantly longer cycle times, resulting in a COP increased by 12%. Thus, the results demonstrate the flexibility of the presented MPC to adapt to the chillers' use case.

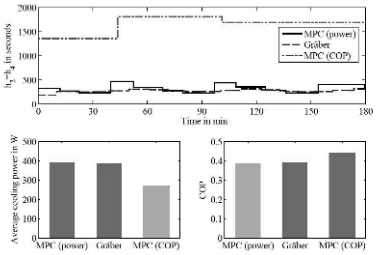

Figure 3: Comparison of the derived MPC control strategy for maximizing power and maximizing COP and a control based on measured states (Gr¨aber, 2013). Top: Phase times for adsorption and desorption (h2 = h4) of compared control strategies. Bottom: Average cooling power (left) and COP (right). (Color online)

4. Summary

This work presents a model predictive control (MPC) strategy for adsorption-based energy systems based on a non-linear process model. The derived MPC uses a two step aproach: (1) The process model is approximated using a system of linear ordinary differential equations. (2) The resulting optimization problem is solved using a sequence of Block-Gauss Seidel iterations on the Karush-Kuhn-Tucker system. Since for adsorption systems, the chosen objective function depends on the operating conditions, the derived MPC is tested with two different objective functions. The obtained results are compared to a control strategy based on measured state variables, which is only able to maximize the average cooling power. As expected, for the case of maximizing cooling power both controllers obtain similar results. For the case of maximizing COP, the MPC increases the COP by 12 %. The presented MPC proves to be a flexible method to control adsorption-based energy systems allowing for further efficiency improvements and faster adaption to changing operating conditions.

Abstract

This paper presents a spatial multi-period MILP optimization model for optimal power generation expansion planning with CO_2 emission constraints. This model examines CO_2 emission and resource adequacy on a regional basis. Resource adequacy constraints, reserve margin, and spinning reserves, ensure safe and reliable operation of the grid in real time. The features of the proposed model are illustrated through case studies related to the Colombian power system, including hydroelectric, coal, and natural gas power plants.

Keywords: optimization, power planning, CO_2 emissions.

1. Introduction

According to the ExxonMobil Energy Outlook (ExxonMobil, 2014), worldwide electricity use is expected to growth by 90 % from 2010 to 2040. Developing countries account for about 85 % of that increase. Therefore, power planning is an important issue in order to provide reliable and sustainable secondary energy in timely fashion, particularly in developing countries. Consequently, energy and power planning problems have captured the attention of the academic research community (Bri-Mathias et al. (2008), Sirikitputtisak et al. (2009), Mirzaesmaeeli and Elkamel (2010), Koltsaklis et al. (2014), and Flores et al. (2014)).

Numerous publications have examined the modelling, simulation, and optimization of energy systems. Sirikitputtisak et al. (2009) and Mirzaesmaeeli and Elkamel (2010) proposed optimization models for the power generation planning of electric systems, which took into account CO_2 emissions. Koltsaklis et al. (2014) presented a spatial multi-period model for optimal long-term planning of a nationwide power generation system. This model includes CO_2 emission constraints and interregional electricity imports. Vinasco et al. (2014) suggested an optimization approach for transmission network expansion planning. The approach was applied to a case study related to the Colombian power system, which took into account various scenarios for electricity generation and demand, using the N-1 safety criterion. Sharan and Balasubramanian (2012) formulated an optimization model that integrated power generation and transmission expansion planning. This model incorporates both the first and second Kirchhoff's laws. Flores et al. (2014) developed a multi-period disjunctive optimization model for investment planning in energy sources. The model was applied to a case study related to the optimization of Argentina's energy matrix under different scenarios over a long-term horizon.

In this work we present a spatial multi-period MILP optimization model for optimal power generation expansion planning. The model includes spinning and non-spinning reserve constraints, as well as CO_2 emission constraints. Carbon Capture and Sequestration (CCS) technologies are considered for coal power plants, in order to mitigate CO_2 emissions. The model also accounts for transmission capacity and cost for power transfer between the interconnected regions. In addition, lead time is considered for construction of new power plants, since such lead times can be quite long. The novelty of the proposed model relies in the integrated assessment of the aforementioned features, which can reveal possible interactions and synergies within the power system. Particularly, the formulation enables the integration of reliability and environmental constraints into the planning of interconnected power systems.

2. Problem Formulation

The optimal design and planning of power systems (i.e. on a nationwide scale) deals with the optimization of power generation capacity expansion of each energy conversion technology for a given electricity demand over a long-term horizon. Usually, different primary energy resources are available for conversion into electricity using different existing and potential power plants that supply the electricity demand that arises in different interconnected regions during a given planning period (i.e. 15 years). Each region is characterized by a subset of existing, planned, and potential power plants, fuel availability and cost, as well as the electricity demand and interregional electricity import/export capacity. Electricity demand at each region can be met either by local power plants or by a combination of local generation and imports from other regions. Power plants (existing, planned, and potential) are characterized by their capacity, location, operating cost (fixed and variable), capital cost (planned and potential power plants only), heat rate (fossil power plants only), CO_2 emission factor, fuel cost, and availability and capacity factors. Reserve margin and spinning reserve factors are taken into account in order to ensure the safe and reliable operation of the grid in real time. Regarding CO_2 emissions mitigation, CCS technologies can be implemented in fossil power plants in order to meet CO_2 emission reduction target. The main strategic decisions related to nationwide power system planning are the timing, location, and capacity of new power plant investments. Furthermore, for each time period, there are operational decisions related to power, reserve margin and spinning reserve allocation, power plant dispatch, and power transfer between regions.

The objective function (to be minimized) is the net present value of the total cost associated with capital investment $Investment(t)$ and operational expenditures for the power system over the whole time horizon, as defined in Eq. (1), where t is the index for time periods (years). Operational expenditures include total fixed $TotFixCost(t)$ and variable $TotVarCost(t)$ cost, total fuel cost $TotFuelCost(t)$ and total transmission cost $TotTrnsCost(t)$. The electricity balance for each region is described in Eq. (2). Indices r and rr are used to denote regions. The link between power plants and regions is defined by the set lri, where i is the index for power plants. Load blocks are represented by the index b. In addition to this balance, the total power allocated for each time period should ensure enough capacity to supply electricity during peak periods while meeting the requirements on capacity reserve, as stated in Eq. (3). Moreover, capacity allocation for each power plant should not exceed its maximum capacity, as described in Eq. (4). The binary variable $Operation(i,t)$ is equal to 1 if

power plant i is operated during period t, the variable is equal to zero otherwise. Electricity output from a given power plant has to be less than or equal to the maximum energy output for that power plant, as specified in Eq. (5). Variable $Ecapture(i,b,t)$ denotes the electricity consumption associated with the operation of CO_2 capture process in power plant i during load block b in period t. A binary variable is included in the model formulation for the selection and installation of CCS facilities. This variable is used to guarantee that electricity consumption and CO_2 emission reduction associated with the operation of CO_2 capture process in power plants is set to zero if the CCS facility has not been installed yet. Spinning reserve should be greater than or equal to the spinning reserve requirements for each period, as specified in Eq. (6). CO_2 emissions are estimated using Eq. (7), where fo is the set containing all the fossil power plants. Parameter $CapPen(i)$ represents the unit electricity consumption (MWh/tonne of CO_2) for capture process in power plant i. Finally, the CO_2 emission constraint is defined in Eq. (8).

$$Min \quad TotCost = \sum_{t} \begin{pmatrix} TotFixCost(t) + TotVarCost(t) + TotFuelCost(t) + \\ TotTrnsCost(t) + Investment(t) \end{pmatrix} / (1+r)\hat{}(t-1) \tag{1}$$

$$(1-EnerLoss) * \sum_{i|(r,i)\in lri} Energy(i,b,t) + \sum_{rr} EnerFlow(rr,r,b,t) = EnergyDemand(r,b,t) + \sum_{rr} EnerFlow(r,rr,b,t) \quad \forall r,b,t \tag{2}$$

$$\sum_{i} Power(i,t) \geq (1+ResMarg) * PeakPower(t) \quad \forall t \tag{3}$$

$$Power(i,t) \leq CapFac(i) * Cap(i) * Operation(i,t) \quad \forall i,t \tag{4}$$

$$Energy(i,b,t) + Spinn(i,b,t) + Ecapture(i,b,t) \leq BlockDur(b) * AvailFac(i) * Power(i,t) \quad \forall i,b,t \tag{5}$$

$$\sum_{i} Spinn(i,b,t) \geq SpinRes * \sum_{r} EnergyDemand(r,b,t) \quad \forall b,t \tag{6}$$

$$Emission(i,t) = CO2Emi(i) * \sum_{b} \left(Energy(i,b,t) + Spinn(i,b,t) + Ecapture(i,b,t) \right) - \sum_{b} \left(\frac{Ecapture(i,b,t)}{CapPen(i)} \right) \quad \forall i | i \in fo, t \tag{7}$$

$$\sum_{i|i\in fo} Emission(i,t) \leq MaxEmi(t) \quad \forall t \tag{8}$$

3. Case Study: Colombian Power System

The proposed optimization problem formulation was applied to a case study related to the optimal planning of Colombia's electric power system which consist of 5 interconnected regions: Antioquia, Caribe, Centro, Oriente, and Valle. Colombia's electricity demand is projected to increase by about 50 % from 2013 to 2027, with different grow rates among the regions. This increase in demand will require an expansion of the power system through selective investments in new power plants in the future. Transmission line capacities are defined according to the expansion plan defined by the Mining and Energy Planning Unit (UPME in Spanish). In addition, CCS

technologies for coal power plants are consider in order meet CO_2 emission reduction targets. However, the best decisions which must be made, with regard to plant capacities, plant locations, timing, power allocation, and CO_2 mitigation strategy are not obvious. The MILP optimization model presented previously will be useful to support these decisions by taking into account economic, reliability, and environmental aspects. Colombia's electricity demand is presented in Figure **1**. In the current situation, the Colombian electric power system has a total of 40 power plants distributed between 5 interconnected regions. Existing power plants include 22 hydroelectric, 15 natural gas, and 3 coal power plants. The total installed capacity is about 13,717 MW. Power plant capacities vary from 42 MW to 1,240 MW. According to the UPME, a total of 17 power plants are already planned to start operation between 2013 and 2022. Those power plants represent a total additional capacity of about 5,139 MW, including hydroelectric, natural gas, and coal power plants. Since the total installed capacity for 2020 will not be adequate to meet electricity demand and reliability targets over the whole time horizon, new power plants, including hydroelectric, natural gas, and coal power plants, are consider in this study. Capacities for these potential power plants vary from 300 MW to 700 MW, with each power plant having a specific capacity and location. Operating parameters for power plants were taken from the Independent System Operator in Colombia (XM). Reserve margin was set to 15 % of the peak power demand. In addition, spinning reserve margin was set to 5 % of current electricity demand. Five scenarios for CO_2 emission reduction were considered, the reduction targets were set to 5 %, 10 %, 15 %, 20 %, and 25 % with respect to the base case (0 % of CO_2 emission reduction) for Scenarios I, II, III, IV, and V, respectively. The developed model has the following characteristic: Mixed Integer Linear Programming (MILP) model with 4,560 constraints (Equalities plus inequalities), 6,920 continuous variables, 1,136 binary variables, and 28,834 non zero constraint matrix elements. The optimization problems were solved in GAMS (version 24.3.1) with CPLEX (version 12.6.0.1) as the MILP solver using an Intel i-7 @ 2.40 GHz processor with 8 GB RAM, running 64-bit Windows 8.1. The relative optimality gap was set to 3 % for all of the cases.

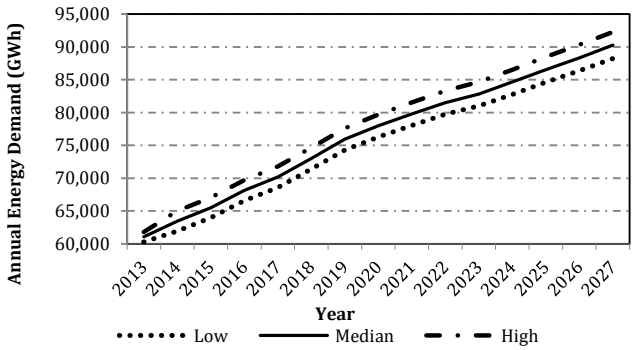

Figure 1. Colombia's forecasted annual electricity demand (GWh).

The results related to the optimal energy mix are presented in Figure 2. For the base case scenario, without constraint on CO_2 emissions, the optimal energy mix was as follows: hydropower plants supply about 75.83 %, natural gas and coal power plants supply about 18.41 % and 5.76 % of electricity requirements, respectively. As expected and confirmed by reports from XM, hydropower plants supply most of the electric

power requirements for Colombia. This is due to the fact that hydropower resources are abundant in Colombia and that hydropower generation is cheaper than other electric power generation alternatives that rely on coal or natural gas. The optimal electricity generation cost was determined to be about 50.53 $/MWh, a value which is close to the estimated generation cost of 51 $/MWh which was reported by the UPME in the power expansion plan for the same time frame.

According to the optimal power generation expansion plan, an additional capacity of around 3050 MW is required in order to meet the potential deficit in electricity supply from 2017 to 2027. To do so, the following additional power capacity should be added to the system: first, a new natural gas power plant with 500 MW of capacity needs to be built and operated from 2017 to 2027. Secondly, a new coal power plant with 300 MW of capacity should be built in 2016 and operated from 2019 to 2027. Thirdly, a new natural gas power plant with 650 MW of capacity needs to be built and operated from 2020 to 2027. Lastly, three new hydropower plants with 400 MW, 600 MW, and 600 MW of capacity should be built in 2020 and be operated from 2024 to 2027. All of the hydroelectric power plants are located in Antioquia, while the natural gas and coal power plants are located in Caribe and Centro, respectively. As regards interregional power transfer, the Caribe, Centro and Valle regions import electricity from Antioquia. Total investment in these new power plants is about $8.63 billion, about $2,829/kW. Total CO_2 emissions, over the 15 year time period considered in this study, were about 14.67 million tonnes per year. These emissions were around 0.191 tonnes of CO_2 / MWh. It was noted that a 10 % of reduction on CO_2 emissions can be achieved by increasing the generation from hydropower plants from 75.83 % to 78.09 %, without using CCS technologies for coal power plants. For a CO_2 emission reduction target of 15 %, one CCS facility should be installed in 2025. Similarly, for a 20 % reduction target, two CCS facilities need to be built in 2013 and 2018. Finally, for a 25 % reduction target, three CCS facilities should be installed in 2015, 2016, and 2025.

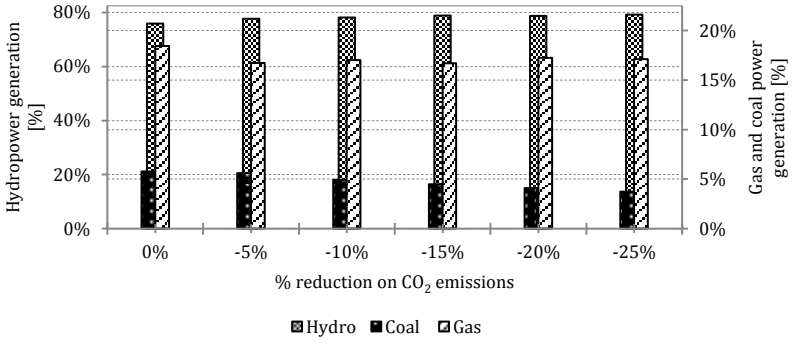

Figure 2. Optimal energy Mix.

Electricity generation and CO_2 emission reduction cost are summarized in Figure **3**. It is observed that electricity generation and CO_2 emission reduction costs increase as the CO_2 emission reduction target increases. In general, the average emission reduction cost was about $12.32/tonne of CO_2 for a reduction target equal or lower than 10 % (Scenarios I and II). Similarly, the average emission reduction cost was about $40.11/tonne of CO_2 for a reduction target equal or higher than 15 % (Scenarios III, IV, and V). The smoothness of the curve of CO_2 emission reduction costs from scenario I to II could be due to variations resulting from the choice of the optimality gap.

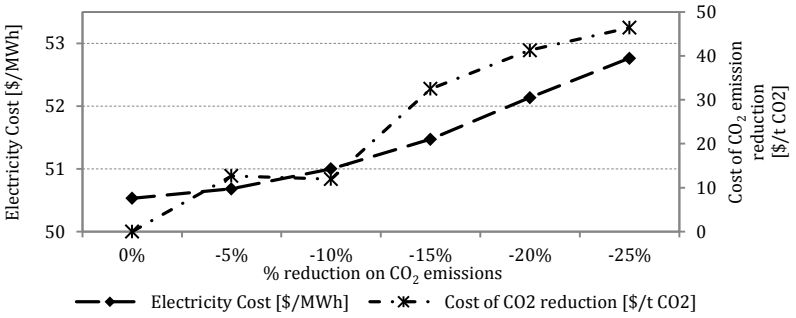

Figure 3. Electricity and CO_2 mitigation cost.

4. Conclusions

In this work, a deterministic MILP optimization model for the optimization of a distributed power systems with CO_2 emission constraints was developed. The capabilities of the proposed model were illustrated using a case study from the Colombian electric power system with different scenarios related to the CO_2 emission reduction targets. It was found that a 10 % of reduction in CO_2 emissions can be achieved by increasing the generation from hydropower plants, without using CCS technologies for coal power plants. In addition, for a CO_2 emission reduction target greater than or equal to 15 %, CCS facilities need to be installed. Future work will be focused on the extension of the deterministic model to a stochastic optimization model in order to take into account uncertainties in energy demand, availability of hydropower resources, fuel cost, as well as capital cost for power generation technologies.

Bringing Non-energy Systems into a Bioenergy Value Chain Optimization Framework

Miao Guo, Nilay Shah*

Department of Chemical Engineering, Imperial College London, SW7 2AZ UK,
**n.shah@imperial.ac.uk*

Abstract

This study presents a multi-objective optimization model configured to account for a range of interrelated or conflicting issues involved in bioenergy systems. A spatial-temporal mixed integer linear programming model - ETI-BVCM (Energy Technologies Institute - Bioenergy Value Chain Model) (Samsatli et al. 2014) - was adopted and extended to incorporate resource-competing systems (bioenergy vs. non-energy) and effects on ecosystem services (ES) brought about by the land use transition in response to bioenergy penetration over five decades. The extended model functionality allows for exploring the effects of constraining ES impacts on other system-wide performance measures such as cost or greenhouse gas (GHG) emissions. The users can therefore constrain a metric which quantifies (to a certain extent) the change in ES from land use transitions. The developed model provides a decision-making tool for optimal design of bioenergy value chains supporting an economically and land-use efficient and environmentally sustainable UK energy system meanwhile delivering multiple ES. The study demonstrates the types of valuable insights the extended optimization modelling framework could provide for policy formulation to accelerate bioenergy penetration and support its sustainable development.

Keywords: optimization, bioenergy supply chain, energy system, ecosystem services

1. Introduction

Energy sectors are responsible for over 80% of the total GHG emissions in the EU-28 (EEA 2014) and approximately 83% of the UK GHG emissions in 2012 (DECC 2014). Bioenergy has been widely recognized as a strategy for mitigating climate change. This has triggered ambitious national/regional policy targets mandating the role of bioenergy within the overall energy portfolio e.g. the Renewable Energy Directive (RED) target of a 20% share of renewable energy in the EU energy mix by 2020 (EuropeanUnion 2009). However, bioenergy is a complex system, which involves many interrelated or conflicting issues e.g. economic development vs. environmental and social sustainability, interaction between energy and food sectors. Thus the large scale deployment of bioenergy requires a thorough understanding of how whole bioenergy value chains perform and the interaction of bioenergy with non-energy systems relying on the same resources and demanding the same productive lands for biomass production. The decision making should be supported by holistic and quantitative design tools considering conflicting objectives simultaneously and assessing the environmental and economic performance of bioenergy systems, considering the entire supply chain over the long-term. Mixed integer linear programming (MILP) represents an effective mathematical modelling approach to solve complex optimisation tasks and identify the potential trade-offs between conflicting objectives, which can provide a better understanding of bioenergy systems and support decision-makers elaborating the sustainable pathways towards bioenergy targets. Landscapes generate a wide range of ecosystem services but these services are often ignored in land use decisions. The land use transitions in response to the penetration of bioenergy over coming decades could affect not only supporting or regulating ES (e.g. GHG emissions, water quality and

carbon sequestration) but also various provisioning ES (e.g. biodiversity, food provisioning services). As highlighted in the Millenium Ecosystem Assessment (2005), with evidenced ongoing global degradation of ecosystem services, it is important to incorporate ES into the economic analysis underpinning real-world decision-making. Most of the optimization studies in this field focus on economic feasibility or trade-offs between economic performance and GHGs for bioenergy supply chain (SC) design but rarely consider the broader ES context. The economic performance can be investigated by conducting supply chain analysis but a full review on the supply chain models is not presented here due to space limit. To our best knowledge, no publically available study has incorporated non-energy systems and ES due to land use transitions over multiple periods into a spatially-explicit optimization model. This study aims to bring ecosystem services into the multi-objectives optimization framework supporting bioenergy SC design and optimal land use for multiple systems (energy and non-energy use).

2. Methodology

2.1 Problem statement

The underpinning concept is to bring resource-competing systems (bioenergy vs. non-energy) and the effects of bioenergy penetration on ecosystems into an optimization framework. This has been implemented by adopting and extending a spatial-temporal MILP model - ETI-BVCM (Samsatli et al. 2014). The ETI-BVCM toolkit encompasses bioenergy systems considering biomass from diverse bioresources including domestic food crops, bioenergy crops, forest, biowaste and imported biomass. It considers various pre-treatment and conversion technologies via biochemical, thermochemical and mechanical routes. It is capable of analysing UK bioenergy supply chains at a grid resolution of $50\,km \times 50\,km$ and identifying the potential trade-off between GHG targets and cost optimal solutions for bioenergy value chain design over five decades (2010s-2050s). Land types including arable lands, forestry lands, pasture lands and potential marginal lands, were considered in ETI-BVCM model and classified into four land levels according to the Corine land cover database. As reported in (Samsatli et al. 2014), level 1 represents land type 1 i.e. arable land and heterogeneous agricultural areas; level 2 is defined as level 1 plus land type 2 (shrub and herbaceous vegetation association and open spaces with little or no vegetation); level 3 is the accumulation of level 2 and land type 3 (permanent crops and pasture lands); level 4 is the accumulation of level 3 and land type 4 (forest and artificial non-agricultural vegetated areas). The non-energy systems incorporated in the extended ETI-BVCM model include food and industrial timber (e.g. roundwood) production and demand, which could compete with the bioenergy system due to their dependence on the same biomass resources and land demands (Fig 1). The economics of the system investigated focus on biomass cultivation, conversion technology, capacity assignment, logistics and transport networks. The model was configured to account for a range of ecosystem services and the ES impacts induced by the land use transition to the production of bioenergy and other products such as food and timber. A performance indicator land use intensity (LUI) was introduced into the model. The model is configured to account for annual harvested biomass extracted for socioeconomic use for multiple systems which lead to an efficient land use system supporting sustainable development of bioenergy and non-energy markets. LUI along with GHGs is evaluated using a life cycle approach to take into account the impacts of the entire bioenergy supply network on ES. Other ecosystem service impacts of land use transitions will be assessed using the matrix approach described by Holland et al. (2014). The research objective of this study is to extend the ETI-BVCM modelling framework to investigate the bioenergy system configuration to deliver optimal value chains best supporting an economically efficient, low-GHG and land-use efficient UK energy system meanwhile limiting the damages on ES and ensure UK food security and sustainable development of a lignocellulose resource market.

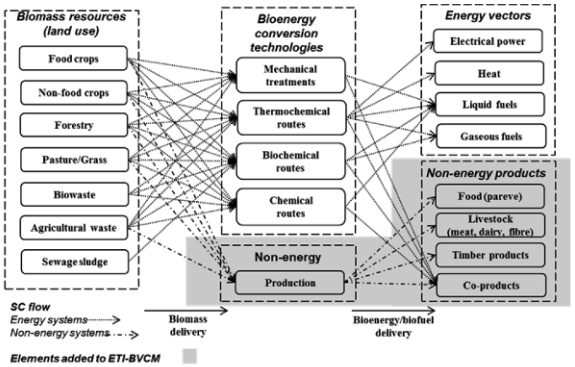

Figure 1 Bioenergy supply chains and non-energy systems

2.2 Model formulation

The multi-objective MILP model ETI-BVCM developed by Samsatli et al. (2014) was extended and formulated to account for non-energy systems, and ecosystem services (sections 2.2.1-2.2.5 & Fig 2).

2.2.1 Objective function

ETI-BVCM adopted a multi-objective optimisation approach in which the objective function was formulated as a weighted sum of costs, GHG emissions, energy production and exergy production. By giving weights, the model could either minimize the total discounted costs, minimize the total GHGs or maximize energy/exergy production or supply chain profit (Samsatli et al. 2014). In this study, the objective function is to minimize the total economic and GHG impacts of a bioenergy supply chain (Eq. (1)).

$$Obj = \sum_d \sum_{kpi} (TSCI_{kpi,d} WeightF_{kpi,d}) \quad (1)$$

2.2.2 Ecosystem services impacts

The variable $ESI_{epi,d}$ represents the change of ES brought about by land use transitions in response to bioenergy system development in each decade (*d*), which is constrained by the user-defined maximum allowed relative change to ES (Eq.(2)). As presented in Eq. (3), the decadal impacts on ES caused by the land transition to these uses can be semi-quantified by introducing land use transition factors $ESIF_{r,al,epi}$. The land transition impact matrix is being developed under this project research agenda to assess the ES impacts of land use transitions associated with a biomass production system. The principles for developing such a matrix, which identifies the direction and magnitude of the changes in ES impacts of new land use patterns have been addressed in (Holland et al. 2014) and some of the land transition matrix data will be derived from the ETI-funded ELUM project. Each land use ES change factor is divided into seven impact levels with indicator scores assigned (not spatially explicit, ESIF scores given in Fig 3). A negative score (-1,-2,-3) indicates that the land use transition would damage the ES whereas a positive (1, 2, 3) or a neutral score (0) represent beneficial effects or little/no impacts on ES. $TR_{r,c,al,d}$ denotes the transitions from areas of a reference cropping system to bioenergy feedstock (*r*) production at each land type al in cell c due to bioenergy penetration in decade d. As given by Eq. (4) decision variable $Tr_{r,c,al,d}$ is dependent on the difference in dedicated areas at each land level for bioenergy feedstock production at the end of each decade compared with the previous time period (decade d-1). A negative land use transition value indicates land use change from a bioenergy to non-energy cropping system whereas a positive value implies land transition from non-energy to bioenergy system use. Therefore, not only the land transition to bioenergy use (positive $Tr_{r,c,al,d}$) coupled with positive influences on a given epi could bring the beneficial effects (positive $ESI_{epi,d}$) but also avoidance of

negative ES impacts of bioenergy cropping system (negative $ESIF_{r,al,epi}$) by moving land use towards non-energy systems (negative $Tr_{r,c,al,d}$)could conceptually lead to an environmentally beneficial system (Fig 3). Note that (i) the key contribution here is the modelling framework and (ii) the results obtained are very sensitive to input data which suffers from paucity, hence the semi-quantitative approach.

$$ESI_{epi,\,d} \geq MinESI_{epi,\,d} \qquad \forall epi, d \tag{2}$$

$$ESI_{epi,\,d} = \sum_{r\in B}\sum_{c}\sum_{al} TR_{r,c,al,d}\, ESIF_{r,\,al,\,epi} \tag{3}$$

$$Tr_{r,c,al,d} = (A1_{r,c,al,d} - A1_{r,c,al-1,d}) - (A1_{r,c,al,d-1} - A1_{r,c,al-1,d-1})\ \forall r \in B \tag{4}$$

2.2.3 Land constraints

In addition to the constraint on land use transitions (Eq. (4)), the land areas allocated for bioenergy and non-energy resources are upper-bounded by the land availability ($MaxA_{c,al,d}$) in each cell at selected land level and the user-defined parameters for land allocation (Eq. (5), (6) and (7)).

$$\sum_{r\in B\cup FT}\sum_{c}(A1_{r,c,al,d} + A2_{r,c,al,d}) \leq \sum_{c} MaxA_{c,al,d}\gamma_{al,d} \tag{5}$$

$$\sum_{r\in B} A1_{r,c,al,d} \leq MaxA_{c,al,d}\alpha_{al,d} \tag{6}$$

$$\sum_{r\in FT} A2_{r,c,al,d} \leq MaxA_{c,al,d}\beta_{al,d} \tag{7}$$

2.2.4 Non-energy system constraints

To achieve optimal design of bioenergy value chains meanwhile limiting the damages on provisioning ES to ensure UK food security and sustainable timber supply, two constraints were introduced to limit the maximum amount of biomass resources to be used for bioenergy production. As stated in Eq. (8), UK local demand for food and timer resource r should be met by resource import and local production, which is determined by the area and annual biomass yield (Eq (9)). To further achieve the domestic food security and sustainable development of lignocellulosic provisioning services, a certain fraction of UK demand for food and timber resources r need to be met by local production(Eq. (10)).

$$\sum_{c}(Im_{r,\,c,\,d} + Pr_{r,\,c,\,d}) \geq D_{r,d} \qquad \forall r \epsilon FT \tag{8}$$

$$Pr_{r,\,c,\,d} \leq \sum_{al} A2_{r,\,c,\,al,d}\, Yield_{r,c,s,d} \qquad \forall r \epsilon FT \tag{9}$$

$$\sum_{c} Pr_{r,\,c,\,d} \geq D_{r,d} SecF_{r,d} \qquad \forall r \epsilon FT \tag{10}$$

2.2.5 Land use intensity

LUI (ton C/ha) formulated in Eq. (11) was introduced into the model - it is calculated after the model is solved. NPP is referred to as the net biomass production of an ecosystem in terms of carbon fixation rate, quantified as the net amount of carbon assimilated in a given period by vegetation (Zhuang et al. 2013). $NPPh_{r,c,s,d}$ represents the biomass extracted for further socioeconomic use and includes harvested crops, consumed crop residues, fuel wood and industrial roundwood as well as forage (including biomass directly consumed by livestock by grazing and biomass indirectly consumed through harvest for production of hay & silage). $NPPh_{r,c,s,d}$ involves above-ground harvested biomass for economic use and the used above-ground residues, which generally can be derived from Eq. (12). The parameters $Fabv_r$ HI_r $Blos_r$ Fh_r Rc_r can be obtained from publically available data sources e.g. (Zhuang et al. 2013). $NPP_{r,c,s,d}$ represents the difference between gross primary production (GPP describe the rate at which the plant produces useful chemical energy and is defined as the total amount of carbon fixed by photosynthesis) and plant respiration, and can be projected by using well-validated process-based simulation models e.g. NASA-CASA model, DeNitrification-DeComposition (DNDC).

$$LUI_d = \frac{\sum_{r\in B\cup FT}\sum_{c}\sum_{al} NPPh_{r,c,s,d}(A1_{r,\,c,\,al,d} + A2_{r,c,al,d})}{\sum_{c}\sum_{al} MaxA_{c,al,d}} \tag{11}$$

$$NPPh_{r,c,s,d} = NPP_{r,c,s,d} \cdot Fabv_r \cdot HI_r \cdot (1 - Blos_r) \cdot (1 + Fh_r \cdot Rc_r) \tag{12}$$

Sets	
$r \in R$	set of resources (biomass, non-energy resources e.g. water, sugar and energy carriers e.g. electricity, biofuel)
b	set of biomass resources used for bioenergy system $b \in B \subseteq R$
ft	set of food and timber resources used for non-energy systems ft∈FT⊆R
s	set of scenarios e.g. low/medium carbon concentration scenarios based on UK Climate Projections 2009
d	set of decades {2010s, 2020s, 2030s, 2040s, 2050s}
c	set of UK grid cells {1, 2…….157}
al	set of land levels concerning four land types {'1': "easy, established technology", '2': "pioneering plant establishment", '3': "challenging from a techno-economic and ecological aspects", '4': "last resort"}
kpi	set of key performance indicators including the cost, CO_2 and other GHGs
epi	set of ecosystem service performance indicators e.g. biodiversity, water quality and soil quality
Parameters	
$MinESI_{epi,d}$	Maximum allowed change to regulating/supporting ES or minimum food/timber/energy provisioning ES (indicator epi) in decade d
$WeightF_{kpi,d}$	Weighting factor for key performance indicator kpi in decade d; in the case of GHGs, market price for traded C emissions may be applied (£/kg CO_2 equivalence)
$ESIF_{r,al,epi}$	Impacts on ecosystem service (indicator epi) due to new land use transition patterns for cultivation of biomass resource r on land type al for bioenergy system development
$Yield_{r,c,s,d}$	Maximum yield (oven dry weight) of resource r in cell c under scenario s in decade d (odt/ha/y)
$MaxA_{c,al,d}$	Maximum available lands for crop plantation in cell c at land level al in decade d (ha)
$\alpha_{al,d}$	Fraction of area allocated for biomass cultivation for bioenergy system at land level al in decade d
$\beta_{al,d}$	Fraction of total area allocated for biomass cultivation for non-energy systems at land level al in decade d
$\gamma_{al,d}$	Fraction of total area allocated for total biomass cultivation for energy and non-energy systems at land level al in decade d
$D_{r,s,d}$	Annual demand of resource r under scenario s in decade d for non-energy system (timber, food etc.) (unit resource/y)
$SecF_{r,d}$	Security factor to ensure a certain fraction of resource r demand for provisioning ecosystem services (e.g. food, timber) to be met by local production in decade d
$NPPh_{r,c,s,d}$	Harvested net primary production (NPP) of biomass r in cell c under scenario s in decade d for socioeconomic use (t C/ha)
$Fabv_r$	Proportion of aboveground biomass for resource r
HI_r	Harvest index of biomass resource r, measuring the proportion of total aboveground biomass allocated to economic yield of crop
$Blos_r$	Proportion of biomass loss or return for resource r
Fh_r	Harvest factor for resource r representing the ratio of available above-ground residues to above-ground economic yield of harvested biomass
Rc_r	Recover rate of biomass r refers to the ratio of used above-ground residues to available above-ground residues
Continuous variables	
$TSCI_{kpi,d}$	Total impacts caused by whole bioenergy supply chain in decade d expressed as key performance indicator kpi (including cost and GHGs), consisting of the decadal impacts caused by crop production, infrastructure/capital, technology operation, resource import and storage, resource purchase, transport, carbon transport, waste disposal, credits brought by carbon capture and storage, carbon sequestration by long rotation forestry and offset by by-products
$ESI_{epi,d}$	Ecosystem services impacts of bioenergy supply chain in terms of indicator epi in decade d
$TR_{r,c,al,d}$	Area expansion/contraction of biomass r in cell c at land type al in decade d (ha) to represent the land use transition
$A1_{r,c,al,d}$	Areas dedicated for cultivation of resource r for bioenergy system in cell c at land level al in decade d (ha, non-negative)
$A2_{r,c,al,d}$	Areas dedicated for cultivation of resource r for non-energy systems in cell c at land level al in decade d (ha, non-negative)
$Im_{r,c,d}$	Import rate of resource r for non-energy systems in cell c in decade d (t/y)
$Pr_{r,c,d}$	Production rate of resource r for non-energy systems in cell c in decade d (t/y)
LUI_d	Land use intensity - harvested NPP for cultivation of a given biomass feedstock per unit available land in decade d

3. Illustrative example

To demonstrate the concept of extended model functionality (rather than to provide any detailed insights), the extended ETI-BVCM model has been applied to a UK case study with the EU RED target of a 10% share of renewables in the transport sector by 2020 (minimum demand of 164 PJ) where 6% share was assumed to be met by UK local production. Transport fuels including bioethanol, biodiesel, bio-butanol, biocrude oil and biomethanol derived from 1G and 2G feedstock (using the ETI-BVCM built-in database) via biochemical and thermochemical routes were modelled. The effect of constraining biodiversity ES on system-wide performance measures (cost and GHGs) for 2020 scenario were investigated. The SC cost increased by approximately 19% (increased from £11.1 bn to £13.2 bn) with shifting the lower bound for SC impacts on biodiversity (maximum allowed damage on ES ($MinESI$) moves within a range of -10,000,000 and +10,000,000). With the shift from an environmentally damaging to beneficial system, a significant reduction in land use for 1G biomass and an increase in land utilization for cultivating 2G feedstock for bioenergy demand are projected. The total UK land allocation for bioenergy system varies within the range of 12-25% whereas winter wheat food production accounts for 9.3-9.6% of total available UK lands across all configurations for 2020s. Nearly 90% of the decadal costs for transport biofuel SC are attributed to the biofuel production (operation and capital). 2G biomass cultivation contributes approximately 13% whereas the share of transport is negligible

4. Conclusion

A multi-objective bioenergy supply chain optimization model - ETI-BVCM - is extended to account for interrelated and conflicting issues in bioenergy SC design e.g. land utilization and resource potential for competing systems (bioenergy vs. non-energy) and a wider range of ecosystem services. With the proposed modelling approaches, this research highlights the valuable insights the extended optimization modelling framework could provide for strategic design of bioenergy supply chains, which best support an economically viable, land-use efficient and environmentally sustainable UK energy system meanwhile deliver multiple ecosystem services.

Abstract

A mixed integer linear programming (MILP) approach is presented for the design of residential distributed energy systems under cost minimisation. A neighbourhood design is determined based on the selection from a pool of energy supply alternatives to meet the total annual energy demand. In addition to distributed generation units, energy integration in the form of microgrid (MG) operation and pipeline networks are considered. Location specific input data regarding cost, climate and regulations are taken into account. The effect of energy interaction restrictions, in the form of residential energy export and MG operation, on neighbourhood design is researched.

Keywords: distributed energy system, energy integration, mixed integer linear programming, trigeneration

1. Introduction

Small-scale generation units that are located close to end-consumers in the central electricity grid - so called distributed generation (DG) units - could help to address climate change issues and the finiteness of conventional energy resources (Pepermans et al., 2005). DG units are ideally combined into highly efficient microgrid (MG) environments that are able to exploit locally available renewable energy resources as well as to share locally generated energy between its participants. Distributed energy systems are therefore tailored to location specific requirements and need a cost effective and efficient design. A superstructure MILP model to achieve such design for a small residential neighbourhood is presented in this work. The decision of investing in and the choice of DG and storage units depends on the ability of the MG to export electricity to the central grid as well as on the electricity exchange allowance between households within a MG. These energy interactions are important to allow local excess generation to be exported in order to avoid MG safety issues due to local generation being higher than local demand. Furthermore, export allows houses to create an income through potential governmental support schemes in the market. Energy interaction allowances of distributed energy systems are therefore determining economic and safety factors for local energy system design and are therefore analysed in this paper.
Various papers in the field of design optimisation of distributed energy systems exist. Manfren et al. (2011) and Keirstead et al. (2012a) provided comprehensive reviews of optimal design models with specific sets of technologies and assumptions. Energy integration of distributed energy systems with regard to MG operation combined with heating is addressed in a residential setting by for example Mehleri et al. (2011, 2013), who employs a cost minimisation MILP approach. District heating and power system MILPs on 'eco-town' levels are addressed by amongst others Keirstead et al. (2012b) and Weber and Shah (2011). With regard to the focus of this work, i.e. full

energy integrated residential distributed energy systems in terms of heating, cooling as well as MG operation, and, the effect of energy interaction restrictions on design, research is limited. A deterministic MILP approach is proposed, building further on ongoing efforts in the field (Keirstead et al., 2012b; Mehleri et al., 2011, 2013; Weber and Shah, 2011). A full energy integrated approach is developed for analysis, continuing previous work of the authors (Wouters et al. (2014)).

2. Methodology

2.1. Problem description

A decision making strategy is formulated for the design of a small residential energy system while minimising the total annualised cost, C^{TOT} [AUD/year], to meet its energy demands in terms of electricity, heating and cooling. A superstructure methodology is adopted with dispatchable and intermittent DG and storage options together with non-loop pipeline and MG operation approaches. The fictive residential neighbourhood under research is framed by South Australian (SA) location specific characteristics. The potential energy supply options are an interconnection with the central distribution network, air-conditioning units, gas heaters, condensing boilers and DG units in the form of PV units (up to 10 kW), small-scale wind turbines (1.5 kW), micro combined heat and power (CHP) units with electrical capacities from 1 to 20 kW, micro absorption chillers and thermal and electrical storage units (Wouters et al., 2014). The houses can be thermally integrated through optimised pipeline networks and electricity integrated through MG operation. The model is optimised in GAMS using the CPLEX 12.4.0.1 solver to global optimum (GAMS Development Corporation, 2012). The optimisation is carried out for a typical day (24 hours) in each season over a yearly planning horizon. Several location specific inputs are required for the deterministic model: (i) climatological data; (ii) technical specifications of units; (iii) cost data with regard to investment and operation and maintenance (OM) and natural gas and electricity prices; (iv) regulations; and, (v) spatial distributions of hourly average energy demand data.

2.2. Model

The objective cost function consists of the annualised investment costs of technologies *tech*, C^{INV}_{tech}, the fixed and variable OM costs, C^{OM}_{tech}, the fuel costs associated with the consumption of natural gas for electricity and heat generation, C^{FUEL}_{tech}, the cost of purchasing electricity from the central grid by house i, $C^{GRID}_{i,BUY}$, the carbon tax imposed on each house, C^{CT}_{i}, and the potential income through governmental support schemes in the market, $C^{GRID}_{i,SELL}$.

$$minC^{TOT} = \sum_{tech}(C^{INV}_{tech} + C^{OM}_{tech} + C^{FUEL}_{tech}) + \sum_{i}(C^{GRID}_{i,BUY} + C^{CT}_{i}) - \sum_{i} C^{GRID}_{i,SELL} \tag{1}$$

The objective function is bound by energy balance equations regarding heating, cooling and electricity as well as design and operational constraints of the energy supply alternatives. The full model is omitted in this paper due to space limitations but builds further on previous work of the authors (Wouters et al., 2014). The relevant electricity interaction equations are detailed below.
Each house can only export electricity from DG units to the grid, $DG^{EXPORT}_{tech,i,s,h}$ [kW], in each hour h in each season s up to a maximum, U^{Export} [kW]. The binary decision variables $X^{snd}_{i,s,h}$ and $X^{rec}_{i,s,h}$ indicate whether a house respectively sends or receives electricity. In each hour, each house can either not interact with the grid or receive or send.

$$\sum_{tech} DG^{EXPORT}_{tech,i,s,h} \leq U^{Export} \cdot X^{snd}_{i,s,h} \qquad \forall i,s,h \tag{2}$$

$$X^{rec}_{i,s,h} + X^{snd}_{i,s,h} \leq 1 \qquad \forall i,s,h \tag{3}$$

Furthermore, each house can import electricity from the grid, $E^{GRID}_{i,s,h}$, up to a maximum U^{Import}.

$$E^{GRID}_{i,s,h} \leq U^{Import} \cdot X^{rec}_{i,s,h} \qquad \forall i,s,h \tag{4}$$

Note that if MG operation is selected, decided through binary selection variable Z, the neighbourhood as a whole can either import or export electricity in each hour. If MG operation is not selected, each house can individually interact with the central grid. MG operation refers to the sharing of locally generated electricity between households.

$$X^{snd/rec}_{i,s,h} - X^{snd/rec}_{i-1,s,h} \leq 1 - Z \qquad \forall i,s,h \text{ and } i > 1 \tag{5}$$

$$X^{snd/rec}_{i-1,s,h} - X^{snd/rec}_{i,s,h} \leq 1 - Z \qquad \forall i,s,h \text{ and } i > 1 \tag{6}$$

Electricity can be exchanged between each pair of houses i and j through MG operation determined by the uni-directional MG connection binary decision variable $MGC_{i,j,s,h}$. These connections are only possible if MG operation is installed in the neighbourhood:

$$MGC_{i,j,s,h} + MGC_{j,i,s,h} \leq Z \qquad \forall i,j,s,h \text{ and } i \neq j \tag{7}$$

The electricity send and received between each pair of households, $E^{snd/rec}_{i,j,s,h}$ [kW], is limited by an upper bound, U^{MG}, and the connection existence. Energy balances also govern this relationship.

$$E^{snd/rec}_{i,j,s,h} \leq U^{MG} \cdot MGC_{i,j,s,h} \qquad \forall i,j,s,h \text{ and } i \neq j \tag{8}$$

Note that since a deterministic approach is employed, parameter uncertainty can affect the obtained results. Further analysis would be required to assess the sensitivity of the developed model.

2.3. Case-study

A fictive neighbourhood consisting of 5 typical households in an Adelaide (SA) setting is under research (Wouters et al., 2014). Typical Adelaide based deterministic heating, cooling and electricity demand profiles are entered for a typical day in each season [kW]. The houses have in percentage varying energy demands from house 5 with the highest to house 1 with the lowest energy demands. Additionally, hourly solar irradiation [kW/m^2] and wind speeds at 15 m above ground level [m/s] are put in. Average utility energy tariffs [AUD/kWh] and the solar feed-in tariff from the SA market (0.06 AUD/kWh) are used. The lifetime of the project is taken to 20 years with an interest rate of 7.5 %. Each house can export excess self generation to the grid but can also buy electricity from the grid if local generation is not sufficient to meet the demand.
With regard to the residential export of electricity in the National Electricity Market of Australia, each state has its own requirements mainly focussing on PV units only. Within SA, a daily PV export limit per household of 45 kWh/day is in place. In Queensland, a restriction of residential PV export is proposed with currently an energy equivalent of 2 % of the installed capacity of a PV unit that can be exported at each time. The impact of this allowance is researched. For the analysis, the maximum allowed values of export and MG interaction are set to:

- the maximum electricity export of each house in each hour is set to the sum of the installed capacities of PV unit, CHP unit and small-scale wind turbine
- the maximum electricity exchange between each pair of houses in each hour through MG operation is set to the total electricity demand of the receiving household in terms of lighting and appliances, electricity for installed absorption chillers or air-conditioning units as well as potential dump loads

Three scenarios are then analysed in section 3 using the above maxima:

1. a percentage decrease of the upper limit of PV electricity export, $U^{ExportPV}$, ranging from unlimited to zero as well as the current daily limit in SA. No other DG export is allowed
2. a percentage decrease of the upper limit of total DG electricity export, $U^{ExportDG}$
3. a percentage decrease of the upper limit of MG operation, U^{MG}, for each household pair

3. Results and discussion

3.1. Scenario 1: PV export restrictions

Additional equations set either an hourly PV export limit in function of a percentage, $U^{ExportPV}$, of its installed capacity, or, a daily export limit (45 [kWh day^{-1}]). The installed capacity is determined through an optimised surface area A_i^{PV} times a rated capacity C_{prat} (Wouters et al., 2014):

$$DG_{PV,i,s,h}^{EXPORT} \leq U^{ExportPV} \cdot A_i^{PV} \cdot C_{prat} \qquad \forall i,s,h \tag{9}$$

$$\sum_s \sum_h h \cdot DG_{PV,i,s,h}^{EXPORT} \leq U_{day}^{Export} \qquad \forall i,s \tag{10}$$

The results are given in Figure 1. The neighbourhood design remains fairly constant with increasing export allowance in that it has PV units and heat storage tanks in each house, one CHP unit of 2.1 kW in house 2, one pipeline connection from the house with the CHP unit to house 4, as well as MG operation. No batteries, absorption chillers or small-scale wind turbines are installed. With increasing export allowance, the total PV capacity in the neighbourhood gradually increases from 6.3 from zero export allowance to 10.5 kW above an export allowance of 50 % of the total installed PV unit capacity. Electricity is exported up to a maximum in all cases. The total PV electricity export is mainly balanced with MG operation to take advantage of the solar feed-in tariff in the market. The design remains unchanged, i.e. constant, from an export allowance above 50 %.

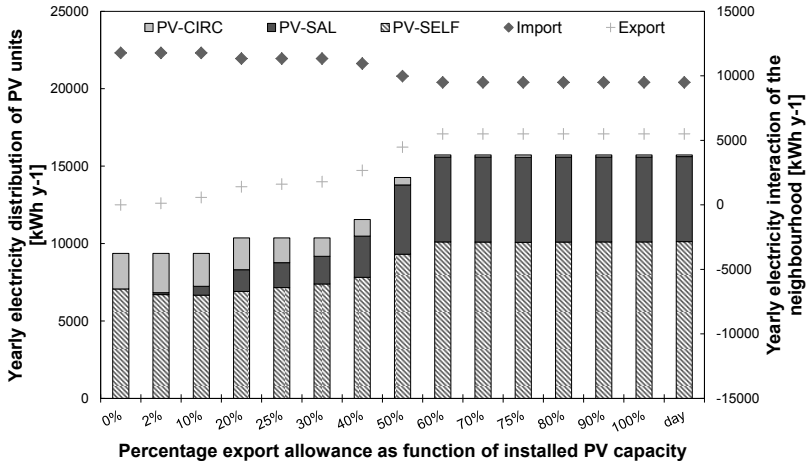

Figure 1: The share of total yearly PV electricity generation in terms of either self use by the accommodating houses, for grid export and for MG circulation [kWh y^{-1}] (see left vertical axis and bar chart) as well as the yearly electricity export and import of the neighbourhood as a whole [kWh y^{-1}] (see right vertical axis and points) in terms of percentage export allowance as function of installed capacity (horizontal axis). day=daily export allowance, CIRC=microgrid circulation, PV=photovoltaic units, SAL=export, SELF=self use.

3.2. Scenario 2: Total export restrictions

Similar constraints as presented in equations 9 and 10 are added when researching total DG electricity export restrictions from the installed PV units, CHP units and small-scale wind turbines. The results are presented in Figure 2. The neighbourhood design remains constant in the same way as in scenario 1. The installed PV unit capacity gradually increases from 6.3 kW at zero export allowance to 10.5 kW from an export allowance above 40 %. The CHP unit and corresponding uni-directional pipeline remain the same as under scenario 1 for each level of total export allowance of the neighbourhood. Additionally, with an export allowance greater than 40 %, dump loads are no longer required to absorb excess generation. The neighbourhood design and interaction behaviour becomes constant from a total DG export allowance above 50 % of the total installed DG capacity in the neighbourhood.

3.3. Scenario 3: Microgrid circulation restrictions

MG circulation restrictions are adopted by varying the percentage, U^{MGrec}, of the total load of a house, $C^{LoadTOT}_{ELEC,i,s,h}$ [kW], that can be received from another house in the neighbourhood through MG operation, $E^{rec}_{i,j,s,h}$ [kW]. The total DG export allowance is set to 45 kWh per day.

$$E^{rec}_{i,j,s,h} \leq U^{MGrec} \cdot C^{LoadTOT}_{ELEC,i,s,h} \qquad \forall i,j,s,h \text{ and } i \neq j \tag{11}$$

Figure 3 illustrates per house the installed capacities for the MG allowances that lead to the most significant neighbourhood design changes. No MG operation is adopted until an exchange allowance above 40 % and no pipeline is installed till an allowance above 60 %. The neighbourhood design becomes constant above 90 % allowance. Note that CHP units are only installed if their electricity can be used for MG circulation. The installed CHP unit changes from 1.8 kW (house 1) to 2.1 kW (house 2) from an allowance above respectively 40 % and 60 %.

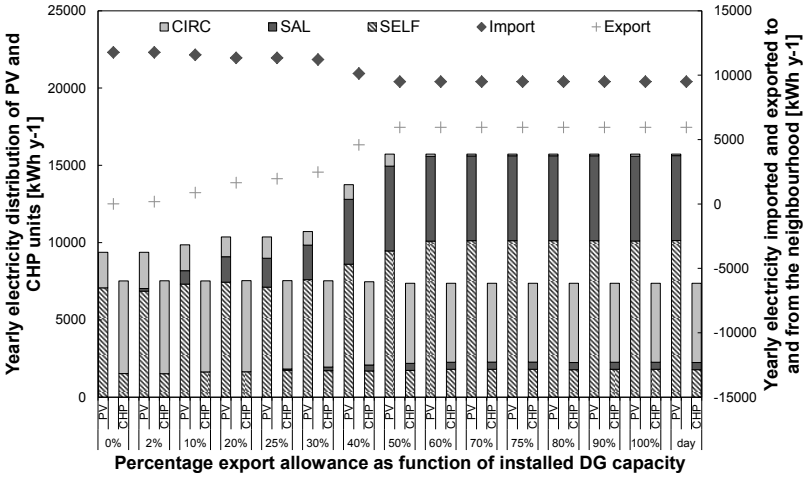

Figure 2: The share of total yearly PV and CHP electricity generation for either self use by the accommodating houses, for grid export and for MG circulation (see left vertical axis and bar charts) as well as the yearly electricity export and import of the neighbourhood as a whole [kWh y^{-1}] (see right vertical axis and points) in terms of percentage export allowance as function of total installed capacity. PV=photovoltaic units, CHP=combined heat and power units, CIRC=microgrid circulation, SAL=export, SELF=self use, day=daily export allowance. No wind turbines are installed.

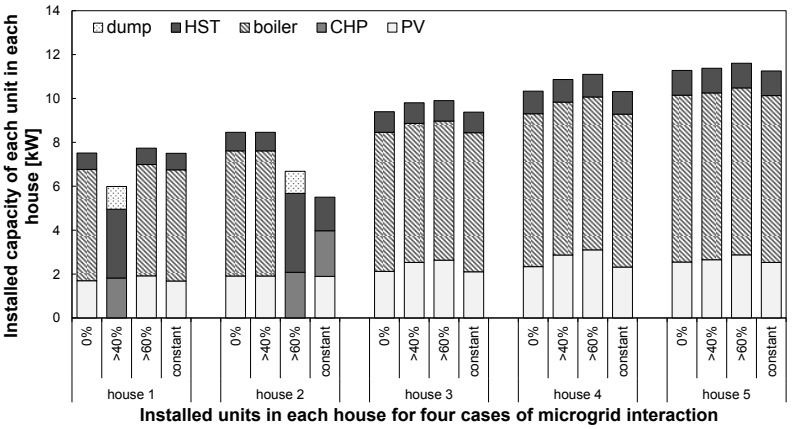

Figure 3: Installed capacities per house [kW] for MG interaction allowance of 0 %, greater than 40 % and greater than 60 % as well as constant design. CHP=combined heat and power, dump=dump load, HST=heat storage, PV=photovoltaic units.

4. Conclusion

An MILP approach has been presented for the design of residential distributed energy systems under cost minimisation. Several energy supply alternatives, such as DG units and storage, as well as energy integration in the form of MG operation and pipeline networks have been considered. The effect of energy interaction restrictions has been researched. This has shown that a total export allowance above an equivalent of 50 % of installed DG capacity leads to a constant neighbourhood design. A variation in MG interaction allowance has shown that above 40 % of the load of a house should be allowed to be supplied through MG operation to initiate the investment in a MG and CHP unit and above 60 % for pipelines in the neighbourhood.

Abstract

Centralised production of essential products and services based on fossil fuels and large scale distribution infrastructures have contributed to a plethora of issues such as deterioration of ecosystems, social-economic injustice and depletion of resources. The establishment of localised production systems can potentially reduce unsustainable resource consumption and bring socioeconomic and environmental benefits. The main objective of this work is to develop engineering tools for the rational design of such systems. Production of products and services is characterised as inter-linked subsystems (e.g. food, energy, water and waste). A sequential design approach is developed to design subsystems in turn, with necessary iterations. The process is illustrated through the co-design of energy, water and food production for a case study locale based on a developing eco-town in the UK. This design approach suggested an integrated system based primarily on locally available resources and allowed greater insight into the drivers and constraints on local resource use.

Keywords: local production network, mathematical programming, resource consumption

1. Introduction

With the advent of industrialisation, the supply of energy and materials to meet human needs has been driven primarily by centralised production based on fossil fuels and large scale distribution infrastructures. However, continuation of this mode of production, coupled with rising economies and growing population, has led to a range of issues such as energy supply insecurity, deterioration of ecosystems, and depletion of resources. In response to these issues, localised production networks based on locally available resources have been advocated as one possible pathway towards sustainability (Middlemiss and Parrish, 2010; The Royal Academy of Engineering, 2011). A local production system is defined in this work as a network of heterogeneous processes, integrated in a synergistic manner to achieve a high degree of resource efficiency, potentially leading to improved economic viability while preserving the ecosystem (Martinez-Hernandez et al., 2014). Such a system contributes to improved prospects for closing loops as any wastes or by-products from production processes and used products from consumption will seek to be looped within the system through symbiotic arrangements. The aim of this work is to propose a systematic design approach for a local production system given a set of local demands by finding the combination of a set of locally available sources and processes which can meet such demands by minimising total resource consumption, while observing a set of ecological and technical constraints. The design approach has so far been developed by analyzing a specific case study. The learning from this particular case study may be generalised into a general

framework for designing such localised production systems. The proposed approach is based on mathematical programming (MP) which has been widely applied in process systems engineering (Klatt and Marquardt, 2009; Klemes et al., 2013) to solve a wide range of problems such as the design of bioenergy network (Beck et al., 2008) and the synthesis of supply chains (Almansoori and Shah, 2012). The present work applies MP in a sequential and iterative approach for the integrated design of multiple production systems.

2. Methodology

Figure 1 presents the proposed framework for the co-design of food, water and energy network supported by a case study with reference to Whitehill and Bordon Eco-Town in the UK. The first step includes representing the components of the food, water and energy network and identifying the potential sources (i.e. supply of resource flow) and sinks (i.e. processes consuming the resource flows) in a superstructure. Mathematical models are then used to represent the processes (e.g. resource processing and conversion), constraints and interactions (i.e. exchange of flows). The least connected subsystem or network, i.e. the one upon which the other networks are least dependent is designed first in view of having a less constrained design problem. Food is considered the least connected network as energy and water are key resources for food production but both water and energy productions do not depend on food production in this particular case study. The water production network is assumed to be the second least connected network and is next designed while the energy production network is designed last. The objective function is to design the production network (food, water and energy) by selecting the production processes and determining the flow rates from source to sink that will minimise total resource consumption while observing a set of ecological and technical constraints for satisfying local demands. The objective function measured in terms of cumulative exergy resource consumption is calculated using the Cumulative Exergy Resource Accounting methodology (Leung Pah Hang et al., 2014).

The generic objective function for an individual production network was formulated as Eq. (1):

$$\text{Minimise } TC = \sum F_{imp} e_{imp} \quad (1)$$

where,
TC is the total resource consumption;
F_{imp} is the flow rate of imported flows to the production network (e.g. imported energy such as electricity from grid, heat from district heating, chemicals, fuels, fertilisers, imported animal feed);
e_{imp} is the cumulative exergy consumption associated with the provisioning of the imported flows.

The optimisation is to be subject to the final local need, land availability, availability of local resource, balance between sources and sinks, concentration balance for water network, nutrient balance for food network and electricity and heat balances for energy network constraints. The optimisation model for each subsystem was solved using GAMS. Both the food and energy network were solved using linear programming while the water network was solved using non-linear programming due to non-linearity in its

concentration balance. The sources and sinks considered for the three networks are shown in Table 1.

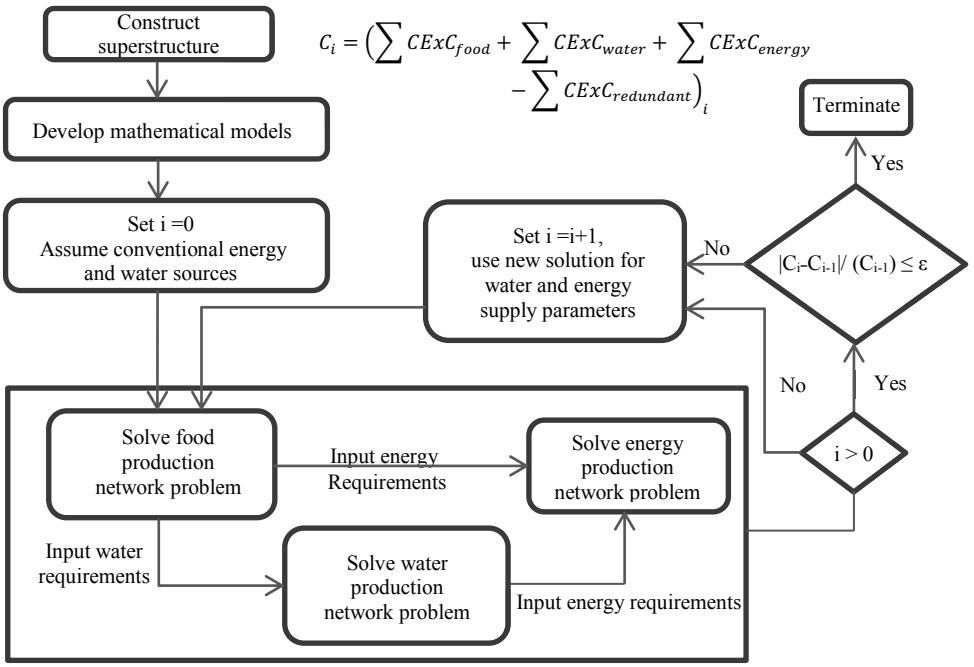

Figure 1: Methodological framework for co-design of food, water and energy network

The initial solution (i.e. i=0) is obtained by solving the three production network design problems assuming conventional energy and water sources in the sequence as illustrated in Figure 1. The conventional energy sources are assumed to be electricity supplied from the grid and heat supplied from a natural gas based district heating network while groundwater is the conventional water source. First, the food production network is designed. Second, the water production network is designed by considering the water sources and sinks in the initial solution of the food production network, which will suggest specific water streams that can be used by the food production network and other local users and the associated resource costs in terms of the cumulative exergy content. Lastly, the energy production network is designed taking into account the energy sources and sinks in the initial solutions of the food and water production networks, to determine specific energy streams that can be generated locally or obtained from centralised supply to meet various demands including those from the food production network. For the next iteration (i=i+1), the water and energy supply parameters from the solution of the previous iteration are used and the same sequence is repeated. The iteration stops when the cumulative exergy consumption to produce the streams exchanged between the three networks become stable, meaning that no further change is incurred by further iterations. This will be reflected in the overall cumulative exergy consumption for production of food, water and energy networks and can be verified using the criterion $|C_i-C_{i-1}|/ (C_{i-1}) \leq \varepsilon$ (where ε can be a small value, e.g. 0.01), as shown in Figure 1. The cumulative exergy consumption of the redundant flows refers to

the cumulative exergy consumption of the flows internal to the whole system and exchanged between the three networks.

3. Results

The initial results from the initial optimisation of the food network suggested that only bread and potatoes be produced locally. The objective function for the food production network was 1.04×10^8 MJ/y. The initial results for the water network indicated that most of the water required by the water consuming processes should be supplied by groundwater. A small portion of the wastewater generated during the bread processing is diluted by groundwater and used for both potatoes cultivation and processing. Similarly, a small amount of the wastewater produced from potatoes processing is used together with groundwater for wheat cultivation and wheat processing into bread. The objective function for the water production network was 2.05×10^6 MJ/y. The results generated from the initial optimisation of the energy production network showed that biomass CHP is the preferred option for supplying all the electricity and energy demands of both the food and water production networks. It can also satisfy all the energy demand for households. The objective function for the energy production network was determined to be 1.19×10^9 MJ/y.

Table 1: Sources and sinks in the food, water and energy production networks

Sources	Sinks	Sources	Sinks
Food production network		*Water production network*	
▪ Imported fertiliser ▪ Imported animal feed ▪ Manure from cattle ▪ Manure from pigs ▪ Wheat residues ▪ Potatoes residues	▪ Wheat cultivation and processing ▪ Potatoes cultivation and processing ▪ Cattle breeding and processing ▪ Pig breeding and processing	▪ Treated food production wastewater ▪ Wheat processing ▪ Potatoes processing ▪ Cattle breeding and processing ▪ Pig breeding and processing ▪ Treated domestic wastewater ▪ Groundwater ▪ Rainwater ▪ Treated wastewater from energy production	▪ Energy production ▪ Wheat cultivation ▪ Wheat processing ▪ Potatoes processing ▪ Cattle breeding and processing ▪ Pig breeding and processing ▪ Residential water ▪ Discharge
Energy production network			
▪ Grid ▪ Wind ▪ Solar ▪ Biomass CHP ▪ Natural gas CHP	▪ Wastewater treatment plant ▪ Food production network ▪ Residential		

The 1st iteration involves feeding back into the food production network the initial results from the optimisation of the water and energy production networks. The exergy parameter for energy used for the optimisation of the food production network now changed from 2.50 MJ/kg bread to 5.78 MJ/kg bread and for water use from 108.60

MJ/kg bread to 107.90 MJ/kg bread. The parameter for energy use for potatoes changed from 0.41 MJ/kg potatoes to 0.81 MJ/kg potatoes and for water use from 1.13 MJ/kg potatoes to 1.12 MJ/kg potatoes while the parameters used for beef and pork production remains unchanged. These changes in parameters now resulted in only potatoes and pork being produced locally; indicating that the food production network is highly sensitive to the water and energy supplies. The new objective function for the food production network after the 1st iteration (i.e. the round following the initial optimisation) was 1.05×10^8 MJ/y which is 0.18% more than the initial value of the objective function. This is because the assumed cumulative exergy consumption for conventional energy sources obtained from literature and used in the initial optimisation is much lower than the cumulative exergy consumption associated with energy supply from biomass CHP. However, there is now more potential for a locally integrated food production network based on locally available resources. The manure from pig is used to partly satisfy the nutrient requirements of potato cultivation. Also, all residues from potato cultivation are now being used as animal feed for pigs. Groundwater consumption for food production has slightly decreased with exchanged water flows from bread and potatoes manufacture being used to supply part of the network's water requirements. Moreover, the resulting integrated food production network is not dependent on imported fossil fuels for its energy requirements. The objective function for the water production network for the 1st iteration was 7.72×10^5 MJ/y; a reduction of 62% from the initial objective function of this network, primarily due to rainwater replacing about 34% of the groundwater. The objective function of the energy production network from the 1st iteration was 1.19×10^9 MJ/y; a very slight decrease of 0.10% from the initial objective function of the energy production network

A 2nd round of iteration was carried out, which led to a solution virtually identical to one obtained from a further (i.e. the 3rd) iteration. The final results are presented in Figure 2. The total potato demand and 11% of total pork demand are to be satisfied locally; water is supplied by both groundwater and rainwater while electricity and heat are supplied locally by biomass wood chip CHP. As compared to the initial solutions, the objective function of the last iteration for the food production network increased by 0.20% while the objective functions of the water and energy production networks have decreased respectively by 62% and 0.10%.

4. Concluding remarks

This work has developed a sequential and iterative approach to the co-design of the integrated production of food, water and energy to satisfy local demands by making the use of locally available resources within technical and ecological constraints while minimising aggregated resource consumption. This design approach has proved to be useful in the analysis of intermediate results contributing to better insight and understanding of the localised production system; offering an added-value to practitioners as compared to designing these three production networks simultaneously. In practice, local situations may well impede the adoption of a simultaneous approach due to the incremental nature of knowledge and data acquisition and options gathering from various stakeholders, thus there is great value in enriching the understanding of the linkages between subsystems which is enabled by the sequential approach. In particular, it was useful in gaining insight, by means of the intermediate results obtained from the iterative process, on the balance of cumulative exergy consumption between the food, energy and water networks and the trade off in using imported flows and conventional sources of energy and water and using locally available resources. As a next step, a

further comparison between this sequential approach and the simultaneous approach can be made, with the possibility of refining the current approach into a hybrid one to benefit from the advantages of both.

Abstract

Multi-stream heat exchangers (MSHE) are single process units that facilitate simultaneous exchange of heat among multiple streams and are mainly used in cryogenic processes like natural gas liquefaction, air separation, etc. Most MSHEs are proprietary and complex, and involve phase changes. MSHE models in the literature are complex MINLP models with disjunctions and are computationally expensive. Since they must be solved repeatedly inside a process optimization framework, simpler models would be highly desirable. In this work, we present a simpler superstructure of 2-stream exchangers to describe an MSHE and propose a non-linear programming (NLP) formulation to obtain a network that best fits given operational data. We demonstrate the usefulness of our work on an existing LNG plant and predict its operation successfully.

Keywords: Multi-stream heat exchangers, phase change, NLP, LNG

1. Introduction

A multi-stream heat exchanger (MSHE) is the most important heat transfer unit in many industrial and cryogenic processes such as air separation, natural gas processing, liquefied petroleum gas (LPG), petrochemicals, and refrigeration systems. (Khan et al., 2012) Some of its attractive attributes are compact design with high heat transfer area, small minimum temperature approaches (as small as 1-3℃), high heat transfer coefficients, flexibility in flow arrangement, high reliability, and ability to withstand a range of pressures. A typical MSHE has a series of sections, called bundles, with spiral wound and plate-and-fin being the most commonly used types. (Hasan et al., 2009)

Most processes employing MSHEs are energy intensive. MSHEs link their upstream and downstream sections, often involving multiple refrigeration systems. Minimizing energy consumption is critical for these processes, but system-wide optimization requires a model for MSHE. Most MSHEs are proprietary black boxes, and involve complex fluid flow patterns and phase changes which make modeling them a challenge. (Hasan et al., 2009) Furthermore, various process variations (e.g. feed conditions, ambient temperature, etc.) make their operation and control difficult. Without an accurate predictive model, the operators must rely on qualitative experience, and employ heuristic single-parameter tweaks of individual process variables. Therefore, it is beneficial to have a rigorous predictive model for an MSHE to reduce the guesswork involved in plant operation, control, and optimization.

Several approaches have been proposed for modeling an MSHE. Rigorous physiochemical models based on first principles (Goyal et al., 2014 and Skaugen et al.,

2013), which are specific to certain types MSHEs, can be developed when the internal details are known. In most cases, however, internal details are unknown, and such models are not feasible. Furthermore, such models are typically compute-intensive, and hence difficult to incorporate in process-wide optimization. Thus, simpler models that relate inputs and outputs are often desirable.

Hasan et al. (2009) proposed the idea of using a hypothetical network of 2-stream heat exchangers to model MSHE operation. They developed a novel mixed-integer nonlinear programming (MINLP) formulation for finding the best equivalent network configuration. While their formulation allowed phase changes, it assumed a single cold stream and zero pressure drops in bundles, and did not allow components such as Joule-Thompson (J-T) valves. Furthermore, their network was complex and its solution compute-intensive. In contrast, Kamath et al. (2012) presented an equation-oriented model based on the pinch concept to ensure minimum driving force and modeled MSHE as a network with no utilities. They proposed a disjunctive formulation to detect phases and perform appropriate calculations. For pressure drops, they made a simplifying assumption that pressure varies linearly with the heat load of the stream. Clearly, there is a need to develop an alternate MSHE model that addresses the aforementioned shortcomings.

In this work, we propose a nonlinear model that can be derived from the historic input-output data of any generic MSHE, and then can be used to predict its performance. Following the idea of Hasan et al. (2009), we present a much simpler superstructure of 2-stream heat exchangers based on the phases traversed by the exchanging streams. In addition, we accommodate mixing, pressure drops, and J-T expansions. Unlike the existing approaches, our approach solves an NLP rather than an MINLP to derive the best equivalent network. It also requires far fewer 2-stream exchangers than those from Hasan et al. (2009). As stated by Hasan et al. (2009), such a network can easily be simulated within a commercial process simulator.

2. Problem Statement

Consider a bundle in an existing MSHE. I hot streams (i = 1, 2. . . I) and J cold streams (j = 1, 2. . . J) pass through this bundle. Operational data for N distinct steady states (n = 1, 2. . .N) of the bundle are available. These include stream compositions, stream flows, and stream inlet/outlet temperatures and pressures. Let F_{in}^{h} be the flow into the bundle, and HIN_{in}^{h} and $HOUT_{in}^{h}$ be the inlet and outlet enthalpies, respectively, of a hot stream i in data set n. Similarly, we define F_{jn}^{c}, HIN_{jn}^{c}, and $HOUT_{jn}^{c}$ for cold stream j. Given these, we aim to derive a network of fixed-area 2-stream exchangers, which best describes the bundle operation over all N states including the streams exchanging heats in each exchanger and their flow fractions.

We assume that no heat exchange occurs between hot (cold) streams. The variations in the operational data are not drastic. Specifically, the enthalpy data for the N datasets are within some $\pm \in$ range. This is merely to ensure that the operational regimes of the exchanging streams are the same in all data sets.

3. Model Formulation

We represent MSHE by a network of simple 2-stream HEs with known heat transfer areas. Each 2-stream HE will match a portion (substream) of a hot stream with another of a cold stream.

Based on the bundle operational data, we first identify the phase regimes for each hot stream i and cold stream j. Since the data sets may vary in feed flows, compositions and ambient conditions, the bubble and dew points of exchanging streams as well as the inlet/outlet temperatures and pressures may also vary to some extents. As a result, if we wish to distinguish operational regimes sharply at the phase boundaries, they could vary between data sets. However, we desire to have a unique heat exchanger network for a particular hot stream i and the cold stream j, using all the N data sets. Therefore we introduce an offset ϵ (corresponding to a small temperature difference), based on enthalpy scale, on either sides of average dew point and bubble point for the given sets of data as shown in Figure 1.

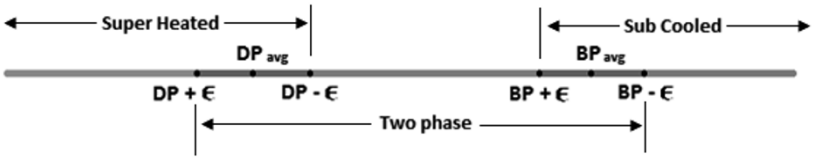

Figure 1. Enthalpy line diagram with extended superheated, two phase, and subcooled region

We include regions near the phase boundaries on either side. In other words, as depicted in figure 1, we extend superheated (SH) regime upto $DP^{avg} - \in$, two-phase (TP) region from $DP^{avg} + \in$ to $BP^{avg} - \in$, and sub-cooled (SC) regime starting from $BP^{avg} + \in$. This extension would not only solve the problem of varying datasets, but also ensures the selection of minimum number of heat exchangers when the inlet and outlet enthalpies are marginally above or below the dew point, or the bubble point.

Using the above enthalpy line, we present a novel superstructure of simple 2-stream heat exchangers between portions of hot and cold streams based on operational regimes. (Figure 2)

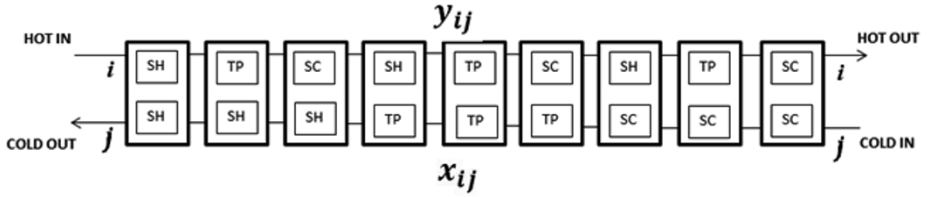

Figure 2. Superstructure for the heat exchanger network based on phase changes

It is evident that the superstructure consists of nine heat exchangers, each representing their operational regimes (Super-Heated, Sub-Cooled and Two-Phase) placed between y_{ij} portion of hot stream i and x_{ij} portion of the cold stream j in a particular bundle of which only some of them are active. This superstructure would yield a maximum of 5 heat exchangers between exchanging a hot stream and cold stream. Unlike Hasan et al., (2009) we avoid multiple heat exchange between a particular hot stream i and various portions of the cold stream j to ensure simplicity. Therefore, a hot stream i would contact only one portion of the cold stream j in a bundle.

First, we find the optimal fraction of cold stream j in contact with a portion of i hot stream which best represent the performance of the bundle. Our objective is to minimize the difference between the actual outlet temperatures and the predicted outlet temperature for hot and the cold streams. We achieve this by minimizing squares of the

differences between the observed and predicted enthalpy changes summed over the n data sets for all the streams. The constraint equations include energy balances, minimum temperature approach (MTA), merging of the substreams, summations of stream fractions. These constraints are specific to each scenario, some of which are discussed here.

3.1 No phase change within the bundle

This is a commonly observed scenario in a bundle of an MSHE. Exchanging streams may not change phase within the bundle. In such cases, only one heat exchanger would be placed between the streams. The log-mean temperature difference is calculated as shown below.Heat duty and LMTD for other heat exchangers are zero.

IF HIN_{in}^{h} & $HOUT_{in}^{h}$ both belong to *SH* or *TP* or *SC* region, according to the figure 1, and both HIN_{jn}^{c} &$HOUT_{jn}^{c}$ also belong to either *SH* or *TP* or *SC* region, we have:

$$Q1_{ijn} = F_{in}^{h} y_{ij} \left[HIN_{in}^{h} - HPOUT_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HPOUT_{ijn}^{c} - HIN_{jn}^{c}\right] \quad (1)$$

$$HPOUT_{ijn}^{h} \geq HIN_{jn}^{c+\Delta T} \quad (2)$$

$$HPOUT_{ijn}^{c} \leq HIN_{in}^{h-\Delta T} \quad (3)$$

$$\Delta T1_{ijn}^{LM} = \frac{\left(TPOUT_{ijn}^{h} - TIN_{jn}^{c}\right) - \left(TIN_{in}^{h} - TPOUT_{ijn}^{c}\right)}{ln\frac{\left(TPOUT_{ijn}^{h} - TIN_{jn}^{c}\right)}{\left(TIN_{in}^{h} - TPOUT_{ijn}^{c}\right)}} \quad (4)$$

$$Q2_{ijn} = Q3_{ijn} = Q4_{ijn} = Q5_{ijn} = 0 \quad (5)$$

$$\Delta T2_{ijn}^{LM} = \Delta T3_{ijn}^{LM} = \Delta T4_{ijn}^{LM} = \Delta T5_{ijn}^{LM} = 0 \quad (6)$$

$HPOUT$ indicates predicted outlet enthalpy for exchanging streams, while eq. (2) and (3) are MTA constraints. $HIN_{jn}^{c+\Delta T}$ is the enthalpy of cold stream j corresponding to temperature $TIN_{jn}^{c} + \Delta T$ at its inlet pressure and $HIN_{in}^{h-\Delta T}$ is the enthalpy of hot stream i corresponding to temperature $TIN_{in}^{h} - \Delta T$ at the inlet pressure.

3.2 One of the two streams changes phase

This scenario is also observed in certain bundles of MSHE. Heat exchangers in series could be used to model such cases. For instance, when a cold stream does not change phase whereas a hot stream exists in both superheated (SH) phase and two-phase (TP), two heat exchangers in series between the streams, separated at the phase boundary, are obtained. Heat duty and LMTD for other three heat exchangers are zero.

$$Q1_{ijn} = F_{in}^{h} y_{ij} \left[HIN_{in}^{h} - HDP_{in}^{h}\right] = F_{jn}^{c} x_{ij} \left[HPOUT_{ijn}^{c} - HOUT1_{ijn}^{c}\right] \quad (7)$$

$$Q2_{ijn} = F_{in}^{h} y_{ij} \left[HDP_{in}^{h} - HPOUT_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HOUT1_{ijn}^{c} - HIN_{jn}^{c}\right] \quad (8)$$

The same approach can be extended to the case with one stream in all three phase while the other stream is does not change phase.

Rarely, when both hot and cold streams exist in multiple regimes within a bundle, it is also necessary to know the relative lengths of the operational regimes for the exchanging streams in enthalpy scale. In such cases, it is essential to evaluate the relative positions of inlet, outlet, bubble and dew points on an enthalpy line diagram and compare the lengths of operating regimes within a bundle to write appropriate energy balance equations. We use average values of inlet and outlet enthalpies, flow rates, dew

points and bubble points to evaluate the lengths of each regime in a bundle. We calculate the following parameters to compare the lengths of regimes.

$$SH_{ij}^{h} = F_{i}^{avg} y_{ij} (HIN_{i}^{avg} - HDP_{i}^{avg}) \quad (9)$$

$$TP_{ij}^{h} = F_{i}^{avg} y_{ij} (HIN_{i}^{avg} - HBP_{i}^{avg}) \quad (10)$$

SH_{ij}^{h} and TP_{ij}^{h} indicate the average lengths of between inlet, and dew point and bubble point respectively for hot streams. Similarly, we have SH_{ij}^{c} and TP_{ij}^{c} for cold streams starting from average outlet to average dew and bubble points.

3.3 Both streams change phase

We illustrate the procedure with the scenario when both hot and cold streams exist in superheated (SH) and two-phase (TP) regime. If $SH_{ij}^{h} \geq SH_{ij}^{c}$, cold stream would first approach the phase boundary.

$$Q1_{ijn} = F_{in}^{h} y_{ij} \left[HIN_{in}^{h} - HOUT1_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HPOUT_{ijn}^{c} - HDP_{jn}^{c}\right] \quad (11)$$

$$Q2_{ijn} = F_{in}^{h} y_{ij} \left[HOUT1_{ijn}^{h} - HDP_{in}^{h}\right] = F_{jn}^{c} x_{ij} \left[HDP_{jn}^{c} - HOUT1_{ijn}^{c}\right] \quad (12)$$

$$Q3_{ijn} = F_{in}^{h} y_{ij} \left[HDP_{in}^{h} - HPOUT_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HOUT1_{ijn}^{c} - HIN_{jn}^{c}\right] \quad (13)$$

If$SH_{ij}^{h} \leq SH_{ij}^{c}$, hot stream would approach the dew point first.

$$Q1_{ijn} = F_{in}^{h} y_{ij} \left[HIN_{in}^{h} - HDP_{in}^{h}\right] = F_{jn}^{c} x_{ij} \left[HPOUT_{ijn}^{c} - HOUT1_{ijn}^{c}\right] \quad (14)$$

$$Q2_{ijn} = F_{in}^{h} y_{ij} \left[HDP_{in}^{h} - HOUT1_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HOUT1_{ijn}^{c} - HDP_{jn}^{c}\right] \quad (15)$$

$$Q3_{ijn} = F_{in}^{h} y_{ij} \left[HOUT1_{ijn}^{h} - HPOUT_{ijn}^{h}\right] = F_{jn}^{c} x_{ij} \left[HDP_{jn}^{c} - HIN_{j,n}^{c}\right] \quad (16)$$

Similar procedure can be followed for other combinations of both streams exhibiting phase change.

Next, we obtain the heat transfer areas of the 2-stream heat exchangers by minimizing the following objective function (Eq. 17), subject to non-negative area constraint.

$$Min. \ \sum_{n} \sqrt{\sum_{j} \sum_{i} [Q1_{ijn} - U1_{ijn} A1_{ij} \Delta T1_{ijn}^{LM}]^2} \ ; A1_{ij} \geq 0 \quad (17)$$

Overall heat transfer coefficients for the heat exchangers which depend on the flow rates, fluid and exchanger properties could be found from simulators like HYSYS, appropriate correlations or experimental values available in literature. LMTD temperatures are found as described previously. Similar equations are used to find $A2_{ij}, A3_{ij}, A4_{ij}$ and $A5_{ij}$.

Overall, the working principle of this model is very simple and efficient. Based on the phases identified from the operational data, the number of active heat exchangers and energy balance is decided prior to the solution of the model, hence resulting in an NLP. The model splits the parent hot and cold streams into sub-streams, allows maximum possible heat exchange in operational regimes while ensuring negligible phase change in a heat exchanger. After having obtained the network of 2-stream heat exchangers that best mimics the operation of MSHE using historic operational data, future performance predictions of the MSHE can be made. Given the inlet conditions, this network can predict the outlet conditions satisfactorily.

4. LNG Case study

Modelling the main cryogenic heat exchanger (MCHE) used in energy intensive the natural gas liquefaction cycle is often the bottleneck in its optimization process. We applied our model on an existing MCHE of an LNG plant in Qatar, with four hot streams viz. Natural gas (NG), mixed refrigerant liquid (MRL), mixed refrigerant vapour (MRV) and liquefied petroleum gas (LPG), and mixed refrigerant (MR) as the coolant. The MCHE consists of three bundles (hot, mid and cold), with LPG being mixed with NG post its exit from the mid bundle. Due to the extreme variations of feed conditions between seasons, we used MCHE operational data over the entire year to include the effects of all possible ambient conditions. Also, we pre-processed data to remove inconsistencies, include J-T valve expansions occurring in the MCHE. Operational data from the LNG plant enables exact accounting of pressure drops and mixing. NG stream changed phase in hot bundle, hence needing two exchangers in series. Since other streams in the bundle did not change phase, a total of five exchangers were obtained. Similarly, five exchangers represented the mid bundle in which only MRV changed phase. In the cold bundle, streams showed no phase change. Overall, our model results in a far fewer 2-stream heat exchangers than Hasan et al. (2009) and successfully predicts the performance of the MCHE within allowable range of error. (Table 1)

Table 1. LNG case study results

Bundle	Hot Streams	Cold Streams	Number of 2-stream heat exchangers
Hot Bundle	NG, LPG, MRL, MRV	MR	5
Mid Bundle	NG, LPG, MRL, MRV	MR	5
Cold Bundle	NG, MRV	MRV	2

5. Conclusions

In this work, a non-linear formulation to model MSHE as a network of 2-stream heat exchangers using historic operational data is presented. The model can satisfactorily predict with the performance of any MSHE without knowing the internal details. It successfully captures phase change, results in a much simpler network of 2-stream heat exchangers, and can be easily used in the system-wide optimization framework.

Abstract

In this paper, the thermodynamic advantage of recovering compressor waste heat in cryogenic air separation unit (ASU) using binary cycle heat engine instead of the conventional use of cooling water is investigated through modeling and simulation using Aspen Plus® simulation software version 8.4. The simulation results based on a cryogenic ASU capable of processing 100 kg/s of atmospheric air show that the overall specific power consumption for the production of pure products of 99.90 mol. $\%O_{2\,(g)}$, 99.99 mol. % $N_{2\,(g)}$ and 97.00 mol. % $Ar_{\,(l)}$ can be reduced from 0.191 kWh/kg to 0.170 kWh/kg by converting the compressor waste heat to electricity using binary cycle heat engine which uses R134a as both the working fluid and the compressor cooling medium as against the conventional process which uses water as the cooling media. This represents an 11% reduction in the power consumed to produce the pure products. In addition, the heat engine generates about 2, 354.22 kW of power which can be sold to generate more revenue.

Keywords: Cryogenic Air Separation Unit; Organic Rankine Cycle; Binary Cycle Heat Engine; Waste Heat Recovery

1. Introduction

Air separation unit (ASU) is an integral process to many other processes mainly because of the importance of its constituent gases to many industrial processes. For example, oxygen is used in medical and other industrial processes such as metal, glass, ammonia, oxy-fuel combustion and integrated gasification combined cycle (IGCC) (Burdyny and Struchtrup, 2010, Jones et al., 2011, Liszka and Ziębik, 2010, Zhu et al., 2008), nitrogen finds use in the chemical and petroleum industries (Vinson, 2006) while argon is used as an inert shielding gas in welding and other electronics such as the light bulb.

Air in its natural form is a free commodity, however its separation into its components is both capital and energy intensive. Although there are several technologies used in the separation of air, this work will focus on cryogenic ASU.

Cryogenic ASU is mainly used for the production of high tonnage and high purity gases. This makes it the status quo in many industrial processes where oxygen and nitrogen are required in high tonnage and high purity (Fu and Truls, 2012, Yan et al., 2010).

As a result of the importance of cryogenic ASU to several industrial processes, many studies have been carried out on how to reduce the capital and energy requirement of conventional ASU. Amongst the studies are (a) the replacement of tray distillation columns with packed columns; (b) operating at higher pressure to reduce the overall column diameter; (c) improving the effectiveness of heat exchangers, the efficiency of compressors and the use of control system with real-time optimization capability (Castle, 2002, Kansha et al., 2011, Rübberdt, 2009). Others include the use of self-heat recuperation system which was found to reduce the overall energy consumption by circa 36% when compared to the conventional process (Kansha et al., 2011). For cases where the product gas (especially oxygen) is required at high pressure, Manenti et al., (2013) found that the specific power consumption of the cryogenic ASU can be reduced by pumping liquid oxygen produced instead of compressing the gaseous oxygen.

Most of the energy consumption in a cryogenic ASU occurs in the air compressor. For example, according to Fu and Gundersen (2012), about 38.4% of exergy loss in a conventional cryogenic ASU occurs in the air compressor unit. This is also confirmed by the work of Cornelissen and Hirs (1998) who found that about one-third of the exergy loss in a conventional cryogenic ASU comes from the air compressor unit. This means that the reduction in the exergy loss of the compressor will drastically improve the energy efficiency of the cryogenic ASU.

In this work, the impact of reducing the energy loss in the air compressor on the specific power consumption of a cryogenic ASU through air compressor waste heat recovery using binary heat engine cycle will be investigated through modeling and simulation using Aspen Plus® simulation software version 8.4.

2. Process Description of a Conventional Cryogenic ASU

Figure 1 shows the process flow diagram of the conventional ASU investigated in this paper. In the process, the atmospheric air is filtered, cleaned and compressed in a 3 stage compressor with intercooling to a pressure of 6.35 bar. The compressed air is split into two streams in the ratio of 5:17 and cooled against the leaving product streams (gaseous nitrogen, liquid oxygen and gaseous waste stream). The stream with the higher flowrate is sent to the high pressure distillation column (HPC) where nitrogen is separated at a pressure of about 5.7 bar. The other stream is expanded to a pressure of 1.2 bar before being sent to the low pressure distillation column (LPC). The top nitrogen product from the HPC is condensed against the boiling oxygen in the reboiler of the LPC, and depressurized before being sent to the top of the LPC. The bottom liquid product from the HPC which is rich in oxygen is also sent to the LPC after been depressurized using a JT valve. In the LPC, pure nitrogen vapour and pure liquid oxygen stream leaves from the top and bottom of the column respectively together with two vapour side streams. The side product stream towards the top of the column is regarded as a waste stream while the one towards the bottom of the column is sent to the side rectifier (ArC) where high purity argon is separated from oxygen (Kooijman et al., 2006).

The entire process is a tight integration of heat exchangers and separation columns. The HPC and LPC share the same column shell to minimize the temperature difference between the condensing nitrogen and evaporating oxygen. The condenser of the LPC exchanges heat with the reboiler of the LPC while the Joule-Thomson (JT) effect cools the rich liquid from the bottom of the HPC such that it can be used as the coolant to run

the condenser of the side rectifier (ArC) which separates argon from the oxygen. Additional cooling was provided by the JT effect of the expander which feeds compressed air directly to the LPC.

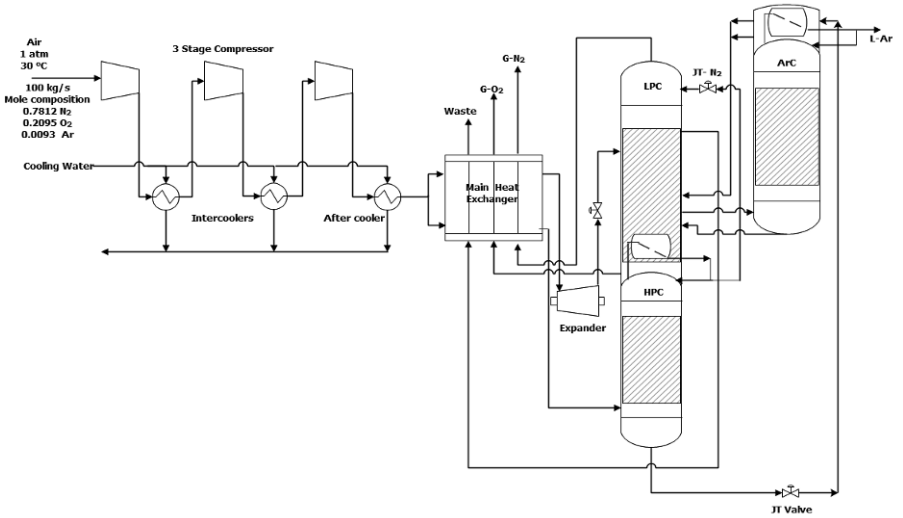

Figure 1: Conentional Cryogenic ASU with 3 Stage Compressor (Kooijman et al. 2006)

3. Cryogenic ASU Compressor Waste Heat Recovery using Binary Cycle Heat Engines

Even with the most efficient system, up to 90 % of the input power to a compressor is lost as heat (ETSU, 1998). This heat increases the temperature of the compressed gas at the compressor outlet. To maintain proper operating condition, the compressor must be cooled. In conventional systems, water is usually used as the compressor cooling medium. The use of water gives rise to a hot water stream which can only be used for heat integration application. Such application is not thermodynamically beneficial in a process such as the cryogenic ASU since there is no need for additional heat integration. Hence, recovering the compressor using a process which can convert the recovered heat to a product that is useful to the process will be of great benefit to the plant.

In a conventional cryogenic ASU described in section 2, the temperature of the air exiting the first stage compressor is 109 ^{o}C. This air is required to be cooled to 40 ^{o}C before it enters into the second stage compressor. Similarly, after the second and third stage compressor, the air temperature rises to 107 ^{o}C and 113 ^{o}C and is required to be cooled to 40 ^{o}C and 30^{o}C respectively. Using water at 20 ^{o}C and 1 bar as the cooling medium gives rise to either a hot water or steam depending on the water flowrate. Water at this condition can only be used for heat integration as explained earlier. This will not be useful in any part of the cryogenic ASU as there is no need for additional heat in the process. The conversion of the compressor waste heat to power using binary heat engines cycle technology will be of utmost benefit to the cryogenic ASU.

3.1. Simulation of Cryogenic ASU with Compressor heat recovery using Binary Heat Engine Cycle

The process flow diagram of the cryogenic ASU with compressor heat recovery using binary heat engine cycle as simulated in Aspen Plus® is shown in Figure 2. The binary heat engine cycle uses R134a as the working fluid. This working fluid also functions as the compressor cooling medium. The process parameters used to develop the Aspen model of the conventional cryogenic ASU is shown in Table 1. The performance parameter for the proposed design and the conventional process were evaluated and compared using the simulation results shown in Table 2.

The specific power consumption for producing any given pure product is defined as:

$$\alpha_{ov} = \frac{\sum(P_{in} - P_{out})}{\sum m} \quad (1)$$

where,
$\sum P_{in}$ = sum of the power inputs to the process (kW), $\sum P_{out}$ = sum of the power outputs from the process (kW), m = mass of the pure product, (kg/h)

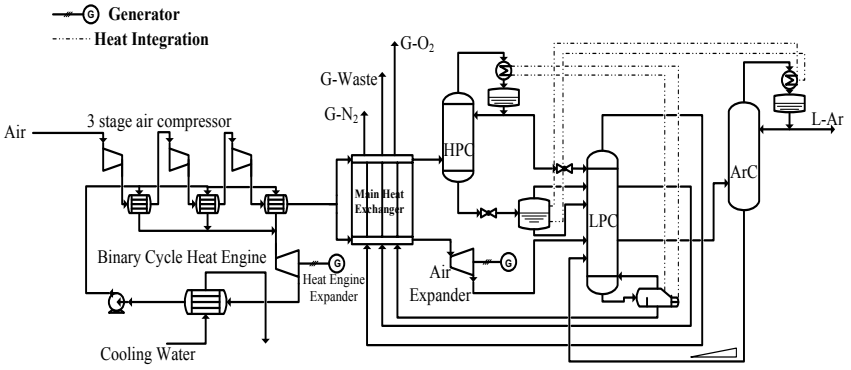

Figure 2: Cryogenic ASU with Compressor Heat Recovery using Binary Heat Engine Cycle

4. Results and Discussions

Table 2 shows the simulation results of the conventional cryogenic ASU and the proposed cryogenic ASU which uses binary heat engine cycle for compressor waste heat recovery.

The results show that the cryogenic ASU modeled in this work meets the tight heat integration required for such a process. The nitrogen produced at the top of the HPC was condensed at -177.57 ^{o}C against the boiling oxygen at -180.33 ^{o}C from the bottom of the LPC. Similarly, the argon produced in the ArC was condensed at -184.90 ^{o}C against the JT effect of the oxygen rich product from the bottom of the HPC which is at -191.10 ^{o}C.

Table 1: Process Parameters

Cryogenic ASU	
Parameter	Value
Inlet Air mass flowrate	100 kg/s
Inlet Air molar composition	
Nitrogen	0.7812
Oxygen	0.2095
Argon	0.0093
Air inlet temperature	30 ^{o}C
Low Pressure Column Pressure (LPC)	1.2 bar
Low Pressure Column no of stages	45
High Pressure Column Pressure (HPC)	6 bar
High Pressure Column no of stages	69
Argon Column Pressure	1.2 bar
Argon Column number of stages	120
Expander isentropic efficiency	80%
Binary Heat Engine Cycle	
Expander isentropic efficiency	80%
Pump efficiency	80%

Table 2: Simulation Results

Parameter	Conventional Cryogenic ASU	Conventional Cryogenic ASU with BCHE
Pure product mass flowrate (kg/h)	114,160.60	
Product purity (mole %)	99.90	
Oxygen	99.99	
Nitrogen	97.00	
Argon		
LPC Condenser duty (kW)	13405.10 @-177.57 ^{o}C	
HPC Reboiler duty (kW)	13402.20 @-180.33 ^{o}C	
ArC Column condenser duty (kW)	1493.79 @-184.90 ^{o}C	
JT Effect duty from HPC bottom (kW)	1512.75 @-191.10 ^{o}C	
LPC Feed Expander Power Output (kW)	561.60	
Compressor power consumption (kW)	22,273.54	
Cooling Water Pump Power consumption (kW)	114.25	--------
Binary Cycle Heat Engine Net Power (kW)	--------	2354.22
Process Net Power Consumption (kW)	21826.19	19357.72
α_{ov} (kWh/kg)	0.191	0.170

For the conventional process which uses water as the cooling media, the net power consumption was found to be about 21, 826.19 kW. This translates into a specific power consumption of 0.191 kWh/kg for the cumulative production of the three pure products (i.e. 99.90 mol. % oxygen, 99.99 mol. % nitrogen and 97.00 mol. % argon). Replacing the cooling water with binary cycle heat engine as proposed in this study shows that the waste heat can be converted to power. The result shows that about 2,354.22 kW of electricity can be generated by the binary heat engine cycle by using the waste heat

from the compressor. This extra power causes the net power consumption of the cryogenic ASU to drop from 21, 826.19 kW to 19, 357.72 kW which represents a reduction of circa 11% in the specific power consumption when compared with the conventional process. The power generated from the compressor waste heat is also a source of revenue for the process thus lowering the operating cost of the process.

5. Conclusions

As shown in this paper, the utilization of compressor waste heat of a cryogenic ASU for power generation is both technologically feasible and economically viable. It can significantly improve the energy efficiency of the process through reduction in the net power consumption which translates into a reduction in the specific power consumption of the process.

IGCC Modelling for Simultaneous Power Generation and CO_2 Capture

Usama Ahmed [a], Umer Zahid [a], Chonghun Han [a*]

[a] *Seoul National University, Seoul, South Korea*
chhan@snu.ac.kr

Abstract

Power producing industry has largely relied on coal as a fuel source and will continue to depend on it for coming decades. However, to address the global warming problem while keeping high efficiency and economic feasibility of the processes is a key challenge. Coal-based power plants with post-combustion capture tend to have lower capital costs and cost of electricity without capture. On the other hand, pre-combustion capture plants tend to be less expensive when current CO_2 capture systems are added. This analysis suggests that pre-combustion plants can be an attractive option for the power generation if carbon capture and storage (CCS) technology is implemented on a large scale. This paper is focused on the in depth modeling and simulation of integrated gasification combined cycle (IGCC) with CO_2 capture using a physical solvent. Three case studies have been developed to analyze the overall plant output with CO_2 capture. In order to ensure a fair evaluation of analysis, a consistent and transparent methodology has been followed for all the cases. First two cases use the water gas shift reactions scheme with sour shift catalysis process. The resulted syngas free of CO_2 can either be combusted by using air or O_2. The first case uses air as an oxidant for burning H_2 and the combustor temperature is controlled by air as well. In the second case, O_2 is used as an oxidizing agent in the H_2 combustion. However, combustion temperature control is achieved by recycling the captured CO_2. In the third model, WGS reactor has been removed. The syngas composed of CO and H_2 is sent directly for combustion which makes it similar to the oxy-fuel combustion process. In this way, captured CO_2 can be recycled back to control the combustor temperature in 2nd and 3rd case. The results show that the overall plant output power for the three cases is 378 MW, 344 MW and 388 MW respectively. Case 1 and 3 are the competitive options in terms of efficiency; however the capital cost may be the deciding parameter.

Keywords: CCS, Selexol, IGCC, Pre-Combustion.

1. Introduction

With the recent studies and report published by International Energy Agency (IEA, 2014) it can be seen that with the continuous increase in electricity production, the greenhouse gas emissions have been tremendously increased during the last few decades and it will continue to increase if the emissions will not be controlled. It is expected that coal will remain the main source of power generation for the coming decades because of its abundant availability, affordability and an already existing infrastructure for power generation. Hence, there is a need to develop and improve the power generation processes that can give maximum efficiency while addressing the global warming issues at the same time.

CCS has been identified as a promising set of technologies to decrease the carbon emissions in the atmosphere. But at the same time, CCS implementation not only

increases the financial and installation cost but also put energy penalties in terms of electricity production. Most of the currently operating power plants in the world are post combustion power plants with efficiencies ranging between 25-30 % with CCS installment. On the other hand, Integrated Gasification and combined cycle (IGCC) power plants, a class of pre-combustion process have a higher efficiency (up to 38 %) when CCS is included. However, with a 90 % CO_2 capture IGCC power plant, the electricity cost is increased by 30 %, whereas the efficiency of the power plant is reduced by 8-10 % points.

Recently, a lot of research has been carried out to investigate the feasible designs for an improvement in the efficiency of IGCC plants. Cormos et al. (2014) proposed a model of IGCC based on coal and biomass co-gasification technique for simultaneous production of electricity, H_2, synthetic natural gas (SNG) and fisher-tropsch (FT) fuel. Co-gasification with multiple fuels both decreases the ash fusion temperature as well as oxygen consumption, thereby increasing efficiency of the process. Padurean et al. (2012) reported that the selexol process has least specific power and heating consumption as compared to the other physical solvents. Kawabata et al. (2013) proposed model for IGCC with exergy recuperation that gives an efficiency of 33.2 % with 90 % CO_2 capture and 43 % without capture. Ferguson et al. (2013) modified the water gas shift design in the IGCC process and showed an improved efficiency of 37.62%. Cormos et al. (2014) used co-gasification technique using different fuels and proposed a design for poly generation with the plant efficiency ranging between 27-37% with CCS technology.

Most of the previous studies were mainly focused on the design modification and optimization of the conventional IGCC process with poly generation. None of the recent studies considered design improvement in IGCC process for power generation. If the sole purpose is the power generation, the conventional design of IGCC with CO_2 capture can be modified and improved to increase the thermal efficiency of power plant compared to that of post-combustion process with CO_2 capture. This paper presents various designs for IGCC with CCS scheme that can be utilized for simultaneous power generation and CO_2 capture. All the IGCC designs are made in Aspen Plus® using Peng-Robinson equation of state and results are compared in terms of overall power generation, net power plant efficiencies and CO_2 emissions. Furthermore the sensitivity analysis has been performed to check the efficiency penalties at different percentages of CO_2 capture.

2. Process Description

IGCC process is based on five major units namely gasification unit (GU), water gas shift reactor (WGS), acid gas removal section (AGR), heat recovery steam generation (HRSG), and combined cycle (CC). Gasification unit contains the gasifier with the coal feeding system. Coal can be fed to the gasifier in two ways i.e. dry process or slurry process. Coal water slurry process has low capital cost and is more stable compared to the dry process because there are no channeling problems as it happens in the dry process. Three type of gasifiers commonly used in industry are moving bed gasifier, fluidized bed gasifier and entrained flow gasifier. Entrained flow gasifiers are best used in the coal-gasification applications as it allows all types of coals regardless of their rank and caking characteristics. It can be operated in both dry mode and slurry mode. This gasifier allows formation of syngas at a pressure and temperature up to 6.5 MPa &

1600 °C respectively with 99.5 % of carbon conversion. The water in the slurry is evaporated during gasification process producing steam that can be used in WGS reactions thus increasing overall plant efficiency. In gasification process, a part of chemical energy is converted into heat forming CO and H_2 and the rest of 65- 80 % of energy is kept into the syngas which is called as syngas efficiency. This energy can be extracted by burning syngas or by transforming syngas to other valuable products. The gasification unit is integrated with the HRSG section to maintain the temperature above the ash melting temperature to avoid any possible blockage due to agglomeration. Syngas coming from the gasification unit is allowed to pass through the water gas shift reactors which are equipped with the catalyst to convert CO in the syngas to H_2 gas as given in Eq.(1).

$$CO + H_2O \rightarrow H_2 + CO_2 \qquad \Delta H = -41 \text{ KJ/mole} \tag{1}$$

Water gas shift reactions can be carried out in two ways i.e. sweet process and sour process. If the sulfur is removed from the syngas prior to the WGS unit, it is called sweet shift conversion whereas if the sulfur is removed after the WGS unit then it is called as the sour shift. Casero et al. (2014) showed that the sour shift catalysis process is more energy efficient as compared to the sweet process because a part of syngas chemical energy is degraded due to alternative cooling and heating of syngas for H_2S removal and WGS reactions respectively. WGS reactions are generally exothermic in nature so intermediate heat exchangers are employed to generate medium pressure steam. WGS reactions lead to more than 99 % conversion of CO to H_2 gas.

3. Design options for power production

Three case studies have been developed in order to analyze the power plant output with CO_2 capture. Coal slurry with 30 % water content is fed to an entrained flow gasifier operating at a temperature and pressure of 1600°C and 32 bar respectively. The syngas produced from the gasifier is rich in CO (33 %) and H_2 (49 %) whereas the rest contains H_2O, CO_2, N_2 .Case 1 and 2 based on sour WGS reactions as shown in Figure 1 and Figure 2 respectively. In the 1st case, both the syngas combustion and burner temperature is controlled by using excess air whereas in 2nd case, the syngas combustion is done by using oxygen and the burner temperature is controlled by recycled CO_2. Figure 3 represents the 3rd case based on non-WGS reactions in which syngas is burned by using high purity oxygen and the burner temperature is controlled by recycled CO_2.To have a consistent design basis, all the case studies have been performed for 90 % CO_2 capture with the final pressure raised to a transport pressure of 80 bar.

4. Results and Discussion

The first and second cases are based on the WGS reactions with the difference in using air or oxygen as an oxidant for the syngas burning. Whereas excess air and recycled CO_2 are being used for burner temperature control in case 1 and 2 respectively. Table 1 shows the summary of all the three case studies along with their specifications, net power output and efficiencies. The net power generated in the first case comes out to be 378 MW with the overall power plant efficiency of 36.18 %. The total power generated in second case is 344 MW with the efficiency of 32.9 %. The third case used high purity oxygen gas for combustion process where the combustor temperature has been

controlled by recycled CO_2. It gave the highest power output of 388 MW with net power plant efficiency of 37.15 %.

1st Case:

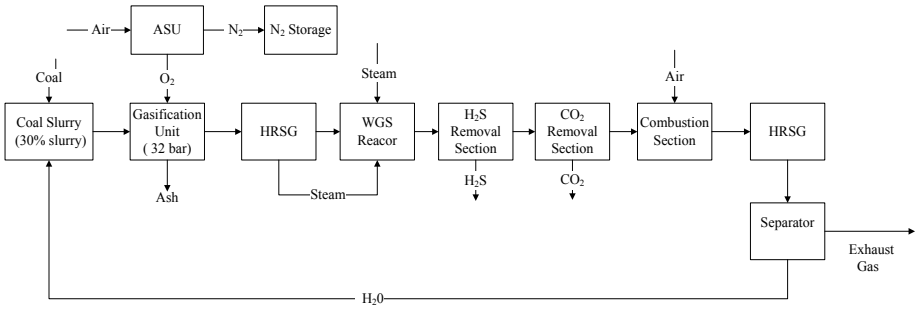

Figure 1: IGCC design with WGS reactor (Combustion oxidant: air, Combustor temp control: air)

2nd Case:

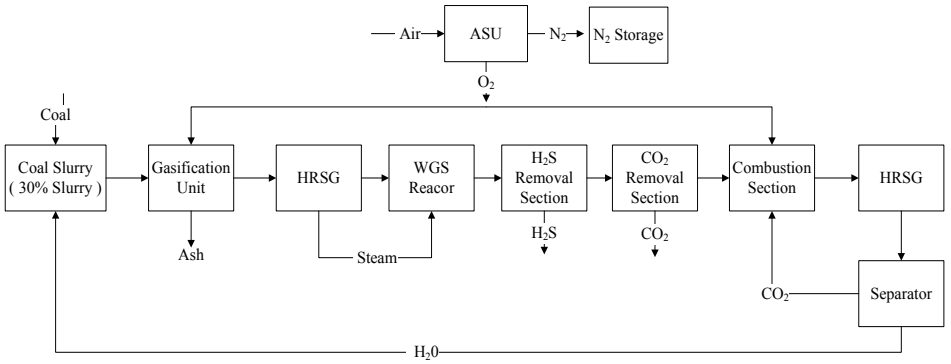

Figure 2: IGCC design with WGS reactor (Combustion oxidant: O_2, Combustor temp control: CO_2)

3rd Case:

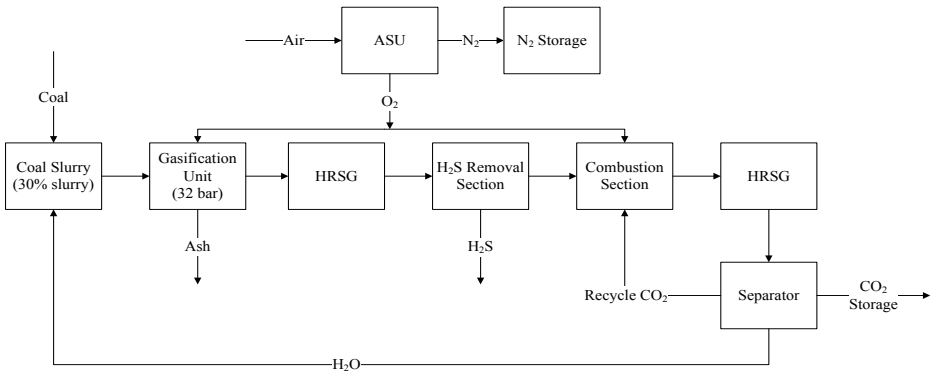

Figure 3: IGCC design without WGS reactor (Combustion oxidant: O_2, Combustor temp control: CO_2)

Case 1 and 2 consumes an intermediate pressure steam to carry out WGS reactions so the power generated from the steam cycle decreases to a great amount as compared to the 3rd case. Since oxygen is used as an oxidant for syngas combustion in the second case, it almost consumes same amount of oxygen as in the third case. However in the second case, only hydrogen is burned in the combustor with oxygen where the temperature is being controlled by using recycled CO_2. Hence, the overall low flow rate of flue gas through the gas turbine results in lesser power generation as compared to first and third case. From the results of second case it can be seen that the IGCC scheme with oxygen being used for syngas combustion along with recycled CO_2 being used for the combustor temperature control is the least efficient process. Case 1 and 3 are very competitive in terms of power production with the efficiency difference of about 0.96 %. However, as evident from the flow sheets (figure 1-3), case 1 has more unit processes along with the operating catalyst. Hence, the capital and operating cost would be much higher for case 1. Furthermore 1st case is more critical as compared to the 3rd case in terms of process control because if the temperature is not controlled precisely at inlet of WGS reactors then the activity of the catalyst will be changed that may affect the overall plant efficiency and the operating cost. On the other hand, there is no WGS and CO_2 capture unit in the third case which makes it more energy efficient process. Sensitivity analysis has been performed to analyze the impact of CO_2 capture percentage on the performance and net power plant efficiency. Figure 4 presents the variation in the net power efficiency of the power plant with the percentage change in CO_2 capture. All the three cases show the same trend of decrease in efficiency with the increase of CO_2 capture percentage.

The cost analysis has been done to estimate the CAPEX (M€) required per unit MW_{el} of electricity generation for all the three cases. The results show that the CAPEX required per unit MW_{el} for case 1, case 2 and case 3 is 2.93 M€, 3.46 M€ and 2.78 M€ respectively. The lowest CAPEX and highest energy efficiency of the 3rd case proves it to be the most economical process among all the three cases. Furthermore, the removal of WGS reactors also avoids catalyst recharging cost in the 3rd case which can save extra operating cost (OPEX).

Table 1: Case studies specification and summary

	1st Case	**2nd Case**	**3rd Case**
	WGS	**WGS**	**Non-WGS**
Gasification Agent	O_2	O_2	O_2
Syn-Gas (For	H_2	H_2	H_2+CO
Oxidant (Combustion)	Air (N_2+O_2)	O_2	O_2
Possible By-Products	H_2O, N_2	H_20	H_2O,CO_2
Burner Temp Control	Excess Air	CO_2	CO_2
Power (MW_{el})	378	344	388
Efficiency (%)	36.18	32.98	37.15

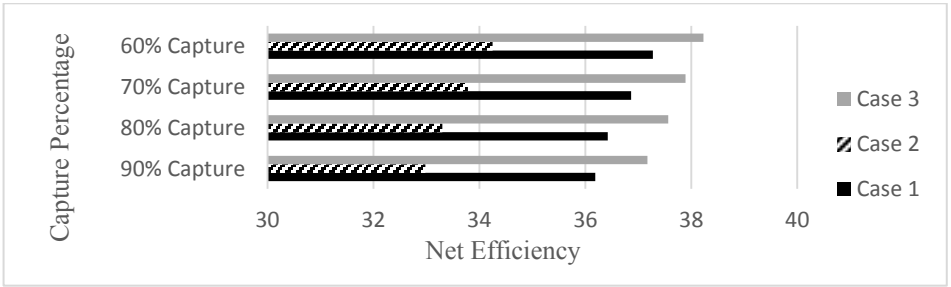

Figure 4: CO_2 capture percentage V/S Net efficiency of Power plant

5. Conclusion

Three design schemes have been developed to investigate the IGCC power plant performance with CCS technology. The 1st and 2nd case used WGS reactor scheme whereas the 3rd case didn't include any WGS reactor. The results show that the power generation from steam cycle has been decreased to a great amount if WGS reactors are used in the process. Whereas the 3rd case based on non-WGS reactors uses high purity oxygen for syngas combustion with the resulting flue gas temperature controlled by using recycled CO_2 offers the best option in terms of power generation and efficiency. Furthermore, the results show that the non-WGS scheme has the lowest cost per unit megawatt of electricity production.

Structural Similarities and Differences between Smart Grids and Process Industry Supply Chains: India Case Study

Nikita Patel, Rishabh Abhinav, Babji Srinivasan, Rajagopalan Srinivasan
Indian Institute of Technology Gandhinagar, Ahmedabad - 382424, India

Abstract

Process industry supply chains have been an active area of research for decades with advances towards decentralized management and development of closed loop resilience. Along similar lines, now electric power systems are moving towards smart grids that allow for decentralized power generation. At the surface level there are many differences between electrical grids and supply chains; for example, there is limited/no storage in case of electric power, hence supply and demand has to be matched at every time instant. However, in the recent times it has been recognized that some of the control and enterprise-wide optimization strategies that are an integral part of supply chain management have analogues in power systems as well. This article seeks to systematically identify the structural similarities and differences between these hitherto unrelated domains. We will illustrate these using a case study of Indian electrical grid.

Keywords: smart grid, supply chain management, decentralization, distributed generation

1. Introduction

The traditional approach to system management in both the supply chain and electric power domains have been (1) unidirectional flows (of material and electric power), (2) near steady supply and demand with low volatilities, (3) use of large inventories (material / spin reserves) at various stages of the system to balance supply and demand, and (4) low uncertainties. As discussed in Ritcher et al. 2012, driven by sustainability-related and other considerations, both systems are undergoing an evolution towards (1) bi-directional flows (for e.g. closed loop supply chains and distributed generation capabilities), (2) uncertain and highly variable supply and demand.

The broad strategies that the two domains have evolved to address these challenges and ensure effective system management also share broad similarities and originate from recent developments in Information & Communication Technology (ICT) and sensing. These similarities are (1) frequent, two-way information exchange between supplier & production, production & distribution, and distribution & customers; (2) shifting from centralized decision making to decentralized decision making; and (3) exploiting spatial and temporal flexibilities. The current work systematically identifies the parallels between closed-loop supply chain and smart grids. Further, implications of this analysis for smart grids in terms of utilizing the modelling and optimization strategies from their well advanced counterpart (SCN) are presented.

This paper is organized as follows: Section 2 compares the smart grid network with supply chain management. Section 3 discusses the existing approaches to model electric grid as a supply chain network. Section 4 describes the present structure of electric grid in India followed with a case study of Indian grid failure. Section 5 brings out the conclusions and future directives for smart grid in India.

2. Smart grid analogy with Supply chain

Prior to the concept of supply chain (before 1950) all the organizations worked serially to produce a single product operating as independent entity. According to M. Habib (2011) first transformation occurred around 1950 and logistics was then considered as a strategic function. The consultants in logistics first coined the concept of supply chain in 1980s. Initially supply chain considered unidirectional flow of goods and bidirectional information flow. The concept of reverse logistics made the supply chain closed loop and led to bidirectional flow of goods. The basic Supply Chain Network (SCN) involves suppliers, logistics/ transportation network, the producer and the consumer. According to Kalaitzidou et al. (2014) SCN design assumes a structure of the network with distinct and consecutive echelons, constituted of nodes with predetermined function.

Like SCN, conventional electricity grid was vertically integrated with centralized generation. Then the concept of Distributed Generation (DG) came, which helped the grid to be self-sustainable and immune to disturbances of other regions. It also helped in increasing the penetration of Renewable Energy Sources (RES). Similar to an advanced closed loop supply chain network, a smart grid comprises of centralized and distributed generation, energy storage, bi-directional electricity and information flow at all levels and an option of choosing the supplier. The smart grid has made the network of electricity complex and as shown in Figure 1 can be viewed as multi-echelon closed loop Supply Chain Network.

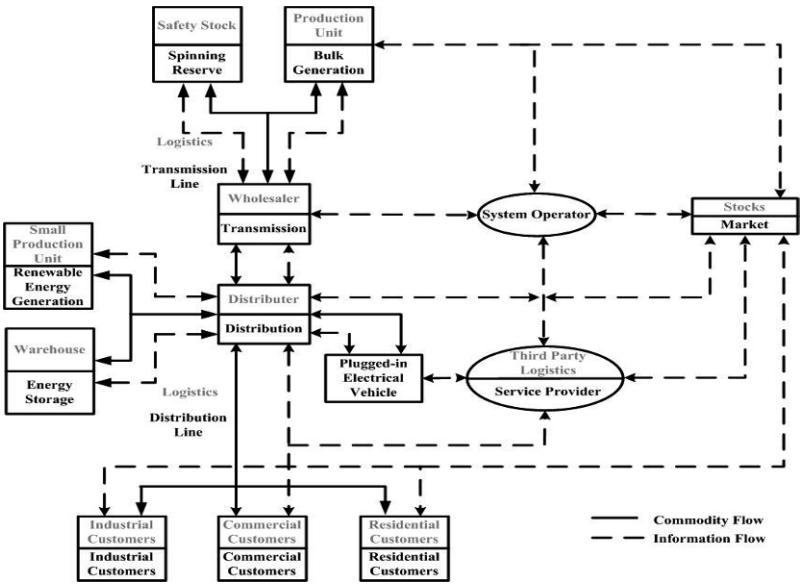

Figure 1: Structural similarities between Smart Grid (in black) and Supply chain (in grey)

2.1. Similarities between modelling approaches for smart grid & supply chain

As shown in Figure 1, smart grid can be related to closed loop supply chain at every level which calls for identifying parallels in modelling in these two domains. Traditionally, SCN is modelled to study develop a configuration to achieve optimal while a model of smart grid is developed to study the behaviour of the electric network and identify a resilient cost-effective grid under various uncertainties. Table 1 presents a comparison of smart grid & SCN in terms of modelling objectives and constraints. This helps in identifying appropriate modelling approaches in closed loop SCN that could be in development of models for smart electric grids.

Table 1: Comparison of modelling objectives and constraints

Supply Chain Modelling	**Electric Grid Modelling**
Reduction of environmental pollution	Greenhouse gas emission reduction
Improve utilization rate of resources	Optimal utilization of assets
Extend the service life of product	Reliability of electricity grid
Minimize the resource consumption	Energy conservation
Intact logistics	Reduce AT & C losses
Reverse logistics for waste management	Optimizing costumer end generation
Can keep some percentage as backup	Proper load forecasting due to storage constrain
Safety factors	
Sustainable development	

3. Modeling approaches for electric grid

As there are many structural similarities between smart grid and supply chain (table 1 & figure 1) a model of the smart grid can be developed borrowing ideas from SCN. In harmony with supply chain, the modelling approaches can be broadly classified into two categories: Top-down approach and Bottom-up approach.

3.1. Top down approach

The top-down approach treats the customer as an energy sink and does not distinguish energy consumption due to individual customer type. One of the popular top down approaches to model electric grid is real power flow method. To capture the power grid behaviour, the alternative current (AC) power flow model is the most accurate one. This model analytically determines the real and reactive flows over all the lines by using the power equations to solve the voltage magnitude and load angles at each substation (node). However, this model is very complicated due to its non-linear feature. Direct current (DC) power flow model is another type of power flow method which uses a linear equation to reflect the relationship between power flow through the lines and the power injection at the nodes. These real power flow methods are very useful in network planning and operation, determining and optimizing generation scheduling and calculating steady state conditions for stability analysis.

The other approach which aims to obtain the dynamic behaviour of the system is frequency analysis. Load Frequency Control (LFC) is the mechanism to regulate the power flow between the different regions of an interconnected system with objective to keep frequency constant. In an electrical network, different regions are interconnected to its neighbouring regions through the transmission lines, called tie-lines. Power

sharing between the two regions occurs through these tie-lines. LFC is used to regulate the flow of power among these tie-lines.

3.2. Bottom-up approach

The bottom-up approach treats all generating units as an energy source and does not distinguish between the types of primary energy used for generation. Rather than focusing on supply optimization it focuses on optimizing the costumer behaviour. In bottom up approach we start with modelling of the load profile. The factors affecting load profile can be broadly classified as technological factors and behavioural factors. Technological factors depend on the appliance type and manufacturer. Behavioural factors depend on socioeconomic and demographic characteristics, environmental conditions and the day of the year. This approach helps us to identify the customer level details of consumption and can thus be used for demand optimization to balance supply and demand. Figure 2 shows the parameters required for bottom-up approach.

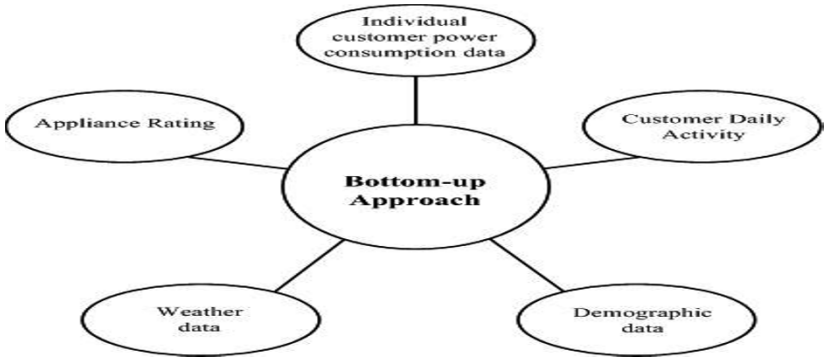

Figure 2: Factors affecting individual load profile

4. Electric Grid network in India

Indian power grid is divided into five regions namely - NR (Northern Region), WR (Western region), SR (Southern Region), ER (Eastern Region) and NER (North Eastern Region). Though these five regions are independent but electrically they are connected constituting a National Grid.

As per Indian Electricity Grid Code (2010, CERC) government organizations responsible for planning, operating and regulating the Indian electricity grid and their respective responsibilities are as follows:

- Load Dispatch Centres at National, Regional and State level (NLDC, RLDC and SLDC respectively) supervise and control the scheduling and dispatch of electricity in order to optimally utilize the available power resources at the respective levels. NLDC and RLDC keeps accounting of inter-regional and intra-regional exchange of power respectively. NLDC also coordinates for trans-nation exchange of power.
- Regional Power Committee (RPC) at regional level undertakes operational planning and analysis of the grid. It plans monthly and annual generators and transmission lines maintenance. It also works out on all issues relating to economy and efficiency in the operation of power system in that region.

- Central Electricity Authority (CEA) is responsible for coordinating activities of planning agencies (RPC) and specifying technical standards for construction, operation and management of the grid. It also collects data for generation, transmission, distribution and trading at the grid level.
- Regulatory Commissions at Central and State level (CERC and SERC respectively) are responsible for defining regulations.

The electricity flow and information flow in the present Indian electricity grid and the percentage installed capacity of generation is shown in the Figure 3.

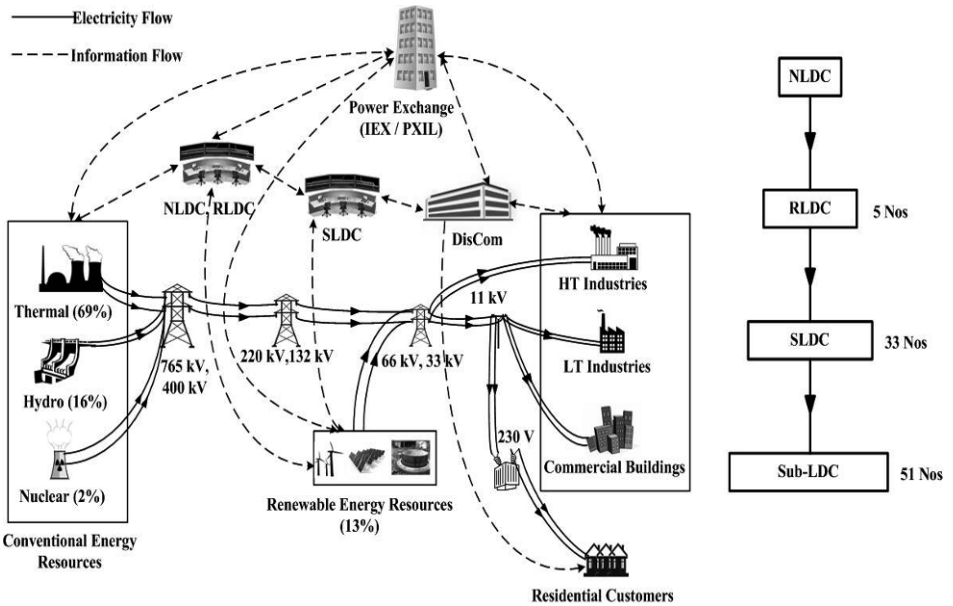

Figure 3: Structure of Present Indian Electricity Grid (Left side) & regulatory agencies (Right side)

4.1. Case Study

On 30th July 2012 and 31st July 2012, the Indian electricity grid saw two successive major blackouts which left more than 600 million people in India with no electricity. It is considered as the largest power outage in history which spread across three regional grids (NR, ER and NER) covering over 21 Indian states and 1 union territory. The main reason for this grid failure was unbalance between demand and supply in the northern region which led to the heavy loading of inter-regional links and resulted in the cascaded failure of grid.

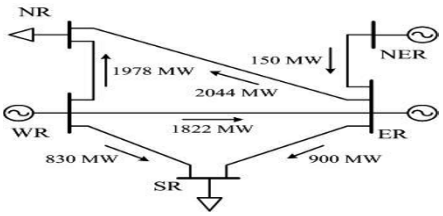

Figure 4: Antecedent conditions of Indian electricity grid on 31st July, 2014

We have studied the cascade event of 31st July and analysed the conditions prior to the event using AC power flow method. Table 2 shows that the voltage and load angle deviation at NR bus was too much which eventually resulted in the grid failure. However the exact system conditions can be obtained by analysing the frequency deviation.

Table 2: Bus voltages and load angles at each bus on 31st July, 2014

Region	Type of bus	Bus Voltage (pu)	Load Angle (deg)
Northern Region (NR)	PQ	0.84	-35.90
Eastern Region (ER)	PV	1.00	-12.92
North-Eastern Region (NER)	PV	1.00	-12.27
Western Region (WR)	Swing	1.00	0.00
Southern Region (SR)	PQ	0.99	-19.92

5. Conclusions and Future Directions

Presently, the Indian electricity system faces a number of challenges: Poor access to electricity, Shortage of power, huge losses in the grid, power theft, shortage of fuel, incompetent power consumption and poor reliability. Over 300 million people in India still have no access to electricity. A smart grid is supposed to be the solution to all these challenges and in fact essential for India's energy security in the future. Smart grid will lead to optimal utilization of resources, cost savings at the operational level and sustainable development. This caters for the need of decentralization of the electric grid with bidirectional power flow and more focus on low voltage level. The introduction of distributed generation, more emphasis on renewable resources, secure and reliable grid operation have driven the electric grid on the path of supply chain network. Due to the aforementioned similarities between closed-loop SCN & smart grids and given the fact that SCN is a well-established domain, the transformation of existing Indian electric grid to smart grids can be achieved using the lessons learnt from closed loop SCN. Acknowledging the existing similarities & differences, our future work is directed towards adapting the existing modeling, scheduling & optimization strategies for resilient supply chain networks to smart grid systems.

Abstract

Microalgae are sunlight-driven cell factories that carry out the same process and mechanism of photosynthesis as higher plants converting sunlight into biomass, performing more efficiently than crops (Chisti, 2007). Nevertheless, high substrate and fertilizer input requirements as well as harvesting and oil extraction costs have been found to play a significant role in both the economic viability and sustainability of microalgal biofuels production (Pittman et al., 2011). Therefore, attention has been drawn to experimental and computational studies on the microalgal oil production, aiming to increase the productivity either through the photosynthesis process or through the application of metabolic engineering (Chisti, 2007) to improve the sustainability and competitiveness of the algal-derived biofuels industry. The objective of this work is the establishment of links between algal strains grown in large raceway open ponds and innovative bioproduct generation technologies including fuels and chemicals in order to achieve positive energy balance and environmental sustainability. Multi-parameter quantification has been employed leading to a predictive model to describe algal growth and lipid accumulation in lab-scale batch systems. The model can also take into account the effects of temperature, light and pH, in order to improve the productivity of microalgae cultivation technologies. Experiments have been conducted to analyse the effect of different input parameters. The model was fitted to data from bench-scale batch experiments. The experimental setup involved tris-acetate-phosphate (TAP) media containing 1.575 g/L and 2.1 g/L acetic acid and 0.098147 g/L nitrogen under constant light illumination of 125 $\mu Em^{-2}s^{-1}$. An in-house developed optimization framework (Vlysidis et al., 2011) has been used for the estimation of the key parameters. The predictive capabilities of the model were tested on batch systems comprising TAP media containing 2.625 g/L acetic acid.

Keywords: *Chlamydomonas Reinhardtii*, Biofuels, Kinetic modelling, Microalgal oil.

1. Introduction

Microalgae are light driven cell factories which convert CO_2 to biofuels, high-value co-products, feeds, and foods (Borowitzka, 1999; Chisti, 2007). Additionally, microalgae species are useful for bioremediation processes and they can be used as nitrogen fixing fertilizers (Chisti, 2007). This work focuses on the potentials of microalgal oil production. Microalgae species produce several types of renewable biofuels such as methane through anaerobic digestion of microalgal biomass (Chisti, 2007), biodiesel from microalgal oil (Demirbas, 2011), and hydrogen through photobiology (Chisti, 2007). Although the potential of microalgae use as a source for renewable fuel

production has been known for more than 50 years (Chisti, 2007), it has just recently been increasingly taken into consideration due to the petroleum price escalation, and more importantly, due to the increasing concern about global warming associated with fossil fuel usage. Microalgal production of biofuels bears significant advantages such as rapid growth rate of microalgae, reduction of greenhouse gas (CO_2) emissions, decrease of consumption of resources (water and land), high production capacity, non-competition with agricultural land and simple growing needs (light, sugars N, P, K and CO_2) compared to other terrestrial plants (Borowitzka, 1992). Economic and scientific interest in microalgal oil production has focused on the increase of microalgal oil productivity through photosynthesis and also on the improvement of the sustainability and competitiveness of the algal-derived biofuels industry.

The main objective of this work is to establish links between algal strains grown in large raceway open ponds and innovative bioproduct generation technologies including fuels and chemicals in order to achieve positive energy balance and environmental sustainability. Therefore, multi-parameter quantification has been employed and a predictive model has been constructed to describe biomass growth, and lipid production in lab-scale batch systems. The predictive capabilities of the model have been tested for a range of growth parameters related to temperature, light and pH, in order to aid the robust design and control of microalgae cultivation technologies. Experiments have been conducted to investigate the effect of each metabolite on biomass growth and on lipid accumulation. Furthermore, an in-house developed Simulated Annealing (SA) scheme is linked to a deterministic MATLAB optimization function for the estimation of key parameters used in the bench-scale batch systems.

2. Materials and Methods

2.1. Strain and Culture Conditions

Chlamydomonas Reinhardtii (CCAP 11/32C) was obtained from the Culture Collection of Algae and Protozoa, UK. Preculture of the strain is carried out in an incubation room at 25ºC using 250 mL conical flasks, each containing 150 mL of Tris-acetate-phosphate (TAP) medium, which was placed in an orbital shaker at 120 rpm for 7-10 days. Constant illumination was used at 125 $\mu Em^{-2}s^{-1}$ intensity with white fluorescent lamps. The preculture of the strain was stopped when sufficient density was reached. An algal inoculum of 1 mL was then added to the experimental culture vessels (500 mL bottles) containing 500 mL of culture medium. The starting cell density was the same in all treatments; 0.024×10^6 cells per mL for *C. Reinhardtii*. To induce nitrogen starvation, different TAP salts solutions containing different nitrogen concentrations have been prepared and used. The samples were centrifuged for 3 min at a full speed to harvest the biomass. The obtained pellet was then washed with cold distilled water and weighed to determine the wet biomass. Subsequently, the wet biomass was dried overnight at 70 ºC to determine the dry biomass weight. The pH of the samples was analysed through the use of a bench type pH meter. The samples were stored in eppendorf tubes and placed in the refrigerator at -20ºC for further analysis of the biomass and the supernatant.

2.2. Analytical Methods

Optical Density: The biomass growth was defined through the measurement of optical density at 680 nm in a UV-VIS spectrophotometer.

HPLC Analysis of Organic Acids: The consumption and production of acids was quantified using a High Performance/Pressure Liquid Chromatographer (HPLC) equipped with a Hi- Plex 8 μm 300x7.7 mm column. Glacial acetic acid (GAA) -which

was added to the growth media as a substrate- and oxalic acid (OA), glycolic acid (GA) and formic acid (FA) -produced byproducts- (Allen, 1956) were added into standard solutions. Sulphuric Acid (SA) solution (0.05% v/v) was used as mobile phase. The flow rate of system was set to 0.6 $mLmin^{-1}$ with a pressure value around 45 bars and temperature of 50ºC while the detection wavelength was set at 210 nm. The sample preparation included filtration through 0.45 μm filter membranes

TOC/TN Analyser: Total dissolved nitrogen concentration in the growth media was quantified by the use of Total Organic Carbon / Total Nitrogen analyser (TOC/TN). Ammonium Chloride (NH_4Cl) -which was added to the growth media as a nutrient- was added into standard solutions.

Soxhlet Solvent Extraction by Using Soxtec: The freeze-dried algal biomass was homogenized with liquid nitrogen in a mortar with pestle and extracted using the Soxtec 1043 automated solvent extraction system. The following procedure was used to quantify lipid content: boiling 2 hours, rinsing 40 min and solvent recovery 20 min. Extraction temperature for the selected solvent (Hexane) was 155ºC (McNichol et al., 2012). After the oil extraction with the Soxtec 1043, extracted lipids were dried at 100ºC for 1 h, placed in vacuum applied desiccator for 1h, and weighed to define lipid yield gravimetrically.

3. Modelling

Economou et al. (2011) have described a single-cell biomass growth and oil accumulation model. Based on that study, here we have developed an improved unstructured process model to describe the microalgal growth and oil accumulation processes. Microalgae growth is given by:

$$\frac{dX}{dt} = \mu_X X \tag{1}$$

where X is the fat-free biomass concentration (g/L), and μ_X is the specific growth rate based on substrate, nitrogen and light (1/h) described by Eq.(6) later in this work.

The lipid accumulation rate can be described by:

$$\frac{dL}{dt} = q_L X \tag{2}$$

where L is the lipid concentration (g/L), and $q_L$the specific lipid accumulation rate of lipids in biomass (g lipids/ (g fat-free biomass h)) described by Eq.(7) later in this work.

The substrate consumption rate can be calculated by a simple substrate- mass balance:

$$-\frac{dS}{dt} = \left(\mu_X \frac{1}{Y_{X/S}} + q_L \frac{1}{Y_{L/S}}\right) X \tag{3}$$

where $Y_{\frac{X}{S}}$ is the yield coefficient for fat-free biomass production with respect to substrate (g fat-free biomass/ g substrate), $Y_{\frac{L}{S}}$ is the yield coefficient for lipid production with respect to substrate (g lipids /g substrate) and S is the substrate concentration (g/L). The nitrogen consumption rate is computed by:

$$-\frac{dN}{dt} = \mu_{SN} \frac{1}{Y_{X/N}} X \tag{4}$$

where $Y_{(X/N)}$ is the yield coefficient for fat-free biomass production with respect to nitrogen (g fat-free biomass/g nitrogen) and N is the nitrogen concentration (g/L).

The dependence of the pH of the microalgae cultivation system on substrate consumption is taken into account here. Thus, the pH change in the system is expressed as (Zhang et al., 1999):

$$-\frac{dH}{dt} = K_H \frac{dS}{dt} \tag{5}$$

where H is the pH of the process and K_H is a coefficient for the dimensionless pH. After the conduction of a number of experiments, we observed that high substrate concentrations lead to a significant reduction of the specific growth rate. Experiments have also shown that nitrogen deprivation triggers lipid accumulation while blocking the biomass growth. Additionally, it was found that biomass production reduces significantly at high light intensities. The Monod-Andrew double-substrate limitation model has been employed to describe both the substrate and the nitrogen effect. An additional term has been added to describe the light intensity effect. Subsequently, the specific growth rate of fat-free biomass and the specific growth rate of lipid formation depending on substrate, nitrogen and light are expressed by:

$$\mu_X(S,N,I) = \mu_{Xmax} \frac{\mathrm{S}}{K_S + \mathrm{S} + \frac{\mathrm{S}^2}{K_{i1}}} \frac{\mathrm{N}}{K_N + \mathrm{N}} \frac{I(l)}{K_I + I(l)} \tag{6}$$

$$q_L(S,N,I) = q_{Lmax} \frac{S}{K_{LS} + S + \frac{S^2}{K_{i2}}} \frac{K_2}{K_2 + N} \frac{I(l)}{K_I + I(l)} \tag{7}$$

where μ_{Xmax} is the maximum specific growth rate of biomass (1/h), q_{Lmax} is the maximum specific growth rate of lipid (g lipids /g fat-free biomass), K_S and K_{LS} are the saturation constants for substrate and lipid respectively (g/L), K_{i1} and K_{i2} are the inhibition constants (g/L) for fat-free biomass growth and lipid production respectively, K_N and K_I are the saturation constant (g/L) for nitrogen and light respectively, K_2 is a constant (g/L) that defines the inhibition of the lipid production process by nitrogen, and $I(l)$ is the local light intensity.

The light distribution during algae cultivation is expressed by the Beer-Lambert law:

$$I(l) = I_0 \exp(-\sigma X l) \tag{8}$$

where $I(l)$ is the local light intensity, l is the distance from the light source to the bottles' external surface, I_0 is the incident light intensity and σ is the extinction coefficient.

4. Results and Discussion

Estimation of the model parameter values was performed through optimisation coupling a stochastic SA algorithm, with a deterministic method, using the 'fmincon' function in MATLAB, to allow the computation of solutions around the global optimum (Vlysidis et al., 2011). The model was fitted to experimental data obtained from cultures, performed on Tris-acetate-phosphate (TAP) media containing 1.575 g/L (Figure 1) and 2.1 g/L acetic acid and 0.098147 g/L nitrogen under constant light illumination 125 $\mu Em^{-2}s^{-1}$. The parameter values obtained are shown in Table 1. The corresponding

model predictions along with the experimental observations for TAP media containing 2.625 g/L acetic acid are presented in Figure 2. As we can see in Figures 1 and 2, our model is capable of predicting the biomass growth, the substrate consumption and the lipid accumulation very accurately both qualitatively and quantitatively. Small differences are observed in the pH profiles due to the production of organic acids that are currently not taken into account in this work.

Table 1: Model Kinetic Parameters.

Parameters	Values	Parameters	Values
μ_{SNmax}	$0.0989h^{-1}$	k_2	$197.6611\frac{g}{L}$
K_S	$1.7160\ \frac{g}{L}$	$Y_{X/S}$	$0.4438\ \frac{\text{g fat} - \text{free biomass}}{\text{g substrate}}$
K_{i1}	$7.5794\ \frac{g}{L}$	$Y_{L/S}$	$0.0664\frac{\text{g Lipids}}{\text{g substrate}}$
K_N	$0.0349\ \frac{g}{L}$	$Y_{X/N}$	$5.3668\ \frac{\text{g fat} - \text{free biomass}}{\text{g nitrogen}}$
q_{Lmax}	$0.184\frac{\text{g lipids}}{\text{g fat} - \text{free biomass}}$	K_H	$0.7651\ \frac{L}{g}$
K_{LS}	$114.6521\ \frac{g}{L}$	σ	$0.0244\frac{m^3}{kg}$
K_{i2}	$6.0739\frac{g}{L}$	K_I	$6.4611\ \mu E m^{-2}s^{-1}$

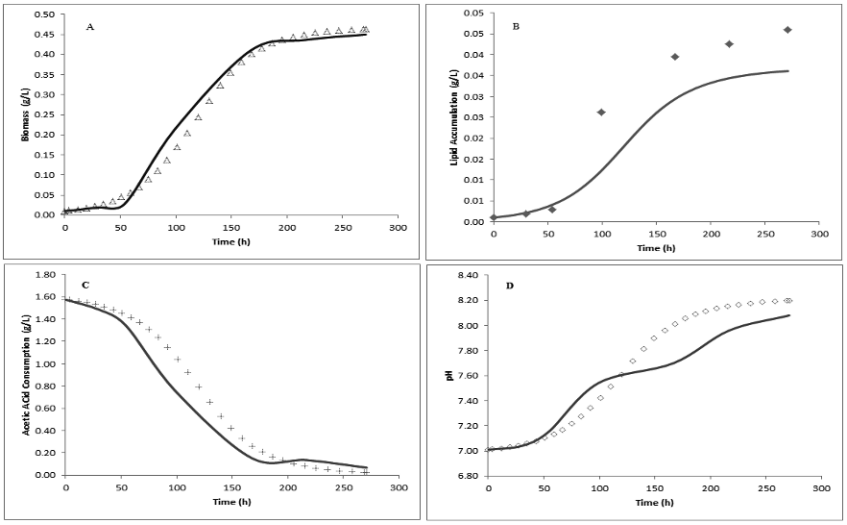

Figure 1: Profiles of experimental results (symbols) and model predictions (lines) for: (a) biomass *(C. Reinhardtii)* growth, (b) lipid accumulation, (c) substrate (acetic acid) consumption and (d) pH change, using 1.575 g/L acetic acid.

5. Conclusions

A multi-parameter model has been developed to describe the biomass growth and the lipid production in bench-scale batch systems. The formulated model also considered a

range of metabolites related to temperature, light and pH. Experiments were conducted for the investigation of the effect of each metabolite on biomass growth and on lipid accumulation. The model was validated for different sets of substrate concentrations. Such a predictive model can be exploited for the robust design and the control of microalgal oil production technologies towards an efficient system scale-up.

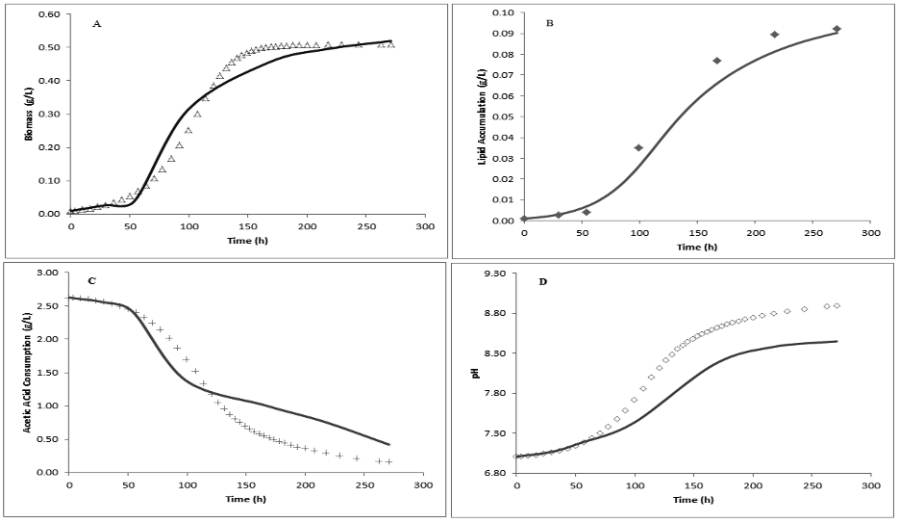

Figure 2: Profiles of experimental results (symbols) and model predictions (lines) for: (a) biomass *(C. Reinhardtii)* growth, (b) lipid accumulation, (c) substrate (acetic acid) consumption and (d) pH change, using 2.625 g/L acetic acid.

Abstract

In this work, we established the material and energy flow charts of a base case which contains the following units: biomass collection and transportation, pretreatment, anaerobic digestion, biogas upgrading and waste management. For this biogas system, the input feedstock are fixed to human feces and corn straw, the anaerobic digestion is performed at normal temperature 25 °C, and the biogas coming from anaerobic unit is upgraded via high pressure water scrubbing method to obtain the 98 % purity biomethane. The system material and energy flows are presented to indicate that the anaerobic digestion unit generate 90 wt % of the biogas slurry and residue, and 70 % of the energy was loss with the emission of the biogas slurry and residue. As for the system energy balance, we calculate the low heating value (LHV) based system energy efficiency considering the biomass feedstocks' LHV. Furthermore, a system energy efficiency comparison between the base case and the modified case with heat exchange between biogas slurry and feedstock is made. The system energy efficiency results indicate that the heat exchange between the biogas slurry and the feedstock can enhance the system efficiency by about 0.3 %.

Keywords: biogas system, energy efficiency, green degree, system evaluation, process integration

1. Introduction

The harmful effects of the use of fossil fuels to the environment, health and society have spurred global interest in the search for cleaner sources of energy (Deng et al., 2014). As an effective method to generate renewable energy, biogas is being developed rapidly and globally, and is playing an increasingly important role in energy production and environmental protection (Wang et al., 2014).

However, biogas production is a huge system which covers different subsystems, such as the feedstock collection and transportation, pre-treatment, anaerobic digestion, digestate management and biogas utilization. All of the above mentioned subsystems contain various technologies. For feedstock transportation, the truck or tractor can be used; for pre-treatment methods both chemical methods, i.e., ionic liquids, alkali and acid are used and physical methods, i.e., steam explosion, chopping, and baling, etc. are available (Risberg et al., 2013); for anaerobic digestion technologies, according to the difference in total solid content and the temperature, methods such as mesophilic-wet, mesophilic-solid, thermophilic-wet and thermophilic-solid, etc. can be chosen. Furthermore, the variety of the anaerobic digestion reactors and one stage or two stage

anaerobic digestion processes are also alternatives for the anaerobic digestion subsystem (Schievano et al., 2014; Wan et al., 2013); for biogas utilization, the combined heat and power (CHP), fuel cell and upgrading technologies, i.e., pressure swing adsorption (PSA), membrane, high pressure water scrubbing (HPWS), etc. are common ways to utilize the biogas; for digestate management technologies, the digestate can be applied for bio-fertilizer, composted and combustion as fuel after drying. The selection or combination of the technologies presented above and the variety of the feedstock used in the process constitute a big topological network, which make the system so complex to study. Thus, giving an assessment of the whole system from energetic, environmental and economic aspects has great significance.

According to the author's knowledge, there is little literature focus on the biogas system evaluation; most of the work on biogas system evaluation was done by Börjesson and Berglund group. The published literature by them is mainly using the LCA-based environmental method to evaluate the system. For example, Börjesson and Berglund (2006) gave an analysis of fuel-cycle emissions of carbon dioxide (CO_2), carbon oxide (CO), nitrogen oxides (NO_x), sulphur dioxide (SO_2), hydrocarbons (HC), methane (CH_4), and particles from a life-cycle perspective for different biogas systems based on six different raw materials. The results indicated that biogas yields and the energy efficiency in the biogas production chain have a significant impact on the fuel-cycle emissions from biogas systems. Börjesson and Berglund (2007) indicated that the environmental impact of introducing biogas can vary significantly due to the raw materials digested, the energy service provided and the reference systems replaced, but there are also some uncertainties regarding the availability of accurate input data, assumptions about technologies and geographical conditions.

As for the energetic assessment of the biogas system, there are not more than ten references. Many studies mainly analyzed the subsystem energy balance or energy efficiency but not the whole biogas system. Chen and Chen (2014) proposed a 3-level emergetic evaluation framework to investigate the energy efficiency and sustainability of a complex biogas system (CBS) in South China. The results suggested that the metabolism of the CBS has increased over years in terms of total emergy input, among which renewable resources and non-renewable purchases contributed most. Poschl et al. (2010) gave an evaluation of the energy efficiency of different biogas systems, including single and co-digestion of multiple feedstock, different biogas utilization pathways, and waste-stream management strategies. The results demonstrated that, co-digestion is more stable process than the single digestion. Furthermore, system energy efficiency could be further enhanced through recovery of residual biogas from anaerobic digestion subsystem. Havukainen et al. (2014) investigated various system boundaries and the evaluating methods of estimating energy performance of biogas production. The results demonstrated that, the comparability of the energy performance of various biogas systems requires that the energy performance is calculated in a more consistent manner.

The aim of this study is to give the energy and material balance of the biogas system defined by ourselves, to calculate the energy efficiency of this system under fixed input feedstock type and anaerobic digestion temperature but different units technologies. Furthermore, the heat exchange between the biogas slurry and the input feedstock is considered to enhance the system energy efficiency.

2. Methodology

2.1. Biogas system description

The biogas system in this work concludes five units: 1) biomass collection and transportation. In this unit, only the corn straw is collected using a truck with 2.5 ton loading, the transport distance is 20 km; 2) biomass pretreatment. The corn straw is pretreated by physical methods, i.e., briquetting and chopping. 3) anaerobic digestion. The digestion temperature is fixed at 25 °C and the total solid content is fixed at 10 wt %, the mechanical stirring is installed to ensure the homogeneous temperature and substrate concentration in the anaerobic digester, and the volume of biogas production rate under this condition is 0.74 m^3/m^3 digester/d; 4) biogas upgrading. The high pressure water scrubbing (HPWS) method is applied with pure water as the solvent, the product CH_4 is then compressed to utilize as the vehicle fuel; 5) waste management. The digestate is handled by separating the solid and the liquid using screwing and pressing, and the solid is then dried by using the heat from outside of the system. The biogas system is presented in Figure 1. All of the data above is from the biogas demonstration project in Nanjing Tech university.

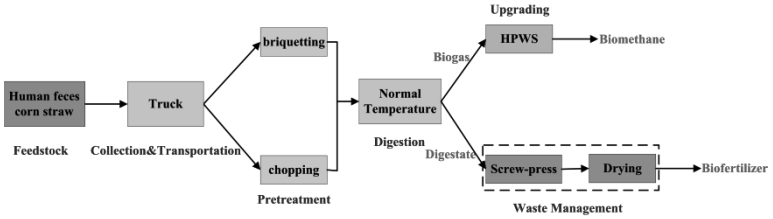

Figure 1. Biogas system boundary

2.2. Biogas system evaluation index

The energetic performance of the biogas system is evaluated by using the low heating value (LHV) based energy efficiency. The input energy into the system concludes the following parts: 1) the energy consumption in biomass collection unit is mainly due to the diesel consumption by the truck, which can be converted to the energy calculated by LHV of the diesel; 2) the energy consumption in pretreatment unit arise from briquetting and chopping the corn straw; 3) the energy consumption in anaerobic digestion unit contains the heating of the feedstock, the maintenance of the temperature of the digester and the mechanical stirring; 4) the energy consumption in biogas upgrading unit mainly contains the energy used to compress the gas mixture and the compression of the product CH_4 to a high pressure as the vehicle fuel; 5) the energy consumption in waste management unit contains separating the biogas slurry and biogas residue by screwing and pressing, and then heating the biogas residue to lower water content. The energy consumption type of the biogas system is mainly the heat and electricity. The energy consumption of electricity is calculated by the LHV of the standard coal, the standard coal consumption of power supply is 0.321 kg/kWh in China, and the LHV of the standard coal is 29.26 MJ/kg. The heat needed in the anaerobic digestion unit, the heat integration and the energy needed in the biogas upgrading unit are calculated using the Aspen plus.

3. Results and discussion

3.1. Biogas system material flow analysis

The biogas system material flow is presented in Figure 2. The material balance is calculated based on the mass of the material. The material balance in Figure 2 indicates that, the biogas and biomethane account for 3.0 wt% and 1.1 wt% of the total feedstock input in this system, respectively. Thus, the material application efficiency is low, it is imperative to develop new digestion technologies to enhance the yield of the biogas and the content of the methane. Furthermore, the process generates about 90 wt% slurry and residue, which also cause huge environment problems. How to handle these nutrient rich materials efficiently is of great importance.

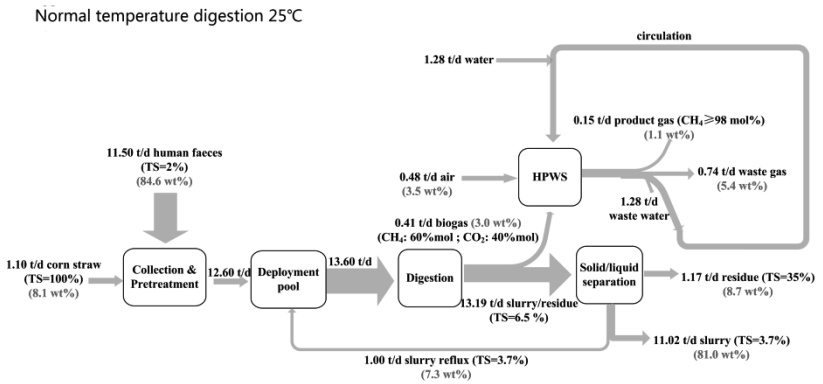

Figure 2. Biogas system material flow

3.2. Biogas system energy flow analysis

The biogas system energy flow is presented in Figure 3. The energy balance is calculated based on the LHV of the material and the standard coal. It can be seen from the Figure 3 that, the raw biogas and product gas account for 29.3% and 28.7% of the total energy input in the system, and 70% of the energy is loss with the waste gas and the slurry and residue. Thus, the heat exchange between the slurry and the feedstock should be conducted to decrease the energy loss.

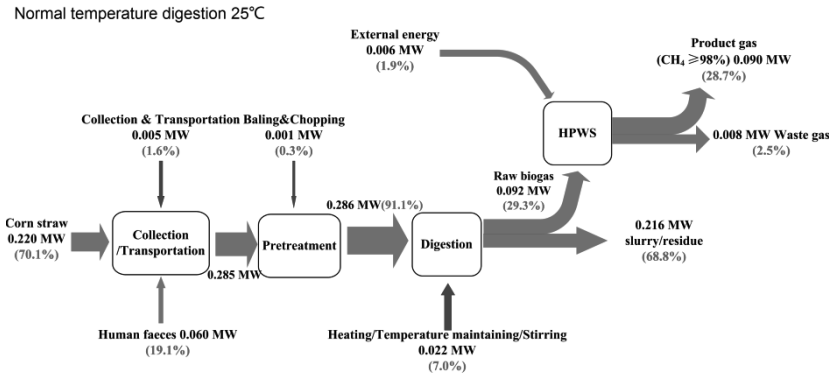

Figure 3. Biogas system energy flow

3.3. Biogas system energy efficiency comparison

To calculate the energy efficiency of the system, the energy consumption distribution should be given, the base case energy consumption distribution with no exchange of the heat between the slurry and the feedstock is presented in Figure 4. The energy efficiency of the base case is 28.7%. For the improvement of the system efficiency, the modified case with heat exchange between slurry and feedstock is calculated, the energy consumption distribution of the modified case is presented in Figure 5. In the base case, the feedstock temperature is the mean temperature of the Nanjing area, which is about 16 °C. However, the modified case assume that we use the most advanced heat exchange technologies, with the logarithmic mean temperature difference about 5 °C, lower than the general reported 10 °C. Though the heat exchange operation, the feedstock can be heated to about 20 °C. The energy efficiency of the modified case is 29.0%, which has only 0.3% enhancement compared with base case. Thus, the improvement of the energy consumption from other unit like upgrading or waste management is necessary to further enhance the energy efficiency of the system.

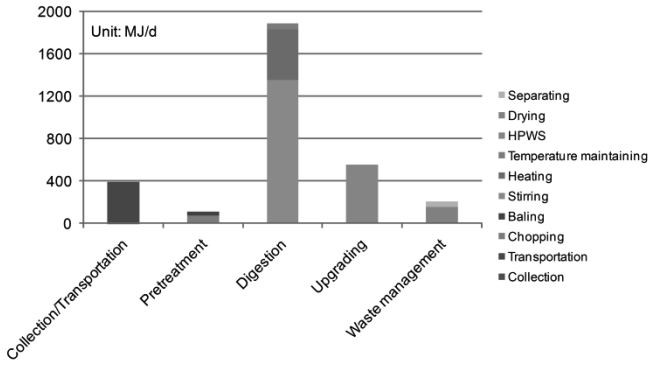

Figure 4. Biogas system energy efficiency of base case

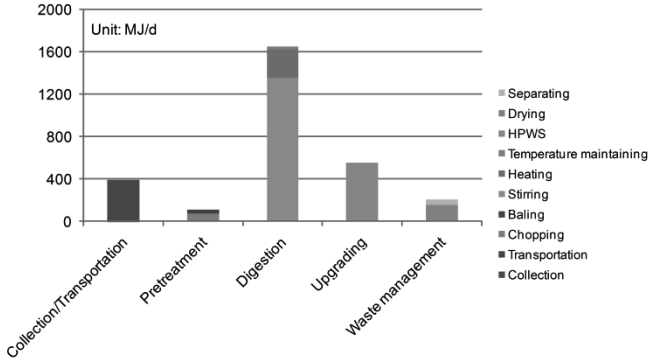

Figure 5. Biogas system energy efficiency of modified case

4. Conclusions

In this work, the biogas system is analyzed by giving the material and energy flow and the energy efficiency of the base case and modified case. First, the material flow indicate that huge amount of biogas slurry and residue (90 wt%) would cause

environment problems which should be paid more attention. Furthermore, the yield of the raw biogas (3 wt%) and biomethane (1.1%) is low, which should be enhanced by developing new anaerobic digestion technologies such as thermophilic technology and new digestion reactors. Second, the energy flow results demonstrate that, the energy loss (70%) of the system is significant due to the emission of the waste gas, biogas slurry and residue. Finally, the energy efficiency of the base case (28.7%) and modified case (29.0%) are calculated, respectively. The system energy efficiency only enhance about 0.3%, which need to improve other unit technologies like upgrading and waste management.

Abstract

Smart drilling fluids containing Fe_3O_4 nanoparticles have advantages toward increasing the hydraulic efficiency of drilling operations in a variety of reservoir environments. Exploring and optimizing the rheological behavior of such new drilling fluids is critical, implying direct and significant economic savings in developing new oil and gas fields. A experimental campaign analyzing the rheology of a bentonite-based fluid produced a new multiparametric dataset, considering a wide range of realistic reservoir conditions. Non-Newtonian behaviour is confirmed by yield stress computation for all these cases. Heating and rotation induce temperature and concentration gradients at drilling depth: it is hence essential to obtain an accurate but also versatile multivariate rheological model, which will enable viscosity prediction for the analyzed and other similar drilling fluids. The enhanced Herschel-Bulkley model is developed on a multiplicative assumption, postulating and analysing candidate equations which quantify the effect of shear rate, temperature and nanoparticle concentration on drilling fluid shear stress and viscosity. Parameter estimates have been subsequently determined via systematic optimisation, using statistical metrics to quantify and compare uncertainty and predictive potential. The trivariate shear stress and viscosity models proposed are similar in form: each requires six parameters used to combine a Herschel-Bulkley yield stress expression, an Arrhenius exponential of temperature and a linear model for nanoparticle concentration.

Keywords: parameter estimation, Hershel-Bulkley model, nanoparticles, drilling fluids.

1. Introduction

Efficient drilling for oil and gas requires the pumping of fluids with specific rheology, which can in principle be achieved by understanding the effect of composition on flow behavior and developing custom-made formulations with desired flow specifications; optimal drilling is thus attainable by matching rock, fluid and equipment characteristics. Flow behavior varies widely with concentration and temperature under constant shear, and successful tuning of rheological properties is critical to efficient drilling processes which achieve high penetration rates without risks of overheating, mechanical wear or excessive cost due to high fluid injection requirements (Sheng, 2011; Dandekar, 2013).

Developing correlations which express shear stress and viscosity as explicit functions of shear rate, temperature and concentration of iron nanoparticles (Waheed et al., 2014) is critical toward modeling, designing and planning of cost-effective drilling campaigns. Because of the multi-parametric uncertainty involved in rock strata mechanical properties, it is important to develop and validate high-fidelity predictive models which can provide online reliable estimates of rheological properties as explicit functions of environmental variables (temperature, mud concentration), to use equipment efficiently.

2. Experimental methods

Bentonite (Gold Seal, Halliburton) (tan powder, mild earthy odour, pH = 8-10) which consists of 1% cristobalite, 1% tridymite, 1-5% quartz and 60-100% actual bentonite and iron oxide nanoparticles (Sigma-Aldrich) in powder form (black powder, spherical shape, diameter of <50 nm, purity of > 97%) have been used to prepare all the samples. De-ionized water (TAMUQ, pH = 6.8-7.2) is used for base bentonite fluid preparation.

2.1. Sample preparation

Samples are prepared as per American Petroleum Institute (API) 13A-13B1 standards: 7% w/v bentonite dispersions of variable concentration in de-ionized water (600 ml) are obtained using a Hamilton Beach high-speed mixer for stirring (11,000 rpm for 20 min), and samples are left to hydrate and reach equilibrium in plastic containers (16 hr). Iron oxide nanoparticles (0.5, 1, 1.5, 2, 2.5, 3% v/v) are added slowly to avoid agglomeration. Before measuring rheological properties (by Couette viscometer–Brookfield rheometer), samples are mixed again (Hamilton Beach mixer, 5 min) to have identical shear history. This procedure is uniformly followed to ensure consistency and minimize bias effects.

2.2. Measurement procedures

A Couette (Grace M3600) viscometer and a vane (Brookfield YR-1) rheometer are used to measure rheological properties at three distinct temperatures and several nanoparticle concentrations (Yan & James, 1995); the Grace viscometer is equipped with a water bath and circulator to set the cup holder at the desired temperature (Fig. 1), so as to obtain and record shear stress and viscosity data (accuracy of experiments: T= ±2 °C).

Direct yield stress measurements are obtained via the Brookfield vane rheometer using two different four-bladed vane spindles, to cover the extended yield stress range: the spindle is immersed in the test material and connected through a calibrated spiral spring to a motor drive shaft, rotating the vane at 0.1 rpm (optimal rheological analysis speed). Material resistance to movement is analysed via increasing torque values: shaft rotation is thus measured by means of calibrated spiral spring deflection via a rotary transducer.

Indirect yield stress measurements are obtained via the Grace rotational viscometer. Output parameters are shear rate (s^{-1}), shear stress (Pa), viscosity (cP), gel strength (Pa). Viscometric data are obtained at fixed speeds (3, 6, 30, 60, 100, 200, 300, 600 rpm) and Newtonian shear rates (5.11, 10.21, 51.069, 102.14, 170.23, 340.46, 510.67, 1021.38 s^{-1}) are induced at the inner fixed cylinder, respectively (Kelessidis and Maglione, 2008). Readings are recorded every 10 s for a period of 60 s periods at each setting, giving 6 measurements at each of the 8 rotational speeds above (sweeped in descending order). Yield stress is estimated in all cases from viscometer rheograms, after extrapolating the shear stress-shear rate curve to zero shear rate and fitting the selected rheological model.

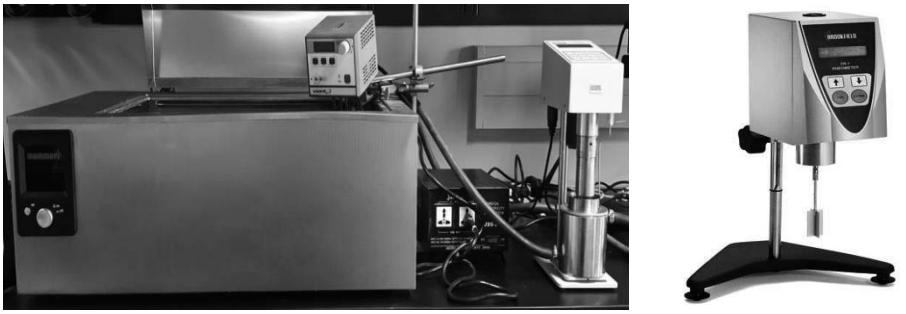

Figure 1: Grace M3600 viscometer with bath and circulator and Brookfield YR-1 rheometer.

3. Rheology modeling and parameter estimation

The prevalent correlation of shear stress and shear rate is the Herschel-Bulkley model (Kelessidis et al., 2006; Kelessidis & Maglione, 2008; Pouyafar & Sadough, 2013), a tri-parametric nonlinear correlation combining the effects of yield stress and power law behavior which outperforms the bi-parametric Bingham, power law and Casson models. The rheological parameters estimated from experimental campaigns are temperature- and concentration- dependent, and literature models are usually condition-dependent. Therefore, it is critical to first solve the optimisation problem for parameter estimation (both the univariate and the bivariate instance, for both shear stress and viscosity), and then develop a unified trivariate model, including all three independent variables (shear rate, temperature and iron nanoparticle concentration) in order to describe in detail the rheological behavior of the bentonite-based injection fluid during all drilling operations.

An extensive literature survey indicates the most widespread and suitable models of drilling fluids (Nguyen & Boger, 1992; Balmforth et al., 2014). Multivariate nonlinear least squares regression (Berge, 1993) has been employed in order to determine the most accurate model (Puxty et al., 2005) for shear stress and viscosity as functions of shear rate, temperature and additive concentration; the multi-parametric estimation problem has been subsequently solved using the novel experimental data, in order to compute the optimal set of parameters which minimise the sum of squared errors (SSE) and maximise the respective coefficient of determination, R^2 (Graybill & Iyer, 1994). Ensuring that a global optimum is achieved is of particular importance, because strongly nonlinear multivariate expressions can induce solver trapping in various local minima; the multivariate nonlinear regression has thus been performed using a systematic strategy and several starting parameter sets (a multi-start strategy) to confirm optimality. Multivariate and multi-parametric nonlinear models are plotted vs experimental data, the standard error for shear stress and viscosity at each combination of independent variables has been computed, and error bars have been obtained to illustrate uncertainty.

Explicit multiparametric rheological models have the general form given in Eqs. (1)-(2). To simplify these we invoke the multiplicative assumption, illustrated in Eqs. (3)-(4). Univariate [Eqs. (5)-(6)], bivariate [Eqs. (7)-(10)] an trivariate [Eqs. (11)-(12)] models thus imply we can consider explicit correlations which are easy to validate accordingly.

Figure 2: Explicit univariate and multivariate shear stress (τ) and viscosity (μ) parametric models.

4. Results and discussion

Nonlinear model plots have been obtained, confirming the rheological behavior of the samples is accurately described by an enhanced multivariate Herschel-Bulkley model for shear stress and a corresponding one for viscosity (Abu-Jdayil & Ghannam, 2014).

4.1. Univariate shear stress and viscosity models

Our shear stress and viscosity correlations for all temperatures appear in Fig. 3-4.

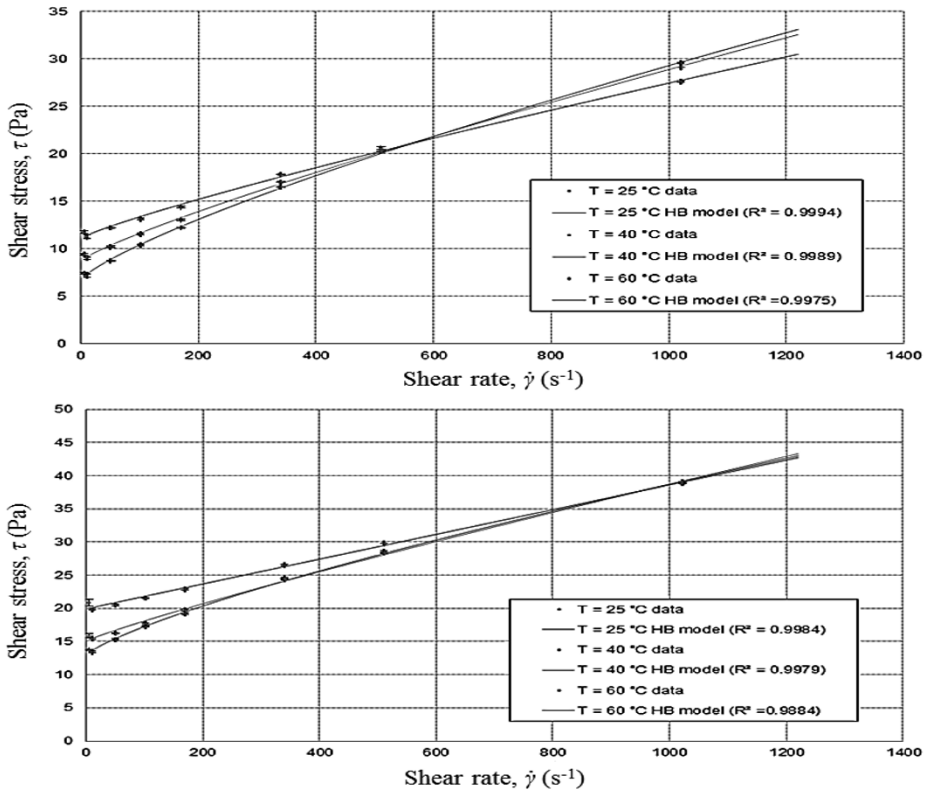

Figure 3: Shear stress vs. shear rate for all campaign temperatures (C = 0.5% up; C = 3%, down).

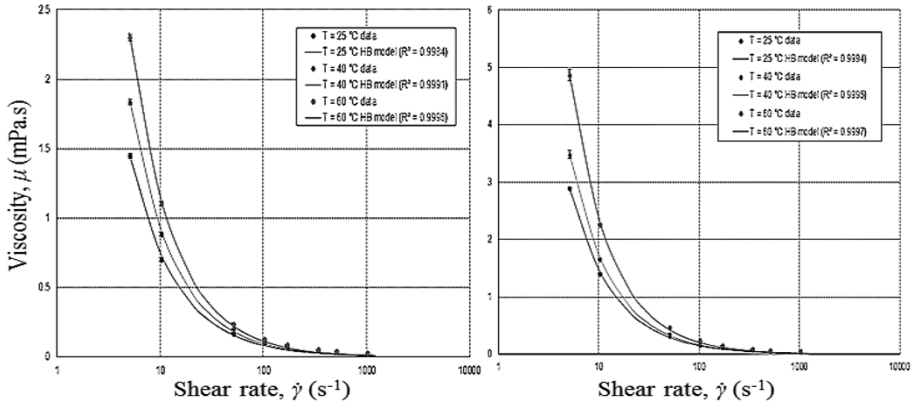

Figure 4: Viscosity vs. shear rate for all campaign temperatures (C = 0.5%, left; C = 3%, right).

4.2. Bivariate shear stress and viscosity models

Our shear stress and viscosity correlations for all three temperatures appear in Fig. 5: to enhance clarity, viscosity surfaces have been separated by displacing the origin by ±2.

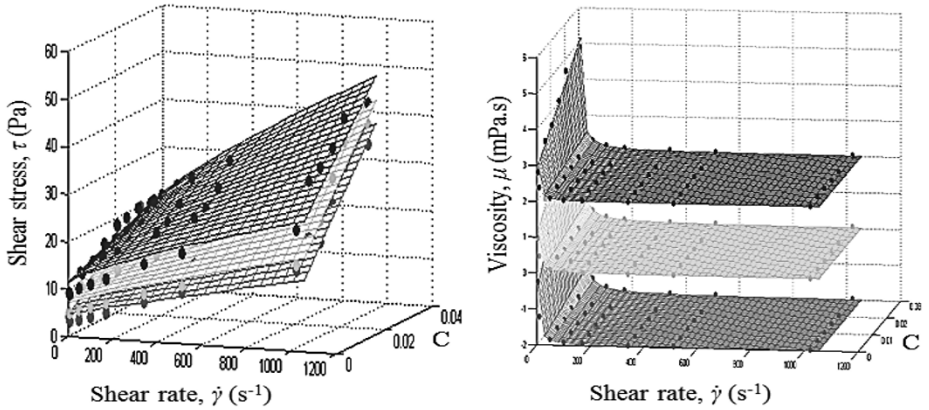

Figure 5: Shear stress (left) and viscosity (right) profiles vs. shear rate and vs. concentration.

5. Conclusions

Our development of an enhanced multivariate Herschel-Bulkley rheological model for a bentonite-based candidate drilling fluid with variable Fe_3O_4 nanoparticle composition is based on original data from an experimental campaign in a wide range of conditions, followed by comparative evaluation of multivariate shear stress and viscosity models. Parameter estimation via systematic optimization and comparative statistical analysis of the resulting uncertainty metrics allows the assessment of candidate expressions toward determining their suitability and quantifying their reliability for modeling and design. The shear stress and viscosity correlations describe the rheological effects of shear rate, temperature and Fe_3O_4 nanoparticle concentration: they encompass a Herschel-Bulkley model, an Arrhenius temperature exponential and a linear equation, respectively, achieving a high predictive potential in both bivariate ($R^2_{\tau(\gamma,T)} = 0.929$, $R^2_{\mu(\gamma,T)} = 0.992$) as well as in the full trivariate version of the model ($R^2_{\tau(\gamma,T,C)} = 0.987$, $R^2_{\mu(\gamma,T,C)} = 0.988$). Higher temperatures induce increased standard error for both shear stress and viscosity; heating affects fluid structure and rheology (hence prediction uncertainty) appreciably. Further investigation of concentration effects for various additives is planned, but the models already provide reliable estimates in a wide range of realistic drilling conditions.

Abstract

Hybrid energy smart grids operate based on power management strategies (PMS) addressing the time-varying reallocation of resources to meet specific targets. The identification of the PMS that best exploits the weather variability is crucial for their efficient operation. In this work, this is approached within a framework which exploits the Power Grand Composite Curves (PGCC) method to perform two functions: a) the identification of renewable energy recovery targets within a short term prediction horizon, and b) the temporal reallocation of the grid subsystems within a control horizon based on the PMS that best matches the identified targets. The PGCC is exploited within a model predictive control framework that enables the satisfaction of the system operating goals by ensuring the maintenance of a targeted minimum energy inventory. The desired energy inventory is guaranteed by selecting the appropriate PMS during the control interval that best matches the identified target. The method is presented within a formal mathematical framework and illustrated for a smart grid with power and hydrogen generation and storage features in year-round operation.

Keywords: Smart grids, power pinch, adaptive management

1. Introduction

Smart grids transform renewable energy sources (RES) into reliable power flows by adapting to unexpected external variability through the use of diverse conversion and storage equipment (e.g., fuel cells, electrolysers, accumulators and so forth). Their coordinated operation is a pre-requisite to address the underlying technical heterogeneity, while satisfying power demands with minimum participation of non-RES components. This goal is generally approached through PMS (Giaouris et al., 2013) which represent a sequence of time-varying decisions offering an efficient utilisation of resources and equipment to meet specific targets. The diverse temporal behaviour of such systems gives rise to a large number of potential PMS. Efficient operation depends on the selection of the PMS that best satisfies the system operating goals in view of RES variability. This is a non-trivial task, driven by complex interactions which are avoided in conventional systems by repeating a pre-specified PMS throughout their operation. The latter results in energy being wasted or increased non-RES power utilisation as the employed PMS is not tailored to the alternating patterns of RES.

This work proposes a more effective approach based on the iterative identification and implementation of a suitable PMS for the immediate short term time horizon, built around the PGCC method (Bandyopadhyay, 2011). Power pinch analysis exploiting power composite curves (Wan Alwi et al., 2012) or PGCC is based on the same concept as the heat pinch (Klemeš, 2013), except that instead of heat flow streams, power flow stream are plotted against time. The method has been previously formulated as the power cascade analysis (PoCA) and storage cascade table (SCT) (Rozali et al., 2013), applied in the optimal sizing of hybrid systems (Rozali et al., 2014), and modified to account for standalone hybrid systems (Ho et al., 2013). Furthermore, Chen et al. (2014) proposed an MILP transhipment model based on power pinch concepts.

2. PGCC for hybrid RES-based systems

Hybrid RES-based flowsheets may be represented through interconnected converters and accumulators that convert or store material and energy; flows and accumulation at different instants are the key features that drive their operation (Giaouris et al., 2013). The activation instance and operating period of each converter are important operating parameters as they determine their utilisation frequency. The state (level) of accumulated energy or materials in the form of diverse energy carriers is also important, prompting the activation of different converters based on their technical characteristics. The duration of activation further depends on a hysteresis based mode of operation, i.e. on whether the converter was active in the previous instant. The combination of these temporal characteristics form complex operating rule sequences called PMS which may be represented through generic models (Giaouris et al., 2013). This work proposes a mathematical framework for power pinch analysis exploiting the previous generic concepts. Let a system operating within an overall time span H divided into equal time intervals. Each interval is divided into subintervals $[t_0, T]$ of duration $\Delta T=T-t_0$ hence for the k^{th} interval $t_0=(k-1)\Delta T$ and $T=k\Delta T$. Also, let a set Q of diverse PMS that can be used in a hybrid system within each interval k, i.e. $Q=\{q_k\}$, $q\in N$. Each PMS q_k is a function of the state of accumulation ($SOAcc^l$) in accumulator l; for any $q_k\in Q$ the plot of $SOAcc^{l,qk}$ vs. time for a range of initial conditions gives the system PGCC (Figure 1a).

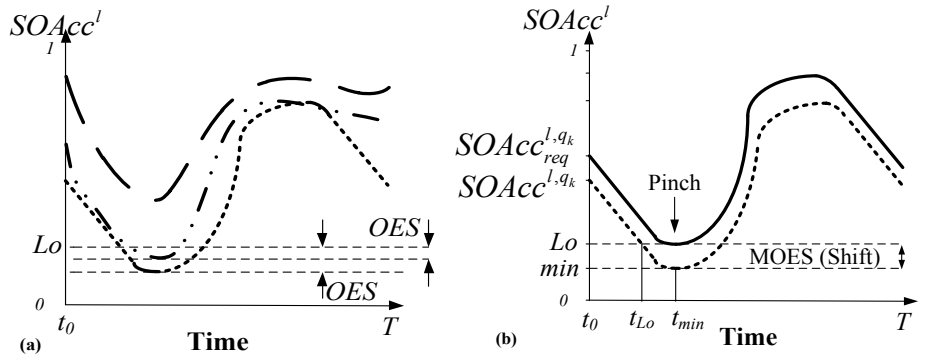

Figure 1: a) PGCCs for various initial values of $SOAcc^l$, b) Shift and Pinch of PGCC.

A major requirement in hybrid systems is to avoid the use of outsourced energy supply (OES) when $SOAcc^{l,qk}$ drops below a limit Lo (e.g., due to insufficient energy in the accumulator, an external source is required to satisfy the load demand). Starting from different $SOAcc^{l,qk}(t_0)$ at t_0 results in different OES (Figure 1a), calculated as follows:

$$OES^{l,q_k}(k) = SOAcc^{l,q_k}(t_{LO}) - SOAcc^{l,q_k}(t_{min}) \quad (1)$$

$$SOAcc^{l,q_k}(t_{\min}) = \min_{t\in[t_0,T]}\left\{SOAcc^{l,q_k}(t)\right\} \quad (2)$$

Finding the PGCC that corresponds to the maximum *OES* (called *MOES*) ensures that by covering this energy from non-RES the system will operate autonomously. Selecting and shifting the PGCC corresponding to *MOES* until it pinches the *Lo* limit at $t_{\min}$ (i.e. $SOAcc^{l,qk}(t_{\min})$) indicates the amount of energy required at t_0 (i.e. amount of $SOAcc^{l,qk}(t_0)$) to avoid the use of non-RES (Figure 1b). This is calculated as follows:

$$MOES^{l,q_k}(k) = \max_{SOAcc^{l,q_k}(t_0)}\left\{OES^{l,q_k}(k)\right\} \quad (3)$$

$$SOAcc^{l,q_k}_{req}(t_0) = SOAcc^{l,q_k}_{\min}(t_0) + MOES^{l,q_k}(k) \quad (4)$$

Note that except for a *Lo* limit several others may appear including simultaneous restrictions on multiple converters (e.g. multiple *Lo* limits or *Up* and *Lo* limits) and on multiple energy carriers. Equations (1)-(4) also apply in multiple *Lo* limits but there will be only one pinch, depending on the desired operating goals. For example, there might be a Lo_1 limit that signifies the use of external power if the energy (*SOAcc*) in the battery is low and a Lo_2 limit slightly higher in the $SOAcc^l$ axis of Figure 1b that signifies the use of a fuel cell to produce power from hydrogen as a measure to avoid external power. It might be desired to avoid the frequent activation of the fuel cell because it may result in frequent need for maintenance. This may be implemented by pinching at the Lo_2 limit. All limit combinations result in similar trade-offs, formalized as transformations of *MOES* and $SOAcc_{req}$.

3. Adaptive management using the PGCC

The described power pinch analysis may be exploited within a model-predictive control framework which is proposed in this work to support the adaptive management of smart grids. After defining the system operating goal (e.g., minimization of *OES* and/or appropriate utilisation of equipment such as fuel cells to avoid frequent maintenance), it is necessary to select a suitable time prediction horizon N_p, for which the behaviour of the system can be predicted and the PGCC estimated. The prediction horizon is an integer multiple of the time interval ΔT used for decision making. The length of the prediction horizon should be sufficient to ensure the satisfaction of the system goals for a selected PMS in view of variations. It is also necessary to select a suitable control time horizon N_c, for which decisions are taken about the sequence of equipment utilisation and operating patterns in the form of a PMS. The aim of this work is not to identify the parameter values, decision sequences or operating constraints that determine an optimum PMS. Instead, a pre-existing set of PMS is considered that enables efficient utilisation of the available resources and equipment to meet specific targets within operating constraints. We therefore propose a method to identify which of these PMS to employ in a given interval so that the system may best adapt to shorter or longer term variability. This is approached through an adaptive management procedure consisting of two successive steps:

- The *stored energy targeting step* involves the identification and shifting of the PGCC in the prediction horizon $(k+N_p-1)\Delta T$ to identify the minimum amount of stored energy (in various forms) that should be recovered from internal resources at the end of the control horizon $(k+Nc-1)\Delta T$.

- The *target matching step* requires the identification of the PMS in the control horizon $(k+N_c-1)\Delta T$ that best matches the target for stored energy identified during the prediction horizon $(k+N_p-1)\Delta T$.

To better understand the concept assume N_p=2, N_c=1 and ΔT=24h, i.e. the control horizon is the current day and the prediction horizon is stretched to the next. The *stored energy targeting step* requires the implementation of the analysis of section 2 in the prediction horizon k+1 for every PMS $q_{k+1}\in$Q, as follows:

$$SOAcc_{TAR}^{l}\left(k+1\right)=\max_{q_{k+1}\in Q} SOAcc_{req}^{l,q_{k+1}}\left(t_0\right) \tag{5}$$

$SOAcc_{TAR}^{l}\left(k+1\right)$ indicates the amount of energy that needs to become available at t=T in control horizon k in order to guarantee that regardless of the PMS that is chosen during the future prediction horizon k+1 the system will always operate above the limit *Lo*, i.e. the use of outsourced (e.g. non-RES) power will be avoided. In the *target matching step,* for control horizon k, a PMS is sought that results in a $SOAcc^{l,qk}(T)$ above and as close as possible to $SOAcc_{TAR}^{l}\left(k+1\right)$. This is expressed as follows:

$$q_k^{opt}=\left(\min_{q_k\in Q}\left(\left|SOAcc_{TAR}^{l}\left(k+1\right)-SOAcc^{l,q_k}\left(T\right)\right|\right)\right)\wedge\left(SOAcc^{l,q_k}\left(T\right)\geq SOAcc_{TAR}^{l}\left(k+1\right)\right) \tag{6}$$

Expression (6) enables the identification of the PMS that best matches the targeted, stored energy required in interval k+1, so that this energy may become available in interval k from internal system resources (Figure 2). After it ends, the time horizons shift forward in time by one decision making interval and the procedure is repeated.

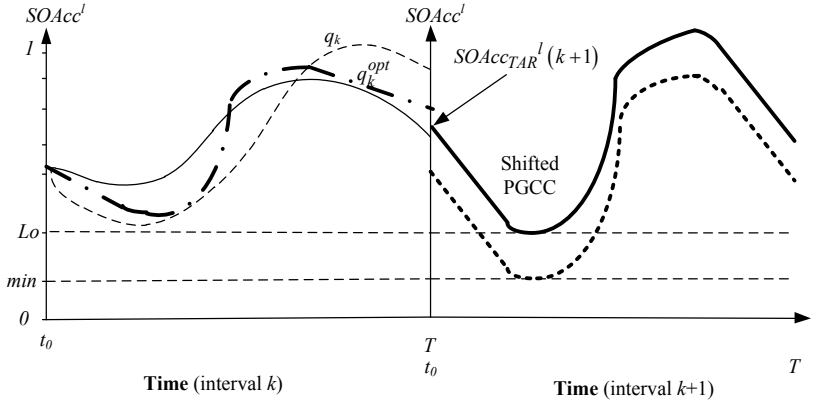

Figure 2: Illustration of the adaptive management procedure

4. Implementation

The proposed approach is illustrated in a system operating in Greece consisting of *PV* panels, wind generators (*WG*), lead-acid batteries (*BAT*), an electrolyzer (*EL*), a fuel cell (*FC*), a hydrogen compressor (*CMP*), intermediate low-pressure (*BF*) and final, high pressure hydrogen tanks (*FT*) and a diesel generator (*DSL*). We apply 9 PMS which activate the associated converters considering $SOAcc_t^{BAT}$ (denoted briefly as *S* in Table 1), the width of the hysteresis ΔH (i.e. the duration of activation or deactivation of a converter based on its previous state) and the net generated power *P*. Table 1 illustrates the combination of these parameters across different PMS (detailed in a formal mathematical framework in Giaouris et al., 2013). In PMS 1, 4 and 7 the power

produced and consumed by the *FC* and *EL* is fixed (based on some heuristic conditions), whereas in all the others the power either depends on the state of charge (PMS 3, 6 and 9) or on the net power *P* surplus/deficit. The hysteresis width is fixed throughout the year in PMS 1-3, whereas it depends on time in PMS 4-6. In PMS 7-9 the hysteresis width is zero depending on previously collected historical weather data (e.g., during summer time the hysteresis width of the *FC* is zero).

Table 1: Description of characteristics for the 9 PMS utilized

PMS	1	2	3	4	5	6	7	8	9
ΔH	Fixed	Fixed	Fixed	$\Delta H(t)$	$\Delta H(t)$	$\Delta H(t)$	0	0	0
P_{FC}	Fixed	P	$P_{FC}(S)$	Fixed	P	$P_{FC}(S)$	Fixed	P	$P_{FC}(S)$
P_{EL}		P	$P_{EL}(S)$		P	$P_{EL}(S)$		P	$P_{EL}(S)$

5. Results and discussion

Figure 3 illustrates the results obtained in several important system operating parameters when the 9 PMS are considered independently and when they are considered simultaneously in the adaptive scheme. Independently, each PMS has both merits and shortcomings. For example PMS 6 resulted in fewer *DSL* activations and minimised the operation of the *FC* but on the other hand it completely depleted the *BAT* (hence the zero $SOAcc^{BAT}$ in Figure 3a). The latter has a detrimental effect on the *BAT* life-time.

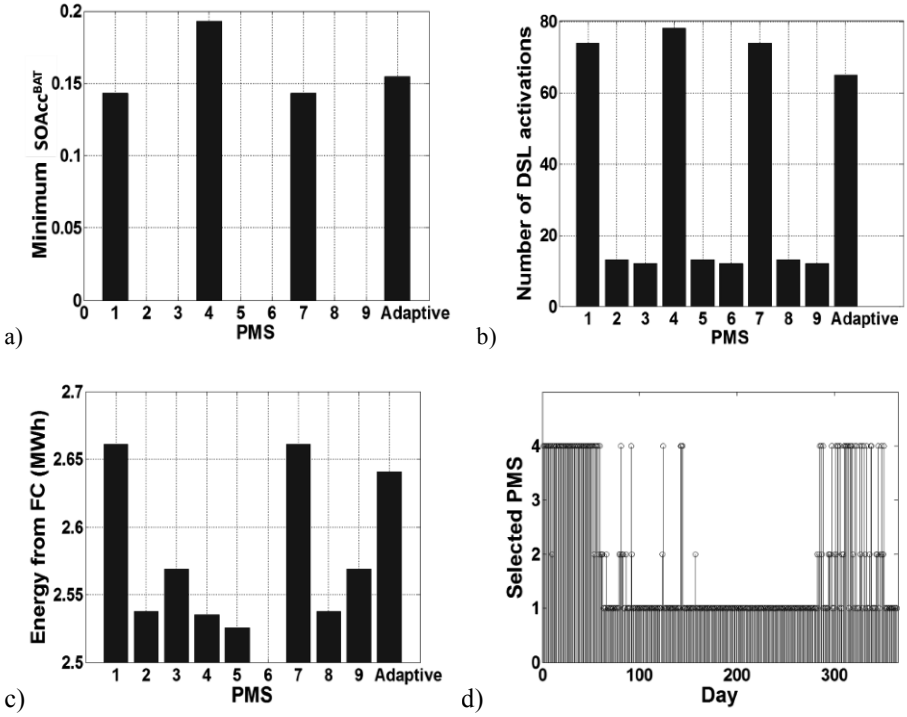

Figure 3: Results obtained from the system after the operation of 12 months under the 9 PMS and the adaptive case: (a) Minimum values reached in $SOAcc^{BAT}$, (b) Number of *DSL* activations, (c) Total energy produced by the *FC* and (d) PMS selected by the adaptive scheme for an entire year.

More specifically, while all PMS requested the same amount of energy from the *DSL* (approximately 410kWh), PMS 2, 3 5, 6, 8 and 9 resulted in fewer *DSL* activations

(around 12-13). This positive result was negated by battery depletion. The *FC* produced around 2.6MWh in all PMS, but this was achieved with approximately 80 activations in PMS 1, 4, 7 and 140 activations in the remaining PMS. The anticipated life-time of the *FC* is prolonged by fewer activations. A similar case is observed for the *EL* (approximate usage at 4.8MWh) where PMS 1, 4 and 7 resulted in 127 activations as opposed to 160 activations resulting from the other PMS. Finally, in all cases the *FT* was left empty at the end of the year, meaning that the hydrogen was depleted.
Comparing the above results with the adaptive case, a considerable improvement is observed by effectively balancing the merits and shortcomings of all PMS to avoid the *BAT* depletion and to reduce the activations of the *DSL*, *FC* and *EL*. In the adaptive case the *DSL* produced 420kWh and the *FC* approximately 2.6MWh while the *EL* consumed 4.96MWh. Although the *DSL* was activated more than it would if PMS 2,3,5,6,8,9 were used independently, the adaptive scheme used PMS 1 and 4 which enable fewer activations of the *FC* and avoid *BAT* depletion thus imposing a regular operating pattern for all units. The use of the *DSL*, *FC* and *BAT* were well balanced in terms of activations or depletion, while the system also required little power from the non-renewable *DSL*. Except for PMS 1 and 4, PMS 2 was also used in the adaptive scheme as it enables the generation of exactly as much power as necessary for the *LD* to avoid *DSL* activation. Note that in PMS where more power is produced than required by the *LD*, this is not wasted but the battery is charged faster instead.

6. Conclusions

In this work we proposed a method of exploiting power pinch analysis to best adapt the operation of a hybrid energy smart grid in view of renewable energy intermittence. The proposed adaptive management method exploits the stored energy PGCC to set energy targets in a prediction time horizon, which can then be matched by an appropriate PMS from a set of pre-selected PMS. The method was illustrated in an actual smart grid. The results showed that by continuously updating the PMS used by the system within short time intervals produces better results than when a particular PMS is employed independently of others for the system operating horizon.

Abstract

Gas turbines are a viable and secure option both economically and environmentally for power and heat generation. The process simulation of the micro gas turbine with exhaust gas recirculation (EGR) and its impact on performance is evaluated. This study is further extended to evaluate the effect of the operating conditions and position of the EGR on the performance of the micro gas turbine. The performance analysis for different configurations of the EGR cycle, as well as flue gas condensation temperature, results in the optimized position of EGR at the compressor inlet with partial condensation resulting in the CO_2 enhancement to 3.7 mol%.

Keywords: Micro gas turbine, Process simulation, Exhaust gas recirculation, EGR condition, EGR position.

1. Introduction

The global energy trend is changing, and this is due to the overwhelming concern regarding greenhouse gas (GHG) emissions from the power generation sector IEA (2012). Our energy supply system is under gradual transition from conventional power generation systems to more sustainable low or "zero" carbon systems. The increasing urbanization and escalating energy demand has led to a shift towards natural gas power plants around the globe in order to meet this demand with reduced emissions. Further, to minimize GHG emissions, the released CO_2 is captured through a post-combustion CO_2 capture system using the most widely adopted method of amine scrubbing. However, CO_2 concentration from the natural gas power plant is lean in comparison to those from coal fired plant, and this result in a major penalty when integrated with a CO_2 capture system. This drawback can be avoided by an exhaust gas recirculation (EGR) back to the gas turbine, which results in the enrichment of CO_2 for improved CO_2 capture efficiency.

The EGR is a novel technology in which the exhaust gas is split; one part is dried and recycled back, while the other with increased CO_2 concentration and reduced flow rate is sent to the CO_2 capture system. Despite these advantages, the maximum amount of exhaust gas to be recirculated needs to be defined, maintaining the required level of combustion stability and emissions. Ditaranto et al. (2009) experimentally reported that the minimum O_2 concentration at the combustor inlet needed for stable operation is 16 %, with CO_2 concentration of 8 % at 40 % EGR. Biliyok et al. (2013) have modelled a 440 MW natural gas combined cycle (NGCC) with EGR and performed a techno

economic analysis. An EGR of 40 % resulted in marginal power recovery with increased cooling water demand. The overnight cost increase for the EGR equipped NGCC power plant integrated with the carbon capture system was less than without EGR. In the case of the micro gas turbine (MGT), the reported literature is much limited. Cameretti et al. (2013) studied the effect of the EGR on the performance and emissions of the MGT for different kinds of fuel through CFD modelling. Majoumerd et al. (2014) studied the MGT for EGR and HAT cycles integrated with the amine capture plant. Also the effect of the ambient temperature on the performance of the MGT was reported.

Due to the limited literature found in this field, an extensive study needs to be performed on the impact of the EGR on the performance of the MGT, including the effect of the operating conditions and position of the EGR. Therefore, this study focuses on the evaluation of the impact of these parameters on the performance of the MGT.

2. MGT Cycle

In this paper, the Turbec T100 micro gas turbine is studied as the base case, which is a 100 kW_e machine capable of combined heat and power generation. The major components include the compressor, turbine, combustor, high speed generator and two heat exchangers to enhance either the electrical or overall efficiency. A recuperator to preheat the compressed air and gas-liquid heat exchanger for thermal power of ~150 kW_{th} are also part of the MGT. The combustor is a lean premixed emission type with low NO_x, CO and unburned hydrocarbons (UHC). A schematic diagram of the components of the MGT is shown in Figure 1 within the dashed rectangle.

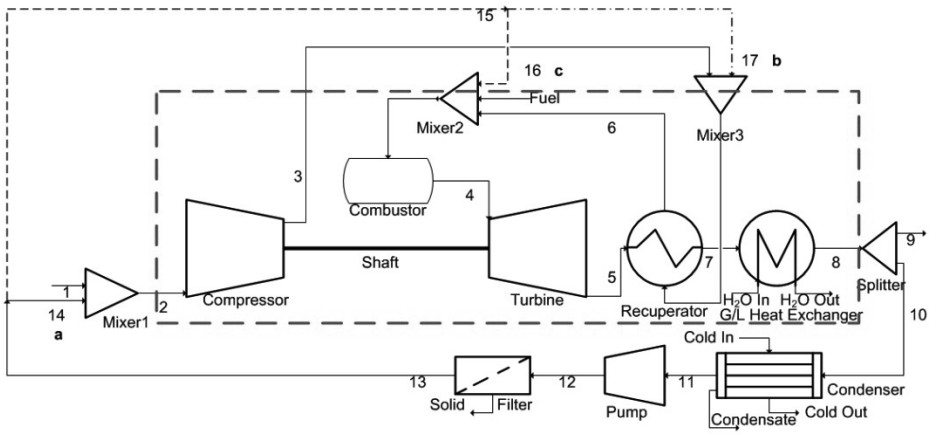

Figure 1: Schematic of the MGT with different options for the position of the EGR, stream 14: location (a), before the compressor; stream 17: location (b), after the compressor; and stream 16: location (c), in the combustor.

Air is compressed to a pressure ratio of 4.5:1 and preheated through the recuperator before the combustor. The combustion products at a turbine inlet temperature of 950 ^oC expand through the turbine to near atmospheric pressure with a turbine outlet temperature (TOT) of 650 ^oC. The exhaust heat is first utilized in the recuperator for boosting the electrical efficiency then used to generate the thermal energy by heating the water in the gas-liquid heat exchanger. The MGT in combined heat and power mode is simulated using Aspen HYSYS® V8.4. The thermodynamic property package used for the modeling is the Peng Robinson equation of state, and the minimization of the

total Gibbs free energy is used for the chemical equilibrium in the combustor. Table 1 shows the base case steady-state performance of the MGT model developed at the ISO conditions (15 ^{o}C, 1 bar and 60 % relative humidity) along with the molar composition of natural gas.

Table 1: Natural gas composition and MGT base case performance at ISO conditions.

Component	Mole fraction	Parameter	Value
CH_4	0.906	Electrical Power (kW_e)	100
C_2H_6	0.051	Thermal output (kW_{th})	153.3
C_3H_8	0.013	Electrical efficiency (%)	32.1
i-C_4H_{10}	0.002	CO_2 in flue gas (mol%)	1.6
n-C_4H_{10}	0.002	O_2 in flue gas (mol%)	17.3
N_2	0.011	Flue gas flow rate (kg/h)	0.67
CO_2	0.014	Fuel consumption (kW)	312

The steady state model is evaluated against the set of experimental data obtained through the UKCCS research centre Pilot-scale Advanced Capture Technology (PACT) facility. The simulations are performed for various power outputs (50-80 kW_e) to represent different operational modes. It was found that the simulated turbine outlet temperature and the combustion gas pollutant concentration were reasonably consistent with the experimental results as reported in (Ali et al. 2014).

The CO_2 concentration at the exhaust is very lean at 1.6 mol% and this will cause a major energy penalty when integrated with the CO_2 capture system. This drawback is avoided by the EGR back to the gas turbine, which results in the enrichment of CO_2 for improved CO_2 capture efficiency.

3. EGR Cycle

Due to the consistency and robustness of the steady state model developed, it is extended to include the exhaust gas recirculation mode to the MGT in order to study the effect of CO_2 enrichment. In the MGT model, one part of the exhaust is dried and recycled back to the MGT. The amount of the exhaust gas recirculated can be defined by the equation:

$$\text{EGR} = \frac{\text{Volume flow of recirculated exhaust gas}}{\text{Volume flow of exhuast gas}} \quad (1)$$

The additional equipment needed for EGR are: the splitter for dividing the exhaust gas into two streams, a condenser for cooling and drying of the recycle stream to the required level of moisture, and a booster fan or a compressor as illustrated in Figure 1 to recirculate the recycle stream from condensing pressure back to required pressure at the injection point. Further, the EGR ratio is varied to check its impact on the system

performance. The increase of EGR ratio results in an increase of CO_2 in the exhaust gas with a decrease in O_2 concentration both at the combustor inlet and exhaust gas, as shown in Figure 2. The decrease in O_2 concentration at the combustor inlet results in O_2 starvation which will affect the combustion stability with higher UHC and CO emissions at the outlet. The modelling suggests that EGR ratios ≤ 55 % should be maintained to stay within the oxygen levels recommended for efficient combustion, and this result in CO_2 enrichment from 1.6 mol% in the base case MGT cycle to 3.7 mol% in the EGR cycle. The enrichment in CO_2 concentration in the exhaust gas increases along with a decrease in the total mass flow, which will influence the performance of the CO_2 capture system.

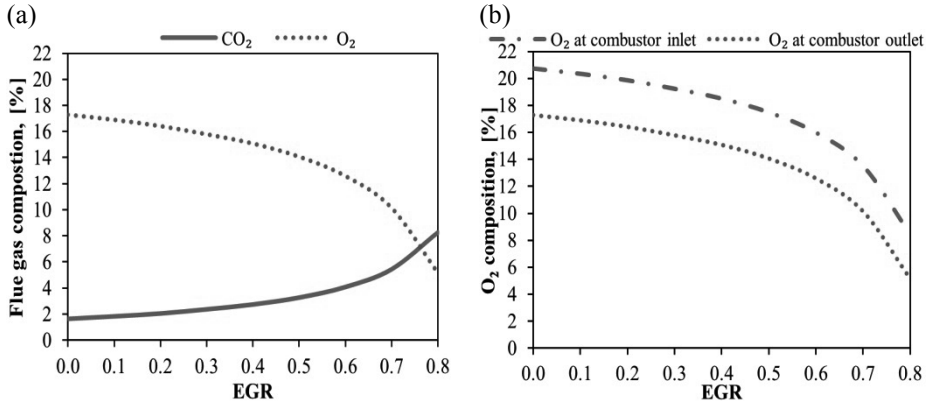

Figure 2: Impact of EGR ratio on (a) CO_2 and O_2 molar composition in flue gas; and (b) O_2 molar composition at combustor inlet and outlet.

3.1. Impact of EGR Position

Three different positions for the EGR injection into the MGT were evaluated: location (a), before the compressor; location (b), after the compressor; and location (c), in the combustor, as shown in Figure 1. These three locations have different conditions and will require varying the thermo physical nature due to the EGR inclusion. The pressure of the EGR stream should be kept the same or above the live pressure of any of the aforementioned injection locations. The process simulation indicates that the EGR injection at these different locations will have a distinctive effect on the system performance in terms of process control, operation and design. The simulations for the injection at different locations are performed at an EGR ratio of 55%. The decrease in the electrical efficiency, as shown in Figure 3(b), for location (a) recycle in comparison to other options is due to the additional work required by the inherent compressor of the MGT. In terms of the additional equipment requirements, the condenser is required for all three of the EGR locations. While the recycle back to location (a) will require a blower/fan for boosting from the condenser pressure back to the compressor inlet. However, the recycle to locations (b) or (c) will require a new compressor in the recycle loop other than the inherent compressor of the MGT, which will affect the machine default control and cause an in shaft imbalance at higher EGR ratios. In terms of CO_2 enrichment, all three cases results in an equal increase of CO_2 concentration in the flue gas, as shown in Figure 3(a). The O_2 concentration at the combustor inlet for EGR to location (c) appears to be maintained higher, however, the internal kinetics of the combustor need to be studied in detail and this may be affected due to the higher EGR

ratios. Therefore, the EGR at location (a) will result in a better performance due to the operational and control difficulties encountered in the other two options. The EGR at location (a) will be evaluated as a function of the EGR ratio and its condition to select the operating condition of the EGR for the MGT.

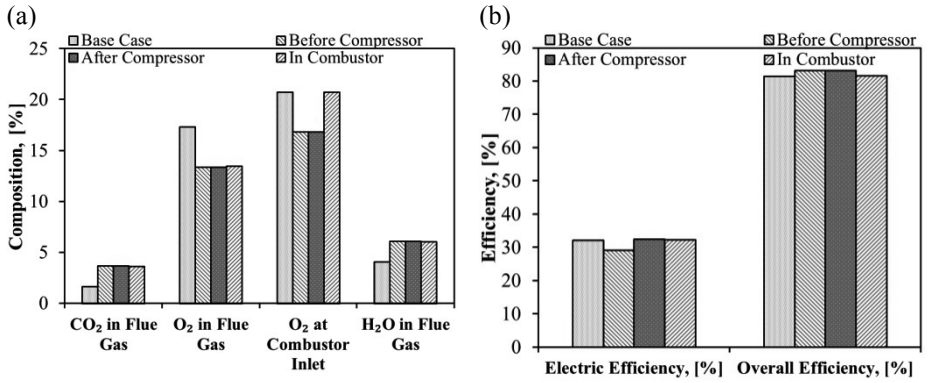

Figure 3: Impact of the EGR position on (a) flue gas, and O_2 composition at the combustor inlet and (b) the electrical and overall efficiency.

3.2. Impact of EGR Condition

The condensation temperature is an important parameter which will affect the performance of the MGT equipped with the EGR at location (a). This defines the dryness of the EGR, and the temperature and water level in the EGR will affect the power requirement for the compressor due to density effects. The three cases are defined in order to assess the impact of the EGR condition: cold EGR at ambient temperature, cold EGR with partial condensation and hot EGR without condensation. The first two cases are realized by varying the condensation temperature while for the last case there is no condenser in the recycle loop.

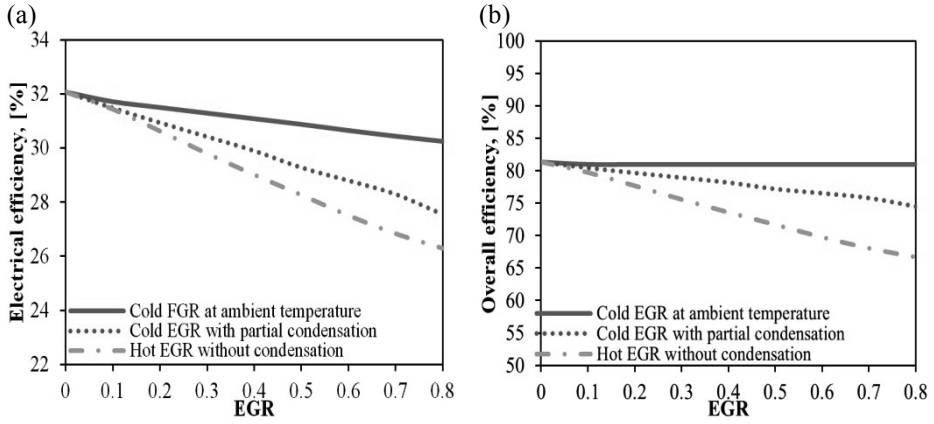

Figure 4: Impact of the EGR conditions on (a) the electrical efficiency and (b) the overall efficiency.

The cold EGR at ambient temperature is maintained at the temperature of 15 ^{o}C, the cold with partial condensation is maintained at 40 ^{o}C and the hot EGR is at 70 ^{o}C. It is observed that the electrical efficiency drop is higher as the temperature of the EGR

increases as shown in Figure 4 (a). This is due to more compressor work and higher fuel feeding requirements as the EGR temperature increases. The overall efficiency follows the same trend by keeping the thermal output of the MGT constant at the same level as in the base case as shown in Figure 4 (b). As a result, the flue gas temperature increases due to the heat capacity change of the resulting flue gas due to the increased amount of water content as the temperature and condensation rate increases. However, the decrease in the condensation temperature may lead to sulfur deposition which will affect the recirculating ducts and the blower or compressor material depending on the sulphur content in the fuel to be burnt.

4. Conclusions

This work evaluates a recuperated micro gas turbine steady state model and its modification into the EGR mode. The results indicate that different EGR cycle options have a distinctive impact on the system performance, process operation, and process design. The process system analysis assists in the selection of the best configuration, the EGR recycle back to the compressor inlet, with the partial condensation and condensation temperature at the minimum to operate. The EGR results in the CO_2 concentration enhancement to 3.7 mol% from 1.6 mol% in the base case which results in an improvement when integrated with the carbon capture system. In conclusion, the detailed analysis, modelling and simulation outcomes are an accurate demonstration for the evaluation of the optimized micro gas turbine EGR mode configuration.

Abstract

The solid oxide fuel cell gas turbine hybrid system (SOFC/GT) is an exciting new approach to producing electricity with high efficiency and lower environmental impacts than conventional power plants. One of its key strengths is the potential for fuel flexibility, which is the ability to transition between different kinds or qualities of fuels during operation. However, there has been very little research into the dynamic performance of SOFC/GT systems in response to changes in fuel. Therefore, the open loop behaviour of SOFC/GT systems in response to fuel composition transients was experimentally investigated. In this study, hardware-based simulations were used to study transitions between using coal-derived syngas and humidified methane. A hybrid test facility at the U.S Department of Energy, National Energy Technology Laboratory, Morgantown, West Virginia, was used to adequately capture the coupling of fuel cell stacks (simulated with hardware driven by a real time dynamic model) and a gas turbine system (from actual equipment) during transient events. Given the dynamic trajectories of key process variables, the impact on the hybrid system was quantified via transfer functions. The results show that the open-loop dynamic behaviour exhibited significant inverse response which limited the range of transitions that could be achieved safely without damage to various system components such as the compressor or fuel cells. However, the results also showed that if a control system could be designed which limited the impact of the inverse response, then transitions between even very different kinds of fuels could potentially be achieved without operational problems. The resulting transient information will be used to develop a new control system for thermal management of SOFC/GT hybrid systems in future work.

Keywords: Fuel cell gas turbine hybrid, fuel flexibility, hardware-based simulations

1. Introduction

The recuperated solid oxide fuel cell gas turbine (SOFC/GT) hybrid system is an alternative power generation system that can potentially provide higher system efficiency, fuel flexibility and economic viability than traditional standalone systems. With high operating fuel cell temperatures, this configuration allows for the recovery of high quality fuel cell waste heat in the recuperated gas turbine cycle. Moreover, previous studies have shown that the overall hybrid system efficiency is not strongly affected by fuel utilization as opposed to standalone fuel cell systems (Haynes and Wepfer, 2000). As such, choosing a lower fuel utilization in a SOFC/GT hybrid would

generally reduce the risk of fuel cell starvation and also increase the fuel cell efficiency via hydrogen partial pressure and Nernst potential enhancement (Haynes and Wepfer, 2000). In that case, the fuel cell life in the hybrid configuration could be extended by ten times compared to a standalone fuel cell system operated under constant power (Tucker et al., 2014).

Integrated gasification fuel cell (IGFC) systems with a recuperated gas turbine cycle can be effectively combined with a Fischer Tropsch (FT) synthesis system in polygeneration plants (Adams et al., 2012). A portion of the coal-derived syngas from the gasification process can be used to generate electricity in the SOFC/GT system and the rest can be used for diesel and gasoline production in the FT section, depending on the desired products. Furthermore, if the downstream sections of the polygeneration system can be operated flexibly such that the amount of syngas fed to the power and fuels sections can be adjusted, it is possible to create diversity of product portfolios to match changes in market prices without having to change the gasifier throughput (Chen et al., 2011). Hence, the plant can be operated at a reduced profitability risk as compared to a 'static' plant which could not be flexibly adjusted.

Despite the aforementioned benefits, SOFC/GT hybrid systems are highly coupled. The strong interaction between the dynamics of fuel cell and gas turbine cycle results in complicated operational and control issues (McLarty et al., 2012). To ascertain that the SOFC/GT hybrid system could be operated in fuel flexible environment, its operability during fuel composition changes was experimentally investigated and presented herein. The ultimate goal for this study was to develop adequate control to support the transient operations, such that, the operability range of SOFC/GT in flexible operations can be enhanced. This provides benefits for advanced power system to maximize fuel utilization as well as to reject unfavourable impacts from fuel composition/quality changes.

2. SOFC/GT hybrid configuration

2.1. System Description

A hardware-based simulation facility of SOFC/GT hybrid system at the U.S Department of Energy, National Energy Technology Laboratory in Morgantown, West Virginia was used to execute the experimentation.

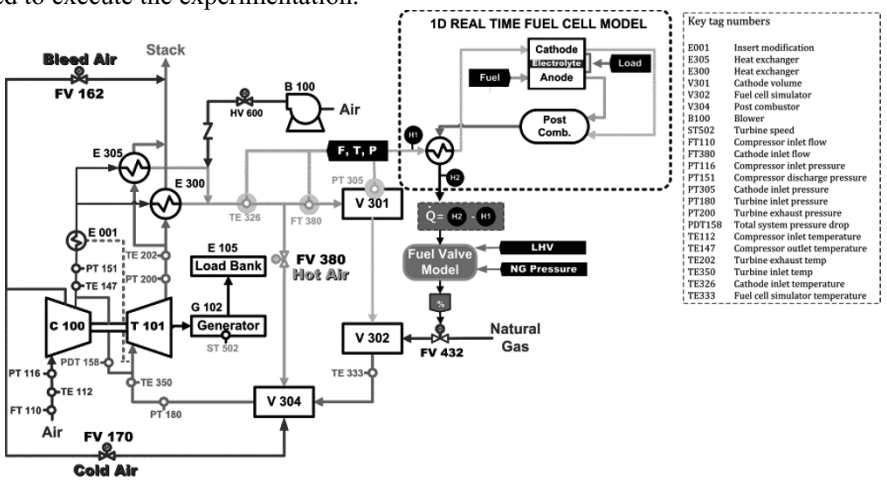

Figure 1 Schematic diagram of a recuperated SOFC/GT hybrid system at NETL (Harun et al., 2014)

This facility was uniquely designed to explore the operability and flexibility of a gasifier fuel cell gas turbine hybrid system during transient events. The complete cycle of the SOFC/GT hybrid facility is illustrated in Fig.1. Due to the prohibitive cost and maintenance of a real fuel cell, a real-time fuel cell dynamic model (as illustrated in a dashed-line box in Fig.1) is integrated to the balance of the plant hardware to represent a fuel cell system such that the exploration of fuel cell dynamics in hybrid power systems can be performed extensively without breaking any real fuel cells.

The hardware provides high reliability in measurements of the balance of the plant and maintains their real fluid dynamic behaviours. In hardware-based simulations of the hybrid power system, real-time data from three sensors that measure mass flow, temperature, and pressure of the physical cathode inlet stream (i.e. recuperated compressed air) are used as model inputs. Other model inputs, the including fuel cell configuration, can be specified by users. Detailed descriptions of this facility were published previously (Harun et al., 2014).

2.2. Test Procedures

System startup was performed using the same approaches described in previous publications (Tucker et al., 2011). Only fuel composition changes were applied in this study, while maintaining the mass flow rate of the fuel and SOFC current constant. The fuel composition changes in the SOFC/GT hybrid system involved a step transition from an initial composition of coal-derived syngas feed (CH_4 0 %, CO_2 12 %, CO 28.6 %, H_2 29.1 %, H_2O 27.1 %, N_2 3.2 %) to humidified methane composition (CH_4 13.6 %, H_2O 86.4 %) at time zero. At 145 g/s fuel mass flow rate, this represents a 20 % reduction in low heating value (LHV) of the fuel.

The turbine load command was maintained at 40 kW during all experiments. From a control perspective, operating the system with a 40 kW turbine load is required for turbine speed controllability, such that the system allows the turbine speed to change within its operational limit during open loop operations. The physical fuel valve (FV-432) corresponds to a fuel cell model output (Q) every 80 ms to simulate the fuel cell thermal effluent that eventually will be recovered in the gas turbine cycle. The interaction between the fuel cell model and the balance of the plant is in a feed forward loop. The test was run for about 5500 s to sufficiently capture the most significant transient impacts of fuel composition changes in the SOFC/GT hybrid system.

3. Open Loop Transient Trajectories

The fuel cell thermal effluent, Q, is the process variable of primary interest in controlling the hybrid system. This is because Q drives the subsequent transient impacts on the entire hybrid system performance, such as turbine speed, cathode inlet conditions (i.e. mass flow, temperature and pressure) as well as the consequent impacts in the fuel cell itself. Theoretically, Q is the total waste heat resulting from the combustion of potential chemical energy combined with thermal energy carried by cathode and anode exhaust streams before entering the gas turbine (Fig. 1).

An example of the impacts on the SOFC/GT hybrid system in response to fuel composition changes is shown in Fig. 2, which provides the trajectories of Q, turbine speed and the corresponding cathode inlet conditions in response to a switch in fuel from coal-derived syngas to humidified methane containing 13.6 % CH_4. The initial condition of each process variable shown in Fig. 2 is summarized in Table 1. As indicated in Fig. 2, without any control system in place, the system exhibited a significant inverse response in Q before slowly decreasing to the expected final transient

response. Due to the immediate overshoot in Q, fuel composition transitions could be performed safely only for a limited range of CH_4 concentrations without violating a key turbine surge margin safety constraint (Harun et al., 2014).

Table 1 Open loop initial conditions

Thermal effluent, Q	Turbine speed	Cathode inlet mass flow	Cathode inlet pressure	Cathode inlet pressure
764 kW	40,500 rpm	1.04 kg/s	973 K	246 kPag

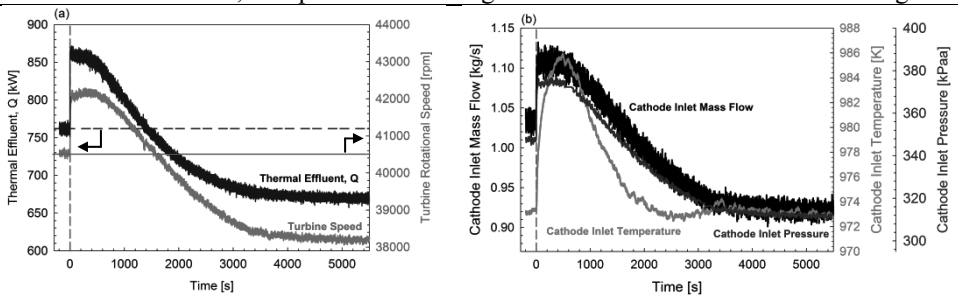

Figure 2 Open loop transient reeponse of SOFC/GT hybrid system during fuel composition changes

During the initial transient period for the example shown, Q increased by 14 %, which caused a 4 % increase in turbine speed. Accordingly, an 8 % increase in cathode inlet mass flow and cathode inlet pressure resulted due to the additional heat supplied to the gas turbine cycle. With that variation, the cathode inlet temperature only increased by 1 % from the initial value. The final reduction of Q was about 13 % below the initial condition. The decreased Q caused a 6 % decrease (from the nominal point) in turbine speed which finally reduced the cathode inlet mass flow and pressure, respectively by 12 % and 10 % (from the initial conditions). Meanwhile, the cathode inlet temperature settled approximately at the same initial temperature at 2000 s after the initiation of the step change and for the remaining course of the test.

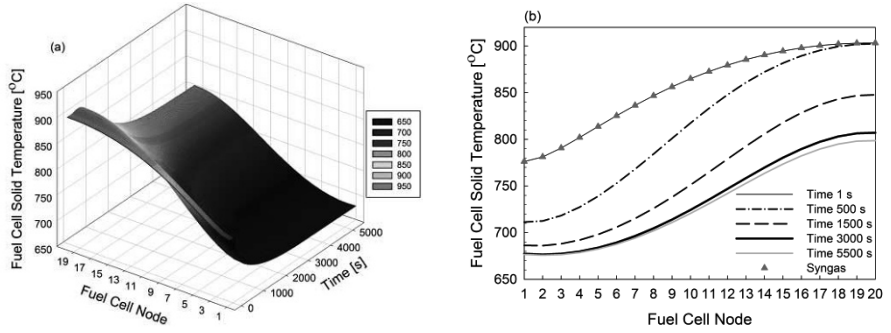

Figure 3 Fuel cell solid temperature profiles

Fig. 3 illustrates the dynamic profiles of fuel cell solid temperature over a 5500 s operation period, from the initial steady state using coal-derived syngas (before the step time) to the final state via humidified methane-feed. As depicted in Fig. 3 (b), over the first 500 s, the solid temperature at the inlet region significantly dropped, approximately by 65 °C, but gradually decreased in the following test period. Meanwhile, the profile at the cell exit clearly contrasts the inlet transient, with more apparent temperature

gradient after 500 s run. Only a slight decrease in the temperature was observed at the downstream region of the cell after time 3000 s when approaching a new steady state. Such a dynamic behaviour was dominated by the highly endothermic steam methane reforming reaction. The energy contained in the new fuel mixture was insufficient to both provide for the heat consumption of the reforming reaction and maintain the same solid temperature as using the prior fuel. Although the change in fuel composition was instantaneous in this experiment, the fuel cell temperature drops gradually because some of the heat stored in the fuel cell itself was used to power the reforming reaction until some of this heat was depleted and steady state is achieved.

On the other hand, the initial sharp rise in Q was primarily influenced by the conversion of humidified methane. This impact was indicated by the elevation in fuel heating value in the anode effluent, which eventually increased the thermal input fed into the gas turbine cycle. This led to the identical transient impacts on turbine speed, and cathode inlet conditions (Fig. 2). Due to conflicting effects between reducing cathode air mass flow and reducing thermal effluent in the SOFC/GT hybrid on temperature response in a long operation, a mitigating impact was exhibited in cathode inlet temperature. Overall, the detailed analysis has shown that Q was strongly affected by complex interactive impacts of direct electrochemical conversion of fuel, solid-gas temperature difference in the fuel cell, fuel cell thermal energy storage (due to the large fuel cell thermal capacitance), and cathode air mass flow.

4. Development of Transfer Functions

Transfer functions of turbine speed, fuel cell temperature gradient, dT/dx, total system pressure drop and cathode inlet mass flow in the SOFC/GT hybrid system in response to the change of steam/carbon ratio during fuel composition transition were developed in order to quantitatively determine the transient trajectories shown in Fig. 4.

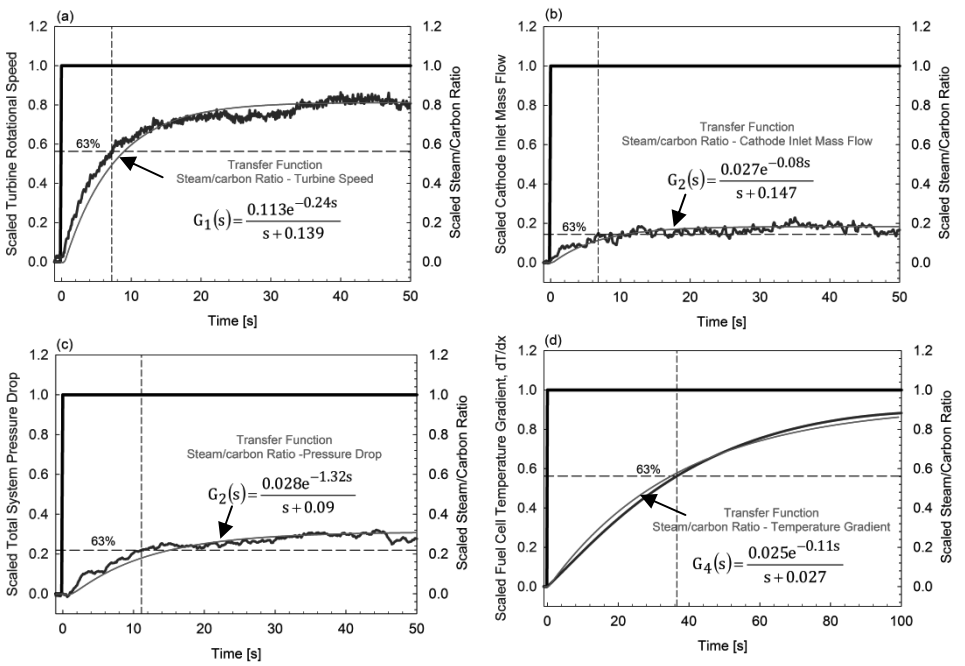

Figure 4 Transfer function shaping for, (a) turbine speed, (b) cathode inlet mass flow, (c) total system pressure drop, and (d) fuel cell temperature gradient

Although the system demonstrated higher order dynamic response in a long run as shown in Fig. 2, only initial transient trajectories (Fig. 4) were considered to mitigate the short-term unfavourable transient behaviour. Padé approximation was used to estimate the Laplace domain of the First-Order-Plus-Dead-Time (FOPDT) transfer functions. The experimental data were compared to the transfer function curves. Substantial agreement between the real behaviours and the estimated profiles was obtained in turbine speed, cathode inlet mass flow, system pressure drop, and solid temperature gradient (dT/dx) using the developed transfer functions.

5. Conclusions

Despite the lack of dynamic transient information of the coupling between the fuel cell system and the recuperated gas turbine cycle, the hybrid configuration provides more flexibility in terms of dealing with operational challenges. There are more manipulated variables that could be potentially used to mitigate the negative impacts. The hybrid system adds some degrees of freedom for control development such that the system operability can be improved. However, no control design associated with fuel flexible operations in the SOFC/GT system has yet been studied. A previous study which focused on the impacts of cathode mass flow on the SOFC/GT has shown that reducing cathode inlet mass flow resulted in a mirrored transient response in fuel cell thermal effluent, Q, as compared to the result obtained in this study (Zhou et al., 2015). The results suggested that modulating cathode air flow could be a potential mitigation strategy for the system thermal management, hence, the overshoot in the fuel cell thermal effluent during fuel composition changes could be reduced/removed to moderate the overall impacts on the hybrid performance. The time constants (i.e. time to achieve 63 % of the total output change, as indicated in Fig. 4) of the developed transfer functions in this study and for the actuator actions of cathode air mass flow were comparable. It is expected that based on these results, a new set of system identification transfer functions can be developed as the baseline for a future control design.

Abstract

In this work we compare two optimization approaches to tackle the short-term operational planning of energy systems including power plants, boilers, heat storage, as well as cogeneration units. We first describe a mixed-integer nonlinear programming formulation for the problem and then a mixed-integer linear one, obtained using piecewise-linear approximations of the nonlinear performance functions. We report and discuss numerical results on a set of realistic test cases, comparing the quality of the solutions and the computing time of the two approaches.

Keywords: cogeneration systems, mixed integer nonlinear optimization, piecewise approximation

1. Introduction

Nowadays quite complex energy systems are used to satisfy the electricity, heat and refrigeration power demand of industrial processes as well as buildings and cities (e.g., district heating networks). Such systems generally include not only conventional power plants, boilers, and refrigeration cycles, but also heat pumps, cogeneration units and heat storage systems. Among them, cogeneration units, also called Combined Heat and Power (CHP) plants, are particularly advantageous because of their improved integration of the heat flows which leads to remarkable savings in primary energy consumption and CO_2 emissions. On the other hand, the operational planning of these units is more challenging than that of conventional power plants as the two power outputs (electricity and heat) are interrelated. In addition, the presence of a heat storage unit further complicates the planning problem as it links all the time periods making time-decomposition-based techniques unsuitable. In short-term operational planning, given a set of cogeneration units and other possible generation and heat storage units, one has to determine for each time period of a time horizon which units must be switched on/off, the value of their operating variables, and the amount of stored energy in order to minimize an objective function, while satisfying the demands of electric and thermal power over all time periods. Since the performance functions of many cogeneration units are nonlinear due to the significant efficiency decrease at partial loads, the operational planning of a cogeneration system is a nonlinear mixed integer optimization problem.

In the literature, two main approaches are adopted to model energy and cogeneration systems. In *data-driven* approaches, the behavior of the energy systems is described with approximate models obtained from experimental data. One can consider an explicit approximation of the performance functions of the units, see, e.g., Zhou et al. (2013), for linear and nonlinear models. An alternative is to project out the input variables (typically fuel), and consider a convex-hull representation in the power-heat-cost space, see, e.g., Lahdelma and Hakonen (2003) and Christidis et al. (2012). In

first-principles approaches, the system is decomposed into simpler components with well-known behavior, and thermodynamic balance equations are imposed to determine the plant operating points. This kind of approach is often necessary, for example, for complex CHP steam cycles and combined cycles with multiple operating variables, see, e.g., Dvořák and Havel (2012) and Mitra et al. (2012). Both types of approach typically lead to mixed-integer (possibly nonlinear) optimization models, that can be tackled with mathematical programming techniques.

In this article we present a Mixed-Integer Nonlinear Programming (MINLP) formulation and a Mixed-Integer Linear (MILP) one, where the nonlinear performance functions are approximated using piecewise linear functions. In the selected computational results that we report, we compare the quality of the solutions and the efficiency of the two approaches with off-the-shelf exact MINLP and MILP solvers for some realistic instances of small-to-medium size and complexity.

2. The short-term operational planning problem

We consider cogeneration energy systems involving the following types of cogeneration units:

- One-degree-of-freedom cogenerative units that simultaneously generate electric and thermal power, e.g., gas turbines, internal combustion engines, fuel cells.
- Two-degree-of-freedom cogenerative units that simultaneously generate electric and thermal power (depending on two operating variables). This class includes, e.g., gas turbines with supplementary firing and steam cycles with extraction-condensing turbine.

The system may also include conventional generation units such as boilers and compression heat pumps. In addition, storage tanks may be connected to the heat network. The electric power generated by the units can be used to fulfill the customers' demands and, at the same time, drive the compression heat pumps. Electric power can also be sold/purchased to/from the electric grid.

Given a cogeneration system, including (co)generation units and heat storage tanks, time-dependent demands of low and high-temperature thermal and electric power, and time-dependent price of electricity, the short-term operational planning problem amounts to determining the schedule that minimizes the total operating costs, while satisfying the given demands for all the time periods in a given time horizon. Adopting a data-driven approach, we consider nonlinear performance functions derived from data, either experimental or provided by the manufacturer, that well approximate the behavior of each unit. We also account for the start-up phase of units, that may incur a significant energy penalty due to their warm-up phase, and there is an upper bound on the number of start-up operations.

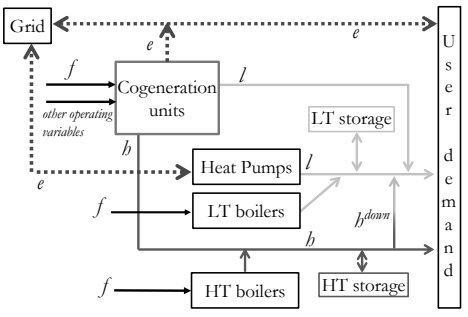

Figure 1: Schematic representation of a CHP system that cogenerates electricity and heat at two temperature levels.

3. MINLP formulation and MILP approximation

Using the sets, parameters and decision variables defined in the nomenclature, the short-term cogeneration systems planning problem can be formulated as the following MI(N)LP:

$$\min \quad \sum_{t\in\mathscr{T}}\left(\sum_{i\in\mathscr{U}} c_i^{\mathsf{OM}} z_{it} + \sum_{i\in\mathscr{U}} c_i^{\mathsf{SU}}\delta_{it} + \sum_{i\in\mathscr{F}} c_i^f f_{it} + b_t e_t^+ - p_t e_t^-\right) \tag{1}$$

$$s.t. \quad \sum_{i\in\mathscr{G}} e_{it}^{gen} - \sum_{i\in\mathscr{E}} e_{it}^{cons} + e_t^+ - e_t^- = D_t^e \qquad \forall t\in\mathscr{T} \tag{2}$$

$$\sum_{i\in\mathscr{H}} h_{it} - h_t^{down} + (u_t - \frac{u_{t+1}}{1-\alpha}) \geq D_t^{high} \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{3}$$

$$\sum_{i\in\mathscr{L}} l_{it} + h_t^{down} + (v_t - \frac{v_{t+1}}{1-\beta}) \geq D_t^{low} \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{4}$$

$$z_{it}F_{it}^{min} \leq f_{it} \leq z_{it}F_{it}^{max} \qquad \forall t\in\mathscr{T}, i\in\mathscr{F} \tag{5}$$

$$z_{it}E_{it}^{min} \leq e_{it}^{cons} \leq z_{it}E_{it}^{max} \qquad \forall t\in\mathscr{T}, i\in\mathscr{E} \tag{6}$$

$$\textit{performance constraints linking } z_{it}, f_{it}, e_{it}^{cons}, y_{it}, x_{it}, e_{it}^{gen}, h_{it}, l_{it} \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{7}$$

$$\sum_{t\in\mathscr{T}} \delta_{it} \leq N_i \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{8}$$

$$\delta_{it} \geq z_{it} - z_{it-1} \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{9}$$

$$e_{it}^{gen}, h_{it}, l_{it}, h_t^{down}, e_t^+, e_t^- \geq 0 \qquad \forall t\in\mathscr{T}, i\in\mathscr{U} \tag{10}$$

$$0 \leq u_t \leq U,\ 0 \leq v_t \leq V \qquad \forall t\in\mathscr{T} \tag{11}$$

$$0 \leq \delta_{it} \leq 1,\ z_{it} \in \{0,1\} \qquad \forall t\in\mathscr{T}, i\in\mathscr{U}. \tag{12}$$

The aim is to minimize the operational costs minus the revenue obtained by selling extra electricity to the grid. In the objective function (1), the start-up penalties c_i^{SU} account for the extra cost due to the warm-up phase, while the fixed cost c_i^{OM} accounts for operation and maintenance costs proportional to the number of working hours. Constraints (2) impose that the net amount of electric power must satisfy the demand D_t^e for period t. It is necessary to distinguish between the energy that is purchased from the power grid, e_t^+, from the one that is sold, e_t^-, since their price is different. Constraints (3) and (4), balance constraints for high and low-temperature heat, ensure that the thermal requirements in period t are satisfied. High-temperature heat can be downgraded to low-temperature via h^{down}. Thermal energy can be stored in the tank for the next period, as long as the capacities U, V are not saturated, and we account for constant loss rates $\alpha, \beta \in [0,1)$. Thermal energy in excess can be dissipated with no additional costs. Constraints (5) and (6) ensure that the operating variables for a unit i (fuel, consumed electricity) are within the technical limits. Constraints (7), that model the nonlinear behavior of the generation units, are described in detail in the next two paragraphs. Constraints (8) and (9) limit the number of start-ups.

Nonlinear performance constraints: Each unit $i \in \mathscr{U}$ is described in terms of nonlinear performance functions $g_{it}(\cdot)$, that map one or more operating variables (fuel, consumed electricity, supplementary fuel) to an output variable (low or high-temperature heat, electric power). The performance functions are in general, non-convex and time-varying due to the non-negligible temperature effect. In addition, if unit $i \in \mathscr{U}$ is off, its output has to be 0. Thus, Constraints (7) can be expressed as inequalities of the form $\zeta \leq z_{it} g_{it}(\underline{\theta})$, where $\underline{\theta}$ is the vector of input variables and ζ an output variable, and the problem can be solved as a Mixed-Integer Nonlinear Program.

In the case of generation or cogeneration units with one degree of freedom (d.o.f.), each performance function g_{it} will be a function of one variable (θ is scalar). For instance, given a high-temperature auxiliary boiler, the output variable is high-temperature thermal power h_{it}, while the only operating variable is fuel f_{it}. The feasible region for h_{it} will be $\{0\} \cup [g_{it}(F_{it}^{min}), g_{it}(F_{it}^{max})]$.

In the case of cogeneration units with more degrees of freedom, the performance functions depend on two or more operating variables ($\underline{\theta}$ is a vector). Two examples are combined cycles with extraction valve regulation (left) and gas turbines with post-firing (right):

$$\begin{cases} l_{it} \leq z_{it} g^l_{it}(f_{it}, x_{it}) \\ h_{it} \leq z_{it} g^h_{it}(f_{it}, x_{it}) \\ e^{gen}_{it} \leq z_{it} g^e_{it}(f_{it}, x_{it}) \end{cases} \tag{13}$$

$$\begin{cases} l_{it} \leq z_{it} g^l_{it}(f_{it}, y_{it}) \\ h_{it} \leq z_{it} g^h_{it}(f_{it}, y_{it}) \\ e^{gen}_{it} \leq z_{it} g^e_{it}(f_{it}, y_{it}), \end{cases} \tag{14}$$

where the operating variables are the fuel quantity f_{it}, the valve opening percentage $x_{it} \in [0, 0.4]$ for the combined cycle (13) and the supplementary fuel y_{it} for the gas turbine (14).

Piecewise linear approximation: An alternative approach consists in approximating the nonlinear performance functions with piecewise linear functions, see e.g. Bischi et al. (2014), obtaining a more tractable Mixed-Integer Linear Program (MILP). The piecewise linear approximation of 1-d.o.f. performance functions is rather straightforward, as it is sufficient to select a set of discretization points on a line, and connect them via line segments. For 2-d.o.f. units the approximation involves functions of two variables. Several approaches are available for approximating 2-D functions, differing considerably in terms of accuracy of the approximation and computational cost of the resulting MILP. In our model, we consider the so-called *lambda method* described, e.g., in Lee and Wilson (2001), that is implemented by triangulating the domain of the nonlinear function. Then, the value in a point $\underline{x}$ is computed as the convex combination of the function values in the vertices of the triangle containing $\underline{x}$. This method requires the introduction of $O(n_1 \times n_2)$ binary variables, where n_1 and n_2 are the number of discretization points per dimension.

4. Computational experiments

Given the wide variety of cogeneration systems, ranging from small to large scale, we consider two scenarios from which we build several test instances.

Scenario 1: The first scenario is a micro-cogeneration system designed to provide low and high-temperature thermal power and electricity to a large building. The system consists of:

- a Solid Oxide Fuel Cell (SOFC) using natural gas to cogenerate electric and thermal power;
- a Heat Pump (HP) using electric power to generate low temperature heat;
- an Auxiliary Boiler (AB), mainly used as a backup;

and a thermal storage for high-temperature heat energy. For this scenario, we consider a single instance with 3 units that we indicate with `1-a`.

Scenario 2: The second scenario is a large scale cogeneration system providing heat to a district heating network. The system may include one or more of the following units:

- Gas Turbines (GT) with heat recovery;
- Gas Turbines (GT-2) with supplementary firing and heat recovery;
- Natural Gas Combined Cycles (NGCC) with a bottoming back-pressure steam turbine;
- Natural Gas Combined Cycles (NGCC-2) with a bottoming extraction-type steam turbine;
- Auxiliary Boilers (AB) burning natural gas to generate heat;

and a thermal storage for high-temperature heat energy. Since only thermal power is required, the whole amount of electricity cogenerated by gas turbines and combined cycles is sold to the grid. This scenario includes units with two degrees of freedom, see Eq. (13) and (14): in GT-2, supplementary fuel can be burned to increase the amount of recovered heat, and, in NGCC-2, opening the steam extraction valve reduces the electric power and increases the thermal power. Four different instances are considered (`2-a`, `2-b`, `2-c` and `2-d`), with, respectively, 5, 4, 12 and 11 (co)generation units. Instances `2-b` and `2-d` include also 2-d.o.f. cogeneration units.

Computational experiments were performed, for the MINLP formulations, with the open-source solver SCIP 3.1.0, while for the MILP formulations IBM Ilog CPLEX 12.6 was used. For the MINLP, we have also experimented with BARON, whose results are not included for sake of brevity, since its efficiency on the considered instances was slightly inferior. The tests were carried out on an Intel Xeon with E3125@3.30GHz CPUs and 16GB of RAM, with a time limit of 2 hours.

Table 1: Optimal values, computing time (seconds) and lower/upper bounds for the MINLP and the approximate MILP with an increasing number of discretization points (d.p.) per dimension.

	2 d.p.		3 d.p.		5 d.p.		9 d.p.		15 d.p.		MINLP			
	time	opt	time	opt	time	opt	time	opt	time	opt	time	LB	UB	gap
`1-a`	0.01	94.33	0.03	91.73	0.06	91.30	0.10	91.17	0.42	91.11	42.58	91.07	**91.07**	0.0
`2-a`	0.04	104.17	0.07	102.49	0.10	101.95	0.12	101.86	0.14	101.82	812.8	101.76	**101.76**	0.0
`2-b`	0.06	-80.12	0.14	-80.24	1.19	-80.33	4.53	-80.36	34.44	-80.36	7200	-94.36	-71.97	31.1
`2-c`	0.15	307.01	0.04	302.73	0.09	300.75	0.09	300.51	0.17	300.43	7200	284.83	300.19	5.4
`2-d`	0.22	121.27	0.29	119.43	0.31	118.20	0.50	118.09	3.43	118.07	7200	-83.01	140.93	∞

Table 1 summarizes the computational results. The MINLP instances turn out to be challenging. SCIP is able to certify optimality for 2 out of 5, and on `2-c` is close to the optimum, while the instances with 2-d.o.f. units are harder. In comparison, the MILP formulations can be solved to optimality by CPLEX in a few seconds. The MILP solutions are not necessarily feasible for the original formulation, since the approximate model might overestimate the amount that is generated. However, it is always possible to recover infeasibility *a posteriori* by increasing the production level. Interestingly, on our instances all the MILP optimal solutions are feasible (barring minor numerical errors), as they tend to be on the discretization points.

The results show that the approximate optimal values approach the optimal value of the original formulation as the number of discretization points is increased. The optimal values are significantly different when the approximation is less accurate – except for instance `2-b`, where the variation is small, since the solution is dominated by a large NGCC-2 unit always at full load.

The structure of the solutions can differ significantly. As an example, we report in Figure 2 two optimal schedules for a low-temperature heat pump in instance `1-a` with a 2-point MILP approximation (left) and with the MINLP model (right). Although the instance is simple, the structure of the optimal approximate solution differs from that of the optimal MINLP solution even when the number of discretization points is increased to 5. To obtain optimal solutions to these two problems that are equivalent, one needs to use at least 9 discretization points.

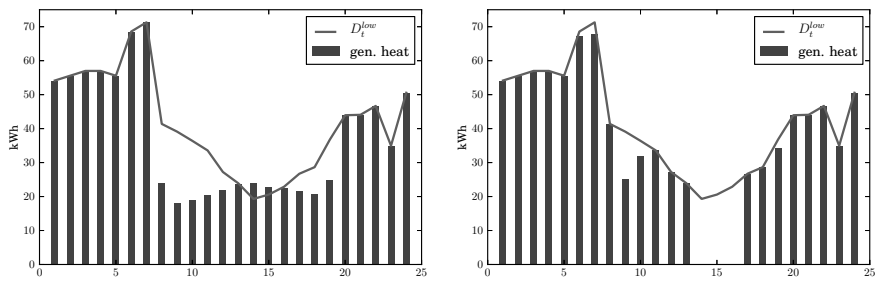

Figure 2: Optimal plan for the heat pump of instance `1-a` obtained with a 2-point piecewise approximation (left) and with the MINLP (right).

5. Concluding remarks

The summarized computational results for two relatively simple scenarios of the short-term operational planning problem indicate that even small-size instances of the MINLP can be computationally very challenging. Approximating the nonlinear performance functions with piecewise linear functions is an alternative that seems to work quite well in practice. For the considered instances, the resulting approximate MILP models can generally be solved more efficiently than their MINLP counterparts, and they appear to be already fairly accurate with a few linear pieces.

Attention must be paid to the feasibility of the solutions obtained with the approximations. Indeed, if the optimal operating point of a unit is far from the approximation discretization points, the piecewise linear function value might be quite different from the actual value. Underestimating the actual performance value may lead to suboptimal solutions with more than 3% error, while overestimating it may lead to infeasible solutions.

Nomenclature

$\mathscr{T}$: set of time periods (hours)
$\mathscr{U}$: set of all generation units
$\mathscr{F}$: set of units consuming fuel
$\mathscr{E}$: set of units consuming electricity
$\mathscr{H}$: set of units that generate high-temperature heat
$\mathscr{L}$: set of units that generate low-temperature heat
$\mathscr{G}$: set of units that generate electricity
c_i^{OM}: hourly operation and maint. cost for unit i [€]
c_i^{SU}: start-up cost for unit i [€]
c_i^f: unit cost of fuel for unit i [€/kWh]
b_t, p_t: unit price of electricity bought/sold from/to the grid at time t [€/kWh]
$F_{it}^{min}, F_{it}^{max}$: minimum and maximum fuel input for unit $i \in \mathscr{F}$ at time t [kWh]
$E_{it}^{min}, E_{it}^{max}$: minimum and maximum electricity input for unit $i \in \mathscr{E}$ [kWh]
N_i: maximum number of start-ups for unit i
U, V: capacity of low and high-temperature heat storage [kWh]
α, β: constant loss rate for thermal storage [%]
$D_t^{low}, D_t^{high}, D_t^e$: demand for low and high-temperature heat, electricity at time t [kWh]
f_{it}: fuel consumed by unit $i \in \mathscr{F}$ in period t [kWh]
y_{it}: secondary fuel consumed by unit $i \in \mathscr{F}$ with post-firing injection [kWh]
x_{it}: extraction valve opening percentage for combined cycle units [%]
e_{it}^{cons}: electricity consumed by $i \in \mathscr{E}$ in period t [kWh]
e_{it}^{gen}: electricity generated by $i \in \mathscr{G}$ in period t [kWh]
l_{it}: low-temperature heat generated by unit $i \in \mathscr{L}$ in period t [kWh]
h_{it}: high-temperature heat generated by unit $i \in \mathscr{H}$ in period t [kWh]
h_t^{down}: high-temperature heat downgraded to low-temperature in period t [kWh]
e_t^+, e_t^-: electricity bought/sold from/to the grid in period t [kWh]
u_t, v_t: high and low-temperature thermal energy stored at the beginning of period t [kWh]
z_{it}: binary variable, on/off status of unit i in period t
δ_{it}: binary start-up variable ($\delta_{it} = 1$ if unit i is switched on at beginning of period t)
$g_{it}^h, g_{it}^l, g_{it}^e$: performance functions for unit i at time t

Abstract

This paper presents a mixed integer linear program (MILP) that maximizes the net present value (NPV) of a biomass-to-biofuels supply chain (BTBSC). The BTBSC includes the biomass growth and its planting-campaign schedule, the location and the capacities of the biorefineries, and the transportation cost from the planting regions to biorefinery locations, and from biorefinery locations to demand centres. The case study considers the design and operation of a BTBSC for 18 counties of the State of Oklahoma with four different types of biomass for producing bioethanol by hydrolysis followed by fermentation route. The model recommends building a biorefinery of 100 MG/yr capacity at Tulsa County, and planting big blue stem at the same location.

Keywords: biomass-to-biofuels supply chain, biomass-planting-campaign schedule, biomass transportation cost, biofuel transportation cost, biorefinery cost

1. Introduction

Biomass is an abundant, locally available, and renewable raw material for liquid fuel production. The biomass-to-biofuels supply chain (BTBSC) contains biomass growth, biorefineries, and demand centres. The optimum design and operation of this supply chain is crucial for cost effective production of biofuels, and there are ample studies in the literature that focuses on optimizing the location and size of biorefineries for selected geographical regions. For example, Kocoloski et al. (2011) concluded that locating switchgrass-to-ethanol biorefineries optimally relative to biomass supplies and ethanol demand may reduce the cost of ethanol by 15-25% relative to uninformed biorefinery placement. Marvin et al. (2012) presented a MILP for ethanol production in a 9-state region in the Midwest and analysed the systems sensitivity to changes in parameters. Giarola et al. (2011) presented a similar model for Northern Italy, and considered a multi-objective problem also minimizing greenhouse gas emissions. However, most models assume a certain amount of biomass availability for a selected region, and hence, fail to consider the overall BTBSC. Cost of biomass growth accounts for a significant portion of the biofuel production cost, and the optimal design of BTBSC should include the batch-like characteristics of biomass growth along with biorefinery locations and capacities.

In this paper, we present a MILP for optimal design of BTBSC with biorefinery location and capacities, and campaign plan for biomass production. The objective of the model is to maximize the net present value (NPV) of the overall supply chain over the planning horizon. The NPV includes biomass growth costs, capital and operating costs for biorefineries, and transportation cost between the locations of biomass growth and

biorefineries, and between biorefineries and demand centres. The addition of biomass-growth campaign planning allows the possibility of incorporating seasonality, crop-rotation, and feedstock diversification at the BTBSC design stage. The model includes multiple potential feedstock crops, and production pathways, and determines the optimal biorefinery locations and corresponding capacities, and the biomass-growth campaign plan. The model is demonstrated with a case study considering the design of BTBSC for a region encompassing 18 counties of the State of Oklahoma.

2. Optimization Model

The biomass-to-biofuel supply chain considered in this study is shown in Figure 1. There are $a \in \mathbf{A}$ potential planting regions, which may be used for growing and supplying biomass to $b \in \mathbf{B}$ potential biorefinery locations, which in turn may supply $k \in \mathbf{K}$ demand centres. Different biomass types, $c \in \mathbf{C}$, and biofuel options, $u \in \mathbf{U}$, are considered for supplying demand. Time is discretized into $t \in \mathbf{T}$ equal time buckets, and each year in planning horizon is represented by $i \in \mathbf{I}$.

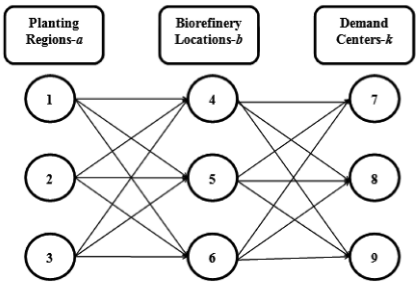

Figure 1. Biomass to biofuels supply chain

The objective is to maximize the net present value (NPV) of the BTBSC over the planning horizon, viz. Eq. (1).

$$NPV = \left[\sum_{i=1}^{|\mathbf{I}|} \frac{\sum_{u} \sum_{b} \sum_{k} BfP_u BfT_{u,b,k,i} - \left(CPL_i + CTR_i + COP_i\right)}{(1+rate)^i} \right] - CINV \tag{1}$$

Eq. (1) discounts the yearly profit using a discount rate of *rate* and subtracts the initial capital investment, *CINV*. The yearly profit is the difference between the total revenue from biofuel sales and total cost. The revenue is calculated as the sum of all biofuel types, u, transferred from biorefinery location b to demand centre k at year i, $BfT_{u,b,k,i}$, multiplied by the corresponding biofuel price, BfP_u. Total cost includes yearly planting (CPL_i), transportation (CTR_i), and biorefinery operating (COP_i) costs.

The biomass-planting-campaign schedule determines the annual planting costs. This schedule requires a finer time grid than years as biomass may be planted more than once and at any time throughout the year. The goal of the campaign schedule is to determine which biomass to plant at which time in which planting area in order to satisfy the biomass demand from the biorefineries. When a certain biomass is planted in a certain planting region, it is occupied during the cycle time (rotation period) of that biomass. The following assumptions are made to capture the dynamics of the biomass growth to an appropriate level of detail: (1) The biomass is grown in marginal farmland with a

known area for each planting region ($area_a$), (2) each area can be planted with a single age class of a biomass type at a time, (3) time is discretized using time buckets of equal size (one month), $t \in \mathbf{T}$, (4) all the properties within a time bucket is assumed to be constant, but may vary from one bucket to the next. Given these assumptions, a binary variable, $X_{a,c,t,p}$, is defined to be equal to one if a biomass type c is planted in planting region a at time bucket p and not harvested at time bucket t. Using this binary variable, the annual biomass planting cost is calculated using Eq. (2),

$$CPL_i = \sum_a \sum_c \sum_{t=12i-10}^{12i+1} \sum_{p=12i-10}^{p=12i+1} area_a PC_c X_{a,c,t,p} \tag{2}$$

where PC_c is the cost of planting biomass type c ($/(acre)(time bucket)).

The transportation costs consider the cost of transporting biomass from planting regions to biorefinery locations, and transporting biofuel from biorefinery locations to demand centres, and is calculated via Eq. (3).

$$CTR_i = \sum_a \sum_b \sum_c D_{a,b}(TCBi) BiT_{c,a,b,i} + \sum_b \sum_k \sum_u D_{b,k} TCBf_u BfT_{b,u,k,i} \tag{3}$$

Here, $D_{a,b}$ represents the distance between planting region a and biorefinery location b calculated as the shortest highway distance between the centres of each region, $TCBi$ is the unit transportation cost for transporting biomass using trucks, and $BiT_{c,a,b,i}$ is the amount of biomass type c transported from planting region a to biorefinery b at year i. By analogy, $D_{b,k}$ is the distance, and $TCBf_u$ is the unit cost for transporting biofuel u.

The annual biorefinery operating cost is assumed to change linearly with the capacity of the refinery. Given an estimate of the operating cost for a predetermined capacity from literature, unit operating cost ($UOC_{u,i}$) per year of the biorefinery configuration used for producing biofuel u is calculated by dividing this estimate with the capacity. The operating costs given in the literature includes the raw material, labour, waste disposal, utility costs, and fixed charges including depreciation, taxes and financing interest. We should note here that the cost of biomass was subtracted from the annual operating costs for calculations as this cost is considered in the biomass-growth campaigns. Hence, the annual biorefinery operating cost is calculated using Eq. (4).

$$COP_i = \sum_u \sum_b UOC_{u,i} Cap_{b,u} \tag{4}$$

The initial capital investment (CINV) is the sum of capital investments made for producing all biofuels in all biorefinery locations, i.e.,

$$CINV = \sum_u \sum_b INV_{b,u} \tag{5}$$

where $INV_{b,u}$ is the total capital investment made for producing biofuel u at biorefinery location b, and it includes the fixed and working capitals. As economies of scale dictates, the total capital investment for a plant is not a linear function of its capacity. In order to keep the model linear, we used piece-wise linear approximations to estimate how the total capital investment changes with biorefinery capacity. For the biorefinery options considered, a three piece-wise functions were deemed accurate enough for the

purposes of this model. The equation set given below summarizes the total investment cost calculation.

$$y_{1,b,u} + y_{2,b,u} \le 1 \tag{6a}$$

$$-M_1(1-y_{1,b,u}) \le INV_{b,u} - \alpha_{1,u} Cap_{b,u} \le M_2(1-y_{1,b,u}) \tag{6b}$$

$$-M_3(1-y_{2,b,u}) \le INV_{b,u} - \left(\alpha_{2,u} Cap_{b,u} + \beta_{2,u}\right) \le M_4(1-y_{2,b,u}) \tag{6c}$$

$$INV_{b,u} - \left(\alpha_{3,u} Cap_{b,u} + \beta_{3,u}\right) \le M_5(1-y_{1,b,u}-y_{2,b,u}) \tag{6d}$$

$$-M_6(1-y_{1,b,u}-y_{2,b,u}) \le INV_{b,u} - \left(\alpha_{3,u} Cap_{b,u} + \beta_{3,u}\right) \tag{6e}$$

$$Cap_{b,u} \le UC_{1,b,u} y_{1,b,u} + UC_{2,b,u} y_{2,b,u} + UC_{3,b,u}\left(1-y_{1,b,u}-y_{2,b,u}\right) \tag{6f}$$

$$Cap_{b,u} \ge UC_{1,b,u} y_{2,b,u} + UC_{2,b,u}\left(1-y_{1,b,u}-y_{2,b,u}\right) \tag{6g}$$

In Eq. (6), the binary, $y_{1,b,u}$ takes the value of one if the biorefinery capacity at location b for biofuel u falls below the upper bound of the first capacity segment ($UC_{1,b,u}$). Similarly, $y_{2,b,u}$ is set to one if the capacity falls between the upper and lower bounds of the second capacity segment ($UC_{2,b,u}$ and $UC_{1,b,u}$). If both binaries are equal to zero, then the biorefinery capacity is greater than the upper bound of the second segment ($UC_{2,b,u}$), and the third linear relationship that approximates how the total capital investment changes with the biorefinery capacity is used. The parameters of the linear total investment cost functions are represented by α's and β's in Eq. (5), and Ms are big-M constraint parameters.

The next set of constraints define the biomass planting schedule. There are six additional parameters, which are type of biomass, c, dependent: (1) $\eta_{c,u}$: biofuel u yield (gal/ton), (2) $cuttingcycle_c$: cutting cycle in units of time bucket, (3) $cycle_c$: cycle time (rotation period) in units of time buckets, (4) $cyield_c$: yield during cutting cycles (ton/acre), (5) $hyield_c$: yield at final harvest (ton/acre), (6) $mature_c$: the initial time the cutting cycles may start in units of time bucket. Using the definition of binary variable $X_{a,c,t,p}$, the constraints related to schedule of biomass planting cycles can be written as:

$$\sum_{t \ge p+cycle_c+1} X_{a,c,t,p} = 0 \qquad \text{for all } a,c,p \tag{7a}$$

$$X_{a,c,t+1,p} = X_{a,c,t,p} \qquad \text{for all } a,c,p \wedge p \le t < \left(p + cycle_c\right) \tag{7b}$$

$$\sum_{c} \sum_{p=1}^{p=t} X_{a,c,t,p} \le 1 \qquad \text{for all } a,t \wedge t < \left(p + cycle_c\right) \tag{7c}$$

Eq. (7a) ensures that a planting area a planted with biomass c at time p is harvested at time $t = p + cycle_c + 1$. Eq. (7b) makes sure that once an area is planted with a biomass type at time p, the area stays occupied until the end of biomass c's cycle time. Eq. (7c) ensures that at any given time t, there is only one biomass type planted on the planting region a.

The biomass may be produced by both interval cuttings and at full harvest. When the planted biomass becomes mature, some of it may be removed by cutting, leaving the rest of the plant intact for continued growth. The biomass related parameter $cuttingcycle_c$ describes the frequency of these cuttings for biomass type c without hindering continued growth. The yield per unit acre of land of these cuttings is defined

by the $cyield_c$ parameter. At harvest, which happens at the end of the cycle time of biomass c, all biomass is removed from the land and the yield per unit acre of land at this point is defined by $hyield_c$ parameter. With these definitions, the annual production of biomass c in area a is calculated as:

$$m_{c,a,i} = \sum_{p \le t - mature_c} \sum_{t=12i-10}^{t=12i+1} \left[\begin{array}{l} X_{a,c,t,p} area_a \left\lfloor \dfrac{t-p-mature_c}{cuttingcycle_c} + 1 \right\rfloor cyield_c \\ + X_{a,c,t,p} area_a \left\lfloor \dfrac{t-p-cycle_c}{cycle_c} + 1 \right\rfloor hyield_c \end{array} \right] \text{for all } c,a,i \qquad (8)$$

where $\lfloor z \rfloor$ is the floor function.

The model assumes yearly biomass transportation from planting regions to biorefinery locations, and ignores the possible biomass spoilage during transportation and yearly storage (Eq. (9a)). Depending on the biomass type, this amount may be significant and is left as a future extension of the model. A mass balance at each biorefinery location calculates the total biofuel production ($PBf_{b,u,i}$) at that site (Eq. (9b)), which cannot exceed the total capacity of the biorefinery at that location (Eq. (9c)). The biofuel u shipped from a biorefinery location b to all demand centres cannot exceed the production at that site (Eq. (9d)). Finally, the total amount of biofuel type u transported from all biorefinery location to demand centres are bounded by the total demand ($DM_{k,u,i}$) at those sites (Eq. (9e)).

$$\sum_b BiT_{c,a,b,i} \le m_{c,a,i} \qquad \text{for all } a,c,i \qquad (9a)$$

$$\sum_a \sum_c \eta_{c,u} BiT_{c,a,b,i} = PBf_{b,u,i} \qquad \text{for all } b,u,i \qquad (9b)$$

$$PBf_{b,u,i} \le Cap_{b,u} \qquad \text{for all } b,u,i \qquad (9c)$$

$$\sum_k BfT_{u,b,k,i} \le PBf_{b,u,i} \qquad \text{for all } b,u,i \qquad (9d)$$

$$\sum_b BfT_{u,b,k,i} \le DM_{k,u,i} \qquad \text{for all } k,u,i \qquad (9e)$$

Eqs. (1) to (9) define the overall MILP for obtaining the supply chain topology, biorefinery locations and capacities, material flows between the planting regions, biorefinery locations, and demand centres, and the biomass-planting schedule.

3. Case Study and Results

The case study considers the design of BTBSC for a region encompassing 18 counties of "Green Country" in the State of Oklahoma for 10 years. The time is discretized into equal sizes of 30 days yielding a total of 120 time buckets. The potential biomass sources include switchgrass, indiangrass, big blue stem, and poplar. The candidate planting and biorefinery regions, and the demand centres are the 18 counties. It is assumed that only marginal farmland is used for growing biomass. We considered only one technology: producing cellulosic ethanol via acid pretreatment and enzymes for the hydrolysis to simple sugars followed by fermentation. Both biomass and ethanol are assumed to be transported between counties using trucks. The distance between the

counties are calculated as the shortest highway distance provided by Google Maps when the start and end points are represented by the names of the counties. The ethanol sale price is assumed to be $2.80/gal. Demand for bioethanol is forecasted using the four-year double moving average for each counties population change over the next 10 years and multiplying this number by the 11.25% of per capita demand for transportation oil in US. All prices are at 2011 US dollars. The remaining model parameters are available from the corresponding author upon request.

The MILP is implemented in GAMS version 24.2.1, and solved using CPLEX 12.6.0.0. It had 548,688 variables of which 531,468 are discrete, and 530,526 constraints, and was solved in 537.6 CPU minutes to 1% optimality gap using an Intel Core i7-3520M CPU @ 2.90GHZ computer with 8.00 GB installed memory. The NPV is $238,390,000. Given the highest biofuel demand and its central location in the Green County, the solution recommends planting big blue stem for the whole planning horizon and building a 100,000,000 gal/yr bioethanol production plant at Tulsa County. The total capital investment is $451,150,000, and the total annual costs are dominated by the biorefinery operating costs (95%). The transportation cost only accounts for 1% of the annual cost as transportation of biomass is avoided by planting at the biorefinery location.

4. Conclusions

This paper presents a mathematical programming model to design a biomass-to-biofuels supply chain (BTBSC) by maximizing the net present value of the chain. To the best of the author's knowledge, it is the first model that integrates the biomass-growth-campaign plan with biorefinery locations and capacities for designing BTBSC. The model is demonstrated with a case study that considers the design of BTBSC for 18 counties of the State of Oklahoma. Future work will incorporate the impact of possible biomass spoilage to the model, and studying the sensitivity of the solution to model parameters. Furthermore, the resulting large-scale MILP takes considerable computational resources to solve. It may be possible to exploit its structure to develop tailored algorithms for quickly locating the optimum. It is worth noting that various model parameters, such as crop yield, demand patterns, are uncertain. Once the parameters with high impacts are identified, stochastic programming may be used to hedge against these uncertainties. However, the deterministic equivalent of this stochastic program would be difficult to solve given the size of the deterministic MILP, and its applicability would depend on the development of tailored solution algorithms.

Energy Consumption Scheduling of Smart Homes with Microgrid under Multi-objective Optimisation

Di Zhang, Sara Evangelisti, Paola Lettieri, Lazaros G. Papageorgiou

Department of Chemical Engineering, University College London, Torrington Place, London WC1E 7JE, UK, p.lettieri@ucl.ac.uk, l.papageorgiou@ucl.ac.uk.

Abstract

Microgrid is regarded as an alternative to the current centralised energy generation systems because of its benefits from various aspects, including economic and environment. And flexible domestic electricity consumption tasks within smart homes with a common microgrid can be scheduled for better mutual benefits. This paper proposes a mixed integer linear programming (MILP) model to schedule the energy consumption within smart homes by coupling environmental and economic sustainability in a multi-objective optimisation with ε-constraint method. Electricity tariff and CO_2 intensity profiles of UK are employed and the Pareto curve for cost and CO_2 emissions present the trade-off between the two conflict objectives.

Keywords: microgrids; planning/scheduling; multi-objective optimisation; ε-constraint method, mixed integer linear programming (MILP).

1. Introduction

Energy cost and pollution reduction are two worldwide popular issues and the UK Climate Change Programming aims to cut down 80% of carbon emissions by 2050 based on Climate Change Act 2008 (Fuselli et al., 2013). Microgrid, which includes a group of distributed energy resources (DER), is regarded as an alternative to the current centralised energy generation systems to deal with these two problems. Environmental benefits can be obtained by utilising DERs with low pollutant generation. Energy management within buildings can result in both energy cost and air pollution reductions since about one third primary energy is consumed in building (Lior, 2010). Smart homes are promising in improving the indoor environmental comfort while reducing economic cost and CO_2 emissions. Customers are encouraged to participate with demand side management through economic or environmental incentive, where time varying electricity tariff or CO_2 emission intensity is available (Kin Cheong et al. 2013).

Domestic appliance scheduling problem has been addressed in several recent work (Rastegar et al. 2012 and Baraka et al. 2013), and Derin and Ferrante develop a model that considers both equipment operation and three domestic appliances order scheduling. However, only economic aspect is considered in those work while the two objectives, economic cost and CO_2 emissions, are not always positively correlated and they may conflict with each other. As an extension of our previous work (Zhang et al. 2013), which targets minimising the total energy cost, this work propose a mixed integer linear programming (MILP) model to investigate the scheduling of DER operation and the domestic energy consumption tasks by coupling environmental and economic sustainability in a multi-objective optimising model with ε-constraint method. The scheduling is based on real-time electricity pricing and CO_2 intensity.

2. Problem statement

Multiple smart homes in a smart building are considered in this work and they have a common microgrid. All the DERs within the microgrid are shared among the smart homes. The microgrid is connected for electricity importation only. The energy demand of each home depends on the household types, available electrical appliances and living habits. The operation time of domestic electricity consumption tasks can be scheduled while will influence the electrical demand. The heat demand of the whole building is provided. Electricity real time pricing and CO_2 emission intensity are forecasted and given one day in advance. The economic cost and CO_2 are desired to be reduced simultaneously although the two objectives may conflict with each other. The overall problem can be stated as follows:

Given are (a) a time horizon split into a number of equal intervals, (b) heat demand of the whole building, (c) equipment capacities, (d) efficiencies of technologies, (e) maintenance cost of all equipment, (f) heat-to-power ratio of combined heat and power (CHP) generator, (g) charge and discharge limit rates for thermal/electrical storage, (h) gas price and real-time electricity prices from grid, (i) CO_2 emission intensity, (j) earliest starting and latest finishing times, (k) task capacity profiles, (l) task duration,

Determine (a) energy production plan, (b) task starting time, (c) thermal/electrical storage plan, (d) electricity bought from grid,

So as to find the optimum energy consumption scheduling and DER operation with minimum economic cost and environmental impact.

3. Mathematical formulation

The energy consumption management problem is formed as an MILP model and the relevant constraints include equipment capacity constraints, energy demand constraints and electrical/thermal storage constraints. The main constraints involved are:

3.1. Energy balances

The electricity demand is fulfilled by the electricity generated by CHP generator, electricity received from the electrical storage and grid minus electricity sent to the electrical storage and grid.

$$\sum_{j}\sum_{i}\sum_{\theta=0}^{p_{ji}-1} C_{i\theta}E_{ji,t-\theta} = u_t + y_t - z_t + I_t \qquad \forall\, 0 \le t \le T \tag{5}$$

The heat demand is fulfilled by the heat generated from the CHP generator, boiler, heat received from the thermal storage minus heat sent to the electrical storage.

$$H_t = \alpha u_t + x_t + f_t - g_t \qquad \forall\, 1 \le t \le T \tag{6}$$

3.2. Starting time and finishing time

The operation of each task must start after the given earliest starting time and finish before the latest ending time. For each task from each home, it has to be started once.

$$\sum_{t} E_{jit} = 1 \qquad \forall j,i,T_{ji}^{S} \le t \le T_{ji}^{F} - P_{ji} \tag{7}$$

3.3. *Objectives*

The first objective is to minimise the total daily electricity cost, which includes: the operation and maintenance cost of the CHP generator, electrical storage and thermal storage; and the cost of electricity purchased from the grid.

$$\phi_1 = \sum_{t}[\delta(r/\alpha u_t + b_t I_t + r/\beta x_t + \mu^E y_t + \mu^T f_t)] \tag{8}$$

The other objective is to minimise the total CO_2 emissions, which includes: the CO_2 emissions from the CHP generator, grid electricity and boiler.

$$\phi_2 = \sum_t [\delta(\xi^{CHP} u_t + \xi_t^G I_t + \xi^B x_t)] \quad (9)$$

The above two objective functions are considered in a multi-objective formulation as

$$\underset{x \in Q}{Min}\{\phi_1(x), \phi_2(x)\} \quad (10)$$

where x is the vector of decision variables and Q is the space of feasible solutions.

3.4. The ε-constraint method with two objectives

Applying the ε-constraint to the proposed multi-objective problem $\underset{x \in Q}{Min}\{\phi_1(x), \phi_2(x)\}$ it keeps ϕ_1 as the objective function, while ϕ_2 is considered as a constraint. A single-objective function is obtained as:

$$\min_{x \in Q} \quad \phi_1(x) \quad (11)$$

s.t. $\phi_2(x) \le \varepsilon_2$

The multi-objective problem is formulated as an MILP model by the ε-constraint method.

4. Illustrative example

The energy consumption scheduling MILP model is implemented on an illustrative example with a smart building of 30 homes with same living habits as given in (Zhang et al. 2013), where 12 domestic electricity consumption tasks are provided with their flexible time-window and processing time. The installed DERs and their capacities are:

- one CHP generator with a capacity of $20kW_e$ and its electrical efficiency is 40%, heat to power ratio is 1.2, and natural gas cost is 2.7 *p/kWh*;
- one boiler with capacity of 120 kW_{th} and efficiency is 85%;
- one electrical storage unit with a capacity of 10 kW_eh; the charge/discharge efficiency is 95%, discharge limit and charge limit are both $10kW_e$, and the maintenance cost is 0.5 p/kWh_e;
- one thermal storage unit with a capacity of 20 $kW_{th}h$; the charge/discharge efficiency is 98%, discharge limit and charge limit are both 20 kW_{th}, and the maintenance cost is 0.1 p/kWh_{th};
- a grid connection for electricity importation.

CO_2 emission rates from CHP and Boiler operation are given in Table 1. They are generated as the results of the LCA, which has been performed using GaBi 6.0 sustainability software. The total heat demand profile is provided as a building with floor area of 2500m^2 on a sample summer day for UK using CHP Sizer Version 2 Software. Profiles of electricity tariff and CO_2 intensity are shown in Figure 1. The MILP model is implemented using CPLEX 12.4.0.1 in GAMS 23.9 on a PC with an Intel(R) Core(TM) i7-4770 CPU, 3.40 GHz CUP and 16.0 GB of RAM. There are 1,179 equations, 17,815 continuous variables and 17,280 discrete variables and for each run it takes about 0.15*s* CUP time.

Table 1 CO_2 emissions from CHP and Boiler for Ireland and UK

	Natural gas supply	Direct emissions	Total
CHP (*kg CO_2 eq/kwh* electrical output)	0.0396	0.5049	0.5445
Boiler (*kg CO_2 eq/kwh* thermal output)	0.0186	0.2923	0.3109

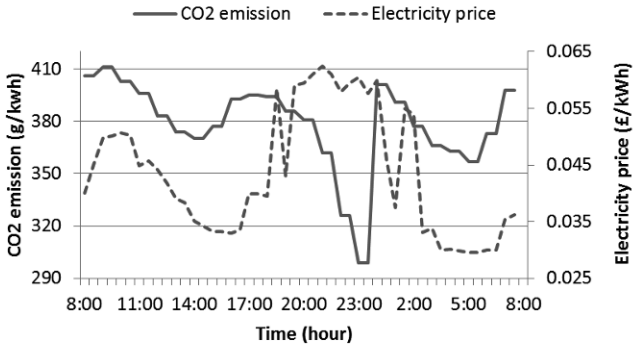

Figure 1: Electricity tariff and CO_2 intensity of UK for Aug 17th, 2013 (Balancing Mechanism Reporting system, 2014 and Earth Notes, 2014)

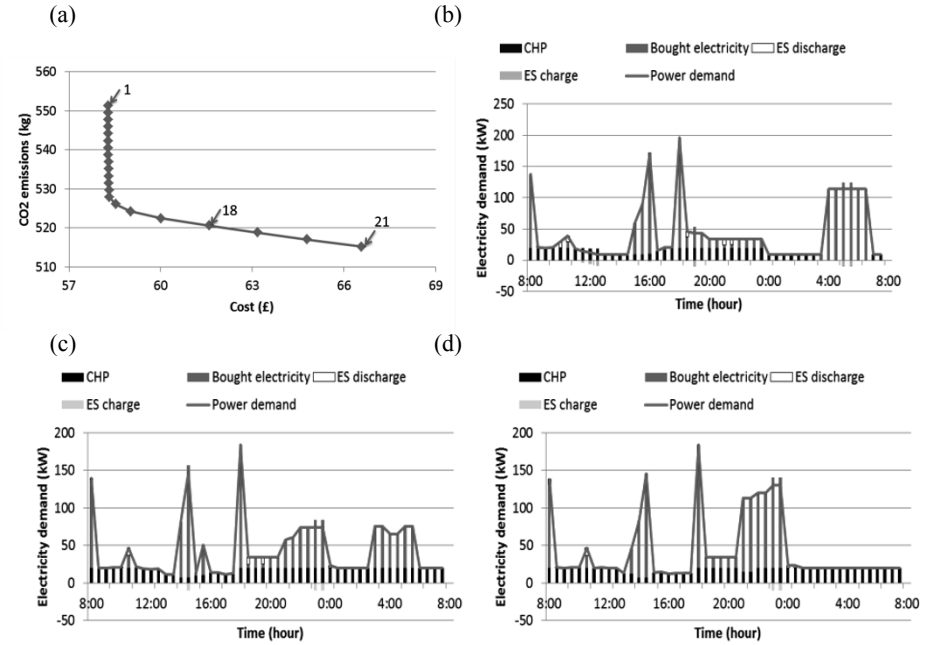

Figure 2: (a) Pareto curve for cost and CO_2 emissions and (b-d) electricity balances for points 1, 18 and 21

Figure 2 presents the optimal results and the Pareto curve for cost and CO_2 emissions is given in sub-figure (a). The differences between the maximum and minimum values for cost and CO_2 emissions are 12.5% and 7.0% individually. Since 20 intervals between the maximum and minimum values are considered in this example, there are 21 points in the curve. For the first 15 points, CO_2 emissions decrease dramatically from 552 to 525 kg while the cost difference is about £1. After point 15, it drops gradually to 515kg by point 21. Sub-figure (b)-(d) present the energy balances of the three points marked in sub-figure (a), points 1, 18 and 21. For point 1 and 21, the cost and CO_2 emissions are minimised individually without considering the other aspect, while point 18 gives the optimal scheduling based on the trade-off between the two conflicting objectives. The electricity peak hours of point 1 appear in the early morning where electricity tariff is low as shown in Figure 1. On the other hand, the electricity peak hours for point 21 are

in the night where CO_2 emission intensity is low. The peak hours move to the midnight to have a trade-off between the two objectives for point 18. CHP generator is not operated constantly mainly because of the low heat demand in summer and CHP cannot provide more electricity unless the corresponding heat generation can be consumed or stored in thermal storage. Thermal storage works here to balance the CHP generation over the day but still it cannot store heat more than its designed capacity.

5. Concluding remarks

An MILP model has been proposed to schedule the energy consumption within smart homes with microgrid on a daily basis to obtain the daily schedule. Both environmental emissions and economic cost can be minimised with trade-off between them by a multi-objective optimisation with ε-constraint method. The model has been implemented on an illustrative example for UK, where twelve domestic electrical tasks are scheduled together with DER operation in the shared microgrid. The obtained Pareto-optimal curve between cost and CO_2 emissions can provide guidelines for the customers and authorities to decide demand side energy management and DER operation. Also, scheduling of the DER operation and electrical tasks depend heavily on the energy demand patterns.

Optimization of Pressure/Vacuum Swing Adsorption with Variable Dehydration Levels for Post Combustion Carbon Capture

Karson T. Leperi, Randall Q. Snurr, Fengqi You

Northwestern University, 2145 Sheridan Road, Evanston, IL, 60208 United States

Abstract

In this paper we address the design and optimization of a pressure/vacuum swing adsorption (P/VSA) process for the post combustion capture of CO_2. HKUST-1, Ni/DOBDC, zeolite 5A and zeolite 13X are considered as potential adsorbents for the P/VSA system. A detailed simulation is set up and then optimized using a nondominant sorting genetic algorithm. This is coupled with an upstream dehydration unit to allow the impact of the presence of water to be analysed. The results show that for both the dry and wet flue gas, zeolite 13X has the lowest overall cost for capturing CO_2, with a cost of \$22.91 / ton of CO_2 captured and \$23.38 / ton of CO_2 captured, respectively.

Keywords: P/VSA, Metal-organic framework, carbon capture.

1. Introduction

In 2010, 30.6 gigatons of CO_2 were emitted into the atmosphere worldwide, with around 38% of the emissions in the US coming from the generation of electricity (IEA 2011). To reduce these emissions, there are substantial efforts to develop renewable energy technologies with minimal net carbon emissions. However, over the next few decades, fossil fuels will continue to play an important role in our energy mix (Anderson et al., 2004). There is, therefore, significant interest in reducing the CO_2 emissions from existing power plants via Carbon Capture and Storage (CCS). For post-combustion CCS, the processes most suitable are absorption (Rao et al., 2002), membranes (Ho et al., 2008), algae (Gong et al., 2014), and adsorption (Haghpanah et al., 2013). Among them, Pressure/Vacuum Swing Adsorption (P/VSA) is perhaps the most promising due to its higher performance and lower energy requirements compared to the other technologies (Zhao et al., 2013). This has led to increased interest in P/VSA cycles for carbon capture. However, in the majority of recent publications, the inlet flue gas stream is assumed to be dried before the carbon capture process. In reality, flue gas from power plants is usually saturated with water, containing around 3-5 mol%.

There are a few studies that have examined the use of P/VSA for carbon capture from wet flue gas. Li et al. (2008) experimentally demonstrated the effect of water on the performance of a VSA process for carbon capture. The VSA process used zeolite 13X as the adsorbent and consisted of three steps: pressurization, adsorption with the feed gas, and counter-current evacuation. With dry flue gas, the process achieved a recovery of 78.5% and a purity of 69%, with a column productivity of 0.287 kg/hr/kg. When wet flue gas was used, the recovery dropped to 60.4%, the productivity dropped to 0.225 kg/hr/kg, and the purity rose to 72%. This drop in performance was due to water adsorbing on the zeolite, reducing the CO_2 capacity of the adsorbent. In a follow up study, Li et al. (2014) examined the use of a layered bed using zeolite 13X along with

F200 and CDX activated alumina as the desiccant. With the layered bed, they were able to achieve a CO_2 purity of 74.8% and a recovery of 77.6%.

The effect of water on the performance of a VSA process through an optimization perspective has been studied by Krishnamurthy et al. (2014). In their work, they studied the effect water had on the performance of a 4 step VSA process with zeolite 13X. They showed that although the process was still able to achieve the overall goal of 95% purity and 90% recovery, the water increased the energy consumption to 230 kWh/ton and reduced the productivity of the bed to 1.03 ton/m^3/day. This is compared to the dry flue gas case, where the energy consumption was 154 kWh/ton and the productivity was 1.52 ton/m^3/day. They then examined a new two-bed, dual adsorbent process. The first bed contained silica gel and dehydrated the flue gas before feeding the product to the second bed containing zeolite 13X. With this configuration, they were able to achieve a minimum energy consumption of 177 kWh/ton and a productivity of 1.29 tons/m^3/day.

In all of these studies, zeolite 13X has been the adsorbent of choice. However, there exist hundreds, if not thousands, of potential of adsorbents, particularly given the recent development of metal-organic frameworks (MOFs). Recently, Liu et al. (2012) showed that the MOFs Ni/DOBDC and HKUST-1 are able to maintain their CO_2 uptake over a larger range of water loadings when compared to zeolites 13X and 5A.

In this work, we propose an integrated process for the capture of CO_2 from wet flue gas incorporating a dehydration unit, the P/VSA process, and a post-capture compression process to prepare the product for pipeline transportation. In order to overcome the limitations of the Skarstrom cycle, we use a two stage process to achieve the purity and recovery goals of CCS (see Figure 1). This process is then optimized to minimize the total cost, while maintaining the purity and recovery goals. HKUST-1, Ni/DOBDC, zeolite 13X, and zeolite 5A, are evaluated as adsorbents to determine the ideal material for obtaining the lowest overall cost of carbon capture. Three case studies are presented. The first case study determines the maximum purity each material can achieve in a single stage and is used to rank the performance of the materials. The second and third case studies use two stage processes to determine the minimum cost for dry and wet flue gas, respectively.

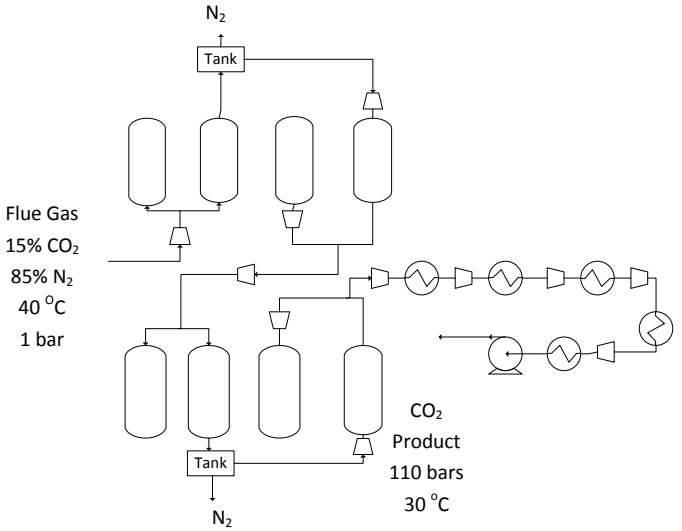

Figure 1. Two-stage P/VSA process coupled with post capture pressurization process.

2. Problem Statement

In this work, we focus on minimizing the total cost of capturing CO_2 from the flue gas of a 30 MW coal power plant. The overall process includes a dehydration unit, the P/VSA process, and a pressurization process. The feed gas is assumed to have a flow rate of 1 kmol/s and to be composed of 15% carbon dioxide, 5.5% water, and the balance nitrogen. This corresponds to the emissions from a 30 MW power plant. While minimizing the cost, the P/VSA process is required to obtain the DOE goals for carbon capture of purifying the flue gas to 90% CO_2 while recovering 90% of the CO_2 fed into the process. For the wet flue gas case study, the 90% purity is on a dry basis.

3. Process Simulation & Optimization

The model is composed of three parts: the process model for the dehydration unit and the post-capture compression, and the mathematical models for the P/VSA process. In all sections, annualized total cost for the system is defined as the sum of the operating costs and the annualized capital costs. The annualized capital cost is the sum of all bare module costs for all equipment multiplied by the capital recovery factor in addition to maintenance costs. The maintenance costs are taken to be 5% of the purchase cost of the equipment. For all equipment, the interest rate is taken as 10% and the life span is 20 years.

3.1. Dehydration Units

Two dehydration technologies were developed: Triethylene glycol (TEG) absorption and cooling and condensation (C&C). In TEG absorption, the flue gas is dehydrated by bringing it into contact with TEG. The TEG is then regenerated through distillation. In C&C, the flue gas is chilled through a refrigeration cycle incorporating Refrigerant-152a. In the cooling process, a portion of the water condenses, which is then separated from the flue gas. At lower levels of dehydration, the C&C is cheaper due to lower capital costs compared with TEG absorption. However, at higher levels of dehydration, the TEG absorption becomes the cheaper technology due to the lower operating costs. It was determined that the water level at which the two technologies are economically equivalent is 0.7 mol% water. Above this value, cooling and condensing is used, while below it TEG absorption is used.

3.2. Material Selection

For this work, four materials were initially evaluated for their potential as CO_2 adsorbents: HKUST-1, Ni/DOBDC, zeolite 5A, and zeolite 13X. For each of these materials, the CO_2 isotherm from the literature was fitted to a dual-site Langmuir model, and the N_2 isotherm was fitted to a single-site Langmuir model. For the wet flue gas case, it was also necessary to have an equation to represent the effect of water on the adsorption of CO_2 and N_2. This adsorption data was taken from the work of Liu et al. (2012). The reduction in CO_2 adsorption based on the adsorbed amount of water was fitted to an exponential function. It was assumed that the decline in performance of the material was only a function of the loading of water on the material. It was also assumed that the N_2 loading experienced a similar reduction as CO_2. For economic calculations, the life time of the adsorbent is assumed to be 5 years.

3.3. P/VSA Process

Except for the determination of the effect of water on the adsorption of CO_2, all of the governing equations, boundary conditions and bed connection equations are the same as in our previous work (Leperi et al., 2014). For determining the effect of water on the performance, both the water isotherm and the reduction in CO_2 uptake were necessary

for each material. Based on the water level in the flue gas, it was calculated how far into the column the water front would penetrate. The performance of the material behind the front was then reduced according to the concentration of water in the flue gas.
In order to solve the system of partial differential equations, they are first spatially discretized. A finite volume method is used to divide the column into 10 sections. The mid points are calculated through the Weighted Essentially Non-Oscillatory scheme (Haghpanah et al., 2013). This system of coupled ODEs is solved using solvers available in MATLAB. For the simulation of the P/VSA, it is assumed the bed is initially saturated with the flue gas. The simulation is then run, where the bed profile at the end of a cycle is the initial condition of the bed for the next cycle. This is repeated until the change in the bed profile between the beginning and the end of the cycle is less than 0.5%. At this point, the bed is assumed to be operating in a cyclic steady state, and the purity and recovery for the process are calculated.

3.4. Post_Capture Compression

For transportation through a pipeline network, it is necessary to compress the CO_2 product to 110 bar. This is accomplished through a 5-stage compressor train with intercooling to compress the stream to 90 bar. At 90 bar, the gas is then cooled and condensed at 22^{o}C. Once the CO_2 is condensed, the stream is then pressurized to 110 bar using a pump.

3.5. Solution Strategy

In order to perform multi-objective optimization on the P/VSA simulation, a nondominant sorting genetic algorithm (NDSGA-II) is employed. For the first case study, the population was set to 40, and the genetic algorithm (GA) was run for 60 generations. For the dry and wet case studies, the population was set to 50 and 55, respectively, and this was run for 100 generations.

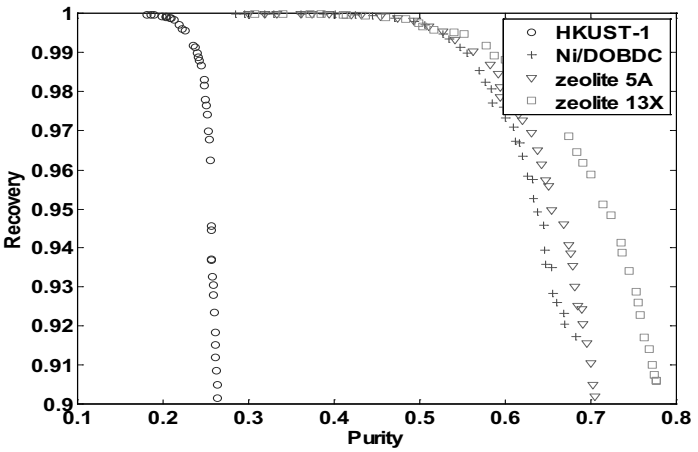

Figure 2. Pareto curves for multi-objective optimization of purity and recovery.

4. Results

4.1. Initial Material Testing

In the first case study, it was desired to determine if any of the materials were able to meet the goals in a single stage. It was also desired to determine if the material would be suitable for a two stage process. For this case study, the purity and the recovery of the

process were optimized for each material. The results from this case study are shown in figure 2.

None of the materials are able to achieve the desired goals of 90% purity and 90% recovery with a single-stage Skarstrom cycle. Thus, with the Skarstrom cycle, it is necessary to use two stages to achieve the purity and recovery goals. It is also apparent that HKUST-1 is the worst performing material of the group, being unable to purify the CO_2 above 27% while maintaining high recovery. This is probably due to its low selectivity for CO_2 over N_2 compared to the other three materials, which were able to achieve over 65% purity in a single stage while maintaining a high recovery. For the case studies below, HKUST-1 was not examined due to its poor performance in a single stage.

4.2. Dry Flue Gas

In this case study, a two stage process is used in order to obtain the desired purity and recovery for CCS. The dry flue gas was assumed to contain 15% CO_2 and the balance N_2. The results from this case study are shown in table 1. From these results, it is apparent that zeolite 13X is the best performing material. Zeolite 13X is able to achieve the desired purity and recovery goals for $3.92 million per year, which is about $ 0.2 million per year less than zeolite 5A and 1.2 million per year less than Ni/DOBDC. When comparing the breakdown of the overall cost, it is apparent that the main difference between Ni/DOBDC and the zeolites is the capital cost. The capital cost of Ni/DOBDC is approximately $600,000/ year more expensive than for the zeolites. This is due to a higher estimated cost for the large scale production of the MOF compared to the zeolites, although it must be noted that this value has a large uncertainty.

4.3. Wet Flue Gas

The results of the wet flue gas case are shown in table 2. From these results, zeolite 13X is again the optimal material, able to capture the CO_2 for $4.08 million per year. For the wet flue gas case, there was no dehydration, with the optimal water level determined to be 5.5%. The capital costs and the post-capture compression costs are roughly equivalent to the dry flue gas case, but the operating costs do increase in the presence of water. This is due to a lower vacuum pressure needed for the depressurization step and purge step to compensate for the reduced performance of the material.

Table 1. Cost break down for minimum total cost for each material for dry conditions. All costs are given in $ million per year.

Material	P/VSA Operating Cost	P/VSA Annualized Capital Cost	Post-Capture Compression Cost	Total Cost
Zeolite 13X	1.45	0.34	2.13	3.92
Zeolite 5A	1.48	0.37	2.32	4.17
Ni/DOBDC	1.95	0.95	2.34	5.24

5. Conclusion

In this paper, the capture of carbon dioxide from wet and dry flue was studied. A non-isothermal P/VSA simulation was used to conduct a GA-based optimization of the overall process. The results of the case studies revealed that the zeolite 13X was the top performing adsorbent among 4 materials studied and is able to capture CO_2 at a total cost of $22.91 / ton for the dry flue gas scenario and $24.02 / ton for the wet flue gas scenario. The results also showed that minimal dehydration occurred for the optimal results, with all three materials having dehydrated water levels above 5%.

Table 2. Cost break down for minimum total cost for each material for wet conditions. All costs are given in $ million per year.

Material	P/VSA Operating Cost	P/VSA Annualized Capital Cost	De-hydration Cost	De-hydrated Water Level	Post-Capture Compression Cost	Total Cost
Zeolite 13X	1.66	0.29	0	5.5%	2.13	4.08
Zeolite 5A	1.74	0.34	0.003	5.38%	2.34	4.42
Ni/ DOBDC	2.00	0.96	0	5.5%	2.38	5.34

Abstract

Drilling scheduling is a challenging task with considerable financial impacts, for which we develop a nonconvex MINLP formulation in this study. We consider the dynamics of the system and well as the economic forecasts and constrains. We develop a toolbox using genetic algorithm and an industrial reservoir simulator to address this important problem. Our method provides detailed information for both short and long-term decisions. It determines the optimal drilling order, time and location, well types and hence the number of new injector and producer wells, and finally the production and injection flow rates. Our results indicate that we can decrease the rate of return (R.O.R) of an exploitation project by optimally scheduling the drilling activities.

Keywords: Drilling schedule, optimal well placement, genetic algorithm, MINLP

1. Introduction and background

As the industrial horizons are constantly advancing, the worldwide energy demand continues to remain as the prime concern. Amongst other resources, exploitation of oil and gas fields plays the paramount role in fulfilling the energy demand (Gupta and Grossmann 2012). This expensive and complex activity requires comprehensive study of the different technical and financial aspects to determine the most efficient production and expansion plan (Tavallali and Karimi 2014). The most risky and costly step is the drilling stage, where a well of few inches diameter should be drilled in a large formation for several kilometers to produce oil and gas (Tavallali et al. 2013). The technical issues are more pronounced when a drilling company needs to drill many wells in a limited time using a few number of drilling rigs. In such cases, complex financial and technical issues related to the subsurface and surface elements and energy market arises; in the heart of them is the drilling scheduling and placement problems (Afshari et al. 2011). These problems are inherently, dynamic, multi period, highly combinatorial and complex.

Apart from the fact that multiphase flow in the porous underground reservoirs is dynamic, drilling each well takes some time and that also adds to the dynamic features of drilling problems. Firstly, wells act as energy providers (injectors) or sinks (producers) in a field under injection drive mechanisms. Hence, their production

(injection) history or future plan can alter the ultimate hydrocarbon recovery from the field. Secondly, wells are not individual entities in a field with no interactions, and in contrast, they communicate through the fluid in the subsurface formation and even the surface network. Therefore, subsurface dynamics can change drastically when a new well is drilled. Unfortunately, predicting all these changes at the initial design stage is not a simple task; there are many nonlinearities with seen and unseen uncertainties (Wang et al. 2012). Clearly scheduling the drilling activities is of utmost importance in such stage. On one hand, the delay in drilling a well can increase the rate of return (R.O.R), and on the other hand, early drilling can add to the maintenance cost without production at the nominal level. Both of which can deteriorate the financial gains.
In the current research, we follow our previous studies (Tavallali et al. 2013, Tavallali et al. 2014) on a different track. In the remaining of this article, we formulate a deterministic drilling scheduling problem, and then employ an industrial reservoir simulator in a black-box optimization structure to develop a user-friendly toolbox. Afterwards we test our approach through a comprehensive case study and analyze its outcomes. Finally, we conclude the study with a concise discussion.

1.1. Problem Definition

A drilling project over a planning horizon of H years in an oil and gas field under water injection mechanism is to be optimally scheduled. The reservoir can be of any shape, and the target wells can be of any types. Here, the problem can be summarized as:
Given:
(1) The geological and petro-physical data of the reservoir and its fluids, (2) Operational data (including the BHP, THP, and throughput limits), (3) the production horizon, as well as economic forecast and number of available drilling rigs over this horizon, (4) a list of potential drillings and their well types.
Determine:
(1) The drilling schedule (where, when and what to drill), and (2) the flow rate plan at each wellhead.
Targeting to maximize the net present value (NPV).
By assuming:
(1) All given data are deterministic. For instance, number of drilling rigs can change over time; however, they should be scheduled from the beginning. (2) Each candidate well follows only one trajectory and does not intersect with other existing or potential wells. (3) No drilling is permitted in the last period of time horizon. (4) Each drilling does not take longer than a given time period.

2. Modeling

Layers related to perforation are predetermined so our variables are just for the top side of wells at the surface. Then this can include both deviated and vertical wells.
Let the time domain be discretized into T time periods of arbitrary length of Δh_t, and the spatial domain into the cubic cells of I, J and K numbers in x, y and z directions of Cartesian system with lengths of $\Delta x_i, \Delta y_j$ and Δz_i (i =1, 2, …, I, j =1, 2, …, J and k =1, 2, …, K). We combine the spatial indices into one index $n=i + (j\text{-}1)I + (k\text{-}1)IJ$. Each well is recognized by the cell at its bottom hole and its trajectory is fixed, therefore we can refer to the well with the wellbore at n cell as well n. We define the following two subsets:
IW=[n | injector well with the bottom hole at cell n]
PW=[n | producer well with the bottom hole at cell n]

2.1. Drilling decisions

We define the following two main binary variables

$$y_n^t = \begin{cases} 1 & \text{the well at cell } n \text{ is drilled at the end of period } t \\ 0 & \text{otherwise} \end{cases}$$

$$z_n^t = \begin{cases} 1 & \text{the well at cell } n \text{ can produce or inject at period } t \\ 0 & \text{otherwise} \end{cases}$$

Logical constraint**:** The above two binaries are tightly related to each other:

$$\sum_{t=0}^{t=t'-1} y_n^t = z_n^{t'} \qquad t' > 0 \qquad (1)$$

This ensures that a well cannot simultaneously be active and be at the drilling phase. Number of drilling is bounded with drilling rigs at each time step (DR^t):

$$\sum_n y_n^t \le DR^t \qquad t < T \qquad (2)$$

Drilling budget constraint: Drilling can only be done when the drilling budget DB^t can support the costs:

$$\sum_n y_n^t C_{d,n}^t \le DB^t \qquad t < T \qquad (3)$$

Where $C_{d,n}^t$ is the drilling cost of well n and might vary over depending on the time of drilling.

2.2. Flow management and well selection

The multiphase flow inside a reservoir is represented via partial differential equations that relate the phase flow rates to the reservoir dynamic variables (saturation, pressure and gas solubility). Due to their nonlinear and complex nature, they are usually solved numerically after they are converted to a set of algebraic equations. Let us refer to them as:

$$h_n^t(q_{o,n}^t, q_{g,n}^t, q_{w,n}^t, V_n^t, r_n) = 0 \qquad t > 0 \qquad (4)$$

where $q_{o,n}^t$, $q_{g,n}^t$ and $q_{w,n}^t$ are the oil and water flow rates from well n (They are rendered as zero for cells that are not existing or potential wells), and V_n^t shows other dynamic variables, and r_n shows system parameters (geological or petro-physical).

Well selection constraint: A well is active only if it is drilled beforehand (hence $z_n^t = 1$), and once active its total (oil + water + gas) flow rate cannot exceed an upper bound (Q_n^t):

$$0 \le q_{o,n}^t + q_{g,n}^t + q_{w,n}^t \le z_n^t Q_n^t \qquad (5)$$

Field-wide flow constraints: Field oil production and water injection cannot go beyond the available surface capacities (C_O^t and C_i^t respectively) for these fluids; furthermore, oil production cannot exceed the oil demand (D_O^t):

$$\sum_{n \in IW} q_{w,n}^t \le C_i^t \qquad t > 0 \qquad (6)$$

$$\sum_{n \in PW} q_{o,n}^t \le \min(C_O^t, D_O^t) \qquad t > 0 \qquad (7)$$

Although more capacity constraints for other producing phases are possible, here we only utilized the one for oil production.

Objective Function: Our objective function comprises the oil and gas selling profits and production and injection costs, and finally the drilling costs:

$$NPV = \Sigma_{t>0} \frac{\left\{\Sigma_{n\in PW}\left(q^t_{o,n}C^t_{o,n}+q^t_{g,n}C^t_{g,n}\right)\Delta h_t - \Sigma_{n\in PW}\left(q^t_{w,n}C^t_{w,n}\Delta h_t + y^t_n C^t_{d,n}\right)\right\}}{(1+\beta)^{h^t/365}} \quad (8)$$

Where $C^t_{g,n}$ and $C^t_{o,n}$ are the oil and gas (revenue – production cost) ($ per unit flow), and $C^t_{w,n}$ is the water injection / production cost ($ per unit flow), and β is the annual discount factor. This completes our MINLP model (**G**), which is nonlinear and nonconvex.

It is necessary to mention that our model can select the most promising candidates and reject the rest. Hence, it is a well placement and scheduling model.

3. Solution strategy and the toolbox

Reservoir simulators effectively solve the governing equations represented by eqn. (4) and are industrially accepted. Having access to the underlying codes and equations of the reservoir simulators can provide much flexibility. Unfortunately, it is not always the case. These simulators serve the best option for black-box optimization approach. Furthermore, Model (**G**) is a nonconvex model and hence is a good candidate for evolutionary solution methods. Hence, in this study we utilized ECLIPSE reservoir simulator of Schlumberger and linked that with genetic algorithm (GA) of MATLAB 2014 that could handle binary variables.

Using the nature of GA, we (1) limit the optimization variables to y^t_n only, and (2) divide the constraints into two parts: drilling and flow constraints. GA uses the drilling constraints to suggests a new individual (y^t_n), and we use eqn (1) to generate z^t_n. ECLIPSE is a script-based software, therefore we translate these binaries and the flow constraints into a set of software keywords. This determines the drilling schedule and prepares required script files to communicate with ECLIPSE. Once ECLIPSE simulates the dynamic production horizon, it returns $q^t_{o,n}$, $q^t_{g,n}$ and $q^t_{w,n}$. Afterwards MATLAB can use this information to calculate NPV. Then it follows the structure of evolutionary methods to declare the termination.

The user provides the reservoir simulation file (without the well control section), list of potential wells (with their trajectory and type) as well as parameters mentioned earlier. The rest is handled automatically.

In what follows we compare the efficiency of our toolbox with a built-in key word of ECLIPSE called QDRILL. QDRILL uses a list of potential wells and activates them sequentially once the targeted production is not met.

4. Example

A 2823m × 6502.4m × 5.56m anisotropic reservoir (with *I*=30, *J*=44 and *K*=1) has been producing oil and gas for the past 380 days. These geological data are obtained from a section of upscaled SPE10 (Christie and Blunt 2001). It has three active producers (P1-P3) and five injectors (I1-I5). Three new producers (NP1-NP3) and one new injector (NI1) are suggested to be drilled for the next 2160 days. We employed 18 periods of 120 days each. All wells are vertical and the drilling cost is considered as 0.3 M$ per well. Their drilling orders and flow rates should be determined.

We define four different scenarios: (1) base case: with no new drillings, (2) QDRILL: when this keyword of ECLIPSE is used and there are no restrictions on the minimum

well flow rates, (3) QDRILL_LB_Flow: similar to scenario 2, however with imposed lower bounds on the well flow rates (at least 20 m^3/day), and (4) optimization via GA. Table 1 summarizes the results.

Table 1. Comparison of the drilling scheduling scenarios

Scenario	Base case	QDRILL	QDRILL_LB_Flow	GA
NPV (M$)	7.131	6.934	6.540	7.340
Drillings	-	NP1-NP3 and NI1 (120 days)	NP1-NP3 and NI1 (120 days)	NP1 (120 days)

This table shows that our toolbox outperforms the other scenarios. The QDRILL could not even improve the base case. This keyword does not consider the drilling (and operation) costs and is activated whenever the production falls, hence is myopic and does not predict the future efficiently. Consequently, it has opened four wells in a same time. In contrast, our toolbox learns well from different solutions. It may even tolerate deviating from the maximum possible production for a period; however, it considers the overall NPV over the entire horizon. Hence has drilled only one well.

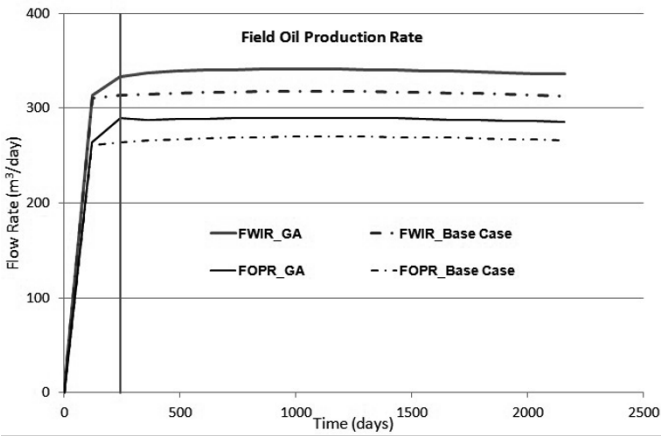

Figure 1: Field flow comparison between the base case and GA solution (FOPR: Field Oil Production Rate, and FWIR: Field Water Injection Rate), the vertical line shows the time of drilling NP1

Since the base case is in the second rank, we use that for the next detailed comparison with our solution. Figure 1 represents this comparison. Although our solution leads to higher field water injection rates, it also provides higher oil production rate. It reveals that our solution has instructed higher capital investment (a new drilling) and operation costs (higher injection cost); however, both orders have supported higher production and hence higher NPV. Clearly, this reduces the ROR of the project and motivates the drilling. This shows the utility of our toolbox.

5. Conclusion

In this study, we developed a versatile and novel toolbox based on the application of evolutionary method to help the management team with the drilling scheduling decisions. Not only it considers the subsurface dynamic, but also it analyzes the

economic concerns of the energy market. Hence, besides scheduling the drillings, it provides the throughput profiles. The case study clearly showed that our method could outperform an industrial software for the same purposes. The main reason is the differences in inspecting the time horizon. Ours considers the entire domain, and the numerical simulator packages inspects only one period at a time.

Our work tackled the large size problem of drilling scheduling by determining the time, location and type of new drillings. However, two concerns remains, one is the scalability of this approach, and the other is optimal planning of the flow rates (Bellout et al. 2012). The former is the nature of such dynamic and large size problems. We are currently addressing the latter.

Acknowledgments

Our collaborations and discussions with Mr. David Baxendale and Dr. Teo Kwong Meng have been very useful and have made indirect contributions to this article.

Abstract

The aim of this work was to develop a method for preliminary evaluation of the ratio between the investment and amount of solar thermal energy, integrated into processes with heat demands. A targeting method has been developed for maximising the amount of integrated thermal energy collected by the required size of solar collector surface area, as well as the size of heat storage. The size of the solar collector area and the heat storage is based on the number of consecutive sunny days and shady days. In the first step the data of the heat demands were collected that could be potentially satisfied from solar sources. In the second step the amount of heat per surface area unit was determined as gained during sunny days (area-specific heat). The collector system and geographical characteristics were taken into account when determining the amount of heat gained. The temperature driving forces were taken into account for heat exchanges between the solar collector medium and storage, and also between the storage and process demands. The required collector surface area has been defined as the heat demands for the sunny and shady days together divided by the product of the area-specific heat of a given collector and the number of sunny days at a given geographical location. The proposed targeting method can be applied for the pre-screening of alternatives in order to eliminate economically non-viable solutions before performing more detailed system synthesis. An illustrative case study has been performed in order to evaluate the applicability of the developed method.

Keywords: solar thermal energy, preliminary analysis, heat integration, storage capacity, solar panel, solar panel area.

1. Introduction

Compared to the annual worldwide energy consumption $5.35 \cdot 10^{11}$ GJ (BP, 2014), a vast amount of solar energy reaches the surface of the planet, $2.7 \cdot 10^{15}$ GJ (Smil, 2006). Despite the enormous differences in magnitude, and a wide-range of promising energy sectors (Lauterbach, 2014), only small amounts of energy demands are covered by solar energy, which indicates the complexity of integrating this type of renewable resource. An overview of the current state on solar collectors and thermal energy storage within solar thermal applications can be found in Tian et al. (2013). One of the major difficulties for solar integration is the fluctuations and the disparities of demand, and the solar irradiation, i.e. the available solar energy (Atkins et al., 2010). A state-of-art regarding the solar thermal technology and strategic research priorities can be found in European Technology

Platform on Renewable Heating and Cooling (2013). Nowadays numerous solar collectors with different characteristics and prices are available. Detailed analyses for all the available integration can be time and resource consuming. Therefore, a preliminary selection with preliminary assessment can decrease the resource requirements when the detailed planning of an energy system is performed only by focusing on potentially appropriate systems. Only those solar thermal integration systems that have promising ratios between the integrated amount of energy from solar source and investment should be considered for further planning.

2. Methodology

The integration system has two essential parts namely, the collector system and the storage. The aim of the first one is to produce as much heat as possible, whilst the second serves for storing heat for later usages, when there is no available energy from the solar source. The sizes of both should be planned carefully in order to allow the highest possible integration, yet still the sizes of both should be reasonable. The performance of the integration system would be affected by the days of sunny periods and days of shady periods. During the days of sunny periods the collectors' area should be large enough in order to gain the required amount of heat for both types of integrations: i) direct, during the sunny days and ii) indirect, during shady days and nights. The storage size should be high enough in order to cover the heat demand during shady day periods and for the nights, when no direct heat integration is possible due to the lack of solar irradiation.

2.1. Estimation of solar collector area

The ratio between the sunny days and consecutive shady days indicates the required speed of collecting the solar thermal energy in order to cover heat demand for this period. The solar collector area has been determined by the following steps:

Step 1. Determining the amount of heat demand within one day, which could be potentially covered by solar thermal energy. The limiting maximal temperature of capture should be taken into account in order to determine the potential heat enthalpy that can be covered by solar thermal energy $\Delta \dot{H}^{D\text{-}STE}$. The demands with higher temperature requirements will be covered by other external sources of energy. The potential amount of heat demand ΔQ_{ti}^{D-STE} that can be covered from solar thermal energy is determined by multiplying the enthalpy flow $\Delta \dot{H}_{ti}^{D-STE}$ by the time-horizon $t_{ti\text{-}1} - t_{ti}$ at each time interval separately by applying Eq. 1.

$$\Delta Q_{ti}^{D-STE} = \Delta \dot{H}_{ti}^{D-STE} \cdot \left(t_{ti\text{-}1} - t_{ti}\right) \tag{1}$$

Step 2. Determining the amount of heat potentially gained during a sunny day per unit of area. Calculating the amount of heat gained from solar source is based on average values. The data applied has been the average daily clear sky solar irradiation determined for each month separately. The sampling time of irradiation measurement has been short, usually around 15 min. The measurement of solar irradiation has been performed each day at the same time, therefore the starting and ending time boundaries of time intervals between two measurements are the same. The average of the irradiations of all of the months is determined within each time interval for obtaining the annual representative sunny day. The same procedure is applied when determining average ambient temperature within a time interval in order to obtain temperature profile of an annual representative sunny day. The amount of heat gained per unit of the solar thermal collector can be determined from the determined representative sunny day for clear sky daily irradiation. The captured amount of heat is firstly determined within each time interval separately and then summed-up over the whole day. The amount of heat from solar source within each time

interval is defined by applying Eq. 2, where ΔQ_{ti} is the amount of heat gained within time interval t_i, where A is the area of the solar collector, G_{ti} is the averaged solar irradiation of clear sky within the time interval, η_0 optical efficiency, a_1 and a_2 are thermal loss coefficients for the solar collector system, $T^{C,in}$ the inlet and $T^{C,out}$ the outlet temperatures of the media flowing through the collector system, T_{ti}^{A} is the average ambient temperature within t_i, with $t_{\text{ti-1}}$ and t_{ti} being the time boundaries of the time interval.

$$\frac{\Delta Q_{ti}^{\text{STE}}}{A} = \bar{G}_{ti} \cdot \left(\eta_o - \frac{a_1 \left(\frac{T^{C,out} + T^{C,in}}{2} - T_{ti}^{A} \right) + a_2 \left(\frac{T^{C,out} + T^{C,in}}{2} - T_{ti}^{A} \right)^2}{\bar{G}_{ti}} \right) \cdot \left(t_{\text{ti-1}} - t_{\text{ti}} \right) \tag{2}$$

Step 3. Determining the required amounts of heat that should be collected during one sunny day in order to cover all the demands set within Step 1

This calculation is based on the number of consecutive sunny and shady days. The ratio $n^{\text{all/sun}}$ between all days n^{all} (sunny and shady days together) and the number of sunny days n^{sun} is determined in order to obtain information about the number of days of heat demand for which the heat should be collected within one day. For example, if the design is made typically for two sunny days followed by three shady days, the solar thermal energy integration system should ensure enough heat for five days demand. However, as there are only two sunny days available for gaining the solar thermal energy, the solar collector system should be able to collect heat demand for $n^{\text{all/sun}}$ =5/2 = 2.5 days (Fig. 1).

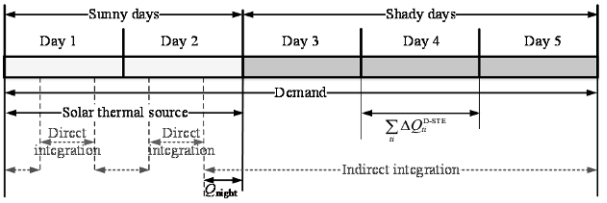

Figure 1: Basis for determining a solar thermal collector's area

Step 4. Determining the solar collection area

The solar collection area requirement can be set after the heat requirement is determined regarding the amount of heat collected during one sunny day. The area calculation is established by calculating the ratio between heat that should be collected during one sunny day and the average amount of heat potentially collected during one sunny day per unit of area (Eq. 3), multiplied by the ratio $n^{\text{all/sun}}$:

$$A^{SC} = \frac{\sum_{ti} \Delta Q_{ti}^{D-STE}}{\sum_{ti} \frac{\Delta Q_{ti}^{\text{STE}}}{A}} \cdot n^{\text{all/sun}} \tag{3}$$

2.2. Estimation of storage size requirement

Another essential part of the integration system is the storage. The estimation of the storage size is based on the previously developed approach of consecutive numbers of sunny and shady days. The storage capacity should be large enough to cover heat requirements for all of the shady days expected plus the night Q_{night} of the last sunny day, which cannot be covered by direct integration of solar thermal energy. Additionally, the heat losses should also be considered for the time period of storing the heat. Therefore, the storage size is determined from Eq. 4, where Q_{st} is the amount of heat that needs to be stored, t_{sh}^{D} is the number of consecutive shady days, t^{sun} is the number of sunny days, and $Q_{oss,day}$ is the average heat loss during one day.

$$Q_{st} = t_{sh}^{D} \cdot \Delta Q_{ti}^{D-STE} + Q_{night} + \left(t_{sh}^{D} + t^{sun}\right) \cdot Q_{loss,day} \tag{4}$$

A cascade for heat demand excluding the demand covered by direct integration of solar thermal energy has to be performed in order to determine the amount of heat required during a sunny day. Therefore, the amount of heat stored during a sunny day can also be observed. Based on this observation, the maximal heat capacity of the storage during a sunny day can be determined. This capacity has to be ensured, additionally to the capacity required for shady days. Therefore, the size of the storage should be increased by this required capacity. In addition to process demand, the preliminary calculation of storage vessel surface area is required in order to determine the heat loss during a day. The storage size depends on the amount of heat stored, the specific heat and temperature ranges of the media within the storage. The storage size is initially determined without considering heat loss. The heat losses can be determined after obtaining the initial surface area of the storage. When heat losses are available, the storage size estimation is performed again, with the amount of heat demand being increased by the amount of heat loss (Eq. 5).

$$V_{st} = \frac{t_{sh}^{D} \cdot \Delta Q_{ti}^{D-STE} + \left(t_{sh}^{D} + t^{sun}\right) \cdot Q_{loss,day} + Q_{night}}{cp \cdot \rho \cdot \left(T^{s,up} - T^{s,lo}\right)} = \frac{Q_{st}}{cp \cdot \rho \cdot \left(T^{s,up} - T^{s,lo}\right)} \tag{5}$$

3. Illustrative Case study

3.1. Estimation of solar collection area

Step 1. For calculation of potentially covered heat demand the solar collector system's upper and lower temperatures should be specified, in this case study between 80 and 120 °C.

Table 1: List of streams after heat recovery as input data (after Perry et al., 2008)

Stream	Temperature, °C		ΔH,	Type	CP,	Time interval	
	Supply	Target	kW		kW/°C	Start, h	End, h
Sanitary water 1	25	55	17.3	Cold	0.576	20	24
Laundry	55	85	18	Cold	0.600	20	24
BFW	33	60	12	Cold	0.446	0	24
Sanitary water 2	25	60	15	Cold	0.429	6	17
Sterilisation	82	121	34.1	Cold	0.874	20	24
Swimming pool water	25	28	23.1	Cold	7.700	6	15
Cooking	80	100	32	Cold	1.600	6	20
Heating	18	25	41.1	Cold	5.864	0	24
Bedpan washers	21	121	5	Cold	0.050	6	17
Space heating	15	25	88	Cold	8.800	0	24
Hot water base	15	45	25	Cold	0.833	0	24
Hot water day	15	45	65	Cold	2.167	6	20

Only one heat transfer is performed when the direct way is used, whilst for indirect heat integration the heat transfer is done twice. For targeting purposes the indirect heat transfer is considered, therefore the minimal temperature difference required for feasible heat exchange is considered twice. In this case study the required minimal temperature difference was assumed to be 10 °C for both heat transfers. Therefore, the maximal outlet temperature from the collector was 120 °C and from the storage 110 °C. Using the stream from storage a heat demand at 100 °C can be covered. Whilst the demand that could be potentially covered from the solar source of energy directly was set at 110 °C.

The heat demands below 90 °C can be covered by solar thermal energy in order to ensure the required temperature difference between the supply stream and demand. After obtaining the potential enthalpy flow-rate within each Time Slice separately, the amount of heat that can be covered from a solar source of energy can be determined by Eq. 1. Table 2 presents the solution for Time Slices separately and the sum. As can be seen in Table 2, the amount of heat that can be potentially covered from the solar source of energy is 5,765.4 kWh, and it represents 95.4 % of all demands for a day, which is 6,040.9 kWh.

Table 2: Determining the amount of heat demand that can be potentially covered by solar source

	TiSl/h				
	0-6	6-15	15-17	17-20	20-24
H^{STE} /kW	166.1	295.9	265.6	247.1	208.4
Q^{STE} /kWh	996.5	2,663.1	531.1	741.2	833.4
				Total	**5,765**

Step 2. The average potential of gaining heat within one day is determined based on an inlet temperature of the collector at 80 °C and the outlet temperature of the stream from the collector at 120 °C. The amount of heat gained during each time interval can be determined. After determining this amount of heat within each time interval separately by Eq. 2, it is summed up over a whole day. The data for solar irradiation was taken from GeoModel Solar (2014) for Veszprém, Hungary. The daily amount of heat gain during a typical sunny day is 3.12 kWh/m^2.

Step 3. When observing the data of sunny and consecutive shady days (e.g. Eumet, 2014-Siófok station) it could be seen that the more common ratio $n^{all/sun}$ is usually between 1.25 (representing four sunny days and one shady day) and 3 (which represents one sunny day followed by two shady days). Therefore, different scenarios are considered in the following analysis. It should be noted that the higher is the ratio $n^{all/sun}$ the larger is the solar collector area requirement. Therefore, for the final decision about the solar collection size (and consequently also the storage size) a trade-off between the number of shady days covered from solar source and the required investment has to be taken into account.

Step 4. The final solar collection area is determined for three different ratios $n^{all/sun}$, namely for 1, 2 and 3 (Table 3). The first results present the area requirements if no heat is stored for shady days.

Table 3: Required area of solar collectors for different time periods of storage

Ratio	1 d	2 d	3 d
A^{SC}/ m^2	1,853.8	3,707.7	5,561.5

3.2. Estimation of storage size

The storage sizes were determined for three different time periods of storing heat. The temperature range of the storage operation was assumed to be between 70 and 110 °C. The heat demand that can be covered from a solar source of energy during one day had already been determined and was 5,765.4 kWh. The amount of directly-integrated solar thermal energy should be evaluated in order to enable further steps when estimating storage size. The required enthalpy flow from storage ΔH_{STE} for covering the heat demand during sunny days was determined as the difference between the required enthalpy flow and the direct enthalpy flow from solar collectors. The required amount of heat ΔQ_{STE} could be obtained by multiplying the enthalpy flow and the time horizon of the interval. For the heat demand, which cannot be covered from solar sources of energy, a constant available utility ΔH_{HU} should be utilised. The initial volume of storage V^{init} is firstly determined where the heat losses are neglected. The surface area of storage is determined with considering a cylinder shape with radius 2.5 m and the height determined from the

initial volume. However, as the heat is stored within all sunny days and all shady days, therefore, the total heat loss for different scenarios is determined by multiplying the heat loss over one day by the number of all days. Finally, the storage volume V^{st} is determined by also considering the heat losses. A comparison between initial and final storage is made, and as can be seen the difference can be up to 5.664 m^3 (2 %).

Table 4: Determining storage size

	1 d	2 d	3 d
V^{init}/m^3	107.46	189.82	272.18
A^{st}/m^2	125.21	191.10	256.99
Q^{loss_1day}/kWh	64.384	98.2657	132.1465
Q^{loss_tot}/kWh	128,768	294,7971	528,586
V^{st}/m^3	108.374	192.625	277.844
V^{st}- V^{init}/m^3	0,914	2,805	5.664

4. Conclusions

The methodology presented in this paper can be applied for preliminary analysis of the available collector systems in order to perform the selection of potentially promising systems that should be further analysed in detail. The analysis is simple enough and can be performed quickly. The methodology has been tested on an illustrative case study. Further analysis is under way in order to evaluate the scope of validity regarding the approach.

Abstract

Nitrogen can be recovered from the liquid fraction of biogas digestate by air stripping in order to make concentrated fertilizers which can be transported more efficiently from an agricultural area with manure nitrogen surplus to an area where it can replace inorganic fertilizers. The product is ammonia sulfate, as sulphuric acid absorption is used to produce the concentrate in a liquid form. Process simulations are carried out to investigate the operational and capital costs of a process treating 30,000 kg/h liquid digestate. Two designs with and without NaOH addition, respectively, are compared. Increased pH of the liquid digestate by NaOH addition favors NH_3 over NH_4^+, and hence increases process efficiency reducing capital costs, but increases the operational costs three times due to the cost of NaOH. Further, the total treatment cost is highly dependent on potential sales price of ammonia sulfate. Without NaOH, the treatment cost is 3.2-7.6 US$/m^3 and with 210kg/h NaOH the treatment cost is 5.2-9.6 US$/m^3.

Keywords: air stripping, ammonia recovery, biogas digestate, process simulation.

1. Introduction

Agriculture and the global society have a growing interest in safe and environmentally sustainable manure handling systems. Sustainable manure handling reduces local and regional pollution such as odour emissions, nutrient leaching and eutrophication as well as greenhouse gas emissions on the global scale. Biogas treatment of manure is one way to recover resources by production of renewable energy and hence reduce GHG-emissions. Furthermore, odour emissions are reduced.

Biogas digestate contains nitrogen (N) and phosphorus (P) of high fertilizer value. The N and P can be recovered and substitute inorganic fertilizers made from fossil fuels. In order to obtain a balanced fertilizer composition based on plant uptake and soil properties, separation of N and P is also of interest. P is mainly attributed to the solid fraction, where the N is mainly attributed to the liquid fraction dependent on the method of separation (Møller, 2000).

Nitrogen can be recovered from the liquid fraction by air and steam stripping followed by acid absorption. The product from the acid absorption will be $(NH_4)_2SO_4$. Air to liquid ratio, temperature and pH can be adjusted for improved mass transfer as shown for biogas digestate (Gustin & Marinsek-Logar, 2011) and swine manure waste water (Liao et al., 1995). Chemical reactions and phase transfers involved comprise both acid/base and vapour/liquid equilibria, and elevated temperature and pH can increase the amount of free ammonia in the air stripping section and hence improve nitrogen

recovery and reduce equipment size (Pryds, 2012). However, the chemical usage to raise pH increases the operational cost of the process, where lower pH increases the equipment size making the capital costs higher. The choice of the mentioned parameters can be analysed with respect to economic potential of the process, which will be done in this paper. The work simulates a plant treating 30,000 kg/hour (kg/h) liquid fraction of biogas digestate with a minimum recovery of 95% N at 90°C, which is a recovery obtained in full scale tests of an ammonia air-stripper (Hoffmann, 2011). A comparison between performance with and without addition of NaOH will be done in order to evaluate the impact of chemical dosage on operational and equipment costs. Additionally, the simulations will be optimized with respect to energy consumption as extensive heat recovery and air recycle are carried out to reduce product treatment costs.

2. Materials & Methods

The liquid biogas digestate fraction for this work is obtained after separation of biogas digestate in a decanter centrifuge. The solid fraction and components are not considered here, so the liquid fraction contains dissolved salts only. It has been defined according to chemical analysis of dissolved salts in a liquid fraction obtained from a thermophilic biogas plant from Lintrup, Denmark. The chemical analysis does not give equal molar amounts of cations and anions, which is required for charge neutrality. Hence, the chemical composition has been adjusted (+ 5.2 % for anions and – 5.2 % for cations based on charge) in order to obtain an overall electrically neutral system, see Table 1, as a requirement of thermodynamic and process simulation software.

Table 1. Liquid digestate composition before and after charge adjustment (±5.2%)

Ion	Molar mass [g/mole]	Mole concentration (before) [mole/L]	Mole conc. (after) [mole/L]	Mass conc. (after) [mg/L]

Process simulations about treatment of 30,000 kg/h of liquid digestate are carried out in Aspen Plus aiming at min. 95% N recovery. The production size is estimated according to digestate treatment from a large biogas plant such as KURANA biogas in Lithuania (800 tonnes/day of stillage and organic waste).

The digestate and air enter the plant at 25°C and the digestate has a pH of 8.1. The steady-state model uses an electrolyte-NRTL thermodynamic model to calculate the properties of the system. In order to develop the model in this study, ENTRL and SRK has been used for liquid and gas calculations.

The model is an unsymmetric Electrolyte Non-Random-Two-Liquid model with Poynting correction, Redlich-Kwong cubic equation of state and a modified Henry's law. The model is useful for CO_2-NH_3-H_2O system in the range of 0-100°C, up to 16 bar and for concentrations up to 23 mole/L NH_3 and 8 mole/L CO_2 (AspenTech, 2012)

The used process simulation software is Aspen Plus 27.0 and Aspen Plus V8.0, and for economic evaluations Aspen Icarus Process Evaluator 27.0 and equipment purchase cost charts from Peters et al. (2003) are used. Equipment costs have been corrected to current costs using Chemical Engineering Plant Cost Index (2012).

The main units of the process are a stripper and an absorber with 38 wt% sulfuric acid. A flash column is included to remove CO_2 prior to the air stripper column.

The feed enters the plant and is heated to the desired temperature in two heat exchangers. A sensitivity analysis is performed to determine the temperature needed to meet the desired recovery. The first heater transfers heat from the stripped liquid to the feed in order to improve energy efficiency. The second heat exchanger raises the temperature to the desired operation temperature. The air that is used to remove the ammonia from the incoming liquid is recycled between absorber and stripper, which improves energy efficiency and reduces the overall water evaporation. However, some air must be purged to avoid accumulation of CO_2 in the air stream. The flow sheet can be seen as Figure 1. All units are assumed to be adiabatic.

A system without addition of NaOH is simulated and compared to a system with addition of 210 kg/h NaOH. The stripper column is a randomly packed column with 90mm poly propylene Flexi-rings (specific surface area 0.7218 m^2/m^3 and a void fraction of 0.95 and price according to column volume after Peters et al. (2003)). The column is designed to operate at 62% of the flooding point. Pressure drops are fixed to 0.02 atm. in the stripper column, 0.01 atm. in the absorber and 0.2 atm. in heat exchangers (Seider et al., 2004). Isentropic compressor efficiency is 72% and the efficiency for conversion of electricity and fired natural gas into heat is assumed to be 80%.

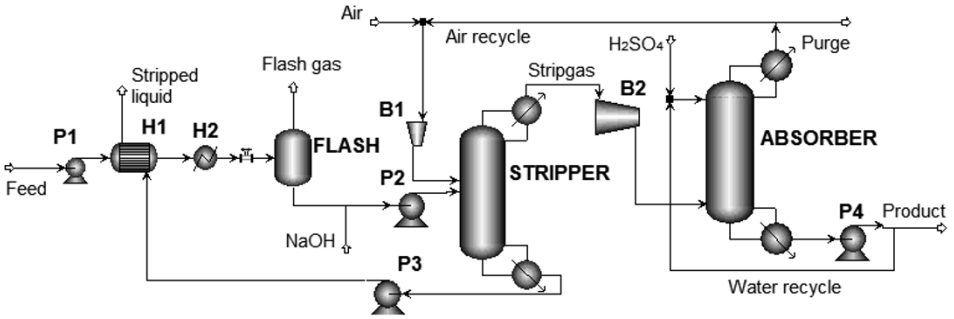

Figure 1: Flow sheet of plant recovering ammonia by air stripping and acid absorption. Prefix: P = Pump, H = Heat exchanger and B = Blower.

The process is designed to meet a minimum of 95% recovery calculated as in Eq. 1. Total ammoniacal nitrogen (TAN) includes $NH_3/NH_4^+/NH_2COO^-$.

$$\text{Recovery} = \text{stripped } NH_3 \text{ [kmole/h]} / \text{TAN in [kmole/h]} \cdot 100\% \quad (1)$$

The basis for the economical evaluation is operation in 8,000 hours/year, where operational costs include chemicals (55 US$/ton 98 wt% H_2SO_4 diluted to 38wt% onsite and 450 US$/ton 50 wt% NaOH), electricity (0.0677 US$/kWh) and natural gas (0.13 US$/$Sm^3$). Two ammonia sulfate prices are used as there is great uncertainty to the potential sales prices of the product (S), so 100 US$/ton (F.O.B China) and 423 US$/ton (USDA, 2011) are used to cover price interval of agricultural grade fertilizer. F.O.B. indicates free on board prices before delivery and installation.
The total equipment cost is calculated based on the 7 major pieces of equipment, which are two heat exchangers, two blowers, a flash drum, a stripper column and absorber column, both with random structured packings and redistributors. Finally, the total capital investment is calculated based on bare module costs (Seider et al., 2004) for installation in Western Europe, see Eq. (2)-(4).

$$\text{Total bare module cost } (C_{TBM}) = 3.291 \cdot C_{BM} \quad (2)$$

$$\text{Total capital investment } (C_{TCI}) = 2.2 \cdot C_{TBM} \quad (3)$$

$$\text{Total corrected capital investment } (C_{TCI,corrected}) = 1.2 \cdot C_{TCI} \quad (4)$$

It is assumed that chemicals and utilities comprise 60% of the total production costs (TPC) (Peters et al., 2003). See Eq. (5), where $C_{chemicals}$ is cost of chemicals and $C_{utilities}$ is cost of utilities.

$$\text{Total production costs (TPC)} = (C_{chemicals} + C_{utilities})/60\% \quad (5)$$

This enables a calculation of a minimum treatment cost [US$/$m^3$] as seen in Eq. (6).

$$\text{Treatment cost (TC)} = (\text{ROI} \cdot C_{TCI,corrected} + \text{TPC} - \text{S})/\text{production rate} \quad (6)$$

Return of investment (ROI) is fixed at 20%. Furthermore, taxes, fees, venture profit and depreciation are excluded as the economic evaluation means to estimate a minimum treatment cost of the process.

3. Results & Discussion

The simulated characteristics of the electrolyte system have been investigated to ensure the prediction of acid/base equilibrium of the species and pH. The treatment of 30,000 kg/h liquid digestate is performed to recover 95% N without addition of NaOH and is compared to addition of 210 kg/h NaOH. The overall simulation results can be seen in Table 2. The number of equilibrium stages of stripper and absorber as well as the column temperature have been determined according to the desired recovery. They are 12 stages, 5 stages and 90°C, respectively. The main difference is the consumption of NaOH and hence that two stripper and two absorber columns are needed without NaOH addition instead of one of each when NaOH is added. This is because less free ammonia is found at pH 8.1 than at higher pH, and approximately three times more air is needed to meet the specified recovery without addition of NaOH. Random-packed columns are generally not designed with a diameter above 1.5 m (Peters, 2003), so when the flow reaches a certain level two columns are needed instead of one. An optimization of purge is carried out to reduce the needed purge fraction as this reduces the overall water evaporation rate and energy consumption to heat up fresh incoming air. The purge fraction is 20%.

The ammonia sulfate is recovered as 47 wt% in water and the flow rate is comparable in the same range for the two simulations. Without addition of NaOH, the product stream has a flow 875 kg/h corresponding to 411 kg/h $(NH_4)_2SO_4$.

Table 2. Overall simulation results.

	210 kg/h NaOH	No NaOH	Unit
Digestate flow rate:	30,000	30,000	kg/h
Recovered NH_3	95.2	95.2	mole%
Air inlet flow rate	985	3,480	kg/h
Air recycled flow rate	7,417	22,162	kg/h
H_2SO_4 flow rate (as 38 wt% H_2SO_4)	925	945	kg/h
NaOH flow rate (as 50 wt% NaOH)	210	0	kg/h
Stripper column diameter	1.14	1.76	m
Stripper column packing height	9.60	9.6	m
Absorber column diameter	0.99	1.59	m
Absorber packing height	4.0	4.0	m
Purge stream flow rate	1,608	4,671	kg/h
Product stream $(NH_4)_2SO_4$ flow rate	864	875	kg/h
Heat exchanger, H1	389.3	289.8	m²
Heat duty, H2	628.8	1006	kW
Net Duty, B1	6.8	2.3	kW
Net Duty B2	14.8	39.1	kW

Total production cost (TPC)	1,678,000	524,000	US$/y
Sales (S) at 100 US$/ton	324,000	329,000	US$/y
Sales (S) at 423 US$/ton	1,370,000	1,392,000	US$/y
Treatment cost at 100 US$/ton	9.6	7.6	US$/$m^3$
Treatment cost at 423 US$/ton	5.2	3.2	US$/$m^3$

The total capital investment is 8,186,000 US$ and 4,708,000 US$ without and with addition of NaOH, respectively, as shown in table 3. Hence, a substantial increase in the capital cost is caused by the need of two columns for stripping and absorption when no

NaOH is added. Contrarily, the production costs are considerably decreased approximately three times from 1,867,000 to 524,000 US$/y when no NaOH is needed. The comparison shows that the use of NaOH should be kept to a minimum as it has a big influence on the operational costs, but cannot be avoided completely as it is needed to reduce the capital costs.
The treatment cost without NaOH will though be lower (3.2-7.6 US$/$m^3$) than with 210 kg/h NaOH (5.2-9.6 US$/$m^3$) highly dependent on the sales price of ammonia sulfate. The treatment costs are in the range in what has been reported in literature.
The study here however, clearly shows the importance of considering the influence of chosen process parameters on operational and capital costs. Furthermore, the uncertainty of the actual sales price of ammonia sulfate is seen and must be considered when evaluating air stripping as mean to recover nitrogen.
Additional points of the process will have an important impact on the plant viability and could be a scope for further research. They are aspects such as fouling of the stripper column, which reduces capacity when cleaning is needed, required product quality and price as well as cost of evaporation following the absorber if a solid product is necessary.

4. Conclusions

Air stripping is simulated to recover nitrogen from the liquid fraction of biogas digestate. The product is ammonia sulfate as sulfuric acid absorption is used to capture the free ammonia. The plant is designed to treat 30,000 kg/h digestate with a recovery of 95%. A design without the addition of NaOH is performed here and compared to the use of NaOH to increase the driving force. The influence of NaOH addition on total production costs and total capital costs has been investigated, where the total production costs were approximately three times higher when 210 kg/h of NaOH were used. On the contrary, the total capital were 4,708,000 US$ when using NaOH compared to 8,186,000 US$ without NaOH. The lower driving force increases the equipment size, so two columns is needed both for the stripper and absorber section to keep the individual column diameter below 1.5 m. The treatment costs are highly dependent on the potential sales price of ammonia sulfate and were 3.2-7.6 US$/$m^3$ without NaOH and 5.2-9.6 US$/m³ with NaOH.

WWSD for Distributed Treatment of Effluents

Abstract

Despite the technologies developed for water conservation inside an industrial plant some effluent streams still exist in the end of pipe. The distributed treatment of these effluent streams brings the opportunity to create wastewater treatments systems to accomplish with the environmental laws and in some cases contributes to water saving for the entire process. Wastewater Source Diagram (WWSD) is an algorithmic procedure for reducing the total wastewater treated flowrate by designing a distributed wastewater treatment system of effluents. Two criteria are taken into account for the synthesis of distributed treatment, the maximum concentration for discharge of contaminants and the treatment efficiency for contaminants. The WWSD procedure was applied to a real case to the treatment of effluents of the bioprocess laboratory with one contaminant and single treatments. The effluents streams have one contaminant and multiple treatments with different removal rates are available for the synthesis of the wastewater treatment system. Although the distributed treatment achieves the lowest treated flowrate, the centralized system uses fewer units of treatment. Multiple scenarios were studied for this minimum treated flowrate but using different units of treatment. These treatments were compared by an economic evaluation carried for the centralized treatment and the distributed treatment of effluents. The comparison with the solution by adopting the effluent centralized treatment shows that these tend to be more expensive once leading to a higher treated effluent flow rate.

Keywords: Wastewater Treatment System; process synthesis; process integration; distributed system.

1. Introduction

Environmental policies lead to the search for synthesis of wastewater treatment system respecting the maximum contaminants discharge. The end of pipe treatment of effluents in a process can have two configurations: centralized or distributed treatment. There are two ways for the distributed end of pipe treatment of effluents, with or without partial treated effluent return to the process. The distributed end of pipe treatment of effluents in a process reduces the capital and operational costs in a process. The capital cost of most treatments of effluent is proportional to the total wastewater flowrate while operational cost of most treatments increases with decreasing concentration and mass load of contaminants to be removed (Kuo and Smith, 1997). The goal is the synthesis of the effluent treatment system with a distributed wastewater treatment in order to reduce the effluent treated flowrate and reach the concentration for environmental disposal. Besides a methodology is necessary for the synthesis of the effluent treatment system with minimal cost. Hungaro (2005) developed a heuristic algorithmic procedure to target lowest flowrates of effluent to be treated. The treatment-limiting characteristics

were the maximum inlet concentrations and the limited flowrate permitted in order to meet the specified removal rate (efficiency). Removal rates were considered constant. Data of maximum concentrations for disposal were also necessary. Treatments were selected by criterion of higher removal rate (efficiency) or the number of different contaminants which could be removed. However, in order to choose treatments with similar efficiencies it would be necessary to estimate its cost as criterion, which was not considered in Hungaro´s work. Delgado (2008) also proposed an algorithmic procedure based on the Water Source Diagram (WSD) for the synthesis based on the efficiency and the minimal operational cost of the units of treatment. Kumaraprasad and Muthukumar (2009) employed the Water Source Diagram (WSD) concept (Gomes et al., 2007) coupled with water mains concept to simplify the piping network and reduce the cost. Liu *et al*. (2012) presented a simple procedure to determine the pinch concentration for the systems with one treatment process. In all situations, the discharge concentration of effluents in the end of pipe must satisfy the limits of environmental law. In this work the WWSD algorithm is been proposed for the synthesis of the distributed treatment of effluents based on some rules of Hungaro's algorithm for the synthesis of the end of pipe wastewater system. The WWSD algorithm is similar to the Water Source Diagram (WSD) to minimize the water use in industries developed by Gomes et al. (2007). The main rules of the WWSD algorithm are similar to Hungaro´s but are applied in a diagram similar to WSD algorithm. The heuristic WWSD procedure was applied in a real effluent from the laboratory of Bioprocess COPPE/UFRJ. It was observed that the WWSD obtained a lower flowrate for the distributed effluent treatment than for the centralized treatment.

2. WWSD procedure for synthesis of distributed treatment of effluent with one contaminant and a single treatment

The main objective of this work is to determine the mass exchange network with the minimum wastewater treated flowrate. The WWSD procedure for a single contaminant has five main steps, which are described in Table 1.

Table 1- WWSD procedure

Step 1: Calculate the mass load in each effluent stream (m) of the contaminant in the effluent streams using Eq.(1). $m_k = f_k (C_k - C_d)$ (1) where m is the amount of contaminant to be removed in each stream k; f_k is the flowrate of the effluent stream k; C_k is the contaminant concentration in the effluent stream k; k=1,…, $N_{streams}$ and i=1,…, N_{int} ($N_{streams}$ is the number of streams and N_{int} is the number of concentration intervals in the WWSD). C_d is the disposal concentration.
Step 2: Generation of the WWSD. Sketches the base for the WWSD, representing the concentration intervals, which are bounded by all contaminant concentrations in effluents and the limit wastewater discharge concentration. Calculate the concentration of effluents streams after treatments using Eq.(2). $C_{T,k} = C_{k,i}(1 - RR)$ (2) where RR is the treatment efficiency for contaminant removal, $C_{k,i}$ is the concentration of the contaminant in the interval i in the effluent stream k and $C_{T,k}$ is the contaminant concentration after the treatment in k.

Table 1- WWSD procedure

Step 3: Introduce the effluent streams in the WWSD diagram. Represent each effluent stream by a line from the respective inlet concentration to the disposal concentration and the limiting concentration in the diagram is the disposal concentration. The limit wastewater flowrates, f_k, are shown in a column on the left side of the diagram.

Step 4: Calculate the amount of mass to be removed by the treatment of the effluent stream in each interval by using Eq.(3).

$$\Delta m_{k,i} = f_k \left(C_{k,i} - C_{k,i-1} \right) \quad (3)$$

Where $\Delta m_{k,i}$ is the amount of contaminant removed of effluent k in interval i; f_k is the flowrate of stream k; $C_{k,i}$ is the upper limit of concentration in interval i , $C_{k,i-1}$ is the lower limit of the same interval.

Step 5: Synthesize the mass-exchange network by calculating the flowrate of the effluent stream to be treated in each interval.

Calculate the flowrate of an effluent stream sent to a treatment using Eq.(4).

$$f^{C_{T,k}}_{k,i} = \frac{\Delta m_{k,i}}{(C_{k,i} - C_{T,k})} \quad (4)$$

where $f^{CTk}_{k,i}$ is the flowrate through treatment to achieve the concentration C_{Tk} of effluent k, Δm_{ki} is the amount of contaminant in stream k removed in interval i; C_{ki} is the upper limit of the concentration interval i and C_{Tk} is the concentration of stream k for the treatment available. In the following intervals the flowrate of an effluent stream sent to a treatment is calculated by Eq.(5).

$$f^{C_{T,k}}_{k,i} = \frac{\Delta m_{k,i} - \left[f^{C_{T,k}}_{k,i-1} \left(C_{k,i} - C_{k,i-1} \right) \right]}{\left(C_{k,i} - C_{T,k} \right)} \quad (5)$$

After these five steps, sketch the mass exchange network.

3. Laboratory Case Study

The WWSD procedure was used to solve a real problem from Hungaro (2005). It deals with five effluents from a UFRJ laboratory. The activities those originate the wastewater are the following: 1.Growing of *Zymomonas mobilis* to obtain etanol; 2.Glucose tolerance test (Kit CELM); 3.Protein concentration measurement (The Bradford method); 3.1Waste from the Bradford reactant; 3.2 Waste from the analysis; 3.3Waste from the glassware cleaning. The analysis is made based on the chemical oxygen demand (COD). The COD is a parameter regulated by the Brazilian water discharge legislation, CONAMA. The limit COD condition for a discharge in saline water is 10 mg/L, therefore it is adopted as the disposal limit concentration ($\boldsymbol{C_d}$) in this case study. The data from the quantified COD from the wastewater streams is presented on the Table 2. The treatments available are activated sludge process, T1, and rotating biological contactor, T2, flocculation with ionic exchange, T3, Coagulation-floculation-sedimentation, T4. The removal rates of COD for these treatments are presented on Table 3. The removal rate of treatments in Table 3 were obtained in Quaglia et al (2013), Joyce et al. (1984), Henriksen et al. (1998) and Delgado (2008).

Table 2 – Wastewater data from Hungaro (2005).

Effluent, k	C_k (g/L)	f_k (L/month)	m_k (kg/h)
1	102.49	2.000	185.0
2	53.44	0.500	21.7
3.1	65.98	0.035	2.0
3.2	59.28	0.064	3.2
3.3	106.01	2.092	200.9

Table 3 – Removal Rate and maximum inlet concentration for the available treatments.

Treatment, T	RR_T (%)	C_{max} (g/l)
Activated Sludge (T1)	0.9	2.5
Rotating Biological Contactor (RBC)(T2)	0.8	-
Floculation and ionic exchange (T3)	0.5	-
Coagulation-Floculation-Sedimentation (T4)	0.6	-

As can be seen the wastewater streams on Table 1 are out of specification and the WWSD is going to be applied for the synthesis of a distributed treatment system for these effluents. The complete WWSD obtained using the five steps of the algorithm for this case study is shown in Figure 1. The total treated flowrate in the effluent treatment system is 7.415 L/month, as can be seen in Figure 2, where the system obtained from the WWSD is shown. In order to compare, in Figure 3 it is shown the corresponding centralized treatment system, where it can be noted a need of treating 9.382 L/month, 26.5 % larger than the amount treated in the distributed system.

The procedure was repeated using treatments T3 and T4. Data for economical evaluation of the distributed and centralized systems using the three treatments were collected from literature. The price of equipment (*Ie*) was corrected by Marshall&Stevens equipment indexes of 1061.9 as reported for the year 1998 and 1244.5 as reported for the year 2005 to calculate the capital cost (IC). Treatment (T2) RBC has an initial capacity of 79.17 m^3/h, the equipment price is 50,000 ($) (Joyce et al., 1984). Treatment (T3) Floculation and ionic exchange has an initial capacity of 0.64 m^3/h and the equipment price is 235,000 (DKK) (Henriksen et al., 1998). Treatment (T4) Coagulation+Floculation+Sedimentation has an initial capacity of 0.64 m^3/h and the equipment price is 4220 ($) (Delgado, 2008).

The treatments were compared by an economic evaluation. Fixed-capital investment was estimated by percentage of delivered equipment cost (Peters and Timmerhaus, 1991). Operational costs were not affordable because of low flowrates in the laboratory effluent streams. Note that in this study there was no need to use treatment 1, activated sludge treatment, as its maximum inlet COD concentration is higher than the disposal concentration. As the effluent is from a laboratorial scale the costs are low in Table 4. In Table 4 it can be seen that treatments costs rises with the total treated flowrate. On the contrary, the higher efficiency (RR_T) leads to the lowest cost using RBC treatment (T2). Whatever the treatment, the distributed system has lower cost than the centralized system.

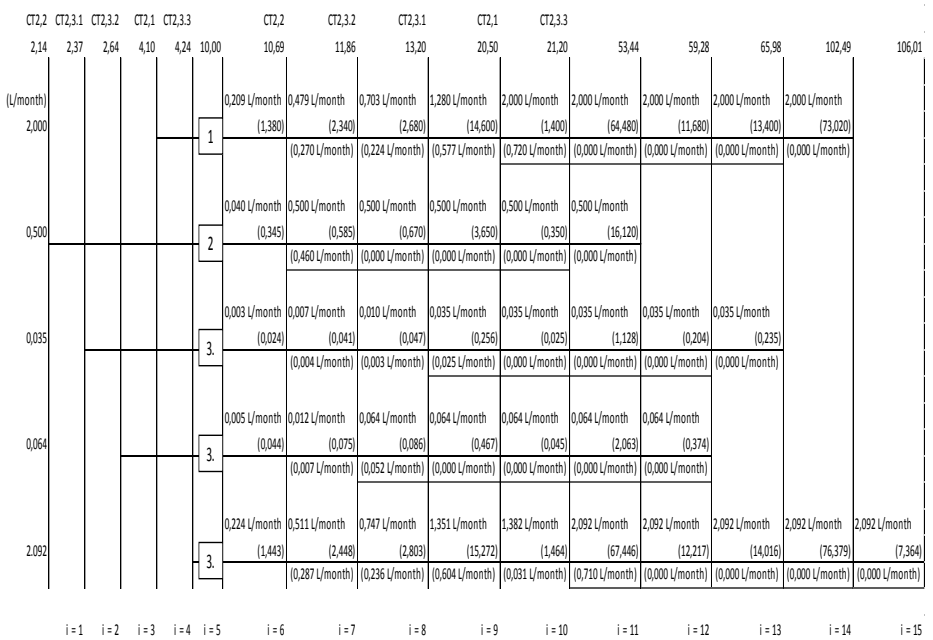

Figure 1 – WWSD for the Laboratory Case Study.

Application of WWSD reduces the treated flowrate by using by-pass of untreated effluent flowrate. The minimum total effluent flowrate found with WWSD sent to the treatment. This reduces directly the operation cost of the treatment system. The WSD (Gomes et al. 2007) provided the path for resolution and synthesis of the distributed treatment of effluent streams with few adaptations in its rules for calculation of mass balance of contaminants concentrations and the minimum treated flowrates. Similar rules of Water Source Diagram (WSD) were followed in the WWSD algorithm.

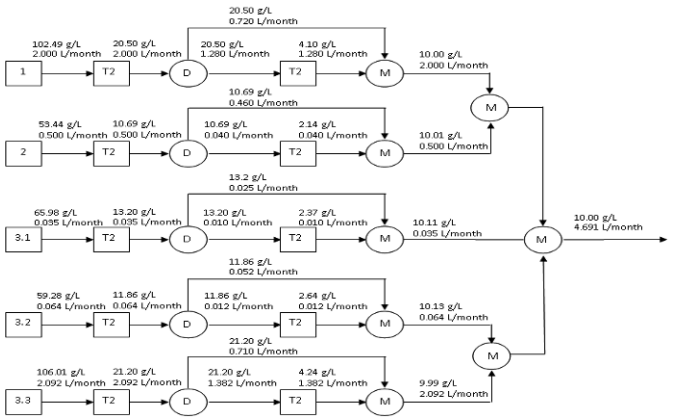

Figure 2– Distributed treatment of the Laboratory Case Study.

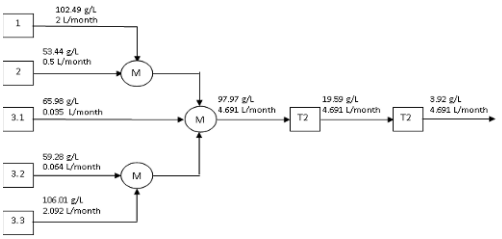

Figure 3– Centralized treatment of the Laboratory Case Study.

Table 4– Results for WWSD for one contaminant and a single treatment.

Configuration	*Flowrate (L/month)*	*Total Fixed capital and labor ($/y)*	*Treatment, T*
T2 distributed	7.42	14.10	Rotating Biological Contactor (RBC) (T2)
T2 centralized	9.38	16.65	
T3 distributed	15.70	545.40	Floculation and ionic exchange (T3)
T3 centralized	18.76	617.90	
T4 distributed	12.20	49.10	Coagulation-Floculation-Sedimentation (T4)
T4 centralized	14.10	54.40	

4. Conclusion

The Wastewater Source Diagram (WWSD) is a simple algorithm procedure for the synthesis of the distributed treatment of effluents. It reduces the total effluent flowrate sent to the treatment by searching the limit concentration for discharging of the effluent streams. The case study showed a real application of the WWSD to a laboratory, which can reduce the volume of effluents treated by applying the decentralized system and achieving the desired disposal concentration, enabling the discharge of the effluent in saline waters, by legislation.

Extending the benchmark simulation model n°2 with processes for nitrous oxide production and side-stream nitrogen removal

Riccardo Boiocchi[a], Krist V. Gernaey[a] and Gürkan Sin[a]

[a]*CAPEC-PROCESS, Department of Chemical Engineering, DTU, 2800-Lyngby, Denmark*

Abstract

In this work the Benchmark Simulation Model No.2 is extended with processes for nitrous oxide production and for side-stream partial nitritation/Anammox (PN/A) treatment. For these extensions the Activated Sludge Model for Greenhouse gases No.1 was used to describe the main waterline, whereas the Complete Autotrophic Nitrogen Removal (CANR) model was used to describe the side-stream (PN/A) treatment. Comprehensive simulations were performed to assess the extended model. Steady-state simulation results revealed the following: (i) the implementation of a continuous CANR side-stream reactor has increased the total nitrogen removal by 10%; (ii) reduced the aeration demand by 16% compared to the base case, and (iii) the activity of ammonia-oxidizing bacteria is most influencing nitrous oxide emissions. The extended model provides a simulation platform to generate, test and compare novel control strategies to improve operation performance and to meet the new plant performance criteria such as minimization of greenhouse gas (in particular of nitrous oxide) emissions.

Keywords: benchmark, nitrous oxide, ammonia-oxidizing bacteria, heterotrophic bacteria.

List of abbreviations:

1. Introduction

The development of novel control strategies for wastewater treatment plant (WWTP) processes is increasingly required to meet both increasingly-strict regulatory limits for effluent water quality as well as to mitigate greenhouse gas (GHG) emissions from the plant. In order to facilitate the development and the application of control strategies for WWTPs, a benchmark simulation framework was developed over the past decades to enable objective and realistic control technology testing and comparison. In particular, simulation models such as the Benchmark Simulation Model No.1 (BSM1) and Benchmark Simulation Model No.2 (BSM2) (Jeppsson et al., 2007) were developed. The main difference between the BSM1 and the BSM2 is in the plant layout. More specifically, while the BSM1 includes just the mainstream treatment unit, the BSM2 layout adds to this the side-stream treatment for wastage sludge. For this reason,

compared to the BSM1, the BSM2 can be considered allowing not only the development of a larger number of control strategies but also a more complete and thorough evaluation of control strategies. As pointed out by Jeppsson et al. (2013), the BSM2 could be further extended in order to meet newly-emerging control objectives. These extensions include the mitigation of nitrous oxide (N_2O) emissions and the enhancement of nitrogen removal through emerging technologies such as partial nitritation/Anammox (PN/A) processes. As a matter of fact, there exist a large number of evidences showing that N_2O, one of the most harmful GHGs and an ozone-depleting substance, can be produced under certain operating conditions in a significant amount during the activity of different species of bacteria typically involved in the biological nitrogen removal processes. With regard to the side-stream process, it is important to acknowledge the fact that WWT designers have been frequently upgrading their plants with PN/A processes in the side-stream in order to cope with the increasingly strict effluent regulatory limits on the reactive nitrogen species in the effluent against a reasonable cost (Lackner et al., 2014). However, in order to take advantage of these technologies, it is important to develop proper process control strategies in order to ensure optimal and stable operation against external disturbances. In this work two extensions of the BSM2 are presented. The first extension regards the mathematical model describing the processes in the mainstream with processes for nitrous oxide production. The second extension concerns the expansion of the layout of the side-stream treatment unit by including a single-stage continuous PN/A reactor. In particular, the Activated Sludge Model for Greenhouse gases No.1 (ASMG1) by Guo and Vanrolleghem (2014) is used as mathematical model instead of the Activated Sludge Model No.1 (ASM1). With regard to the layout extension, the single-stage granular reactor performing Complete Autotrophic Nitrogen Removal (CANR), whose processes were modelled by Vangsgaard et al. (2012), is included in the side-stream of the BSM2 at the bottom of the dewatering unit of the reject water from the anaerobic sludge digestion.

2. Development of the Benchmark Simulation Model for Nitrous Oxide and for side-stream Complete Autotrophic Nitrogen Removal (the BSM2NplusCANR)

The development of the new benchmark simulation model (the BSM2NplusCANR) required the following additions and modifications:

1) replacement of the ASM1 with the ASMG1,
2) extension of the ASM1-to-ADM1 and of the ADM1-to-ASM1 interfaces,
3) inclusion of new state variables in both the CANR model (CANRM) and in the ASMG1, and
4) development of interfaces mapping the state variables of ASMG1 into the ones of the CANR model and vice versa.

As an outcome from point 2), the BSM2N is obtained.

2.1. The implementation of the Activated Sludge Model for Greenhouse gases No.1

The mathematical model considered suitable for the inclusion of N_2O production into the BSM2 was the ASMG1 by Guo and Vanrolleghem (2014). This choice was taken in virtue of the fact that the model was calibrated and validated against the ASM1 which is considered to provide a realistic description of the WWT processes. Hence the effluent concentrations predicted by the model can be considered reliable. However, it should be pointed out that there are no data validating the emissions of N_2O predicted and future investigations are required to validate the model not only for the effluent concentrations

but also the nitrogen gas emissions. The mass balance equations used to model the biological reactors in the mainstream can be generically represented as:

$$\frac{dC_i}{dt} = \frac{Q}{V} \cdot (C_{in,i} - C_i) + r_i \quad (1)$$

In Equation (1) C_i is the concentration of the generic component i, Q is the volumetric flow rate (in and out the reactor), V is the reaction volume and r_i is the reaction rate. For further information, the reader is referred to Guo and Vanrolleghem (2014).

2.2. The Complete Autotrophic Nitrogen Removal model

A complete overview of the Complete Autotrophic Nitrogen Removal model used to decribe the PN/A occurring in the side-stream reactor on bottom of the dewatering unit is available in Vangsgaard et al. (2012). Here the main mass-balance equations are shown, as follows:

$$\frac{\partial S_i}{\partial t} = D_i \cdot \frac{1}{z^2} \cdot \frac{\partial}{\partial z}\left(z^2 \cdot \frac{\partial S_i}{\partial z}\right) + r_i \quad (2)$$

$$\frac{\partial X_i}{\partial t} = -\frac{\partial (X_i \cdot u_F)}{\partial z} + r_i \quad (3)$$

$$\frac{dC_i}{dt} = \frac{Q_{in} \cdot C_{i,in} - Q_{out} \cdot C_{i,bulk} - j_{bio,i} \cdot A_{bio}}{V} + r_i \quad (4)$$

In Eqs (2-4), D_i is the diffusion coefficient for soluble components S_i, z is the radial distance from the center of the granule, u_F is the biofilm net growth velocity and $j_{bio,i}$ the flux in and out the biofilm.

2.3. The ASMG1-to-ADM1 and the ADM1-to-ASMG1 interfaces

Interfaces are tools linking two mathematical models with different sets of state variables (SVs). These tools have been used in the BSM2 to map the state variables of the ASM1 into the ones of the Anaerobic Digestion Model No.1 (ADM1) and vice versa. When replacing the ASM1 with the ASMG1, the set of SVs of the mainstream model is augmented. In particular, while in the ASM1 the ammonia-oxidizing bacteria (AOB) and nitrite-oxidizing bacteria (NOB) are represented as a single variable, in the ASGM1 they appear separately. Nitrite, nitric oxide, nitrous oxide and dinitrogen represent new SVs. In order to map these new SVs, in the ASM1-to-ADM1 interface nitrite, nitric oxide and nitrous oxide were added to the pool of electron acceptors jointly with oxygen and nitrate to be consumed during the oxidation of biodegradable organic carbon by HB. AOB and NOB are used in the same way as the ASM1 variable "autotrophic bacteria", meaning that they are summed up together and assumed to decay releasing X_{ND}, X_P and X_S.

2.4. Inclusion of new state variables in the CANRM and in the ASMG1

New state variables needed to be added in both the ASMG1 and the CANRM in order to make the two models compatible with each other. These additions consisted of: anaerobic AOB (X_{AnAOB}) into the ASMG1 and soluble inerts (S_I), particulate inerts from influent (X_I) and alkalinity (S_{ALK}) into CANRM.

2.5. Development of the ASMG1-to-CANRM and of the CANRM-to-ASMG1 interfaces

Figure 1 shows schematically how each state variable of one model is mapped into those of the other model.

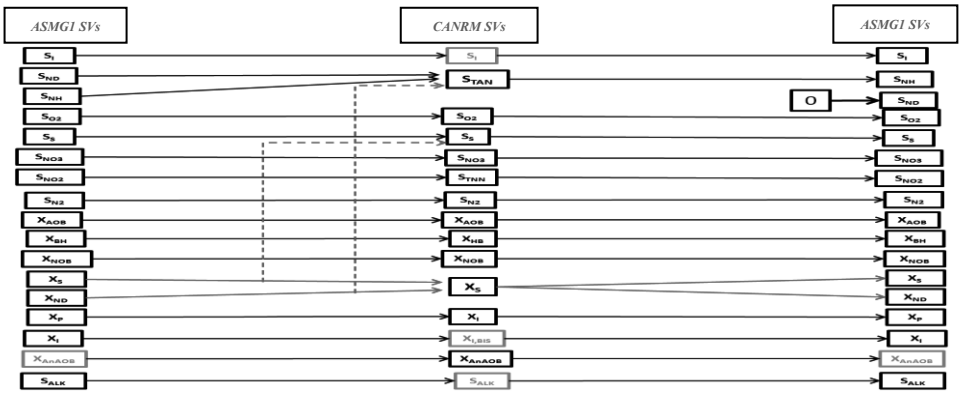

Figure 1: ASMG1-to-CANRM and CANRM-to-ASMG1 Interfaces (added SVs in green boxes, conditioned mapping in red arrows (first choice normal arrow, second choice dashed arrow)).

3. Results and discussion

In this section the impact on the model predictions of the two extensions performed is evaluated through steady-state simulation results of the BSM2N and of the BSM2NplusCANR. The results of these simulations will be used here to study:

- how the oxygen set-point in the aeration tanks affects the N_2O emissions,
- how the CANR reactor in the side-stream affects the performance of the plant,
- how the oxygen set-point in the aeration tanks affects the TN removal,
- how the oxygen demand is affected by the location of the CANR reactor.

The simulations are performed by controlling the oxygen concentration in the three mainstream aerobic tanks at 0.5 – 1 – 2 mg (-COD).L^{-1}. The reject water from the dewatering unit is recycled directly before the first mainstream anoxic tank following treatment in the CANR reactor. The water separated during the thickening of the wastage sludge is recycled before the primary clarifier (see Figure 2).

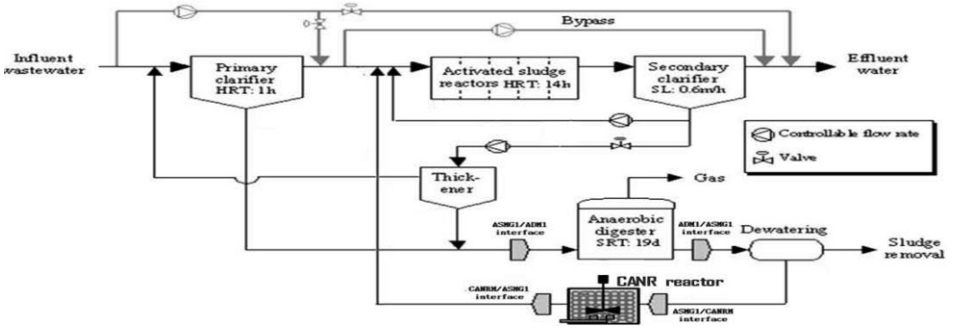

Figure 2: BSM2NplusCANR layout used for steady-state simulations.

3.1. Effect of oxygen on nitrous oxide emissions from the mainstream

The effect of the oxygen concentration in the three aerobic tanks on the emissions of N_2O from the five tanks in the mainstream of the BSM2N is here investigated. Table 1 shows: the emission factors of N_2O with respect to the N in the influent at different oxygen set points, the N_2O production and consumption rates by HB and the N_2O production by AOB.

Table 1: BSM2N N_2O emission factors and overall N_2O production and consumption rates by AOB and HB in the five biological tanks of the mainstream.

DO	N_2O emission factors	PRODUCTION RATE by HB	CONSUMPTION RATE by HB	OVERALL CONTRIBUTION by HB	PRODUCTION RATE by AOB	Liquid N_2O in the effluent
[mg(-COD).L^{-1}]	[% of g N_2O_{emit}-N.g^{-1} N_{inf}]	[g.m^{-3}.d^{-1}]	[g.m^{-3}.d^{-1}]	[g.m^{-3}.d^{-1}]	[g.m^{-3}.d^{-1}]	[g.m^{-3}]
0,5	**0,043**	412,64	-412,73	-0,09	$2{,}56 \cdot 10^{-4}$	$5{,}88 \cdot 10^{-5}$
1,0	**0,02**	402,60	-402,36	0,25	$2{,}02 \cdot 10^{-4}$	$2 \cdot 10^{-5}$
2,0	**0,022**	390,87	-390,56	0,31	$3{,}21 \cdot 10^{-4}$	$1{,}14 \cdot 10^{-5}$

First of all, it can be observed that there is no proportional correlation between the N_2O emissions and oxygen concentration. This could have been foreseen from the fact that the ASMG1 includes the N_2O production by two different types of bacteria with different kinetics. Furthermore, AOB themselves are modelled to produce N_2O through a Haldane-type function, according to which the role of oxygen switches from enhancing to inhibiting in function of the concentration of oxygen itself. Besides the mere production rates by these two species of microorganisms, also the stripping is important. Low N_2O productions occurring in a well-aerated aerobic zone can lead to significantly-high N_2O emissions due to the enhanced stripping capability. According to the model simulations, it can be observed that AOB are the driving force determining the N_2O dynamics in the system, whereas heterotrophs play a marginal role.

3.2. Effect of the inclusion of the CANR reactor on TN removal contributions

Table 2 shows the steady-state TN removal contribution by the different units respectively in the BSM2N and the BSM2NplusCANR at different operating oxygen set points. As can be noted, in the BSM2N most of the TN from the influent is removed in gaseous form (42.5 % of g N_{gas}-N.g^{-1} N_{infl}) while 13.4 % of influent TN is removed through assimilation into biomass cells through biomass growth. According to the BSM2NplusCANR approximately 17% of the influent TN is removed through the processes in the CANR reactor whereas 7% less is removed by the mainstream AS unit. The nitrogen removed through biomass growth remains unchanged. The decrease in the N removed by the processes in the AS unit is the consequence of the decrease in the nitrogen load recycled to the mainstream when the new reactor is added. As a matter of fact, this leads to a decrease in the concentration of AOB and NOB and in turn to a decreased conversion of influent nitrogen into gas in the mainstream. Summing up, when the CANR reactor is added, the total nitrogen discharged in the effluent from the plant decreases by approximately 10 %.

With regard to the effect of O_2 set-points, the main impact observed is in the decreased TN removal for increasing DO in the main activated sludge units. This is the consequence of the lower heterotrophic denitrification rate caused by oxygen inhibition.

Table 2: TN removal partitioned among the different units in function of DO set point for BSM2N and BSM2NplusCANR.

DO [mg.L^{-1}]	BSM2N		BSM2NplusCANR		
	AS N removal [%]	N storage in sludge [%]	AS N removal [%]	N storage in sludge [%]	CANR removal [%]
0,5	44,3	13,3	36,5	13,4	16,9
1	42,5	13,4	36	13,4	16,9
2	41,2	13,4	35,5	13,4	16,9

3.3. Effect the CANR reactor on total oxygen demand of the plant

Table 3 shows the different oxygen consumptions in both the BSM2N and the BSM2NplusCANR at different oxygen set points and the contributions in percentage by the three oxygen-consuming microorganisms, namely heterotrophs, ammonia-oxidizing and nitrite-oxidizing bacteria (AOB and NOB, respectively). When the CANR reactor is included, the nitrogen load recycled to the mainstream decreases considerably. At the same time the concentration of nitrifying biomass (both AOB and NOB) decreases as

well. This leads to a decrease in the total amount of oxygen consumed by AOB and NOB for nitrification. Contrarily, the heterotrophic consumption of oxygen increases. This can be explained by the fact that, as the production of nitrate by NOB is decreased, more organic biodegradable matter is available for aerobic oxidation rather than anoxic. Summing up, the savings of oxygen obtained from AOB and NOB compensate the increased oxygen consumption by HB, thus leading to an 16% overall reduction in the total plant oxygen requirements. This value may appear lower compared to the aeration requirements (i.e. 60%) reported in (Lackner et al., 2014). However it should be noted that those values reported in the literature consider local analysis of a PN/A system and not the plant-wide analysis presented here which provides a more accurate and realistic evaluation of the impact of PN/A technologies.

Table 3: Oxygen consumption by heterotrophic, ammonia-oxidizing and nitrite-oxidizing bacteria and total oxygen consumptions in both BSM2N and BSM2NplusCANR. The differences are calculated by subtracting the oxygen consumed in the BSM2N (*) and the one consumed in the BSM2NplusCANR (**).

DO_{sp} [mg/L]	OXYGEN CONSUMED [kg.d^{-1}]											
	HETEROTROPHS			AOB			NOB			TOTAL		
	(*)	(**)	Difference	(*)	(**)	Difference	(*)	(**)	Difference	(*)	(**)	Difference
0,50	1582	1734	**-153**	2959	2178	**781**	778	562	**216**	5318	4474	**844**
1	1671	1801	**-130**	2979	2195	**784**	593	419	**174**	5243	4415	**828**
2	1756	1869	**-113**	2982	2201	**782**	504	355	**149**	5241	4424	**817**

4. Conclusions

A new benchmark simulation model, the Benchmark Simulation Model No.2 for Nitrous oxide and for side-stream Complete Autotrophic Nitrogen Removal (BSM2NplusCANR), was developed. The aim of the extended model is to provide a reference simulation scenario enabling the development and the objective evaluation of novel control strategies for mitigating N_2O emissions in the mainstream and for autotrophic nitrogen removal in the side-stream. Simulation results have shown that AOB are the microorganisms with the major impact on the total N_2O emissions and that an increase of about 10% in the total nitrogen removal efficiency can be obtained when a new reactor for side-stream PN/A is implemented. At the same time, 16% savings in oxygen demand are achieved. With regard to process control options the results suggest that control strategies for N_2O emission minimization in the mainstream should focus on the AOB activity whereas in order to increase the energy savings a better PN/A performance would be needed.

Abstract

Photosynthesis-Irradiance (PI) response curves constitute a powerful tool for characterizing the photosynthetic properties of microalgae. This paper presents a dynamic model capable of predicting the photosynthesis rate under dynamic light conditions. Fast and slow time-scale processes are coupled using fluorescence data for three different photoacclimation states. The model shows a very good agreement with the available experimental data and the values of the calibrated parameters are consistent with biological evidence. The predicted PI curves exhibit all the expected trends regarding their initial slopes, maximum photosynthesis rates, and photoinhibion effects. By analyzing the effect of different experimental protocols on the PI curve predictions, our results highlight the importance of an accurate description of the protocols used to obtain the experimental data.

Keywords: modeling, fluorescence, microalgae, PI curves

1. Introduction

Microalgae-based processes are considered one of the most promising alternative technologies for the production of liquid fuels for the transportation sector (Chisti, 2007). The main advantages of microalgae compared with other renewable feedstocks are their high potential productivity and the absence of competition with traditional crops for arable land. However, this potential is still theoretical, and algal-derived biofuel on large-scale is not profitable as of yet. Several issues need to be addressed to reach this objective, including algae cultivation, harvesting and products extraction (Williams and Laurens, 2010; Mata et al., 2010).

Reliable models of microalgae growth, able to capture the dominant physical, chemical, and biological phenomena, can expose the interactions between equipment design and product yields and eventually help to scale-up and optimize process design and operation. In practice though, and even in lab-scale conditions where certain physical phenomena can be controlled or neglected, predicting growth rates is quite complicated due to the presence of intricate mechanisms spanning multiple time-scales: *Photoproduction* encompasses all the processes from photons utilization to CO_2 fixation that occur within milliseconds (Williams and Laurens, 2010); *Photoinhibition*, the observed loss of photosynthetic production due to excess or prolonged exposure to light, acts on

a time scale of minutes to hours; *Photoregulation*, also known as non-photochemical quenching (NPQ), the set of mechanisms by which microalgae protect their photosyntheti apparatus via the dissipation of excess energy as heat, occurs within minutes; *Photoacclimation*, the ability of the cells to adjust their pigment content and composition under varying light and nutrient conditions, occurs within hours or days; finally, the mechanisms involved in *nutrient internalization* and their *metabolism* into useful products occurs within hours or days as well (Falkowski and Raven, 1997). In addition to these biological mechanisms, physical phenomena such as hydrodynamics and light attenuation also have an effect on the apparent growth rate of a microalgae culture.

Photosynthesis-Irradiance (PI) response curves constitute a powerful tool for characterizing microalgae growth rate. Accurate representation of such curves in a mechanistic manner has been an important challenge for many years, since both the effects of light and nutrients can be captured and optimal productivities of large scale production systems can be inferred this way (Bernard, 2011). The most usual approach for representing PI curves includes the use of static input-output relationships (Jassby and Platt, 1976). Despite their simple form and handiness, these models fail to explain the effects of the various biological mechanisms on the photosynthesis rate. Moreover, the experimental procedure currently in use for obtaining PI curves is not only time consuming, but a precise estimation of the growth conditions, that is, the level of photoregulation or photoinhibition, is hardly possible.

The main objective of this paper is to represent the rate of photosynthesis under varying light conditions, by accounting for the dominant regulatory and inhibitory mechanisms. More specifically, we predict PI curves using the dynamic model of chlorophyll fluorescence by Nikolaou et al. (2015), which makes use of fluorescence data to characterize the quantum yield of photosynthesis when photoproduction, photoinhibition and photoregulation are all taking place. We discuss an extension of this model for describing photoacclimation phenomena, and we calibrate the model using fluorescence data for the microalga *Nannochloropsis gaditana* acclimated at three different light intensities. Finally, we analyze the predicted PI curves and investigate the effect of different experimental protocols on these predictions.

2. Dynamic Modelling of Photosynthesis-Irradiance Curves

2.1. Fluorescence model

Fluorescence refers to the re-emission of photons by chlorophyll molecules, which can be measured by fluorometers (Papageorgiou, 2004). Modern fluorometry, such as Pulsed Amplidute Modulation (PAM), relies on complex light protocols to trigger various mechanisms in the photosynthetic response of microalgae. Specifically, under nutrient-replete conditions and at a given photoacclimation state, the fluorescence flux, F, depends on the state of the photosynthetic apparatus and the activity of photoregulation (Nikolaou et al., 2015):

$$F = \frac{S_{\mathrm{F}}\sigma}{1+\eta_{\mathrm{D}}+\overline{\eta}_{\mathrm{qE}}\,\alpha+A\,\eta_{\mathrm{P}}+C\,\eta_{\mathrm{I}}}\,, \tag{1}$$

where S_{F} is a scaling parameter proportional to the chlorophyll content, *chl*, of the sample; σ denotes the total cross section $[\mathrm{m}^2\,\mathrm{g}_{\mathrm{chl}}^{-1}]$; and $\Phi := 1/(1+\eta_{\mathrm{D}}+\overline{\eta}_{\mathrm{qE}}\,\alpha+A\,\eta_{\mathrm{P}}+C\,\eta_{\mathrm{I}})$ represents the quantum yield of fluorescence. The latter depends on: the parameters η_{P}, η_{D}, $\overline{\eta}_{\mathrm{qE}}$ and η_{I}, which stand for, respectively, the rates of photoproduction, basal thermal decay, quenching linked to photoregulation and quenching linked to photoinhibiton, all relative to the rate of fluorescence; the variable $\alpha \in [0,1]$, which represents the activity of photoregulation; and A and C are the fractions of PSUs in open and inhibited states, respectively. The flux F is minimal, denoted as F_0, when $A = 1-C$; whereas F is maximal, denoted as F_m, when $A = 0$.

The state of the photosynthetic apparatus is represented by the mechanistic model by Han (2002). According to this model the physical entity responsible for the production of one O_2 molecule,

usually refered to as Photosynthetic Unit (PSU), has three possible states: open PSUs are ready to accept photons and produce O_2; closed PSUs are occupied with already accepted photons; and damaged PSU, arise when closed PSUs receive extra photons due to excessive irradiance. The fractions of open A, closed B and damaged C PSUs, which sum to 1 at all times, are represented by the following set of differential equations:

$$\begin{aligned} \frac{dA}{dt} &= -I\,\sigma_{\mathrm{PS2}}\,A + \frac{B}{\tau} \\ \frac{dB}{dt} &= I\,\sigma_{\mathrm{PS2}}\,A - \frac{B}{\tau} + k_{\mathrm{r}}\,C - k_{\mathrm{d}}\,\sigma_{\mathrm{PS2}}\,I\,B \\ \frac{dC}{dt} &= -k_{\mathrm{r}}\,C + k_{\mathrm{d}}\,\sigma_{\mathrm{PS2}}\,I\,B\,, \end{aligned} \tag{2}$$

where I denotes the light intensity [$\mu\mathrm{E\,m^{-2}\,s^{-1}}$]; τ, the turnover time [s]; k_{d}, the damage rate constant [–]; k_{r}, the repair rate constant [$\mathrm{s^{-1}}$]; and σ_{PS2}, the effective cross section [$\mathrm{m^2\,\mu E^{-1}}$]. Following Falkowski and Raven (1997), the latter is related to the total cross section, σ, as

$$\sigma_{\mathrm{PS2}} = \Phi_{\mathrm{p}}^{A}\,\frac{\sigma}{N}\,, \tag{3}$$

where N is the number of PSUs [$\mathrm{mol\,e^-\,g_{chl}^{-1}}$], which remains constant for a given photoacclimation state; and Φ_{p}^{A} is the quantum yield of photosynthesis of an open PSU, equal to $\eta_{\mathrm{P}}/(1+\eta_{\mathrm{D}}+\overline{\eta}_{\mathrm{qE}}\alpha+\eta_{\mathrm{P}})$.

On the other hand, the activity of photoregulation, α, is described by first-order dynamics as

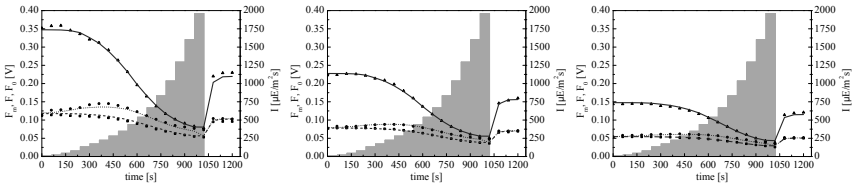
$$\frac{d\alpha}{dt} = \xi\,(\alpha_{\mathrm{ss}}(I)-\alpha)\,, \quad \text{with} \quad \alpha_{\mathrm{ss}}(I) := \frac{I^n}{I_{\mathrm{qE}}^n + I^n}\,, \tag{4}$$

where ξ [$\mathrm{s^{-1}}$] denotes the photoregulation time constant; and $\alpha_{\mathrm{ss}}(I)$ is the steady-state value of the photoregulation activity. Based on preliminary experimental data, the latter is modeled as a sigmoid (Hill) function of light intensity, using the parameters I_{qE} [$\mu\mathrm{E\,m^{-2}\,s^{-1}}$] and n [–].

2.2. Photoacclimation Extension

Photoacclimation refers to physiological adaptations of the photosynthetic apparatus in order for phototrophs to optimize their growth under long-term variations in the light intensity (MacIntyre et al., 2002). The most profound effect of photoacclimation is a decrease in the chlorophyll content *chl*, as the irradiance increases and vice-versa (Fisher et al., 1996). In turn, the variation in chlorophyll content affects the photosynthetic apparatus: the total cross-section σ decreases as chlorophyll increases due to shading effects (Falkowski et al., 1985), whereas the number of PSUs N can either increase or decrease as a function of chlorophyll for different species (Falkowski and Owens, 1980). Moreover, the variation in pigment composition can affect the activity of photoregulation (Anning et al., 2000). In consequence, microalgae samples that are acclimated at different light intensities will present different fluorescence responses to the same PAM protocol.

An extension of the model by Nikolaou et al. (2015) is needed in order to account for the effect of photoacclimation on the fluorescence flux. Both σ and N, which depend on the chlorophyll content, become functions the photoacclimation state, and so does the parameter S_{F}. Moreover, the photoregulation activity α can depend on the photoacclimation state via its parameters I_{qE} and η_{D}. While empirical equations could be used to describe all these dependencies, we decided not to do so in this work because the available data would not be sufficient to estimate these extra parameters confidently or discriminate between alternative modeling hypotheses. Instead, we use replicates of the fluorescence model for various photoacclimation states, whereby each replicate takes a different set of parameter values for σ, S_{F}, N, I_{qE} and η_{D}, while using the same values for all the other parameters.



(a) $I_g = 15\mu\text{E/m}^2\text{s}$ (b) $I_g = 100\mu\text{E/m}^2\text{s}$ (c) $I_g = 625\mu\text{E/m}^2\text{s}$

Figure 1: Fitting results of the fluorescence fluxes for three different photoacclimation states.

2.3. Photosynthesis Rate

An expression of the photosynthesis rate comes forward in the form (Falkowski and Raven, 1997):

$$P = \sigma\Phi I\,, \tag{5}$$

with Φ the photosynthesis quantum yield [mol O_2 μE^{-1}]. The aforementioned units, give dimensions for P in [mol O_2 $g_{chl}{}^{-1}$ s^{-1}], which by definition is the chlorophyll specific photosynthesis rate, in terms of the oxygen production. The dynamic model of fluorescence predicts the value of the realized quantum yield of photosynthesis, Φ_{PS2} in units of [mol e^- μE^{-1}]. From the literature, it is known that Φ_{PS2} is closely related to Φ (Suggett et al., 2003). Here, we introduce a stoichiometric coefficient that aligns the electrons required for the production of each O_2 molecule. Considering the water dissociation reaction ($2H_2O + 4e^- \rightarrow O_2 + 4H^+$), we obtain a theoretical minimum value of 4 mol e^-/mol O_2.

3. Results and discussion

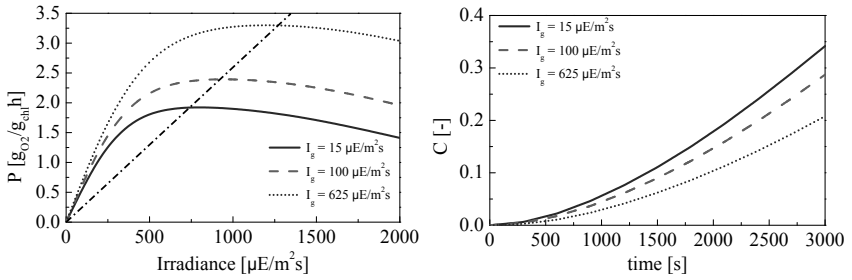
3.1. Model Calibration

The extended fluorescence model for PI curve prediction is calibrated using three experimental data sets of chlorophyll fluorescence for the microalga *Nannochloropsis gaditana*. Each set corresponds to a different photoacclimation light intensity, I_g, namely 15, 100 and 625 μE m^{-2} s^{-1}. Model calibration is performed in the modeling environment gPROMS (`http://www.psenterprise.com`) using maximum likelihood estimation. The model fits are presented in Fig. 1, and the values of the acclimation-dependent parameters are reported in Table 1.

Table 1: Parameter values for different photoacclimation states.

Parameter		15 μE m^{-2} s^{-1}	100 μE m^{-2} s^{-1}	625 μE m^{-2} s^{-1}
I_{qE}	[μE m^{-2} s^{-1}]	762	847	1048
σ	[m^2 g_{chl}^{-1}]	1.64	1.73	1.79
η_D	[-]	6.64	6.75	7.8
N	[mol e^- g_{chl}^{-1}]	3.5×10^{-7}	4.50×10^{-7}	6.62×10^{-7}
S_f	[g_{chl} μE^{-1} V^{-1}]	1.59	1.00	0.7

The calibration results show a good agreement between the model and the experimental data. Regarding the parameter estimates, observe that these values are consistent with the theoretical considerations discussed in Sect. 2.2. In particular, S_F, which depends linearly on the chlorophyll content shows a decreasing trend with I_g; σ is inversely related to S_F; N and η_D are both increasing with increasing I_g, an expected behavior for η_D as it linked to the accumulation of photoprotective pigments; and I_{qE} turns out to be almost linearly related to I_g, suggesting that photoregulation is activated at higher light irradiance when microalgae are also acclimated at higher light irradiance.



(a) PI curves (b) *C* profile

Figure 2: PI curves (left plot) and photoinhibition evolution (right plot) for three different photoacclimation states. Dotted, dashed and continuous lines correspond to 625, 100 and 15 μE m^{-2} s^{-1}.

3.2. Dynamic Simulation of PI curves

PI curves are predicted for the same three photoacclimation states as in Sect. 3.1. A fictitious experimental protocol is considered, whereby the microalgae sample is exposed to progressively increasing light intensities from 0 to 2000 μE m^{-2} s^{-1} in 10 constant light stages of 5 minutes each (increasing the irradiance by 200 μE m^{-2} s^{-1} at every stage). Then, the value of the photosynthesis rate P at the end of each stage is plotted against the corresponding light intensity. Note that during each 5-minute stage, that is between a change in the light intensity to the measurement of P, the sample does not reach static growth conditions because neither photoinhibition nor possibly some components of photoregulation have reached equilibrium yet.

The experimental protocol is simulated using the three calibrated model replicates from Sect. 3.1, which correspond to the photoacclimation states at 15, 100 and 625 μE m^{-2} s^{-1} growth irradiance. The initial fraction of inhibited PSUs is taken as $c(0) = 0$ in agreement with the experimental data used for model calibration (Nikolaou et al., 2015). It is seen on the left plot of Fig. 2 that the initial slope of the predicted PI curves is constant and that the maximum photosynthesis rate is greater for higher acclimated cells, in agreement with results from the litterature (Anning et al., 2000; MacIntyre et al., 2002). Moreover the optimum light intensities and the maxima of photosynthesis rate for different acclimation states are linearly related (Hartmann et al., 2013). Finally, the photoinhibition profiles, reported on the right plot of Fig. 2 show that cells acclimated at lower light irradiance (hence with higher chlorophyll content) are more prone to photoinhibition.

Fig. 3 compares three predicted PI curves for a sample acclimated at 100 μE m^{-2} s^{-1}. The dashed curve is identical to the profile reported in Fig. 2; the dotted line represents the profile predicted if the value of C at the beginning of the protocol is 0.1; and the continuous curve represents the predicted PI curve if a longer protocol with 20 (instead of 10) stages of 5 minutes constant light is used. We can observe that both the initial slope and the maximum photosynthesis rate decrease if the sample has a certain amount of inhibited PSUs at the beginning of the protocol. Moreover, the dynamic simulation of PI curves shows that if a longer protocol is considered, the initial slope is not affected, but a reduction of the maximum photosynthesis rate and a larger reduction of P at high irradiance are obtained.

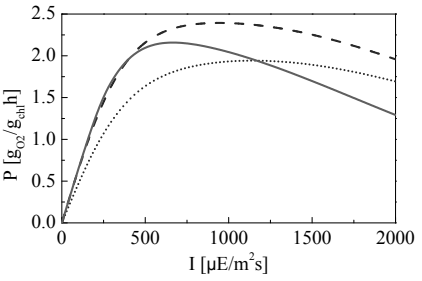


Figure 3: PI curves for a sample acclimated at 100 μE m^{-2} s^{-1}.

Note that in most of the literature, the light protocol used to derive them is not given. Our findings clearly show that the light protocol has a strong influence on the PI response curves and should always be considered to avoid drawing of misleading conclusions.

4. Conclusions

A semi-mechanistic model describing photoproduction, photoregulation and photoinhibition in microalgae has been extended to account for photoacclimation by varying a subset of the model parameters. The model predicts well experimental data of PAM fluorescence for three different acclimation states. Subsequently, a light-dependent photosynthesis rate expression has been formulated, which enables simulation of experimental protocols for the prediction of PI curves. Our results show that it is thus possible to predict PI curves using fluorescence measurements, thereby making the characterization of microalgae growth both faster and more robust. Moreover, our results underpin that the exact experimental protocol used to obtain PI curves and the initial condition of the photosynthetic apparatus are paramount and would thus need to be reported systematically. Future directions include the development of empirical relationships for photoacclimation-dependent parameters and the concurrent use of PI curve and fluorescence data for the purpose of model calibration and validation.

Abstract

This work presents the overview of process systems engineering (PSE) studies on water network and the industrial applications in China. The progresses are reviewed according to three levels: (1) water network integration and optimization at a single enterprise level; (2) multiple water network integration at inter-plant level; and (3) virtual water and water footprint analysis across regions/countries. The industrial implementation approach called "three-step approach" is demonstrated in China. The three steps are: (1) enterprise-wide water balance test and measurement; (2) water system decomposition and integration; (3) wastewater regeneration and reuse. According to Chinese experience of more than 20 petrochemical and coal based chemical enterprise projects, the reduction target of 20% ~ 60% of the freshwater could be achieved with using this approach.
Keywords: water network, water footprint, process integration, three-step approach

1. Introduction

The water crisis is becoming more serious. Stricter environmental regulation, higher cost in water tariff and wastewater treatmen, and shortages of freshwater resource have encouraged efforts for water management improvement and minimization of water consumption in process industries. Research papers published on water network study have dramatically increased since about 2005 (Yang et al., 2015). This paper consisted of two parts. In the first part an overview of the progresses of PSE studies on water network is described. The industrial application approach with a case study is introduced in the second part.

2. Brief overview for water network integration

2.1. intra-plant water integration

A considerable amount of work has been reported since Wang and Smith (1994a) initiated the insight-based approach on pinch analysis for Water Using Network (WUN). In their later work, the approach was extended into Wastewater Treatment Network (WWTN) synthesis (Wang and Smith, 1994a). Kuo and Smith (1998a; 1998b) proposed an approach to optimize the water using network with regeneration unit, then to optimize Total Water Network (TWN). Bagajewicz and Faria (2009) added a water pre-treatment unit into TWN called Complete Water Network (CWN), which can further reduce freshwater consumption. Ku-Pineda and Tan (2006) considered the environment impact of the retrofitting water network with a higher environmental cost as measured using a more comprehensive metric. Recently the simultaneous integration of the water network and the surrounding watershed is presented to satisfy process and

environmental constraints (Fernando et al., 2011) . The relation of these different system boundries is shown in Figure 1.

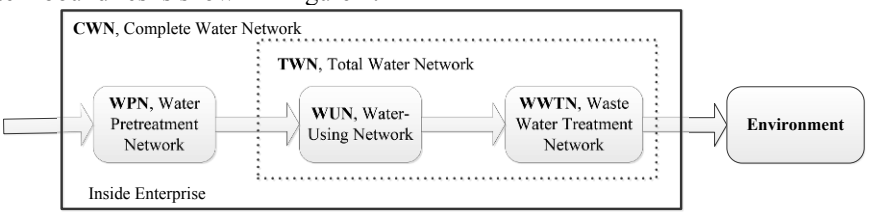

Figure 1 Different system boundaries for water network

In general, systematic design for water integration is in either of two ways: (i) targeting for the optimum profile of the process, ahead of detailed design and without commitment to the final system configuration. It is called *insight-based method;* (ii) putting the alternatives in the form of an optimization problem, using a superstructure which should be reduced to optimal solution. This method is *mathematic programming*. Various graphical techniques were proposed since the initiation of the water pinch analysis technique. Among these insight-based techniques, the three best developed techniques are limiting composite curve, material recovery pinch diagram and water cascade analysis (Foo, 2013). For the mathematic programming method, the optimization of the mathematical model associated with the superstructure is based upon non-linear programming/mixed-integer non-linear programming. An integration approach which combined the graphical approach with mathematical programming is proposed to minimize the industrial wastewater (Aiva-Argaez et al., 1998).

There are three special issues in the intra-plant water network integration, i.e. cooling water system, water-using network with internal water main and batch water network. Kim and Smith (2001) extended the water pinch analysis principle into the cooling water system. Majozi and co-workers made some extension (Majozi et al., 2006). Kim and Smith (2004) introduced the superstructure approach into the batch water network, which made the water network to be segregated by time. Since then many papers have been reported for the batch water network which have been reviewed by reference (Gouws et al., 2010).

Lots of studies have focused on the simultaneous optimization of water allocation and heat exchange network based on the mathematical programming (Klemes, 2013), which is called WAHEN (Water Allocation and Heat Exchange Network) problem. More over, in order to compare the best feedstock for gasoline schools led by Grossmann and Floudas extended into process optimization to meet the minimum freshwater, energy consumption targets (Ahmetovic et al., 2010; Baliban et al., 2011).

2.2. inter-plant water integration (IPWI)

Since the single plant can achieve the minimum freshwater consumption through direct reuse, recycle and regeneration scheme, the water minimization targeting approach for single plant is both simple to use and powerful. The system boundry is extended to two or more plants, the water saving opportunities will be improved. Indeed, in practice each water network may be grouped according to the geographical location of the water-using processes or as different plants operated by different business entities. Olesen and Polley (1996) first addressed the IPWI problem using the pinch-based load table technique. Among IPWI studies, there are two different schemes, i.e. direct and indirect integration (Chew et al., 2008). In the direct integration scheme, water sources may be integrated with sinks in different water networks directly. On the other hand, indirect integration is achieved via the centralized utility hub scheme. The implementation of

centralized utility hub improves the overall water network practicability and flexibility when serving a greater number of plants comprising the individual water network.

Recently the increase of public awareness towards eco-industrial parks (EIP) has inspired many researchers. Rubio-Castro et al. (2012) considered the optimal retrofit of water networks in the industrial zone. The freshwater cost presents a total of 75% savings with respect to the existing networks. Boix et al. (2012) formulated industrial water networks based on mixed-integer linear programming using a multi-objective optimization strategy, where fresh water, regenerated water flow rates as well as the number of network connections (integer variables) are minimized. Aviso et al. (2009) formulated a model which incorporates the benefits of networking relating to the individual goals and targets of the participants through fuzzy mathematical programming. Under the condition of freshwater price influenced by the market, Jia et al. (2010) proposed a superstructure based mathematical optimization method for total water networks with consideration of minimum cost in an industrial park.

2.3. Virtual water and water footprint studies across prefectures /countries

Virtual water refers to the water amount incorporated into the specific product such as rice and wheat, thus quantifying water consumption embodied in international trade (Allen 1997). Besides the amount, where and how water is consumed and/or discharged also affects the environmental pressure to water usages units at different scales, from process, product and company at micro level, to regional and watershed at meso-level, and to national and global scale. This consideration leads to the concept of water footprint which refers to the water amount required in the production or consumption of all goods and services at targeted scales. Three types of water footprint have been defined, including blue, green and grey water footprints, with the blue and green water footprints emphasizing the consumption of water and the grey water footprint highlighting the environmental impact of pollution (Hoekstra et al., 2012).

The water footprints concerned with industries, from the viewpoint of process systems engineering, mainly include but not limited to process, product and corporate water footprints. Process water footprint refers to the water consumption or pollution by the specific processes or plants. Product water footprint is defined as the water consumption or pollution along the product life cycle, which means the water consumed or polluted in the upper supply chains is also included. Corporate water footprint refers to the water consumption directly or indirectly to business operation.

One corporation may produce one or more products, and one product may need one or more processes to produce, thus the three kinds of water footprints are closely coupled (Sun et al., 2014). Generally, there are two methods to calculate water footprints. One is production tree method, which accounts for the water consumption of products based on the specific production cases and the utilization of water resources in different areas from the producers' point of view (Hoeksrea and Chapagain, 2007). The other is suggested by Zimmer and Renault (2003), which accounts for the water consumption by dividing products consumed into different types from the consumers' point of view.

Up to now, product water footprint has been more widely appreciated and applied. For crops, product water footprint is actually its virtual water in essence. Thus corn, wheat, rice and cotton were studied first. Later, the research extended to bread, butter, beer and other agricultural products, and then to meat, lamb, beef, chicken and other livestock products. Most of these products have high water footprints, and the livestock much higher than cropping. For example, the EU's research shows, the average water footprint of 150g beef burger is 2,350L water, nearly 15 times higher than the same amount of soy burgers (Hoekstra, 2009).

With the maturity of the water footprint concept and method, more and more industrial products such as steel, textile, paper, and even automobile complex products have been studied. Some results are shown in Figure 2. The results showed that huge structural differences between different industrial sectors and different life cycles. For example, the Volkswagen sedans have the water footprint of 52~84 m^3/car, with 95% of water consumed in the production stage, while only 1% consumed in the direct production process for papers (Manzardo et al. 2014). Unlike agriculture products, the challenges for industrial products lie in how to accurately track and quantify the complex and high-interwoven supply chains. Thus, PSE is expected to make a contribution to explore accounting, tracking and even mining policy implications to water footprints of industrial chains, industrial clusters and industrial layout on systematic level.

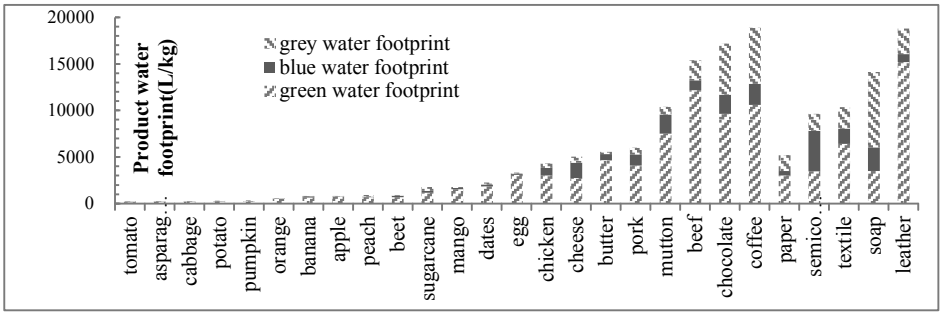

Figure 2 The water footprints of some selected agricultural and industrial products

3. Industrial application practices in China

In order to apply some developed water network integration methodologies, an approach called "three-step approach" is demonstrated in China (Yang et al., 2008; 2012). The first step is enterprise-wide water balance test and measurement. This is the most time consuming step.Water balance data are the basis of a whole project. The major results of this step are all concerned economic-technical criteria which representing the operation standard of the enterprise, such as quantity of water intake for per ton product, quantity of water intake for desalination water, steam condensate recovery ratio, quantity of wastewater for per ton product, wastewater recovery ratio, etc. The second step is water system integration and optimization in order to maximize the water reuse and minimize the wastewater discharge. The enterprise-wide water system is decomposed into seven subsystems, as shown in Figure 3. They are: freshwater treatment system, water pipeline system, process water-use system, cooling water system, condensate water system, living water system, and wastewater system. The third step is wastewater regeneration and reuse after wastewater reduction. This approach has been applied to more than 20 petrochemical and coal-based chemical enterprise projects since 2003. According to our experiences, 20% to 60% of freshwater intaken could be saved with this approach.

As a case study, this approach was applied in a coal to olefin (CTO) enterprise in Baotou, Inner Mongolia, China. According to the water balance measurement, quantity of water intake for ton olefin is 24.4 t (its designed value is 32 t); freshwater used for ton chemical water is 1.54 t (it standard value of chemical industry is 1.33 t); steam condensate recovery ratio is 85% and wastewater recovery ratio is 43.6% (its standard is ≥50%). Through improvement of the instrumentation and leakage check, about 30 t/h water could be saved. In the freshwater treatment subsystem, after optimizing the

desalination water processing and recovery of blowdown water from boilers and wash water of ultra-filter, 284 t/h of freshwater could be saved. In process water-using subsystem the water reallocation calculation was implemented with 5 impurity components, the result showed that 270 t/h freshwater could be saved. In cooling water subsystem, 1,000 t/h water is vaporized through cooling water towers. a new vapor recovery facility will recover 20% of this amount of vaporized water. The wastewater from cooling water plant is also recovered and reused as makeup water. After optimizing the whole cooling water plant, 390 t/h water could be saved. In the condensate water subsystem, recovery of vent vapor contributes 37 t/h condensate water. After above improvements of those 6 subsystems, the quantity of wastewater discharged was reduced 37%, a near zero liquid discharge technique called Non-Thermal Brine Concentrator (NTBC) is recommended. 95% inlet concentrated wastewater could be recovered for reuse; this will save 331 t/h water. Therefore, the freshwater intake is reduced from 1,796 t/h to 515 t/h. The quantity of water intake for per ton olefin from 24.4 t reduced to 7.01 t.

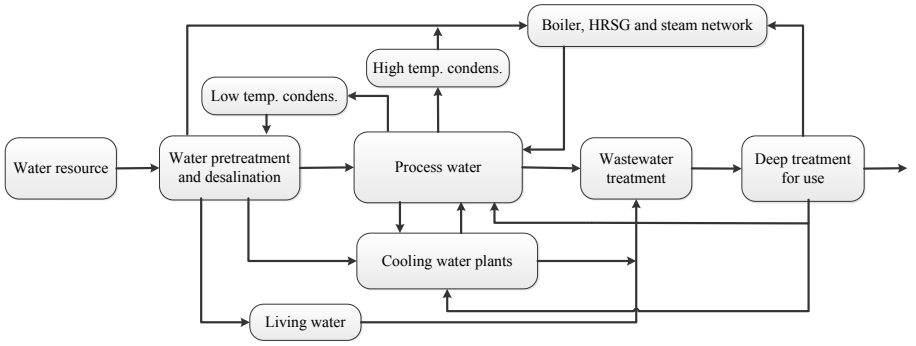

Figure 3 Seven subsystems for enterprise-wide water networks

4. Conclusions

Industrial water system optimization is a multi-scale and complex topic. Process integration and optimization methods in PSE not only play an important role in water conservation and wastewater reduction, but provide a theoretical basis for policy decisions. According to the scale boundries, this work reviewed the water network research via three levels, i.e. intra-plant, inter-plant, and regional-based. Specially, virtual water and water footprint study further broadened the field of industrial water systems. From the Chinese experiences, the industrial application of water network integration lagged far behind the theoretical studies. However, even though only few of them have been used in industries, the water saving effect is significant.

Abstract

This paper deals with the multi-objective optimal control of a small-size wastewater treatment plant, where the excess sludge produced is incinerated for electricity production. The trade-offs between the treatment quality and operating costs are characterized. Emphasis is put on a proper formulation of the problem so as to get physically relevant solutions. Sludge incineration is shown to be quite profitable energetically, especially when a high nitrogen discharge is tolerated.

Keywords: Multi-objective optimization; Wastewater treatment; Activated sludge.

1. Introduction

The activated sludge process, ASP (Figure 1), is nowadays the most widely used process for municipal wastewater treatment. Most small-size wastewater treatment plants (WWTPs) use the alternating activated sludge (AAS) version of the ASP. It consists of: (1) a reactor operating continuously where bacteria degrade the incoming pollutants, (2) a settling tank where activated sludge (flocculated biomass) is separated from the treated wastewater, (3) a sludge recycle line allowing to keep convenient bacterial concentration in the reactor, (4) a wastage line where excess sludge is purged. The reactor is sequentially aerated to provide alternating aerobic (supplies dissolved oxygen, DO, to bacteria) and anoxic conditions (depletion of DO but presence of nitrate/nitrite, S_{NO}): this operating policy constitutes the most economical nitrogen abatement strategy. Under aerobic metabolism, ammonium is oxidized into S_{NO} (nitrification process). The aeration-off periods enable minimizing the electrical consumption, and by depriving bacteria from DO, force them to use S_{NO} as a substitute terminal electron acceptor and reduce it into nitrogen gas (denitrifcation process).

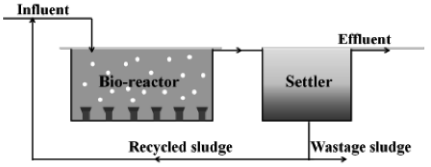

Figure 1. Schematic diagram of the activated sludge process.

Nowadays, since complying with the continuously strengthening environmental regulations involves additional costs, the wastewater industry is forced to improve the ASP functioning. In this context, dynamic optimization turns out to be a quite gainful technique since it can deal simultaneously with different objectives (minimize cost, comply with effluent limits…) and handles the high non-linearity inherent to the underlying biochemical phenomena, which is challenging even for experienced designers. Optimization has been applied to select the most lucrative operating strategy for existing ASPs, e.g. Chachuat et al. (2005), and for WWTPs to be designed (i.e. no infrastructure build yet), to simultaneously determine the units sizing and operating conditions that provide the most cost-effective treatment, e.g. Espírito-Santo et al. (2007).

However, the single-objective optimization approach hides the real nature of the problem since the conflicting aspects between the treatment quality and costs are not recognized. Therefore, in the framework of optimal control/design of ASPs, there is an increasing attention to multi-objective optimization (MOO), e.g. Hakanen et al. (2013). MOO generates a set of optimal solutions (named Pareto front, PF) expressing the minimal cost enabling to reach a given treatment efficiency. A decision maker (e.g. an expert), DM, then examines these solutions and selects which one to be implemented on the real-scale ASP. A primary advantage of MOO is that it allows benefiting from the DM experience. Indeed, given his/her expertise, he/she will avoid for example solutions that may lead to suboptimal operating conditions (e.g. poor sludge settleability).

This paper deals with the multi-objective optimal control of a small-size WWTP, where the excess sludge produced is incinerated for electricity production. Emphasis is put on a proper formulation of the MOO problem so as to get physically relevant solutions.

2. Multi-objective optimization problem statement

2.1. Process layout

The investigated ASP consists of a reactor (V=6000 m^3) equipped with a diffused aeration system, and of a cylindrical settler (height = 4 m, cross-section = 1,500 m^2). The injected air flow rate can be controlled by means of valves. During non-aeration periods, a mixer maintains the solids in suspension. The excess sludge produced is valorized in an incineration plant to produce electricity. Influent characteristics reflect typical disturbances resulting from the life patterns of households (dry-weather file by Copp (2002)). The average incoming flow rate is about 18,000 $m^3.day^{-1}$.

2.2. Process model

The bio-reactor is treated as an ideal continuous stirred-tank reactor. The occurring biochemical reactions are modelled using the well-known ASM1 model (Henze et al., 1987) which tracks the evolution of the process key variables (e.g. DO concentration). Mass balances around the reactor for each of these variables give rise to 13 highly non-linear ordinary differential equations (ODEs). Liquid-solid separation in the settler is modelled using the well-known Takács et al. (1991) model, and leads to 80 ODEs.

2.3. Optimization problem formulation

The MOO problem can be stated as follows:

$$\min_{\boldsymbol{u}} \boldsymbol{J}(\boldsymbol{x}, \boldsymbol{u}, t_f) = [\text{Operating costs}, \text{Nitrogen discharge}]^{\mathrm{T}} \quad (1)$$

Subject to:

$$\text{Process model equations: } \boldsymbol{f}(\boldsymbol{x}, \dot{\boldsymbol{x}}, \boldsymbol{u}, t) = \boldsymbol{0} \quad (2)$$

$$\text{Initial conditions: } \boldsymbol{x}(t_0) = \boldsymbol{x}_0 \quad (3)$$

$$\text{Constraints: } \boldsymbol{g}(\boldsymbol{x}, \boldsymbol{u}) \leq \boldsymbol{0} \quad (4)$$

$$\text{Decision variables bounds: } \boldsymbol{u}_L \leq \boldsymbol{u} \leq \boldsymbol{u}_U \quad (5)$$

$$\text{with } \boldsymbol{u} = [Q_{Air}(t), Q_w(t), Q_R]^{\mathrm{T}}$$

where t is the time and t_f the time horizon; $\boldsymbol{x}$ represents the set of the 13 process state variables (and $\dot{\boldsymbol{x}}$ its time derivative); $\boldsymbol{u}$ is the set of decision variables (DVs): Q_{Air} the injected air flow rate, Qw the sludge wastage flow rate and QR the external recycling flow rate. u_L and u_U are the DVs' lower and upper bounds respectively; g represents the set of inequality constraints that must be fulfilled by the optimal solution.

Nitrogen discharge is chosen as an objective function in order to characterize the trade-offs between the treatment's cost and efficiency. Indeed, it is much harder to remove nitrogenous than carbonaceous matter from municipal wastewater (Chachuat et al., 2005).

Q_{Air} and Q_w are considered as time-varying DVs. The situation can be achieved physically thanks to valves installed on the air and sludge lines. Time-varying aeration rate is necessary to allow performing nitrification and denitrification in the same tank. These variables are parameterized using the 'Control Vector Parameterization' (CVP) approach. Q_R is treated as a time-independent DV: in practice, the recycle flow is lifted by a screw pump which is generally operated at constant capacity.

The MOO problem seeks for the optimal daily operating strategies and considers a time horizon of 100 days. Such a large time frame is required so as to get solutions ensuring a sustainable plant operation: as shown by Chachuat et al. (2005), operating procedures determined from a short time operation optimization can lead to biomass washout. The operating costs objective function involves pumping, aeration and mixing power consumptions. The produced sludge is valorized through incineration to produce electricity, what reduces operating costs. The treatment quality objective function is stated as the minimization of the effluent average nitrogen concentration between the 86th and the 100th day. Such a formulation (Copp, 2002) ensures that the objective function is computed during the cyclic steady regime only, and hence, mitigates the effect of the plant's initial state with regard to the computed PF. In fact, the initial conditions should not influence the optimal solution since their effects vanish with time.

The problem is solved using an elitist genetic algorithm of which details can be found in (Benyahia et al., 2011). For all the investigated cases, a population of 400 individuals is used, and the maximum number of generations equals to 35.

2.4. Cost functions

Q_{Air} and the oxygen mass transfer coefficient (k_La) are linked through the empirical formula derived by Gillot and Héduit (2004) from on site measurements in ASPs:

$$k_L a = 1.477 h^{-0.136} S^{-1.175} S_p^{0.042} S_a^{0.145} Q_{Air}^{1.037} \quad (6)$$

where h is the water column height in m (taken as 4 m), S_a the surface covered by the diffusor modules in m^2 (taken as the surface of the reactor), S_p the total membrane surface in m^2 (taken as 7 % of the reactor surface), k_La is in h^{-1} and Q_{Air} in Nm^3.h^{-1}. To account for the detrimental effect of the concentration of suspended solids (SS) in the mixed liquor on the oxygen transfer rate, Eq.(6) is corrected using the mass transfer reduction factor α (Marrot et al. (2005); formula valid for 0 g.L^{-1}≤ SS≤ 10 g.L^{-1}):

$$\alpha = -0.072 \times SS + 1 \quad (7)$$

Thus, Eq.(6) is multiplied by (α/0.712): it is considered that the mean SS in the reactors investigated by Gillot and Héduit (2004) is 4 $g.L^{-1}$, a concentration to which corresponds an α of 0.712. Accounting for this effect is novel in the framework of the optimization of ASPs operation/design. Finally, the power delivered by the blower is calculated assuming an adiabatic compression and an efficiency of 70 %.
Recycling pumping power is calculated according to the formula:

$$Pumping\ power = \frac{\rho g Q_R \Delta H}{\eta_P} \quad (8)$$

where ρ is the fluid density, g the gravitational acceleration, ΔH the differential head (taken as 4 mWC for simplification purposes) and η_P the pump efficiency (taken as 50 %). Sludge wastage is gravity-driven and does not require pumping. Mixing is modeled according to the formulation by Alex et al. (2008): the mixer is used when $k_L a$ is lower than 20 h^{-1}, and its specific power consumption is 5 $W.m^{-3}$. The extracted sludge is thickened, dewatered and dried so it can burn. These operations are supposed to cost 1 kWh per kg of dry sludge. The dry sludge (its calorific value is taken as 15 $MJ.kg^{-1}$) is valorized in an in-site incineration plant (30 % efficiency) for electricity production.

2.5. Constraints and decision variables bounds

Effluent limits for chemical oxygen demand, biological oxygen demand and SS are handled through inequality path constraints: their instantaneous concentration must remain below the specified limits, 100, 10 and 30 $g.m^{-3}$ respectively. Compared to the literature, a more correct formulation is provided: these constraints are accounted for only after the 86th day. Indeed, activating a constraint during the transient period makes the solution depending on the arbitrarily guessed plant's initial state. Sludge age (i.e. solids retention time) is restricted between 4 and 30 days. The lower bound deals with bio-flocculation requirements, while the upper bound limits the sludge mineralization as it alters its calorific value. The screw pump is supposed to provide a maximum flow rate Q_R of 40,000 $m^3.day^{-1}$. The maximum value of Q_w is set to 1,000 $m^3.day^{-1}$. According to Grady et al. (1999), to prevent bioflocs shearing, Q_{Air} should comply with:

$$\frac{1000 Q_{air}}{Lim} \leq V \quad (9)$$

where the *Lim* factor is about 90 m^3/(min.1,000 m^3). However, in the present study, a value of *Lim* of 50 m^3/(min. 1,000m^3) is assumed so that the maximum Q_{air} matches the capacity of aerators typically used nowadays.

3. Results and discussion

3.1. Preliminary results

The MOO problem is solved for 3 situations. In the 1st problem, Q_{Air} and Q_w are allowed to change every 2 hours (12 cycles by day), which results in 25 DVs. The 2nd problem is similar, but sludge disposal and valorization are not accounted for in the exploitation costs objective function. In the 3rd problem, Q_{Air} and Q_w are taken as time-independent DVs (thus the problem involves 3 DVs) so as to characterize the benefits provided by dynamic operating conditions (sludge-related charges are taken into consideration). The PFs corresponding to the first two problems are shown in Figure 2. Each one required

about 6 days of CPU time on a 3.1 GHz personal computer. The results show that the operating costs increase with increased efficiency of nitrogen removal, and that sludge incineration is more profit-making when high nitrogen discharge limits are tolerated.

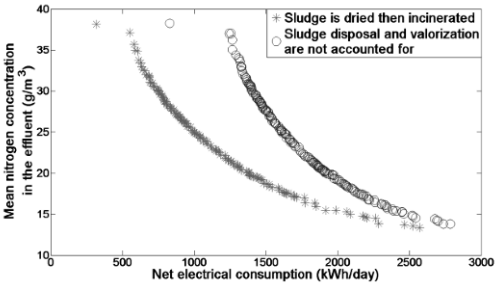

Figure 2. Effect of sludge disposal and valorization on the Pareto front.

When the 3rd problem was solved, the resulting PF (not shown here) was found to be nearly the same as for the 1st problem. At first sight, this outcome is quite surprising since a constant Q_{Air} does not allow performing both nitrification and denitrification. A closer look to the results revealed that for the 3 problems, the optimal solutions correspond to conditions of low DO in the reactor, in the range of about 0.2-0.4 $g.m^{-3}$. In fact, in the framework of ASM1, such conditions allow simultaneous nitrification and denitrification at low aeration costs, i.e. an excellent treatment with low operating charges. Although the results are mathematically correct, they are physically irrelevant since in practice, ASPs cannot achieve an efficient treatment in this range of DO concentrations. In fact, as discussed by Rigopoulos and Linke (2002), the accuracy of ASM1 in this range of DO conditions is questionable.

3.2. Results using additional constraints relative to DO concentration

To provide realistic results, supplementary constraints were used in order to restrict the solutions space to physically relevant operating conditions: at each cycle, the mean DO should be higher than 2 $g.m^{-3}$ (aerobic conditions; a similar constraint was used by Espírito-Santo et al. (2007) who focused on the static optimization of a classic ASP) or lower than 0.1 $g.m^{-3}$ (anoxic conditions). With this realistic problem formulation, MOO showed that, when using time-independent DVs (Pb. 3), the ASP could not achieve lower nitrogen discharge than 35 $g.m^{-3}$ (results not shown here). Problems 1 and 2 were also solved again, however, for computational expenses reasons, 4 h cycle lengths were used (instead of 2 h as previously). In fact, this new problem formulation results in 12 additional constraints (2 DO constraints per cycle) which dramatically increased the computational time: each PF (Fig. 3) required about 21 days of CPU time. In fact, as the feasible solution space is reduced, the genetic algorithm required more trials before it could generate a child solution that dominates its parents (Benyahia et al., 2011).

Fig. 3 shows the PFs corresponding to problems 1 and 2. Sludge incineration is shown to be quite profitable energetically, especially when a high nitrogen discharge is tolerated. Comparison with Fig. 2 reveals that the use of DO related constraints results in higher exploitation costs, and the lowest nitrogen concentration in the effluent that can be achieved increases to about 16.9 $g.m^{-3}$. However, these results are more realistic since the optimal solutions are maintained within the limits of validity of the model. For high nitrogen removal efficiencies, the optimal solutions correspond to an AAS operation: aeration is alternated so as to provide cycling anoxic and aerobic conditions.

For low treatment efficiencies, the operation strategy differs from the AAS operation since the optimizer favours non-aerated cycles in order to reduce the operating costs.

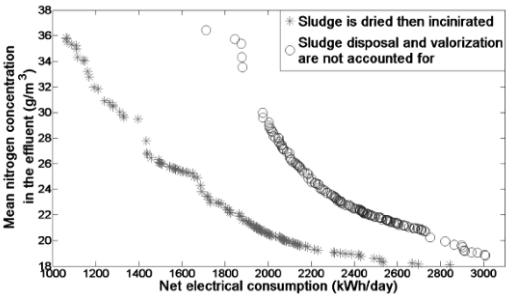

Figure 3. Pareto fronts when DO-related constraints are included in the optimization problem.

4. Conclusions

In this work, a multi-objective dynamic optimization of the operating strategy of a small-size wastewater treatment plant is carried out. The trade-offs between the treatment quality and operating costs are characterized. Compared to the literature, emphasis is put on a proper formulation of the optimization problem so as to get physically relevant solutions. Sludge incineration is shown to be quite profitable energetically, especially when a high nitrogen discharge is tolerated.

Abstract

The development of effective wastewater regeneration and reuse networks has been a prominent research focus, in response to the growing demand for freshwater use by the industrial sector. Moreover, many industrial cities are recognizing the benefits of reducing freshwater utilization, and wastewater discharge, by promoting effective wastewater treatment. Much of the research attention so far has primarily involved identifying optimal wastewater treatment and reuse strategies, in which several wastewater-producing operations are matched with a number of water-consuming operations, and/or assigned to undergo a series of treatment steps before reuse, if necessary. Moreover, a single pipeline is designated for every viable water allocation identified. This has been consistently observed in many of the previous research contributions that involve interplant water network synthesis. In an attempt to enhance the water network design process, several representations that account for a number of pipeline merging scenarios have been investigated for wastewater reuse networks. In addition to the improved design-screening ability of less complex pipeline networks, merging together common pipe segments that carry similar water qualities have been found to allow for various cost-enhancements in the designs obtained.

Keywords: Water Networks, Industrial Cities, Pipelines, Merging

1. Introduction

Industrial water and wastewater management has become a crucial research priority in many regions, due to the immense scale of water-intensive industrial activities. Wastewater reuse certainly alleviates the depletion of available freshwater sources that are present around industrial areas. Moreover, many industrial sites that lie in proximity to coastal areas involve large volumes of unused wastewater being diverted back into the sea, which negatively impacts aquatic life (Englert, 2013). Hence, wastewater reuse also helps reduce the excessive wastewater quantities being discharged back into natural water bodies. Identifying appropriate wastewater treatment alternatives is considered of significant importance due to the stringent discharge limits being imposed on industrial wastewater, as well as the strict effluent standards that industries are expected to adhere to. Potential opportunities for industrial wastewater reuse would absolutely vary from one industry to another, depending on the quantity and quality of wastewater produced.

2. Previous Work

The design of cost-effective wastewater regeneration and reuse networks has been the primary focus of many previous studies. For instance, Chew et al. (2009) developed a centralized hub topology for collecting, treating and redistributing water amongst groups of coexisting plants. Rubio-Castro et al. (2010) devised a MINLP optimization model for interplant water networks whilst incorporating environmental regulations for wastewater discharge. A problem reformulation that handles bilinear terms was also proposed. Biox et al. (2012) also studied water network design using a multi-objective optimization strategy. Later on, a structured representation has also been proposed, so as to capture the spatial aspects of water network design (Alnouri et al., 2014a). Effective planning of wastewater reuse networks have been captured with a focus on the following elements: (1) existing processing facilities, water consumption and wastewater production capacities, (2) site locations and the spatial distribution of all site entities that entail water use or production, and (3) common infrastructure boundaries, such as the existence of industrial corridors that can be utilized for water transportation. Subsequently, the spatial aspects of wastewater regeneration and reuse networks have also been studied (Alnouri et al., 2015). Several different options for the selection of appropriate treatment technologies, as well as the efficient placement of corresponding treatment facilities, have been incorporated as follows: (1) a cluster of processing establishments sharing a common treatment facility (centralized), (2) the placement of a treatment facility as an individual entity belonging to a particular industrial site (decentralized). So far, most interplant water integration problems that have been studied associate every water allocation with a separate pipeline. In this work, a pipeline merging and assembling strategy for wastewater regeneration and reuse networks has been carried out.

3. Research Background

Exploring interplant water integration in terms of less complex and more economical options for the transmission and distribution of water in pipelines has been previously introduced for wastewater reuse networks (Alnouri et al., 2014b). In this work, efforts have been made to further improve the design process for wastewater reuse and regeneration networks. Most importantly, constructing interplant pipeline networks for water collection and transmission requires infrastructure availability, usually amongst a group of plants within geographic proximity. Moreover, the decision-making procedure involved with designing a cost-effective pipeline network for water transport can range from simple to complex. Various factors can greatly influence the design, such as the material choices available, as well as pipe construction and installation costs. Generally speaking, it is always considered more economical to employ a single-pipe transmission rather than multiple parallel pipes, especially when multiple locations are simultaneously involved. Hence, pipelines are usually constructed to accommodate a number of supply and destination points. Moreover, since pipeline systems are often made available in standard sizes, optimal diameter selection strategies for various pipe segments must also be incorporated, based on size availability.

4. Methodology

This work provides an extension to our work (Alnouri et al., 2014b) by incorporating options for the synthesis and design of merged pipeline networks involving wastewater treatment, regeneration, and reuse. In order to avoid unwanted water mixing in the merging procedure, the proposed methodology can be carried out on pipelines that carry

treated, and untreated water qualities, individually. Hence, identifying cost-effective opportunities that allow the screening of less complex pipeline networks by assembling together commonly existing pipe sections, in the course of determining optimal water networks, have been based on the following two schemes:

4.1. Forward Branching Scheme

This pipeline branching approach corresponds to the transmission of water from a common location, to multiple nearby destinations. Hence, pipelines that apply a forward branching scheme is assembled by starting with one large pipe segment that combines all water in a given location to be distributed. The segments then narrows down to smaller ones that connect to multiple destinations. Forward branching can be applied to (1) source-to-sink and (2) fresh-to-source, and (3) source-to-treatment, (4) treatment-to-sink, and (5) treatment-to-waste connectivity categories.

4.2. Backward Branching Scheme

This pipeline branching approach corresponds to the transmission of water from a number of nearby locations, to a single destination. Hence, pipelines that apply a backward branching scheme is assembled by starting with multiple small pipe segment that connect to a single location. The segments widen up and combine as the destination is approached. Backward branching can be applied to (1) source-to-sink and (2) sink-to-waste, (4) treatment-to-sink, and (5) treatment-to-waste connectivity categories.

5. Case Study

The illustrative case study described below has been utilized to demonstrate the proposed methodology. Figure 1 provides the layout of the industrial zone that has been assumed. A total of 4 co-locating plants are incorporated, 3 of which involve an on-site wastewater treatment facility. Additionally, a centralized treatment unit shared amongst all plants has also been provided, for which a specified treatment option can be selected. The total area of the region was assumed to be 64 km^2. Table 1 provides the case study flowrate and composition data for all available source and sink water streams. A total of 3 pollutant concentrations has been provided for this case study, as 3 different contaminants were assumed in all process water streams. Table 2 outlines all contaminant removal ratios, as well as the corresponding fixed and operating cost elements that are associated with the decentralized treatment units, as well as the centralized treatment option. Additional information requirements that were associated with the individual plants involve the following: (1) freshwater cost =0.13 $/t, (2) waste disposal cost =0.9 $/t, and (3) operating hours =8760 h/y. Moreover, carbon steel Schedule 80 welded pipes were assumed throughout, and the calculated pipeline diameters were rounded up in increments of 0.1, to the nearest standard size in meters. All piping costs were annualized over a 20-year lifetime. In this case study, only forward branching has been applied for the purpose of pipeline merging.

The problem described above has been formulated as a mixed integer nonlinear optimization problem (MINLP) for treatment and direct recycling. The corresponding water allocation strategy has been obtained using “what’sBest9.0.5.0” LINDO Global Solver for Microsoft Excel 2010, using a desktop PC with Intel® Core ™ i7-2620M, 2.7 GHz, 8.00 GB RAM, and a 64-bit Operating System.

Table 2. Wastewater treatment parameters in terms of pollutant removal ratios, and costs

Interceptor	Y 1	Y 2	Y 3	CAP.EX ($)	OP.EX ($-kg)
TR-P1	0.7	0.6	0	0	0.203
TR-P2	0.8	0	0.6	0	0.444
TR-P4	0	0.9	0.8	0	0.752
CTR-1	0.9	0.9	0.9	12,400	0.908

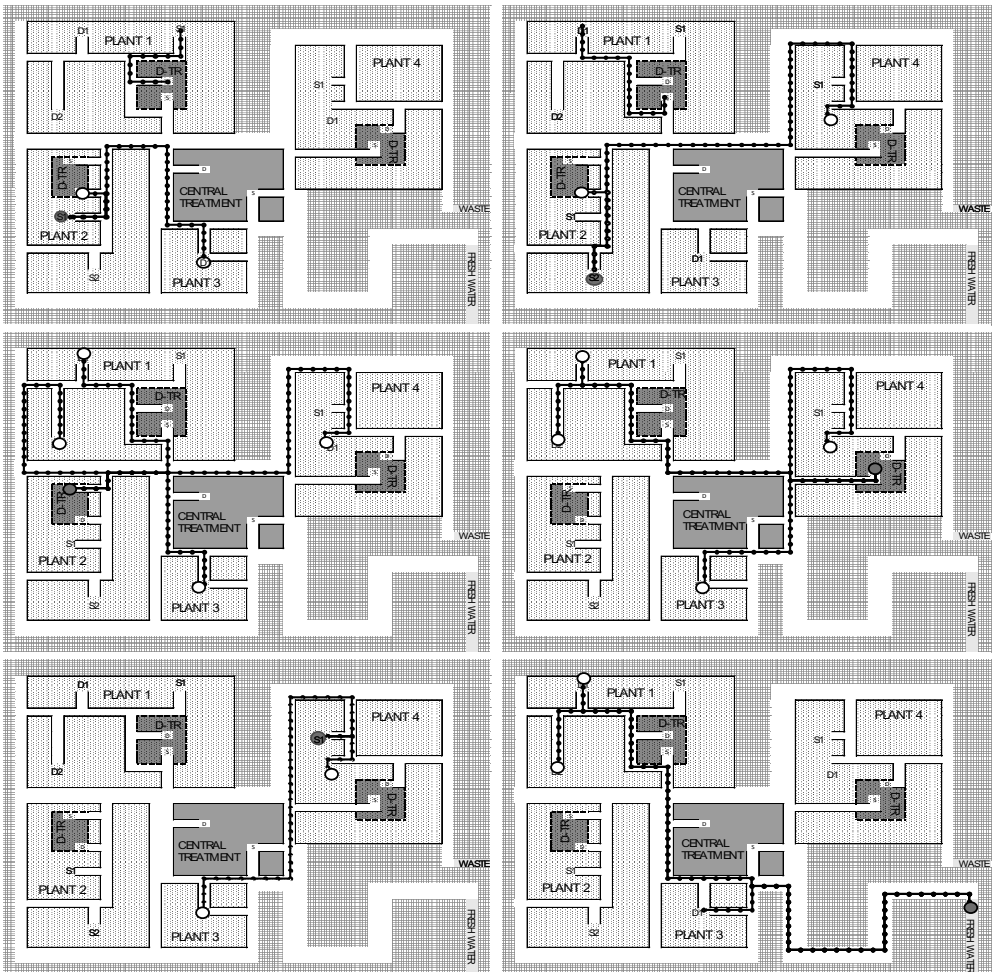

Figure 1. Forward pipeline branching illustrated

Table 3. Water flows obtained

(t/h)	P1D1	P1D2	P3D1	P4D1	TR-P1	TR-P2	TR-P4	C-TR	Waste
P1S1	0	0	0	0	100.00	0	0	0	0
P2S1	0	0	10.51	0	0	59.49	0	0	0
P2S2	0	0	0	9.69	0	150.31	0	0	0
P4S1	0	0	5.51	8.94	0	0	115.56	0	0
TR-P1	100.00	0	0	0	0	0	0	0	0
TR-P2	41.32	84.71	28.08	55.69	0	0	0	0	0
TR-P4	21.42	49.36	9.09	35.69	0	0	0	0	0
C-TR	0	0	0	0	0	0	0	0	0
Fresh	17.26	15.92	36.82	0	0	0	0	0	0

Table 3 summarizes all flowrates associated with the water allocation strategy obtained. Figure 2 illustrates the pipeline merging scenarios that have been achieved via forward branching. The total annualized cost of the water network attained was found to be $9.83x10^5$ \$/yr, after incorporating a forward branching scheme as a pipeline merging option. Freshwater consumption was found to be 70 t/h, while 0t/h of wastewater was obtained. Hence, no wastewater disposal costs were reported. The total treatment costs= $4.66x10^5$\$/yr, freshwater costs =$7.97x10^4$ \$/yr, and pipeline costs =$4.38x10^5$ \$/yr. The total annualized cost of the water network attained when no pipeline merging was involved yielded a total of $1.04x10^6$ \$/yr, with a similar treatment and freshwater performance. However, the total pipeline costs were found to increase to a total of 4.93 $x10^5$ \$/yr when no merging was implemented. Hence, the case that incorporates forward pipeline merging, allowed up to 5.64% savings on total costs (corresponding to a total of 12.7% savings on pipeline costs), when compared to the standard design.

6. Conclusions

In this work, additional considerations that account for pipeline merging scenarios has been studied for wastewater regeneration and reuse networks. The proposed framework allows cost-effective interplant water network designs to be identified, by implementing a systematic approach for interplant water network synthesis and design that incorporate for pipeline merging. An artificial case study has been implemented, involving a number of water-consuming and wastewater producing processes. Moreover, a number of centralized and decentralized wastewater treatment options were also incorporated. The results indicate very attractive wastewater treatment and reuse schemes for the water network designs extracted. Cost-efficient water networks that involve merged pipeline segments in the designs extracted, have been identified.

Simultaneous Design and Planning of CO_2 Transport Pipeline Network for Carbon Dioxide Capture and Sequestration Project

Xiong Zou,[a] Hongguang Dong,[a*] Jian Li,[a] Jinqu Wang[a]

[a]*School of Chemical Engineering, Dalian University of Technology, 2 Linggong Road, Dalian 116024, China*
hgdong@dlut.edu.cn

Abstract

Carbon dioxide Capture and Sequestration (CCS) is a major method to decrease the emissions from centralized large industrial plants. Multi-period planning and design of CCS is still a challenging problem. In this work, a superstructure-based mathematical model for the design and planning of multi-period CO_2 transport pipeline network is presented. The mapping between incidence matrix and pipeline structure is employed and the model is formulated within a mixed integer nonlinear optimization framework where the objective function is to maximize the profit of CCS while satisfying mass, pressure drop and logic constraints. A real life example is studied to demonstrate the advantages of our proposed approach.

Keywords: CCS, design, planning, supply chain, multiple-period.

1. Introduction

Carbon dioxide (CO_2) capture and sequestration (CCS) can significantly reduce emissions from large stationary sources of CO_2, which include coal- and natural-gas-fired power plants, as well as petro-chemical plants. CCS is a three-step process that includes: capture and compression, transportation (usually in pipelines), and injection and sequestration. The capital investment and operating cost of the pipeline network have a direct impact on the success or failure of a CCS project.

Considering the complexity of the scheduling of network pipeline system, several techniques are used to enhance the model performance. A hierarchical approach was developed by Beschetto and Magatão et al (2012), where the problem is decomposed into planning and assignment levels and two MILP models were solved sequentially. Fimbres Weihs and Wiley (2012) used incidence matrix to express the structure of the CCS and they obtained the design of CCS network under the assumption of fixed state flow. Recently, Zhou et al (2014) introduced a new decomposition algorithm to overcome the computational difficulty. In their work, intermediate sites were included in the network superstructure and the optimal capture amount of CO_2 was also considered.

To the best knowledge of the authors, there is no current work that considers the influence of multiple-period planning in the procedure of network and pipeline design. In this work, a superstructure-based MINLP approach for simultaneous design and planning of CO_2 transport pipeline network is presented in an attempt to maximize the

profit in a CCS project under the framework of supply chain. The advantages of this approach are summarized below:

1. The diverse CO_2 capture and sequestration capacities and costs in different sources and sinks are considered. The transporting amount of CO_2 is optimization variable rather than predefined parameter.
2. Supplier-intermediate site-customer and supplier-supplier connections are introduced in the network superstructure to achieve the sharing mechanism of pipelines in the long distance transportation, which leads to cost reduction.
3. The fluctuations of plant capacity and cost in the time horizon are also considered in the model. The planning, network structure and design specification of each pipeline in multiple periods are optimized simultaneously.

2. Problem statement

Consider a supply chain of CO_2 with all alternative sources, sinks and intermediate sites. The following information should be provided: (1) The longitude and latitude values of place nodes (2) The CO_2 capture and sequestration capacities of each source and sink in each time period (3) The seasons-dependent cost information of CCS (4) The physical property of CO_2 stream in the compressed pressure and temperature.

3. Superstructure

Our scenario of CO_2 supply chain superstructure is schematically presented in Figure 1(a), which contains 9 sources, 2 intermediate sites and 3 sinks. The circle, the triangle, and the square represent the sources, the intermediate sites, and the sinks respectively. The sources and sinks are linked by pipelines, where CO_2 is transported. Intermediate sites, where multiple streams could be mixed, also exist in the network. Each source is regarded as a supplier, which provides CO_2 raw material at its own capture cost. Each pipeline and intermediate site is treated as a factory which transports CO_2, and each sink is treated as a customer, who wants to buy CO_2 product at the price of its own unit sequestration revenue. Supplier-supplier and supplier-intermediate site-customer connections are introduced in the network superstructure. The supplier-supplier and supplier-intermediate site connections are realized by reversal pipelines. Customers are assumed to be not link to each other.

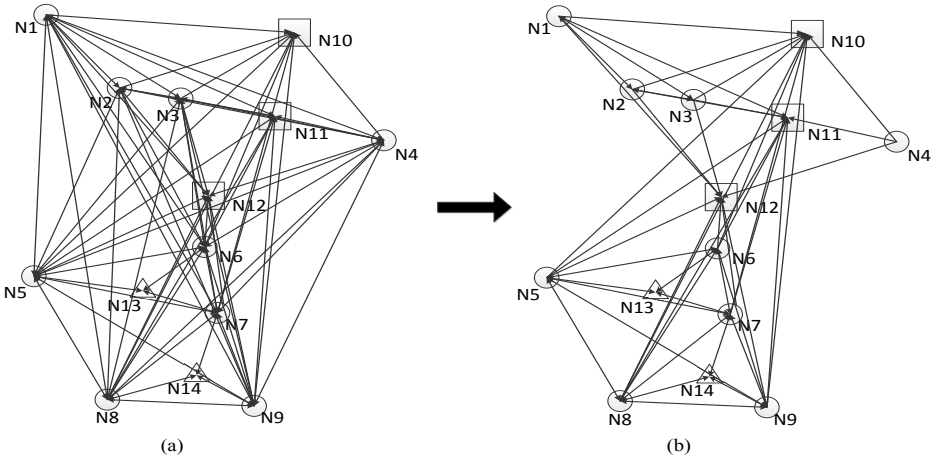

Figure 1. The superstructure of the example

To reduce the network complexity, the sources are divided into 3 parts based on cluster analysis method and only the sources in the same part are linked to each other with reversal pipeline. Each source is linked to 3 sinks respectively with directional pipeline. The first part includes N1, N2, and N3. The second part only has N4. The third part has N5-N9. The distance between sources in the different part is always overlong. So the superstructure can be simplified from Figure 1 (a) to (b) by eliminating these pipelines.

The topology relationship between the pipelines and place nodes is expressed by a node-arc incident matrix. The columns of the incident matrix represent each of the pipeline links and the rows of the matrix represent each of the place nodes. The value of element $w_{i,i}$ in the matrix is determined by the following rules: $w_{i,i}=1$ if pipeline j is the input of place node i; $w_{i,j}=-1$ if pipeline j is the output of place node i; $w_{i,j}=0$ if there isn't a connection between pipeline j and place node i. Notice that all the pipelines, between sources and intermediate sites and between sources and sources, are bidirectional and that they are represented by two single directed pipelines which cannot be activated in the same time interval.

4. Mathematical formulation

Some sets are defined for more logical and clear expression. Sinks, sources and intermediate sites are represented by set S(s_1, s_2, s_3,..), O(o_1, o_2, o_3,..), E(e_1, e_2, e_3,..), respectively, and I={S,O,E}. Pipelines are represented by set J (j_1，j_2，j_3...). Different seasons are represented by set T (t_1, t_2, t_3, t_4).

4.1. Mass balance constraints

Carbon dioxide captured from sources should be compressed and then transported to sinks. The amount of CO_2 captured is determined by the economic benefit and environmental regulation policy. $P_{s,t}$ represents the capture capacity of source *s* in the time interval *t* and PP_t represents the minimum capture quantity in the whole district based on regulation policy. $Q_{j,t}$ represents the flowrate of pipe j in time interval t. $C_{s,t}$ represents the CO_2 capture quantity of source s in time interval t. The mass balance constraints of sources are expressed as

$$\sum_j -w_{s,j} \times Q_{j,t} = C_{s,t},\ s \in S,\ t \in T \tag{1}$$

$$\sum_s \sum_j -w_{s,j} \times Q_{j,t} \geq PP_t,\ t \in T \tag{2}$$

The amount of CO_2 sequestrated should be smaller than the sequestration capacities of the sinks ($P_{o,t}$). Similarly, the mass balance equation of each sink can be expressed as follow.

$$\sum_j w_{o,j} \times Q_{j,t} = SE_{o,t},\ o \in O,\ t \in T \tag{3}$$

There are no emission and storage of CO_2 in the intermediate sites. The mass balance equation of each intermediate site can be expressed as follow.

$$\sum_j w_{e,j} \times Q_{j,t} = 0,\ e \in E,\ t \in T \tag{4}$$

4.2. Pressure drop constraints

The pressure drop ($P_{j,t}$) in the pipeline is relevant to diameter (d_j), length (L_j), and physical properties. ρ and σ are the density and viscosity of CO_2 in 9 MPa, 283K.

$$P_{j,t} = k_{drop} \times L_j \times Q_{j.t}^{2.84} \times d_j^{-4.84} \times \rho^{0.84} \times \sigma^{0.16},\ j \in J, t \in T \tag{5}$$

4.3. Logic relations

For reversal pipelines, they are represented by a couple of pipelines, which are not activated at the same time, and their diameters should be the same. Binary variable $y_{j,t}$ is used to expressed whether the pipeline j is activated in time interval t. If a pipeline j is activated in time interval t, it is equal to 1. Otherwise, it is equal to 0.

$$y_{j,t} + y_{j',t} \le 1, \text{ if j and j' are couple pipelines} \tag{6}$$

$$d_j = d_{j'}, \text{ if j and j' are couple pipelines} \tag{7}$$

When all the binary variables for the same pipeline j in different time intervals equal 0, the pipeline j does not exist. M_1 is the upper bound of the pipeline diameter.

$$d_j \le M_1 \times \sum_t y_{j,t},\ j \in J \tag{8}$$

The diameter of a pipeline should not be too small if the pipeline exists. The lower bound of the pipeline diameter M_2 is set as 0.15.

$$M_2 \times y_{j,t} \le d_j,\ j \in J, t \in T \tag{9}$$

Once the pipeline is activated in the time interval t, the flow in the pipeline should be suitable for real case, and it cannot be too small or too large. If the pipeline is not activated in the time interval t, the flow in the pipeline should be 0. The lower bound of flow M_3 equals to 0.10 and the upper bound M_4 equals to 30.

$$M_3 \times y_{j,t} \le Q_{j,t} \le M_4 \times y_{j,t}, j \in J, t \in T \tag{10}$$

4.4. Objective function

The profit is established with 5 items: government subsidy (GS), capture cost ($C_{capture}$), transportation cost ($C_{transportation}$), pipe cost (C_{pipe}) and sequestration cost ($C_{sequestration}$). The unit capture cost $U_{s,t}$, unit sequestration cost ($U_{o,t}$) and government subsidy of unit CO_2 reduction(U_{gs}) are given. Transportation cost is proportional to pressure drop. Pipe cost is related to the length and diameter of the pipe. k_{drop}, k_{pipe} and $k_{transport}$ are the coefficients of pressure drop, pipe cost, transportation cost, respectively. The sequestration revenue of each sink equals to the government subsidy of CO_2 reduction minus sequestration cost. Now the government subsidy is quite higher than the sequestration cost.

$$GS = \sum_o \sum_t (U_{gs} \times \sum_j (-w_{o,j} \times Q_{j,t})) \tag{11}$$

$$C_{pipe} = k_{pipe} \times \sum_j (L_j \times d_j^{1.5}) \tag{12}$$

$$C_{transportation} = k_{transport} \times \sum_{j} \sum_{t} P_{j,t} \tag{13}$$

$$C_{capture} = \sum_{s} \sum_{t} (U_{s,t} \times \sum_{j} (-w_{s,j} \times Q_{j,t})) \tag{14}$$

$$C_{sequestration} = \sum_{o} \sum_{t} (U_{o,t} \times \sum_{j} (-w_{o,j} \times Q_{j,t})) \tag{15}$$

$$Max \ \text{Profit} = GS - C_{pipe} - C_{transportation} - C_{capture} - C_{sequestration} \tag{16}$$

5. Example

This example is abstracted from a real-life CCS project in north China. The emission, sequestration capacity ($P_{s,t}$ $P_{o,t}$) and capture, sequestration cost ($U_{s,t}$, $U_{o,t}$) change with time periods. The computing platform is a PC with 6GB RAM memory, and Intel Core TM i7 CPU (2.67GHz). The solver DICOPT is used for solving the MINLP model to optimality in GAMS 22.5.

Case 1. The base situation of fixed planning without intermediate sites in multiple-period is solved, and the optimum results are given in Figure 2(a). Numbers around each place node represent the flowrate (kg/s) from t1 to t4 (up to down). The number in the last row represents the diameter (m) of pipelines. We have noticed that some sources are linked to the sinks directly. On the contrary, some sources prefer to link to the other sources. The total profit is 1.7427e9 $, which illustrates that the CCS project is profitable because of the government's subsidy.

Case 2. If there are intermediate sites embedded in superstructure, some new pipelines should be added into the former superstructure. The intermediate place N13 is serviced for N6, N7 and N8, and N14 is serviced for N7, N8, and N9. After optimizing the problem with intermediate sites, the results are presented in Figure 2(b) and we find that intermediate site N13 is not activated and pipeline connections between N7, N8 and N9 are different from Figure 2(a) due to the addition of intermediate site N14. The length of pipelines linking N7, N8 and N9 becomes shorter, but at the same time, a larger diameter pipeline which links N14 to N7 is used. As illustrated in Table 1, both pipe cost and transportation cost decrease. This result indicates that the added intermediate sites will provide a more completed superstructure and lead to a reduction in the total annual cost.

Case 3. In the former two situations, all CO_2 produced in the source should be captured and transported to sinks. In case 3, the minimum capture quantity in the whole district based on regulation policy is provided.

Table 1. The total annual cost, pipe cost, transportation cost of different case studies

Example	Profit ($)	Pipe cost ($)	Transportation cost ($)
Case 1	1.7427e9	7.3917e7	2.2952e7
Case 2	1.7435 e9	7.3292 e7	2.2758 e7
Case 3	2.1039 e9	6.4475 e7	2.0021 e7

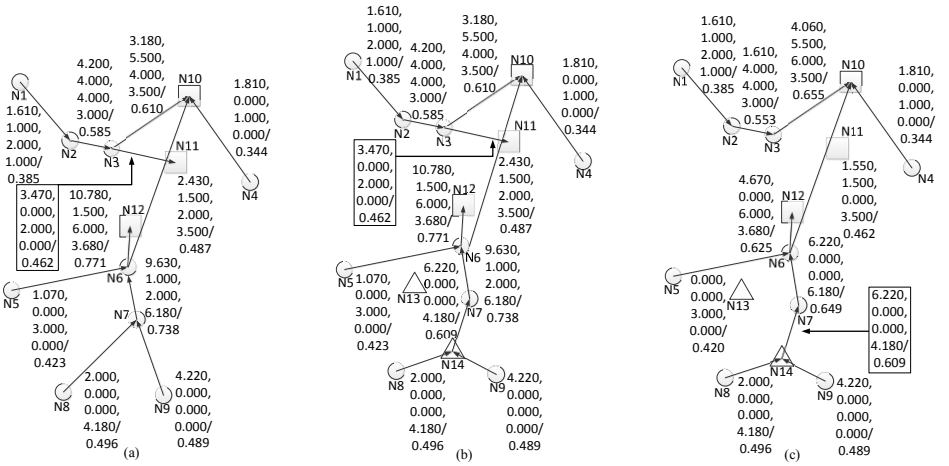

Figure 2. The results of three cases in multiple periods.

The unit capture cost is higher in some sources and the capacity of sinks with lower sequestration cost is limited, so the trade-off between different sources and sinks should be considered. In Figure 2(c), we note that in some period there are no CO_2 capture in some sources such as N2, N5, N7 and the diameters of some pipelines becomes smaller. As illustrated in Table 1, the pipe cost and transportation cost decrease substantially. If there is no restrict regulations from the government, disposing all the CO_2 is not economical and the optimal flexible arrangement is more profitable.

6. Conclusions

A superstructure-based mathematical model to simultaneously optimize the design and multiple-period planning of CO_2 transport pipeline network from the perspective of supply chain is proposed. The structure of the pipeline network is mapped to the incidence matrix and cluster analysis is applied to reduce the complexity of the superstructure. The model is formulated within a mixed integer nonlinear optimization framework where the objective function is to maximize the profit of CCS with considering government subsidy and the cost of capture, transportation, pipeline, and sequestration, while satisfying mass, pressure drop and logic constraints. The results of multiple-period real life example indicate that appropriate intermediate places and flexible arrangement have economical advantages.

Abstract

The objective of this contribution is to present a mathematical model (Mixed Integer Linear Programming) for the facilities and biorefinery locations, and the logistic management. For the model formulation, we first need a geographical discretization of the region in which the supply chain would be implemented and the identification of the different biomass sources and their availability in this region. The technological, ecological, economic and social data are also mandatory to run the model. As in supply chain there are short-term and mid-term decisions, the time horizon must be discretised. The original contents of the model are threefold: integration of multiscale aspects, taking into account of the biomass characteristics, optimization of the supply chain with economic, environmental and social criteria. As a result the model determines the number, the location and the capacity of bio refinery and facilities.

Keywords: Biomass, Supply Chain, Multi Objective Optimization, Location problem

1. Introduction

In order to reduce greenhouse gas emissions and fossil reserve dependency, biomass has received increasing interest as a renewable source to meet the increasing demand for energy and materials substitution or complement. The two first criteria were largely discussed on the literature but on the social aspect, few studies are published in the supply chain optimization. Biomass has also an important role to play as it has the potential to promote rural development thanks to job creations for example. Consequently, we need to evaluate and to include these criteria in decision making. The sustainable utilization of biomass requires advanced approach for biomass supply chain that range from harvesting to bioproduct delivery, in order to conceive long term viable projects and to deal with biomass specificities (heterogeneity, seasonality, degradation…). This work deals with the strategic and tactical levels of the biomass supply chain by considering location problems coupled with biomass production, and biomass and bioproduct storages, transportations as they significantly influence economic, environmental and social impacts. (Kravanja and Cucek, 2013) and (Perez-Fortes et al., 2014) have presented a detail state of the art in the combination between multi objective optimization and mathematical programming. Indeed the formulation of MILP (or MINLP) allows to reach relevant data for facility and for flow. The aim of this contribution is to propose a multi objective optimization problem to fill two gaps left by previous researches. First, the social criteria were very little introduced in the objective function. To evaluate this criteria a new approach is proposed to estimate the number of jobs created by the activity generated by the implantation of a new firm in a specific area. Secondly, we propose a new mathematical approach to solve the multi objective optimization model.

2. Superstructure

The first step is to define the system boundaries, because the development of a biomass supply chain for bioethanol production considers a succession of activities from biomass harvesting to blending facilities. Once harvested the biomass is shipped to collection facilities or directly to biorefineries. In the collection facilities, the biomass is stored and then sent to processing facilities (biorefineries). The bio ethanol produced is then delivered to blending facilities. The goal of the mathematical model is to take decisions related to the supply chain and to optimize the facilities (i.e. the biorefineries and collection facilities) number, sizes and locations but also to determine the connections and the flows between collection facilities and biorefineries and between refineries and blending facilities. These decisions are based on multi criteria analysis relying on economic, environmental and social (limited to the number of jobs created) evaluations. As underlined by (Eksioglu et al., 2009) the mid and short-term decisions in a biomass supply chain relate to determine for each time period: (i) the amount of biomass harvested, (ii) the amount of biomass and bioethanol transported, (iii)) the amount of biomass processed in each biorefinerie, (v) the level of inventories of biomass in collection facilities and in biorefineries, (vi) economic, environmental and social metrics quantification…In the proposed model, the locations of the harvesting sites and blending facilities are supposed fixed and the other facilities locations are to be determined. A superstructure of complete biomass supply chain model and weekly periods are considered (Figure 1). In order to support the model formulation, we use a standardized format for the activity model.

3. Mathematical Model Description

Thanks to the activity model and a deep literature analysis, we have identified that the model proposed by (Eksioglu et al., 2009) gives an interesting base to design the supply chain and manage the logistics of biorefineries. This model relies on three types of discretization:

***Spatial discretization*:** it consists in decomposing the particular area under study into counties. For each county, we identified the harvesting sites, the blending facilities and the town where facilities can potentially be located.

Size discretization: the collection facilities and biorefineries capacities are decomposed onto a finite number of potential facilities sizes, i.e. capacity of production.

Multiperiod discretization: to take into account the dynamic nature of the decision and the biomass seasonality, the time horizon T is decomposed into a finite number of time periods. In the remainder of the paper the time horizon T is one year and the time period is fixed to one week to be coherent with the data. As the basic model was described in the paper of (Eksioglu et al., 2009), the remainder of this article presents the model evolutions and the new equations relating to the evaluation of environmental and social criteria. Our mathematical model adds two major evolutions:

-1- in the original model, there is only one type of biorefineries with different sizes. In our model we have the possibility to choose between different types of biorefineries with their specific production capacity, operating costs, investment costs… This improvement is important because it allows to compare the first and second (and later the third) generation of biorefineries. This comparison is not a posteriori but a priori as the choice of the biorefineries type is a decision variable of the model. Furthermore, with this modification the original MILP model has been transformed into a MINLP one because of new economic terms in the objective function. But a piecewise linearization of the investment costs permits to keep a MILP form to the model.

-2- probably the most important evolution is the multi criteria aspect of our objective function since it adds new constraints to the model. Indeed we found very different results according to the criterion that we wanted to favour. In addition to the economic and environmental criteria, we have included a social evaluation of a supply chain. The description of the different terms of the objective function is given.

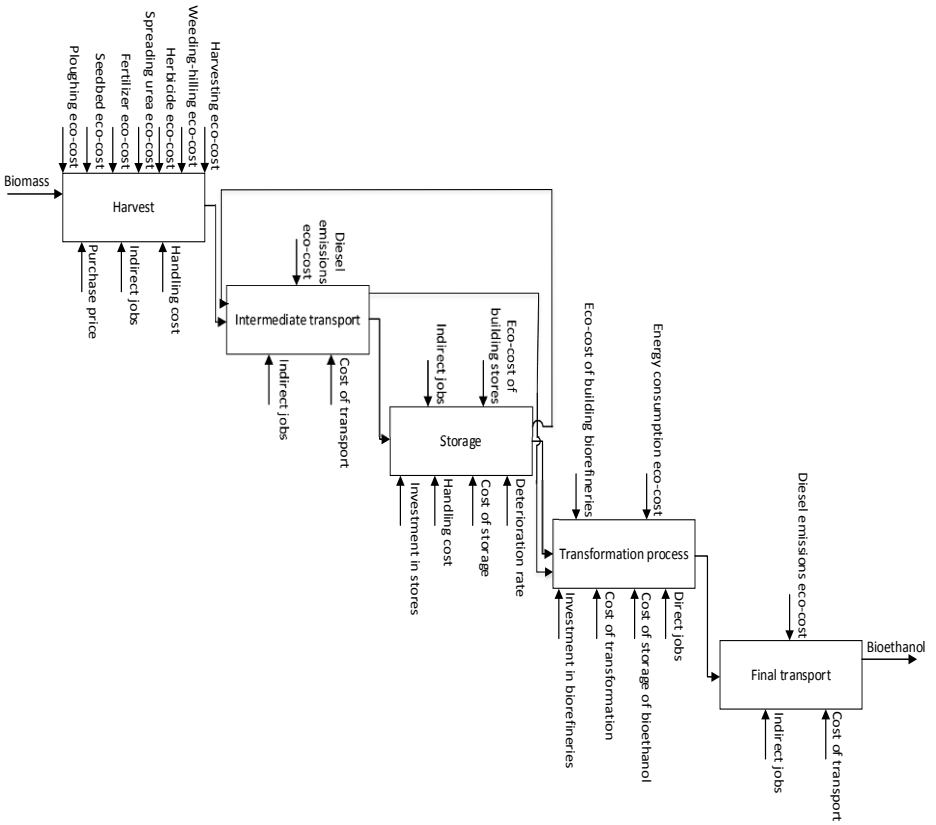

Figure 1 Superstructure of biomass supply chain model

Economic criteria: The costs of the supply chain are: the cost of raw material, transporting the raw material to the collection facility, the cost of handling and storage of biomass, the cost of transport to the biorefineries, the cost of transformation into bioethanol (discounted investment and operating costs for one year) and the cost of final transport to the blending facilities.

Environmental criteria: To evaluate the environmental impact, the Ecocosts are used. Ecocosts are a measure that expresses the environmental load of a product on the basis of prevention of that burden during the product life cycle: from the raw materials until its end of life. This indicator represents the necessary costs that should be made to counteract the negative impact of the activity made on the capacity of earth (Cucek, et al., 2012a). It quantifies the impact in terms of pollution and material depletion by allocating a cost penalizing the use of an alternative that would reduce its impact on the environment and would be called sustainable solution. The total Ecocosts are calculated with the sum of the following contributions: (i) Depletion of natural resources, (ii) Effect on ecosystems, (iii) Effects on human health, and (iv) Global warming (CO_2 and other greenhouse gases). Ecocosts allow quantifying the environmental impact as a

simple indicator easy to understand and compare with other criteria, for example economic. Furthermore, as (Cucek, et al., 2012a) have underlined, the main advantages of these Ecocosts are: (i) they are expressed as a monetary value, (ii) there is no need to compare with another product (often the case with other life cycle assessment methods), and (iii) calculations are based on European price levels and the costs are updated. In our study, Ecocosts are applied to all the activities of the supply chain. The more penalising conditions are applied in order to not underestimate this environmental impact. For calculations, the different eco-costs are divided into two groups depending on whether they are fixed or variables:

- Those that do not change whatever the solution such as cultivation of corn, denaturant added…
- Those that can have an influence on the solution and depend on decision variables of the model such as: transportation, energy consumption, creation of collection facilities or biorefineries…

Social criteria: In their review on footprint as defined indicators on order to measure impacts on sustainability (Curcek et al., 2012b) have eight social footprints: human rights, corruption, poverty, online social (online information available about a person), job, work environmental (number of lost day per unit of product or number of accidents per person), food to energy (competition between the food and energy sectors) and health. Moreover, for the design of a new system in a specific region some criteria would have no influence on the choice between some alternatives as they would not undergo large variations. As a result, for our application we only keep the employment criteria. The number of job created can be divided into three categories:

- Direct jobs: number of jobs directly created by the activity
- Indirect jobs: number of workers in subcontractors working for the new activity.
- Induced jobs: number of jobs created in the local economy. This number evaluates the employments generated by the two previous categories due to their (and their families) consumption in the local economy. It depends on the firm location because it will be more important in rural area than in densely populated area.

The difficulty of the number of jobs created calculation is that it depends on many parameters like: the size of the firm, the activity sector, the level of automation, production quantity…

Our method is based on economic data coming from the annual event and not the initial investment. Therefore, one of the advantages is the consideration of the evolution of a firm in the time that includes all the firm features. Also, job indicators are linked to the economic situation of a firm and not a supposed state estimated when it was under construction. The goal of this study is to be able to give a good estimation of employment for a new company and its impact on local employment faster and with very few data. To validate our approach, we use balance sheets published of companies in France between 2010 and 2014. We selected several companies in different sectors to compare if there is an impact on the estimation and if the proposed method can work with any kind of company. However there are some limitations as the size of samples for each sector and the validity of them. The sectors chosen are the following: Rubber and plastic, Chemical sector, Steel sector. With this way to estimate jobs we have an error of ±15%. To estimate the indirect and induced jobs we use the following equations:

$$\text{IndirectJobs} = \text{pCA} * \text{NbW}$$

Where pCA is the part of turnover coming from the activity studied on the global turnover of the contractor and NbW is the number of jobs in the subcontractor.

$$InducedJobs = JIA * PWLP * (DJ + IJ) * SF/P$$

Where DJ is the number of direct jobs, IJ number of indirect jobs, SF the average household in the place where the activity is, P the size of the population, PWLP the part of local workers supported by the local population and JIA number of jobs working in the area of the study. The parameter SF, P and PWLP are given data coming from the French statistical institute INSEE in 2012.

4. Multi Objective optimization methodology

The CPEX 12.5 algorithm implanted in ILOG is used to solve the mono objective optimization problem. The criteria are antagonistic and moreover a range of each criterion is very large. In this case, it is very important to find a good compromise between these three criteria. Several alternatives can be proposed: build the Pareto Front using an epsilon constraint method and use a Multi Criteria Decision Methodology like (Topsis) or use a goal Programming methodology. A post optimal analysis in the mono objective optimization leads to the fact that the binary variables are the most sensitive variables in the MILP optimization. Generally speaking, in the great majority of works dealing with optimization network design, the formulation of the problem only contains continuous variables what leads to continuous (or discontinuous by jumps) Pareto curves. Although not always fast enough, the research of a feasible solution in this case is consequently easy because one solution is known to exist. The great advantage of applying the methodology of goal programming to problems of supply chain network design is to avoid the generation of a complex research tree with no solutions available and thus large computational times. This method has never been applied to networks design although it is performing and particularly adapted to these problems containing binary variables and very few solutions in the research interval. The aim of the goal programming methodology is to minimize the deviation of the different objective functions. In order to do it, objective functions become constraints and deviation variables are added to them. So the value that restricts the constraint is the sum of the goal and the deviation. In this case, the goal value for each constraint is obtained when minimizing each objective function separately. Then, the objective function is the sum of all deviation variables.

5. Results and discussions

The problem is based 400 000 t per year of ethanol production in the south west of France using corn and wood as a raw material. In the table 1, the raw materials using in this biorefineries are corn and wood. Several optimizations are realized with different weights in the goal programming method to explore some points around the best compromise. The environmental impact is lower when using more wood than corn due to the storage circumstances. In addition, the best economical solution is the one that establishes a single biorefinery and uses 75% of wood. The solution that provides more employment processes more wood than corn. The investment required for the project as defined in this section ranges from € 330 million to over 420 million euros per year, depending on the number of biorefineries. This investment in biorefineries would generate between 1,500 and 3,000 jobs directly related to the biorefinery and induced jobs, for example in local trade. Either the price of bioethanol 0.73 €/ liter from the sale of 400,000 tonnes of bioethanol would be around 370 million euros.

Table 1 Results using corn and wood as raw material

6. Conclusions

In this study, using the goal programming methodology, the bioethanol supply chain is optimized in the case of the first and the second generation. This methodology well suited for this kind of problem in order to find the compromise point between the three objectives. Moreover, the raw material is a mix of corn and wood. Biorefineries correspond to an economic model of a mature industrial sector. The actors can then determine with very competitive prices and all parameters have been optimized (purchasing, logistics, processing, etc). However, the study will be continued using a production of biobutanol, or a third-generation bioethanol.

Abstract

One of the key steps of coking wastewater treatment is ammonia nitrogen removal. It is normally realized by a process combining distillation operation with bio-treatment, in which the high cost distillation is designed to reduce ammonia nitrogen low enough for the following low cost bio-treatment. Many efforts have being done to optimize the structure and operating parameters of this process. However, to the authors' best knowledge, little work has been done considering the interactions between them. In this paper, a mathematical model of the overall ammonia nitrogen removal process, which combines distillation with shortcut nitrification/ANAMMOX/denitrification (short as O_1-A-O_2), is proposed for its operation and structural optimization. The proposed model is formulated as a mixed integer nonlinear programing (MINLP) problem with aim of minimizing overall operating cost. The main decisions include determining ammonia-nitrogen concentration of distillation bottom outlet, reaction recycle time and passby flowrate of O_1 reactor subject to compliance with the maximum allowable inlet ammonia nitrogen concentration limits of the bio-treatment and discharge regulations. For simplicity, we adopt shortcut models for the ammonia distillation and bio-treatment process based on rigorous model calculation data and theoretical analysis to enforce solution convergence. Computational studies are carried out via GAMS/DICOPT using industrial operating parameters of the typical coking wastewater treatment system as input. The results indicate that the minimum operating cost is obtained at ammonia-nitrogen concentration of 128 mg/L from distillation bottom outlet, 10 h reaction recycle time of O_1 and passby flowrate of 11.448 m^3/h when the ammonia-nitrogen inlet concentration of distillation column is 4,000 mg/L.
Keywords: coking wastewater, optimization, MINLP

1. Introduction

Coking wastewater discharged from coking plants contains high concentration of ammonia nitrogen and carries a lot of phenols and tars (Ren et al., 2007). For example, the concentration of ammonia nitrogen in residual ammonia water coming from coke making is 2,000-4,000 mg/L, which is much more than domestic sewage and other industrial wastewater (An and Zhang, 2004). It is needed to reduce ammonia nitrogen concentration to a very low level before discharge, i.e. 10 mg/L in China (Ministry of Environment Protection of People's Republic of China, MEPC, 2012). Currently, such treatment is difficult and expensive. Thus, how to effectively treat such coking wastewater with reasonable cost is of great importance.

To economically treat coking wastewater, it is normally realized by a process combining distillation operation with bio-treatment, in which the high cost distillation is designed to reduce ammonia nitrogen low enough for the following low cost bio-

treatment to remove residual ammonia nitrogen and other pollutants. It has been widely used in the coking wastewater treatment. Currently, high operating cost is the major obstacle for its operation. In order to reduce the treatment cost, many efforts have being done to optimize the structure and operating parameters of the energy intensive distillation unit, i.e., operating pressure, temperature and reboiler heating mode (Qiu, 2007; Guo, et al., 2009). The results show that bottom outlet ammonia nitrogen concentration of distillation has big impact on both distillation and bio-treatment, and improper operation will lead to higher total treatment cost (Liao et al., 2014). However, to the authors' best knowledge, little work has been done considering the interaction between them. For such problem, process optimization is one efficent way to solve the tradeoff given by the minimization of investment, operational and environmental costs (Martin-Sistac et al., 2008).

In this paper, a mathematical model of the overall ammonia nitrogen removal process, which combines distillation with bio-treatment of O_1-A-O_2, is proposed to study the interactions between distillation and bio-treatment and to obtain optimal operating parameters and optimal process configuration leading to minimum total operating cost. The paper is organized as following. First, models for distillation and O_1-A-O_2, and an optimization model for overall process are set up in section 2. Then, the case study is carried out in section 3. Last, conclusions are summarized in section 4.

2. Optimization Model formulation

2.1. Coking wastewater treatment process

Coking wastewater contains high concentration of ammonia nitrogen, phenols and tar, general treatment process involves pretreatment to remove oil, phenols and ammonia nitrogen, followed by bio-treatment, and optional advanced treatment to further remove residual pollutants to meet discharge requirements. In this work, our efforts is put on the ammonia nitrogen removal, a process involving the operation of a distillation tower to pre-remove the ammonia nitrogen to acceptable level (<500 mg/L) for the following bio-treatment as shown in Figure 1 is studied. For such process, if more ammonia nitrogen can be removed via ANAMMOX, lower operating cost can be obtained. Therefore, it is very important to keep the ANAMMOX reactor work at a proper operating condition. It is normally realized by keeping the ratio between nitrite nitrogen and ammonia nitrogen, R_{na}, by adjusting the concentration of nitrite nitrogen in the reactor. To realize this objective, the process configuration of O_1-A-O_2 is proposed to adjust as: if R_{na} in O_1 outlet is too low, part of O_1 outlet is directly recycled to O_1, otherwise, part of distillation outlet is directly sent to A.

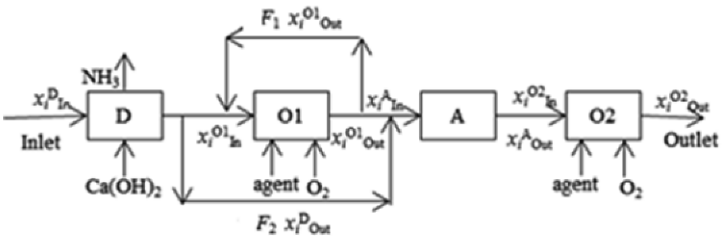

Figure 1 Ammonia nitrogen removal process

2.2. Ammonia distillation model

For ammonia distillation operation, many parameters, *i.e.*, cost of utility, reboiler heating mode, and benefit of ammonia as byproduct all can affect its operating cost. The relationship between operating cost and these parameters is very complex. According to our study on ammonia distillation operation, the concentration of ammonia nitrogen in inlet and bottom outlet of the tower is the major factor affecting its operating cost under the normal operating condition (Liao et al., 2014). In order to simplify the model, a regressed model is established based on the dataset obtained by a series of simulation of the distillation operation under the different concentration of ammonia nitrogen of inlet (x_{in}) and outlet (x_{out}) while keep other parameters constant. It is given by,

$$C^D=P_A x_1^2+P_B x_1 exp x_2+P_C x_2^2+P_D x_1 + P_E x_2 + P_F \quad (1)$$

where $x_1=x_{in}/1000$, $x_2=log(x_{out})$. The obtained parameters are listed in Table 1, which shows that model gives reasonable agreement with the error of 0.002￥/t. It should be noted that direct heat mode is adopted in our proposed model due to its better performance (Liao et al., 2014), and steam consumption is fixed as 0.084t for treating 1t wastewater. It is due to steam consumption varies in a small range (0.078-0.090 t) when x_{in} and x_{out} vary in the range of 1,000-11,000 mg/L and 10-350 mg/L for treating 1t wastewater.

Table 1 Parameters for ammonia distillation model

P_A, $\times10^{-2}$	P_B $\times10^{-4}$	P_C $\times10^{-1}$	P_D	P_E	P_F	E_{avg} $\times10^{-3}$
-5.768	4.555	1.025	-3.134	-3.028	3.274	1.889

2.3. Bio-treatment model

Conventional models for wastewater bio-treatment are based on Active Sludge Model (ASM) by assuming that overall nitrification process for ammonia nitrogen removal (Gernaey et al., 2004). In this work, O_1-A-O_2 process is adopted, which involves short nitrification process and ANAMMOX process. ASM is not the proper model for such process, the Monod equation is thus adopted for its ability to describe short nitrification process and ANAMMOX process (Monod, 1949). For simplicity, a number of assumptions are made in this model:

- All units are operated under the condition of designed pH, DO and temperature,
- O_1 reactor is an ideal tanker batched operated only for ammonia nitrogen nitrification and with stable nitrite accumulation of 95% (Xue et al., 2011),
- A is plug flow reactor and is operated only for ANAMMOX reaction,
- O_2 reactor is an ideal tanker batched operated only for overall nitrification of ammonia nitrogen and all the nitrite is removed due to enough O_2 input.

2.3.1. Ammonia nitrogen nitrification model

For ammonia nitrogen nitrification, it is realized by two steps as shown in following equations:

$$2\ NH_4^+ + 3\ O_2 \rightarrow 2\ NO_2^- + 4\ H^+ + 2\ H_2O \quad (2)$$

$$2\ NO_2^- + O_2 \rightarrow 2\ NO_3^- \quad (3)$$

To model such process, Lawrenence-McCarty equation (Christensen and McCarty, 1975) is adopted,

$$v=v_{max}\ S/(K_s+S) \quad (4)$$

Where, v is the specific degrading rate of ammonia nitrogen, d^{-1}; v_{max} is the max value of v; K_s is saturation constant, *mg/L*; S is the concentration of ammonia nitrogen, *mg/L*. The above equation can be further transformed to an equation listed as below.

$$P_G\ (exp(P_H\ t)-1)+(S-S_0)+P_1\ (lnS-lnS_0)=0 \quad (5)$$

Where, S_0 is the concentration of ammonia nitrogen in inltet, *mg/L*; PG, PH and PI are the parameters. In our work, all these parameters are obtained via regression using Li 's (Li et al., 2011) experimental data. The result is listed in Table 2.

Table 2 Parameters for ammonia nitrogen nitrification model

Parameters	P_G	P_H	P_I	E_{avg}
Value	65.560	0.124	25.889	10.646

2.3.2. ANAMMOX model

According to Jin et al. (2008), ANAMMOX reaction can be descripted by second order reaction kinetics, and the concentration of ammonia nitrogen (S_t *mg/L*) at time t (d) can be obtained using following equation using initial concentration S_0 as input,

$$S_t=S_0\ [1-\ t/\ (0.699+1.004\ t)] \quad (6)$$

In order to keep the proper R_{na} for ANAMMOX operation, it is proposed to adjust the process configuration via recycling or bypass as shown in Figure 1. The material balance equations before and after O_1 reactor are listed below.

$$F_1+F^D{}_{Out}=F_2+F^{O1}{}_{In} \quad (7)$$

$$F_2+F^{O1}{}_{Out}=F_1+F^A{}_{In} \quad (8)$$

$$F_1\,x_i^{O1}{}_{Out}+F^D{}_{Out}\,x_i^D{}_{Out}=F_2\,x_i^D{}_{Out}+F^{O1}{}_{In}\,x_i^{O1}{}_{In} \quad (9)$$

$$F_2\,x_i^D{}_{Out}+F^{O1}{}_{Out}\,x_i^{O1}{}_{Out}=F_1\,x_i^{O1}{}_{Out}+F^A{}_{In}\,x_i^A{}_{In} \quad (10)$$

To simplify the model, two constraints are incorporated into our model as followings:

- Forbid both recycling and bypass are selected

$$y_1+y_2\le 1 \quad (1)$$

- The R_{na} is kept in optimized range

$$1.2\le R_{na}\le 1.4 \quad (12)$$

2.4. Objective function

The objective function of the model involves minimizing the total operating cost as contributed by the economic and environmental sustainability drivers. It consists of costs for distillation and bio-treatment. The former can be obtained by Eq.(1). The latter consists of chemical cost C^{ag}, aeration cost C^{ae}, pollution fees C^{ch}, and sludge treatment cost C^{SS}, which is given by Eq.(13),

$$C^{BIO}=C^{ag}+C^{ch}+C^{ae}+C^{SS} \quad (13)$$

With four cost components defined as follows,

$C^{ag}=F_i p_i$ *(i=*Na_2CO_3*, F= consumption, t/h, p=price, ¥/t)*

$C^{ch}=e\,F^{O2}\,x_i^{O2}{}_{Out}$ *(i=* NH_4^+*, F=discharge, t/h, e=penalty factor)*

$C^{ae} = p_{elec} W$ *(W=power consumption, kW,* p_{elec}*=electricity price, ¥/kWh)*

$C^{SS} = F_{SS}\, p_{SS}$ *(*F_{SS}*=sludge flo, t/h,* p_{SS}*=sludge treatment cost, ¥/t)*

Combing above defined equations, the overall optimization model is thus obtained, which is a nonconvex MINLP. In our work, it is implemented on GAMS using the general MINLP solver DICOPT to obtain optimal solution.

3. Case study

We implement the proposed MINLP on an industrial-scale case study of a coking wastewater treatment process. Data on parameters for the model are provided in Table 3. The optimal configuration of the process involves the use of the bypass to adjust the R_{na} for ANAMMOX operation, which leads to minimum overall operating cost of 7.638 ¥/t, including 6.009 ¥/t for distillation, 1.592 ¥/t for O_1, 0.020 ¥/t for A and 0.017 ¥/t for O_2. It suggests further optimizing work should be put on D and O_1. In current case, the optimal operating are: bypass of 11.448 m^3/h, 128 mg/L of concentration of ammonia nitrogen in distillation bottom outlet, and 10h for O_1 recycle time.

Table 3 Parameters for operating optimization model.

parameters	Value	parameters	Value
t_{fix} /(h)	1.5	p_{elec} /(¥ kW^{-1} h^{-1})	1
t_2 /(h)	8	p_{Na2CO3}/(¥ t^{-1})	1,900
F^{D}_{In} /(m^3 h^{-1})	35	p_{ss} /(¥ t^{-1})	1,000
x^{D}_{In} /(mg L^{-1})	4,000	x^{CHG}_{Out} /(mg L^{-1})	10

To further investigate the impacts of outlet concentration of distillation on the overall operating cost, a series of calculations are carried out. As shown in Figure 2, it can be found that the cost of bio-treatment linearly increase with outlet concentration of distillation operation, while operating cost of distillation decreases correspondingly. It thus needs to keep proper balance between them. In current case, the overall cost reaches minimum at 128mg/L.

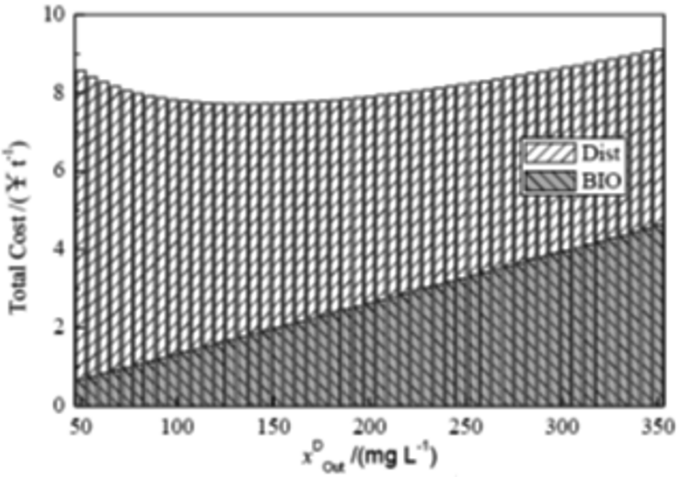

Figure 2 The relationship between operating cost and x^{D}_{Out}

4. Conclusions

This paper focuses on the optimal operation of the ammonia nitrogen removal process, D-O_1-A-O_2, for coking wastewater treatment by proposing a MINLP model. The proposed model is applied on an industrial case study with promising results.

- Bypass operation is better than recycling due to lower O_1 treatment duty leading to reducing operating cost,
- Under the operating condition of case study, optimal operating parameters are: x^D_{out}=128 mg/L, t_1=10 h, F_2=11.448 m^3/h,
- For overall process, D accounts for nearly 80% of total cost; For bio-treatment, O_1 accounts for major part of bio-treatment, while the parts of A and O_2 are negligible compared to O_1.

In our following work, we will incorporate tight bounds on the variables and more constraints that enforce certain operation and design specifications in order to more effectively solve the MINLP model to global optimality.

Solubility Measurement and Process Simulation of CO_2/CH_4 Gas Mixtures Using Ionic Liquids

Jubao GAO,Yajing XU, Xin ZHANG,Xiangping ZHANG*

State Key Laboratory of Multiphase Complex Systems, Institute of Process Engineering, Chinese Academy of Sciences, Beijing, China
xpzhang@ipe.ac.cn

Abstract

Using room temperature ionic liquids (RTILs), the desirable properties of RTILs with low heat capacity, low corrosive, nonvolatile and good CO_2 solubility can be employed to separate CO_2/CH_4 gas mixture, may offer help to improve energy efficiency. Although the solubilities of CO_2/CH_4 in pure RTILs, such as 1-butyl-3-methylimidazolium tetrafluoroborate ([C4mim][BF_4]), 1-butyl-3-methylimidazolium hexafluorophosphate ([C4mim][PF_6]), 1-butyl-3-methylimidazolium acetate ([C4mim][acetate]), 1-butyl-3-methylimidazolium dicyanamide ([C4mim][DCA]) and 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([C4mim][Tf_2N]), have been measured in widely temperature and pressure, corresponding process simulation is scant and necessary. In this work, the solubility of CO_2/CH_4 in [C4mim][PF_6] and [C4mim][Tf_2N] is measured, and corresponding thermodynamics model is developed based on the ionic fragment method and the experimental data. An absorption and desorption flowsheet for CO_2/CH_4 separation using ionic liquids is developed and the energy consumption of CO_2 separation is evaluated. Results show that simulated solubility of CO_2/CH_4 is in good agreement with the experimental data from literature data. The total work demand for CO_2/CH_4 separation of [C4mim][PF_6] is a little smaller than that of [C4mim][Tf_2N].

Keywords: carbon dioxide, methane, solubility, simulation, ionic liquids

1. Introduction

The CO_2 capture from various mixtures of gases is of wide concern because it will contribute to global warming and climate change. The current CO_2/CH_4 separation include chemical and physical solvents, such as $Mg(OH)_2$-based sorbent, natural limestone, polyethylene glycol derivatives, refrigerated methanol, N-methyl-2-pyrolidone, zeolite and N-methyldiethanolamine (James et al., 2011; Anamaria et al., 2012). In general, carbon capture faces huge energy consumption especially for shale gas, natural gas, biogas and syngas industry. About 2% energy efficiency can be improved by saving 1 GJ/t CO_2 regeneration energy (Goto et al., 2013). To develop absorbents and optimize system process are efficient method.

Ionic Liquids (ILs), with unique feature of low heat capacity, low corrosive, nonvolatile and good CO_2 solubility (Zhang et al., 2012), are potential candidates to be applied for CO_2 separation from shale gas, natural gas, biogas and syngas with lower energy consumption on a large scale and commercialization. Pure imidazolium-based ILs, such as 1-butyl-3-methylimidazolium tetrafluoroborate[C4mim][BF_4], 1-butyl-3-methylimidazolium hexafluorophosphate [C4mim][PF_6], 1-butyl-3-methylimidazolium acetate [C4mim][acetate], 1-butyl-3-methylimidazolium dicyanamide [C4mim][DCA]

and 1-butyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide [C4mim][Tf_2N], have been studied for separation of CO_2-CH_4 gas mixture (Privalova et al., 2013; Ramdin et al., 2014a; Khonkaen et al., 2014). The real and ideal CO_2/CH_4 selectivities were provided by Ramdin, and results show that the latter decreases with temperature and ILs molecular weight increase (Ramdin et al., 2014b). However, simulation of CO_2/CH_4 separation process by pure imidazolium-based ILs is quite few, in particulate their energy consumption performance. In this work, [C4mim][PF_6] and [C4mim][Tf_2N] is employed in CO_2/CH_4 separation process to evaluate their separation performance by experiments and simulation. The solubility of CO_2/CH_4 in [C4mim][PF_6] and [C4mim][Tf_2N] is measured using a vapour-liquid equilibrium (VLE) apparatus reported by our previous work (Xu et al., 2014a; Xu et al., 2014b) to offer necessary parameters for simulation process, and evaluate selectivity coefficient, absorption rate and capacity. And then, an absorption and desorption flowsheet for CO_2/CH_4 separation is proposed and simulated to evaluate the CO_2 separation energy consumption.

2. Measurement and simulation

A schematic diagram of the VLE apparatus is shown in Figure 1. The apparatus comprises a feed tank and two equilibrium tanks which are in a temperature controlled oil bath to obtain uniform temperature of gas and liquid in the tanks.

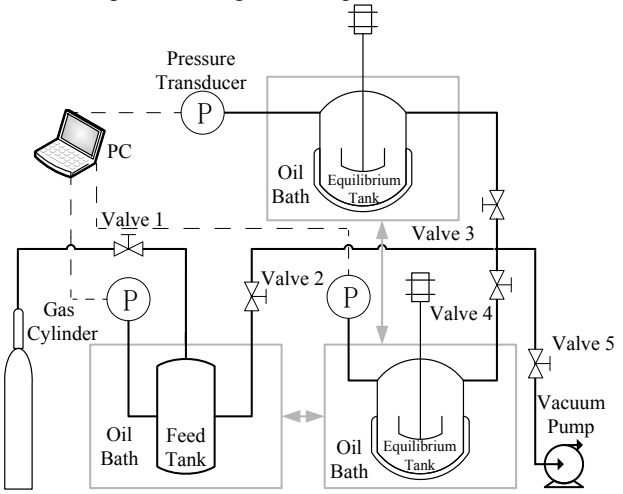

Figure.1 Flow diagram of experimental system

About 40g absorbents are weighted by an electronic analytical balance (PL4002, Sartorius Scientific Instrument Co. Ltd., China) with an accuracy of±0.01 g, and then placed in the equilibrium tank. After that, the equilibrium tank is sealed from the atmosphere environment and evacuated by vacuum pump. Meanwhile, the magnetic stirrer and oil bath is turned on to reach thermal equilibrium as soon as possible. Gas is injected to the equilibrium tank from the feed tank after achieving thermal equilibrium. All pressure is measured by Rosemount engineering pressure transducers with an

accuracy of $\pm 0.065\%$ of full scale up to 3MPa and automatically recorded per second by a program.

Experiments are carried out by pressure swing. Peng-Robinson equation is employed to calculate the number of moles of gas in absorbents as follows (Peng et al., 1976):

$$p = \frac{RT}{v-b} - \frac{a}{v^2 + 2bv - b^2} \tag{1}$$

$$a = 0.457235 \frac{R^2 T_c^2}{p_c} [1 + (0.37464 + 1.54226\omega - 0.26992\omega^2)(1 - T_r^{0.5})]^2 \tag{2}$$

$$Tr = \frac{T}{T_c} \tag{3}$$

$$b = 0.07780 \frac{R\, T_c}{p_c} \tag{4}$$

where P and T are the pressure and the temperature of gas in tank, respectively. Tc and Pc represent the critical temperature and the critical pressure, respectively. R and ω denote the universal gas constant and the acentric factor, respectively.

The thermodynamic models of VLE of separation system and the parameters are regressed based on the experimental data using Aspen plus. The physical properties of ILs, including density, viscosity, surface tension, heat capacity and critical properties, are estimated by a ionic fragment contribution-corresponding states (FCCS) method and the corresponding states principle, and the details is described in our previous work (Huang et al., 2013).

3. Results and discussion

Figure.2 showed the comparison between predicted solubility of CO_2/CH_4 with temperature ranging from 283K to 323K and pressure till to 10bar and experimental data from Anthony et al (2002).

It can be found from Figure.2 that the solubility of CO_2/CH_4 decreases with temperature but pressure increase it. The CO_2 solubility is obviously higher than CH_4 solubility. Low temperature and high pressure induce to good selectivity because of a difference of curve slope which means ILs are prefer the high CO_2 partial pressure industry process, such as biogas and syngas industry.

The predicted heat capacity using the FCCS method and the comparison with experimental result from Holbrey et al (2003) with temperature from 303K to 433K were shown in Figure.3. The heat capacity of ILs is one of the important physical properties while used to estimate the energy consumption. It is increasing with temperature as shown in Figure.3. Hence, low temperature separation is profited for energy saving.

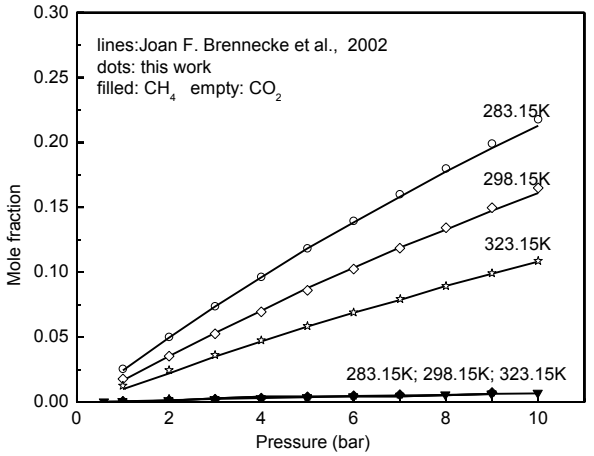

Figure.2 Predicted solubility of CO_2/CH_4

The predicted solubility of CO_2/CH_4 from the thermodynamic models and the predicted heat capacity using the FCCS method in Figure.2 and Figure.3 are in good agreement with the experimental results which implies that the models are suitable for the simulation of the whole CO_2/CH_4 separation process.

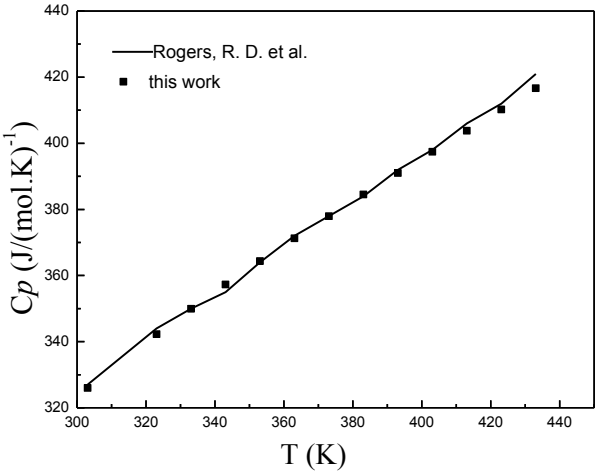

Figure.3 Predicted heat capacity using the FCCS method

In Figure.4, an absorption and desorption flowsheet for CO_2/CH_4 separation was proposed to evaluate the energy consumption of CO_2 separation with [C4mim][PF_6] and [C4mim][Tf_2N] based on the thermodynamic models using Aspen plus. The CO_2/CH_4 feed gas was first compressed to about 10bar. The CO_2 and CH_4 was separated in an absorber. The rich CH_4 as treated gas leave from the absorber top. And the rich solvent at the absorber bottom was desorbed by two stage flash. The second flash top is the rich CO_2. The CO_2 and CH_4 capture ratio are set to 97% and 95%, respectively. Total flow rate of the feed gas is 500Nm^3/h. The lower absorbent circulate rate of [C4mim][PF_6]

was found to be 57t/h, but for [C4mim][Tf_2N] it was 65t/h which results in higher pump work. It may be attributed to the good selectivity of [C4mim][PF_6] although [C4mim][Tf_2N] shows better CO_2 solubility than [C4mim][PF_6]. The compress work and vacuum work of [C4mim][PF_6] and [C4mim][Tf_2N] are almost no difference. Hence, the total work of [C4mim][PF_6] is about 0.383MJ/kgCO_2 which is a little smaller than that of [C4mim][Tf_2N] of 0.388MJ/kgCO_2.

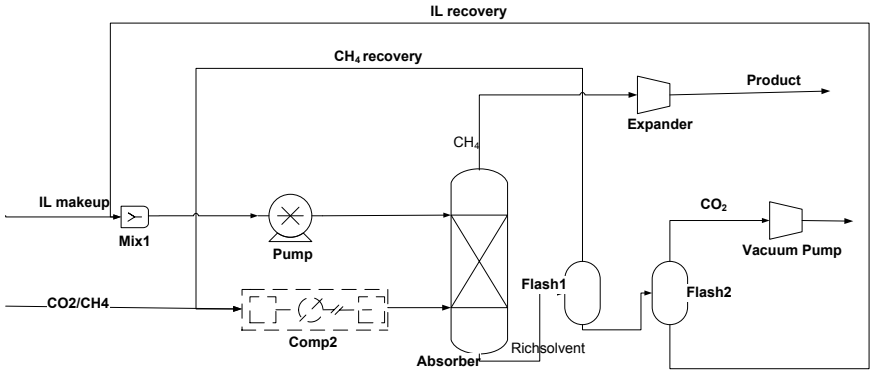

Figure.4 Flow diagram of CO_2/CH_4 separation system

4. Conclusions

The VLE apparatus was used to measure the solubility of CO_2/CH_4 in [C4mim][PF_6] and [C4mim][Tf_2N]. FCCS method based on the ionic fragment method was used to predict the physical properties of ILs. The thermodynamics model was developed based on the experimental data using Aspen plus. An absorption and desorption for CO_2/CH_4 separation was proposed to evaluate the energy consumption of CO_2 separation with [C4mim][PF_6] and [C4mim][Tf_2N] based on the thermodynamic models. The experimental and simulated results show that the FCCS method combined with the proposed thermodynamic models can be used to simulate accurately the whole CO_2/CH_4 separation process. It is suggest that the simulated method can also be used to screen ILs for CO_2/CH_4 separation. All these results in this work demonstrate that ILs is a promising solvent for CO_2/CH_4 separation technologies.

Abstract

Ammonium (NH_4^+) load based aeration control on biological wastewater treatment plants saves costs and enhances nitrogen removal. However, the need for maintenance intensive NH_4^+ sensors hamper the controls application in practice. Alternatives, in the form of soft-sensors are broadly discussed in academia. A soft-sensor recently described in literature exploits the pH effects induced by biological NH_4^+ oxidation. This concept is now further developed by means of qualitative trend analysis (QTA). Previously, the qualitative path estimation (QPE) algorithms was proposed as a fast and reliable QTA algorithm for batch process data analysis. It does not allow online application in continuous flow systems however. In this work, a modification of QPE, call qualitative state estimation (QSE), is proposed as a suitable algorithm for continuous-flow systems. Initial tests indicate that the QSE algorithms is a robust technique for extraction of relevant information in a full-scale environment. At the WWTP Hard in Winterthur, this resulted in cost-saving automation of the aeration system. This contribution summarizes these first results.

Keywords: ammonia control, biological wastewater treatment, hidden Markov model, kernel regression, process monitoring

1. Introduction

Ammonium (NH_4^+) controlled aeration is a well known and widely applied technique (Åmand et al., 2013) for automation of biological wastewater treatment plants (WWTPs). By controlling the ammonium concentration in the effluent, energy costs can be reduced while violation of effluent concentration limits can be avoided. Furthermore, optimization of the oxidation processes ensures that denitrification capacity can be increased and enhanced biological phosphorus (bio-P) removal can take place without the need to increase reactor volumes (Rieger et al., 2014). However, economical application of such ammonium control is only feasible on larger WWTPs, where the energy and cost savings outweigh the NH_4^+ sensors installation and maintenance costs (Winkler et al., 2004; Åmand et al., 2014). Haimi et al. (2013) present numerous studies dealing with NH_4^+ soft-sensors evading the need for a physical NH_4^+ sensor. Importantly, these studies mainly investigate black-box models, which give rise to a series of challenges for widespread full-scale application such as the need to recalibrate the methods for each application, lack of transparency and trust by operators, and potentially difficult implementation and fine-tuning. A soft-sensor based on a mechanistic principle was presented by Ruano et al. (2009). This soft-sensor takes advantage of the acidifying effect of biological NH_4^+ oxidation, which is also known as nitrification. Instead of estimating the NH_4^+ concentration, the soft-sensor monitors the net effect of nitrification (acidifying) and CO_2 stripping (proton-consuming). In locations of a WWTP where nitrification

occurs, a net production of protons is typical and causes the pH to drop. Where nitrification is not occurring, a net increase of the pH results due to CO2 stripping. Ruano et al. (2012) manipulated the aeration intensity in an activated sludge system to keep the difference between two pH measurements located at the in- and outlet of an aerated tank sequence at a given setpoint. Practically, the pH difference is as a proxy for the balance between proton production due to nitrification and the proton consumption from CO_2 stripping. The combined effects of hydraulic transport, mixing conditions, oxidation, and stripping contribute to a complex relationship between the ammonia concentration and the pH. This relationship can however be understood qualitatively most of the time so that this concept is relatively easy to use for a diverse set of WWTP configuration. Under steady-state conditions, a certain pH difference corresponds to a certain NH_4^+ effluent concentration. Unfortunately, using a fixed pH difference as a control setpoint assumes perfect pH sensors. In practice, significant signal drift occurs, which can only be kept in check by a prohibitively high maintenance effort. This eliminates the advantage of pH sensors over conventional NH_4^+ sensors for ammonium control. We however claim that the pH difference signal can also be used in a less stringent fashion so that monitoring the pH difference remains useful in practice. Fig. 1 shows the recorded pH difference (top) and the measured NH_4^+ concentration measured (bottom) from the setup at the Winterthur WWTP as described in section Hardware Setup. The qualitative similarity between these two signals is obvious as the maxima in both signals are remarkably synchronous. Consequently, we present in this paper a qualitative trend analysis (QTA) method to use this qualitative similarities for an NH_4^+ load dependent aeration control. This QTA based method is used to detect peak NH_4^+ loads entering the WWTP. This detection allows to adjust the setpoints for the dissolved oxygen (DO) concentration accordingly and thereby optimise the aeration energy costs of the plant. The QTA method used here is referred to as Qualitative State Estimation (QSE) and is based on the earlier Qualitative Path Estimation (QPE) algorithm Villez (2015). The main differences are *(i)* that the Hidden Markov Model (HMM) now represents an ergodic process, as opposed to the linear Markov chain for the QPE algorithm and *(ii)* that the state estimation method is different from the Viterbi algorithm used for QPE.

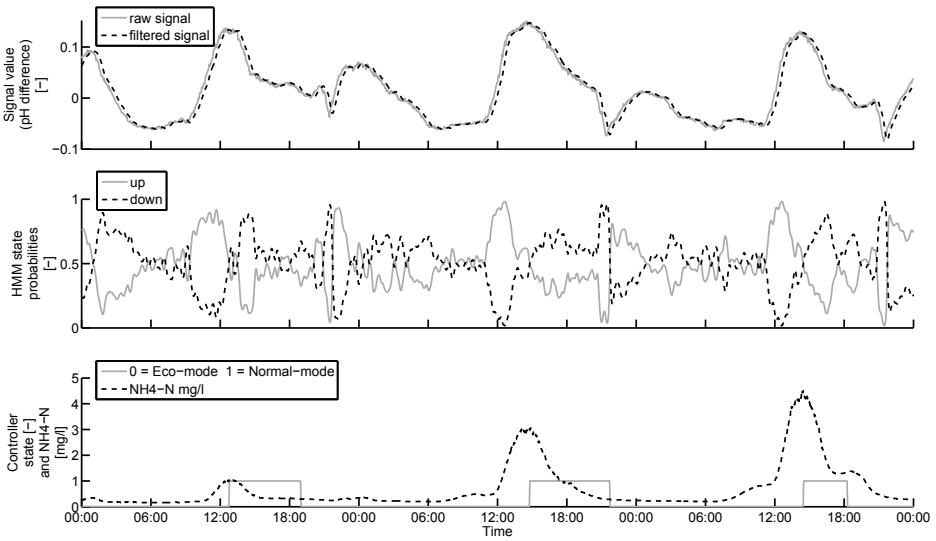

Figure 1: Demonstration of the QSE algorithm: Top – pH difference raw/filtered; Middle – Qualitative trend probabilities; Bottom – Control state and NH_4^+ measurements.

2. Methods

2.1. Hardware Setup

The studied municipal WWTP Hard, Winterthur, Switzerland exhibits one stirred and three aerated activated sludge tanks for oxidation of organic compounds as well as NH_4^+ (cfr. Fig. 2). These are located between the primary clarifier and the secondary clarifier. The signal used in the proposed control system, consists of the difference between a pH measurement in the first aerated tank (upstream, *us*) and the last aerated tank (downstream, *ds*). An ion selective electrode (ISE) measuring the NH_4^+ concentration is placed in the second aeration tank in order to validate and fine-tune the pH difference based control loop.

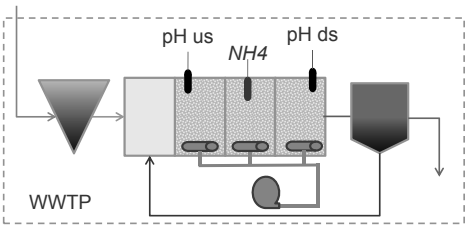

Figure 2: Location of pH sensors (pH *us* and pH *ds*) and ammonium sensor (*NH4*).

2.2. Qualitative Trend Analysis

As mentioned above, QTA comprises a set of algorithms for segmentation of time series. Each segment, referred to as an *episode*, is defined by a start and end time. Within these time points, the sign of one or more of the signal's derivatives is considered constant. In this application only the sign of the first derivative is considered as this is sufficient to define the qualitative features of interest, namely the minima and maxima. A specialised algorithm, called qualitative state estimation (QSE), is developed to enable fast and reliable identification of these extrema. It is based on the QPE algorithm, which was found to be fast and reliable for batch process diagnosis (Villez, 2015). The QSE algorithm consists of two steps.

Step 1 – Qualitative trend probabilities via kernel regression: First, the algorithm estimates the likelihood that the analysed signal is decreasing or increasing at given time points. This assessment is based on local polynomial fit to the data, which consist of pairs of an independent variable, t_j $(j = 1...m)$, which is time in our case, and the dependent variable measurement, y_j, which is a pH difference signal in this study. The polynomial coefficients, β_i, are computed for sample index i by minimising the following weighted least squares (WLS) objective function:

$$\min_{\beta_i} \sum_{j=1}^{m} K_{i,j} \cdot (y_j - \mathbf{x}_j^T \cdot \beta_i)^2 \tag{1}$$

$$\text{with } \mathbf{x}_j = \begin{bmatrix} (\mathbf{t}-t_j)^0 \\ (\mathbf{t}-t_j)^1 \\ \vdots \\ (\mathbf{t}-t_j)^p \end{bmatrix}, \quad d_{i,j} = \frac{|t_i - t_j|}{\lambda}, \quad K_{i,j} = \begin{cases} (1-d_{i,j}^3)^3, & \text{if } d \leq 1 \\ 0, & \text{otherwise} \end{cases} \tag{2}$$

The polynomial degree p is 2 or higher. Furthermore, the tri-cube kernel function is used to determine the weighting of the data points. The weights, $K_{i,j}$, are completely specified by a meta-parameter λ. Only data points within the distance of λ to the sample of interest i have a weight larger than zero and contribute to the local model. The data weights decrease as the distance from the considered sample, i, increases. Eq. 1 can be solved analytically as follows:

$$\begin{aligned} \beta_i &= \mathbf{H}_i \cdot \mathbf{y} \\ \mathbf{H}_i &= (\mathbf{X}_i^T \cdot \mathbf{W}_i \cdot \mathbf{X}_i)^{-1} \cdot \mathbf{X}_i^T \cdot \mathbf{W}_i \\ \mathbf{X}_i &= \begin{bmatrix} (\mathbf{t}-t_i)^0 & (\mathbf{t}-t_i)^1 & \cdots & (\mathbf{t}-t_i)^p \end{bmatrix} \end{aligned} \qquad \underset{m\times m}{\mathbf{W}_i} = \begin{bmatrix} K_{i,1} & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & & \vdots \\ 0 & & K_{i,j} & & 0 \\ \vdots & & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & K_{i,m} \end{bmatrix} \tag{3}$$

The matrix $\mathbf{X}_i$ is a polynomial basis matrix whereas $\mathbf{W}_i$ is a diagonal sample weight matrix. The polynomial fitting problem is also known as kernel regression and is equivalent to a linear projection. Theoretical point-wise covariance matrices can thus be computed when the measurement errors are assumed to be drawn independently and identically from a Gaussian distribution ($N(0;\sigma_y)$):

$$\Sigma_{\beta_i} = \mathbf{H}_i \cdot \sigma_y \cdot \mathbf{I}_n \cdot \mathbf{H}_i^T \tag{4}$$

The point-wise distribution for the coefficient of the linear term in the polynomial is then:

$$\beta_{1,i} \sim N(\beta_{1,i}(2), \Sigma_{\beta_i}(2,2)) = N(\mu_{1,i}, \sigma_{1,i}) \tag{5}$$

By integration of the probability mass under this density curve over the positive (negative) section of the real axis, one obtains the probability for a upward trend, $P_{u,i}$ (downward trend, $P_{d,i}$). More specifically, one computes these *qualitative trend probabilities* as (Fig. 1 middle):

$$P_{y,i}(1) = P_{u,i} = \int_{u=0}^{+\infty} \frac{1}{\sigma_{1,i}\sqrt{2\pi}} \cdot exp\left(-\frac{(u-\mu_{1,i})^2}{2\cdot\sigma_{1,i}^2} du\right) \qquad P_{y,i}(2) = P_{d,i} = (1-P_{u,i}) \tag{6}$$

Step 2 – Probability integration by means of a Hidden Markov Model (HMM): Discrete state estimation by means of a Hidden Markov Model is used as a filtering step to remove noisy features in the qualitative trend probabilities for the derivative signs as computed in the first step of the QSE algorithm. To this end, the monitored discrete state process is assumed to be represented by a Markov process. Mathematically, a Markov process is described by expressing the likelihood for each of the process states at time i conditionally to the likelihoods of the same states at time $i-1$:

$$\Lambda(\mathbf{s}(i) = t \mid i-1) = \sum_{p=1}^{q} \mathbf{T}_i(t,p) \cdot \Lambda(\mathbf{s}(i-1) = p \mid i-1) \tag{7}$$

The likelihoods, $\mathbf{T}_i(t,p)$, express the chance that the process state will be the target state t at time i conditional to the process being in the state p at time $i-1$. Whereas the QPE method makes use of an upper triangular matrix, $\mathbf{T}$, implying a non-ergodic Markov process, the QSE method proposed here poses no such restrictions. In addition, all transition likelihoods on the diagonal are set to one (1) and the off-diagonal elements are set to an identical and time-invariant value (γ):

$$\mathbf{T}_i(p,t) = \begin{cases} 1, & p = t \\ \gamma_i(t,p) = \gamma, & \text{otherwise} \end{cases} \tag{8}$$

The maximum likelihood (ML) state estimate at time i, $\hat{s}_i$, is now given as:

$$\hat{s} = \underset{t}{\operatorname{argmax}}\, P_{s=t}(i|i) \quad \text{with} \quad P_{s=t}(i|i) = P_{y,i}(t) \cdot \sum_p \mathbf{T}_i(t,p) \cdot P_{s=t}(i-1|i-1) \tag{9}$$

By means of the above recursive equations, one tracks the most likely state at a given time conditional to the evidence gathered until that time and represented by the qualitative trend probabilities computed by Eq. 6. It is this series of ML state estimates that are fed into the controller logic.

3. Results

3.1. Feedback Control Based on QTA

The proposed feedback control based on the QTA is a bang-bang controller. In low load situations (a.k.a. *Eco*-mode) the dissolved oxygen (DO) concentration is lowered in all tanks by reducing the DO setpoint for the corresponding slave proportional-integral (PI) control loops. This slows the nitrification process down, which in turn reduces the oxygen demand and thus the aeration energy and costs. When facing a NH_4^+ peak load (a.k.a. *Normal*-mode), one increases the DO setpoint to speed up the nitrification process so that a violation of the effluent concentration limits is prevented. Proper recognition of peak and normal loads is critical to maintain environmentally safe operation limits while minimising operational costs associated with aeration. QTA is deployed to detect the two modes (Eco and Normal) online (see Table 1). A small width for the support window (λ (cfr. Eq. 1) allows a short response time. However, small oscillations lead to the identification of irrelevant minima and maxima. The HMM-based method was therefore complemented with a number of heuristic quantitative rules, which enable the separation between these small oscillations, which are unrelated to changes in the NH_4^+ concentration, and large trends, which correlated to significant dynamics of the NH_4^+ concentration. Firstly, the recognition of the switch from Eco- to Normal-mode incorporates three rules, which are: *EN1* – At least one minimum, i.e. switch of the HMM state estimate from the downward to upward state, needs to be registered in Eco-mode; *EN2* – The difference between the current pH difference signal value and the lowest minimum registered in the Eco-mode is larger than a critical minimum level, called the *Minimal Difference*; and *EN3* – A maximum, i.e. switch of the HMM state estimate from the upward to downward state, needs to occur after both *EN1* and *EN2* are evaluated as true. These rules ensure *(i)* that the minimum NH_4^+ concentration as occurring during the Eco-mode is recognised properly and *(ii)* a recognised maximum truly corresponds to an NH_4^+ peak load. To switch back from Normal- to Eco-mode, the following heuristic rules are applied: *NE1* – The pH difference signal has to drop below the level defined by the minimum pH difference signal registered in the last Eco-mode plus a tolerance, called *Maximal Difference*. This rule ensures that the nitrification activity is at a similar (low) activity as recorded before; *NE2* – At least one minimum needs to occur after *NE1* is evaluated as true. *NE3* – The Normal-mode needs to be active for a minimal time period. These rules ensure that nitrification activity is always brought to its minimum thereby allowing for proper registration of the minimum NH_4^+ concentration. These rules govern the bang-bang controller, which switches between the Eco-mode, corresponding to low NH_4^+ loads, and the Normal-mode, which corresponds to high NH_4^+ loads.

Table 1: Control states and qualitative process properties.

Control Mode	Ammonium Load	Oxygen Setpoint	pH Difference
Eco	Low	Low	Low
Normal	High	High	High

3.2. Integration into the pre-existing control scheme.

The QTA based bang-bang controller only determines if the plant faces a high (Normal-mode) or low (Eco-mode) NH_4^+ load situation. In the Normal-mode, a high DO setpoint is set for the slave PI controllers regulating the DO concentrations. In Eco-mode, a low DO setpoint is implemented. Because the slave controllers and the aeration system exhibit their own response times, a number of safety rules are implemented to ensure the QTA-based bang-bang controller output is handled well and only when appropriate. One additional rule checks if the plant is facing a high hydraulic load. Detection of peak hydraulic loads are detected faster by means of flow measurements at the inlet of the WWTP and induce a switch to the Normal-mode without further delay. Similarly, a pH sensor at the inlet of the plant can be used as a proxy for toxic, industrial wastewater. By switching to the Normal-mode maximum survival of the sensitive bacterial community is then ensured.

3.3. Experiences and Outlook

The proposed bang-bang controller has been tested on the full-scale WWTP Hard in Winterthur. During this time, the effluent concentration of NH_4^+ did not increase significantly compared to exclusive operation in Normal-mode and remained below the legal limit. Current estimates of the aeration energy savings amount to 15%. Early development and testing was executed jointly with Rittmeyer AG, which has developed a commercially viable version as a module in the RITUNE® software for WWTP supervision and optimisation. Further work is focused on testing and evaluation of the QTA-based controller for other WWTPs. Special attention will be given to *(i)* the ease of implementation and fine-tuning and *(ii)* transparency of the controller to technical operators. QTA methods are being developed to handle *(i)* inflection points, *(ii)* discontinuities (Villez and Habermacher, 2015), as well as *(iii)* multivariate data series.

4. Conclusion

A new method for qualitative trend analysis (QTA) has been developed and tested as part of an advanced control strategy for NH_4^+ removal in biological WWTPs. By means of the QTA method, called qualitative state estimation (QSE), one can differentiate between high and low NH_4^+ load situations on the basis of cheap and reliable pH sensor signals only. Initial tests with this controller delivered reduction in aeration energy requirements of over 10%. As such, the proposed method holds great promise as a robust approach to minimise energy costs in small biological WWTPs.

5. Acknowledgement

This work was supported by the Commission for Technology and Innovation (CTI) of the Swiss Federal Department of Economic Affairs Education and Research (EAER). (CTI project no. 14351. PFIW-IW). The authors thank the staff of the WWTP Hard in Winterthur for the opportunity and assistance with this study.

Abstract

One of the biggest operational risks to water companies arises from their ability to control the day-to-day management and optimisation of their water treatment systems. With emerging pressures to remain competitive within national and global markets, companies are looking for solutions to be able to make predictions on how their chosen treatment processes can be improved. The objective of this work is to develop a detailed mathematical modelling methodology of a conventional clean water treatment plant which includes detailed models of each of the key processing unit operations. The methodology is first validated by individual unit examples based on experimental data from literature, before the operation of a complete water treatment plant is considered.

Keywords: Clean water treatment, dynamic modelling, water purification.

1. Introduction

Supplying water of adequate quality and in sufficient quantities is one of the major challenges facing modern society. These challenges are intensified by a combination of rising populations, increased industrial and agricultural water usage, climate changes and the increased difficulty of building major new water infrastructure due to limitations in the amount of land accessible for the new developments. With growing pressures on the water treatment industry, there is now a greater need to optimise water treatment works, whether to increase throughput, reduce operational costs, or minimise capital expenditure as demonstrated by Bozkurt et al. (2014). Although clean water treatment plants have been functioning for more than a century, during the last few decades, as technology has developed, the operation has become increasingly more complex.

The operation of drinking water treatment plants are largely based on experience, but due to more stringent regulations, treatment plants have to produce water of increasingly higher quality. The European Union follows standards for potable water that has been set by a Drinking Water Directive (98/83/EC, 1998). The technologies utilised in water treatment can be energy intensive and costly, and a methodology which can predict energy usage and other key performance indicators will therefore be of great benefit to this industry. Most modelling work within clean water operations has so far been based on empirical observations or hydraulic modelling, rather than mathematically describable relationships of the process, which will be considered in this work. An accurate mathematical model can enable quick and efficient investigation and screening of different design and operating alternatives. From the concept of modelling within the process industry, it can be inferred that modelling and control is likely to lead to better water quality, cost reduction and to a more stable performance of a plant, as

well as to a better understanding of the individual treatment processes. According to Rosen (2000), by 2050 a drinking water treatment plant will be entirely controlled from a central control centre, where dedicated integral control programs, which incorporate advanced process and control models, will control the treatment processes and mitigate risk. Acquiring detailed mathematical model representations of each water treatment process is therefore essential to meet this objective.

In this work, we demonstrate the novel use of a mechanistic modelling approach to generate individual models of different types of clean water treatment process units. We then combine the models together to depict an overall process flowsheet. The main objective is the development of a complete mathematical model of an entire water treatment plant. The model is able to accurately predict the performance of the overall process, which enables a wider view on how changes in one processing unit will affect the treatment process as a whole.

2. Process description

The plant considered in this case study consists of the three main physical processes typically available on a conventional water treatment plant; a coagulation/flocculation unit, a clarification unit and a rapid gravity filtration unit. As illustrated in Figure 1, raw water, possibly from different sources, first enters the coagulation/flocculation unit, where a chemical coagulant is added. The coagulant destabilises the colloids present in the raw water by neutralising their negative charges (coagulation). The colloids will then subsequently aggregate to form flocs (flocculation). These flocs of colloidal impurities behave as suspended solids within the water as it enters the second unit, a clarification unit. Within this unit, the flocs will settle to the bottom, and this concentration of solids is then removed as a sludge flow through the bottom, thus producing an almost clear effluent at the top of the unit which flows into the final main unit to undergo filtration. During filtration, the water is passed through a bed of adsorbent material, for instance sand, which allows for the impurities to attach to the material, thus removing the impurities from the water, leaving this as clean purified water. The filtration unit will require regular back-washing. The water will then go to a final disinfection unit (this step is not considered in this work) before a holding tank.

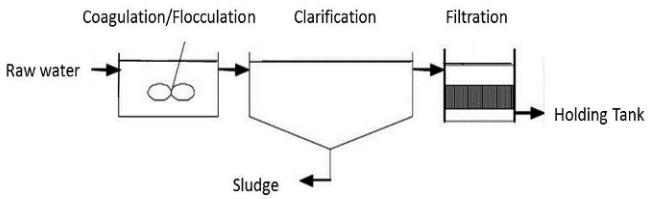

Figure 1: Flowsheet of a conventional clean water treatment work

3. Model development

The main objective of this work was to develop a mathematical model representation of clean water treatment works with sufficient accuracy to allow a detailed investigation of the behaviour, both of individual processing units, and of the overall treatment work. The individual unit models are derived based on previous work from literature and is coded within gPROMS, an equation based modelling and simulation software package (Process Systems Enterprise, 2014).

3.1. Model of the Coagulation/Flocculation unit

Argaman and Kaufman (1970) proposed a diffusion model for orthokinetic flocculation at steady state. They assumed that particles suspended in a turbulent regime experience a random motion which is similar to that of gas molecules (Equation 1):

$$\frac{\partial n}{\partial t} = K_B n G^m - K_A n_D G \tag{1}$$

where n is the number of primary particles per unit volume of water (m^{-3}), n_D is the number of floc particles formed per unit volume of water (m^{-3}) t is time (s), G is the velocity gradient (s^{-1}), m is a parameter, K_A is the floc aggregation coefficient (-), and K_B is the break up rate coefficient (s).

In developing their model, Argaman-Kaufman considered floc formation in a single continuously stirred tank reactor (CSTR) and assumed that the primary particles collide into flocs and that these flocs are removed in the following clarification unit. The model was validated experimentally by Haarhoff and Joubert (1997). The model developed in this work was validated against both the original model and the experimental data and showed good agreement (see Figure 2).

3.2. Model of the Clarification unit

The theory from secondary settling tanks in wastewater treatment works can be applied to the clarification unit in clean water treatment works (Head et al., 1997). Burger et al. (2012) proposed a non-linear partial differential equation (PDE), then used finite difference methods to derive at a one-dimensional settling-compression-dispersion model (Equations 2 and 3):

$$\frac{\partial}{\partial t}\int_{z_1}^{z_2} AC(z,t)\partial z = A\left(\emptyset|_{z=z_1} - \emptyset|_{z=z_2}\right) + \int_{z_1}^{z_2} Q_f(t)C_f(t)\,\delta(z)\partial z \tag{2}$$

where A is the cross sectional area (m^2), C is the concentration of suspended solids within the water (mg/L), Q_f is the feed volumetric flowrate (m^3/s), C_f is the feed inlet concentration, δ is the dirac delta distribution (m^{-1}), t is time (s) and the total flux, $\emptyset$ *(m^2/s)*, can be expressed as:

$$\emptyset\left(C, \frac{\partial C}{\partial z}, z, t\right) = F(C,z,t) - \left(\gamma(z) d_{comp}(C) + d_{disp}\left(z, Q_f(t)\right)\right)\frac{\partial C}{\partial z} \tag{3}$$

where F is the convective flux function ($mg/(m^2 s)$), γ is a characteristic function, d_{comp} is the compressive function and d_{disp} is the dispersion function (m^2/s).

The model describes thickening and clarification dynamically in order to predict the sludge bed height and concentration of the suspended solids in the water. In this work, the model is validated by comparing model predications using gPROMS with the batch case study presented by Burger et al. (2012), showing good agreement (see Figure 3).

3.3. Model of the Filtration unit

Han et al. (2008) developed a model for the rapid gravity filtration process, which utilised the simplified mass conservation of particles within the filter (Equation 4):

$$u\frac{\partial C}{\partial z} + \frac{\partial \sigma}{\partial t} = 0 \tag{4}$$

where C is the particle concentration (mg/L), σ is the specific deposition on the filter (mg/L), u is the superficial velocity (m/s), z is the axial position in the filter bed (m) and t is time (s).

For filtration with a clean filter, the initial and boundary conditions can be defined as:

$$C = 0, \ \sigma = 0 \quad for \quad z \geq 0, t = 0 \tag{1}$$

$$C = C_{in} \quad for \quad z = 0, t > 0 \tag{2}$$

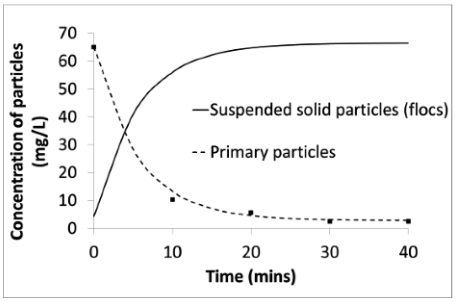

Figure 2: Model validation for the coagulation/flocculation unit. Concentration of suspended particles (flocs being formed from primary particles) as a function of time. Lines: simulation predictions from this work, Symbols: experimental results from Haarhoff and Joubert (1997).

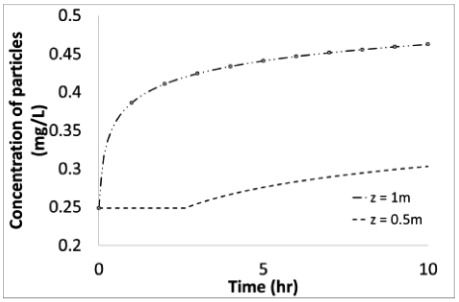

Figure 3: Model validation for the clarification unit. Concentration of setting particles in clarification unit with time from the bottom and middle of the tank. Lines: simulation predictions from this work, Symbols: simulated results from Burger et al. (2012).

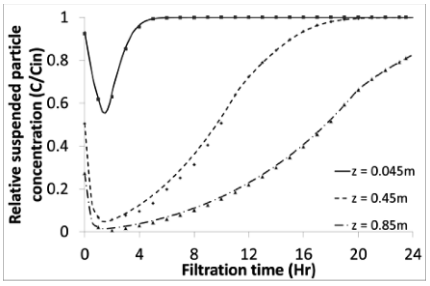

Figure 4: Model validation for the filtration unit. Relative suspended particle profiles with filtration times at varying positions within the unit. Lines: simulation predictions from this work, Symbols: experimental results from Han et al. (2008).

The authors utilise a two-stage assumption, which details that during the first stage, previously deposited particles serve as collectors to improve particle removal efficiency and the detachment of deposited particles does not occur until the specific deposit reaches a certain transient specific deposit where the second stage starts. The second stage is assumed to be a function of relative specific deposit and hydrodynamic conditions within the filter media. For validation of the filtration unit, the authors propose a ratio of suspended solid concentration remaining within the unit over the suspended solid concentration at the inlet to represent the relative suspended particles. The authors validate their model experimentally. The model developed in this work was validated against this experimental data, showing good agreement (see Figure 4).

3.4. Model of the overall plant

In a conventional water treatment plant, the main processing units are connected by pipes or troughs. In this work, these are described by simple non-reacting plug flow models. These plug flow models, combined with the individual unit models described and verified above, together constitute the overall plant model.

4. Results and Discussion

To demonstrate the applicability of the overall plant model, a sensitivity analysis was performed by considering the impact of a disturbance propagating through the process for an illustrative case study where the concentration for source of raw water inlet changes. After 2 hrs, a decrease of 40% was imposed on the inlet raw water source to test how the process would respond to a temporary change (Figure 5a). It can be seen from Figure 5 that the change in the inlet raw water concentration propagates through the whole process. There is a decrease in the concentration of flocs being formed due to the decrease of the inlet impurity concentration, which leads to a second order change in the clarification unit. As there are less flocs being formed, there is less concentration of particles settling in the clarification unit, as can also be seen from the gradual decrease in the concentration of particles settling in the clarification unit, which eventually reaches a new steady state. Within the filtration unit, there is a gradual change in concentration: this is due to the assumption that the filtration unit is used after back wash, which enables a greater deposition of particles onto the surface.

Note that a decrease in raw water inlet concentration can have a negative impact on the water purity if the number of primary particles entering is not sufficient to create flocs in the coagulation/flocculation unit, in which case these smaller particles will go through to the clarification unit. As there are more small suspended solids to floc ratio, the small particles will not settle to sludge and may pass through to the filtration unit. In theory, this can make the filtration unit saturate at a faster rate, leading to cloudy water being sent to consumer taps. The impact of the change greatly affected the first two units, as can be observed between times 2 – 6 hours, as the flocculation/coagulation unit relies on the primary concentration of particles to form flocs and the clarification unit uses the weight of the flocs as a form of separation.

5. Concluding Remarks

In this paper, a mathematical modelling representation of a conventional water treatment plant based on detailed models of individual processing units has been presented. The developed models allow a better understanding of individual unit

behaviour as well as provide a guideline of overall clean water treatment assessment. Current works involve implementing a similar methodology for alternative units of clean water treatment operation in order to develop an efficient optimisation strategy which will allow both optimal design and operation to be considered.

Abstract

In this work, we propose an integrated mechanistic model for a freshwater eutrophic reservoir and an artificial wetland and within a dynamic optimization framework. A partial differential equation system results from dynamic mass balances for the main phytoplankton groups; two zooplankton groups and two size classes of zooplanktivorous fish in the reservoir, as well as dissolved oxygen and main nutrients in both the reservoir and wetland. Algebraic equations stand for forcing functions profiles, such as temperature, solar radiation, river inflows and concentrations, etc. The model is formulated as an optimal control problem within a control vector parameterization approach in gPROMS. Optimization variables are the fraction of nutrient rich water stream that is derived through the wetland and fish removal rates from the reservoir. The objective function is the minimization of a weighted sum of integrals along the entire time horizon: the quadratic difference between phytoplankton concentration and a desired value below eutrophication limits and the quadratic difference between phosphate concentration in the wetland outflows and a desired value. Numerical results provide optimal profiles for restoration actions and their effects on the studied ecosystem.

Keywords: Optimal Control Problem, Eutrophication, Restoration, Biomanipulation

1. Introduction

Eutrophication, associated to high nutrient concentrations and recurrent algae blooms, is the most important environmental problem in many lakes and reservoirs. An issue of concern associated with algal blooms is the potential production of toxins by different phytoplankton species within the blooms, which are dangerous for human health (Paerl and Otten, 2013). The implementation of short and long term restoration strategies that contribute to health recovery of water bodies requires deep knowledge of the aquatic system, as well as detailed modelling and optimization (Estrada et al., 2011).

Water resources management must include restoration of water bodies not only affected by point sources (which has been intensively addressed by the construction of water treatment plants), but also those affected by nonpoint nutrient sources (Jeppesen *et al*., 2012). One approach applied to address the problem of nonpoint nutrient sources for water bodies is the use of artificial wetlands. They are portions of land, covered with macrophytes, through which a water stream is derived, to reduce its nutrient

concentration (nitrogen and phosphorus) before being discharged into the water body under study. Many physicochemical processes are involved in the reduction of nutrient concentration within wetlands, such as retention and assimilation by macrophytes, plankton and other microorganisms; sedimentation, adsorption from the sediments, among others (Langergraber et al., 2009). During the last decades, artificial wetlands have become an attractive alternative for water treatment since they have low maintenance cost, have a high efficiency and productivity and present ecological benefits (Reddy et al., 1999). Many lakes and water reservoirs have a positive response to reduced nutrient discharge, while others present a great resistance to improve their trophic condition due to nutrients discharge from sediments, internal recycle of nutrients and, in some cases, the presence of zooplanktivorus fish that cause a reduction on zooplankton population, which can no longer control phytoplankton growth by grazing. In this case, it may become necessary to implement inlake restoration strategies like sediment dreadging, hypolimnetic oxygenation and biomanipulation.

Experimental analysis of restoration actions is time-consuming and monitoring for long periods has large associated costs to implement. The development of ecological water models integrated to optimization strategies can help to propose and evaluate management strategies in both the short and long term (Estrada et al., 2011).

In this work, we propose an integrated mechanistic model for an eutrophic reservoir and artificial wetland within a dynamic optimization framework. Dynamic mass balances have been formulated for the main phytoplankton groups, two zooplankton groups and two size classes of zooplanktivorous fish in the reservoir, as well as dissolved oxygen and main nutrients. A simplified model has been considered for the artificial wetland. Algebraic equations stand for forcing functions profiles, such as temperature, solar radiation, river inflows and concentrations, etc. The complete model is formulated as an optimal control problem with a control vector parameterization approach (gPROMS, PSEnterprise 2014). Optimization variables characterize external reduction of nutrients (fraction of nutrient rich water stream that is derived through an artificial wetland) and biomanipulation strategies (fish removal rate). Numerical results provide optimal profiles for restoration actions. The present study has been carried out on Paso de las Piedras Reservoir, which is the drinking water source for two cities in Argentina.

2. Model description

We have formulated a water quality model as a differential algebraic system that describes temporal and spatial profiles of three phytoplankton groups (cyanobacteria, diatomea, chlorophyta), two zooplankton groups (cladocera, copepoda) and two size classes of zooplanktivorous fish (Odontesthes bonariensis), dissolved oxygen and main nutrients in the reservoir. Algebraic equations stand for forcing functions profiles, such as temperature, solar radiation, river inflows and their associated nutrient concentrations. The model takes into account concentration gradients along the water column (two horizontal layers) and horizontal averaged concentrations, constant water density and constant lake transversal area. Equations (1) to (6) correspond to main equations in the wetland and the reservoir, respectively. Equations (1) and (2) are phosphate mass balance and retention equation in the wetland:

$$V_w \frac{dC_{PO_{4,w}}}{dt} = Q_w c_{PO_{4,DIV,IN}} - kC_{PO_4,DIV,IN} Q_w - Q_w c_{PO_{4,w}} \quad (1)$$

where $\boldsymbol{C_{PO4,w}}$ is phosphate concentration at wetland output; $\boldsymbol{Q_w}$, and $\boldsymbol{V_w}$ correspond to inlet flowrate and wetland volume, respectively; $\boldsymbol{C_{PO4,DIV,IN}}$ is phosphate concentration

in wetland inlet stream and the nutrient retention rate $\boldsymbol{k}$ has been obtained from a pilot plant scale artificial wetland in the site. Equations (2) to (4) are component mass balances for the upper and lower layer in the reservoir and total mass balance, as follows:

$$\frac{dC_{Uj}}{dt} = \sum_k \frac{Q_{IN,Uk}}{V_U} c_{IN,Ujk} - \frac{Q_{OUT,U}}{V_U} c_{Uj} + r_{Uj} - \frac{k_d A}{\Delta h V_U}\left(c_{Uj} - c_{Lj}\right) - \frac{C_{Uj}}{h_U}\frac{dh_U}{dt} \quad (2)$$

$$\frac{dC_{Lj}}{dt} = -\frac{Q_{OUT,L}}{V_L} c_{Lj} + r_{Lj} - \frac{k_d A}{\Delta h V_L}\left(c_{Uj} - c_{Lj}\right) \quad (3)$$

j = NO_3,NH_4, ON, PO_4, OP, BDO, DO, Cyanobacteria, Diatomea, Chlorophyta, Cladocera, Copepoda, Odontesthes (2 size classes)

$$\frac{dh_T}{dt} = \frac{1}{A}\left[Q_{rain} - Q_{evap} + \sum_k Q_{IN,k} - \sum_m Q_{OUT,m}\right] \quad (4)$$

where $\boldsymbol{C_{IN,Ujk}}$ is component j concentration in the upper layer for tributary k (Sauce Grande River and El Divisorio Stream, in our case study); $\boldsymbol{C_{U,j}}$ and $\boldsymbol{C_{L,j}}$ are component concentrations within the water body in the upper and lower layer, respectively; $\boldsymbol{r_{U,j}}$ and $\boldsymbol{r_{L,j}}$ stand for generation/consumption terms; $\boldsymbol{Q_{IN,U}}$ refers to tributaries inputs (Sauce Grande River and El Divisorio Stream), $\boldsymbol{Q_{OUT,U}}$ is the Sauce Grande River output, $\boldsymbol{A}$ and h_T are the lake transversal area and depth, respectively, and $\boldsymbol{Q_{OUT,L}}$ refers to outputs for drinking water and industrial activities. Model parameters have been estimated based on collected data during 2004-2005 for Paso de las Piedras Reservoir (Estrada et al., 2009). For a more detailed description of the generation/consumption rate terms, see Estrada et al. (2011). The entire model has 42 differential and 110 algebraic equations.

3. Optimal Control Problem

In this work, we formulate a model including two restoration strategies: the reduction of external loading of nutrients as an optimal control problem along a long term time horizon of twelve years, and an internal lake strategy, biomanipulation, that is based on the food chain theory and is supported on top-down control on phytoplankton growth (Søndergaard *et al*., 2013). The basic idea is to perform zooplanktivorous fish removal to keep a high grazing pressure on the phytoplankton community by the herbivore zooplankton. In this work, we have considered the application of biomanipulation by fish removal, considering fish removal rate as control variable, which are included as negative terms ($S_{1.,Removal}$ and $S_{2,Removal}$) in the rate equations of fish biomass (Eqs. 5 and 6) for both size classes of *O. bonariensis* (S_1 and S_2).

$$r_{iS_1} = R_{im,pred} - R_{im,bmetab} - R_{iS_3,canib} - R_{im,recruit} + R_{im,spaw} - S_{1,Removal} \quad (5)$$

$$r_{iS_2} = R_{im,pred} - R_{im,bmetab} - R_{im,recruit} + R_{im,spaw} - S_{2,Removal} \quad (6)$$

The objective function is the minimization of a weighted sum of two integral terms. The first integral corresponds to the square difference between phytoplankton concentration in the upper layer of the lake and a tight desired value of 0.25 mg/l. The second integral is the square difference between phosphate concentration in the wetland outlet stream and a desired value of 0.02 mg/l. Both desired values are below eutrophication limits. The dynamic optimization problem is formulated as:`

$$min\ \emptyset = \left[\int_0^{tf}\left(\sum_{j=C,D,G} C_{U,j}(t) - 0.25\right)^2 dt + \int_0^{tf}\left(C_{PO_4,w}(t) - 0.02\right)^2 dt\right] \quad (7)$$

subject to

DAE Integrated Model for Wetland and Reservoir

$0 \le Q_w \le 0.5\ Q_{DIV,IN}$ (L/ day)

$LB \le C_m \le UB$ (mgC/L day) $m = S_1, S_2$

4. Results and Discussion

The optimization problem was implemented within a control vector parameterization framework in gPROMS (gPROMS, PSEnterprise, 2014), considering a time horizon of two years. Numerical results for the case study are shown in Figures 1 and 2. Optimization control variables are the fraction of tributary stream that is derived through the wetland and removal rates for the two fish size classes. Based on experimental results, obtained in a pilot scale artificial wetland, phosphorus retention of 50% and nitrogen retention of 60% are considered.

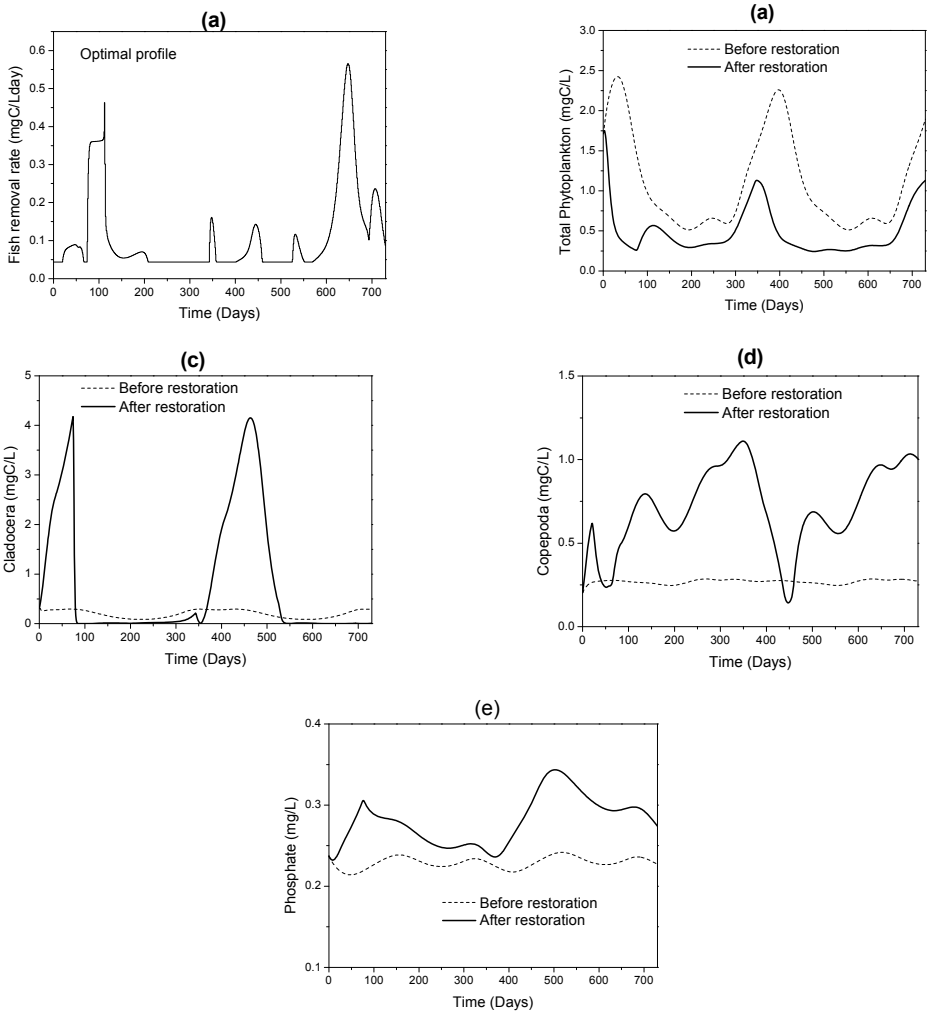

Figure 1. Optimal profiles for restoration along two years for fish removal rate (a); total phytoplankton concentration before (dashed line) and after restoration (solid line) (b), Cladocera concentration (c), Copepoda concentration (d) and phosphate concentration (e)

Figure 1(a) shows zooplanktivorous fish removal rate profile along the time horizon of two years. It can be seen that the obtained removal profile allows an important increase on

zooplankton concentration (Figs. 1(c) and 1(d)), which increases its grazing pressure on phytoplankton. Figure 1(b) shows total phytoplankton biomass profile before and after restoration, it can be seen that phytoplankton biomass peaks are reduced after restoration actions due to the increase of zooplankton biomass. Figure 1(e) shows phosphate concentration profile before and after restoration actions, it is observed that its concentration increases after fish removal, even though the fraction of tributary stream deviated through the wetland (control variable) is at its upper bound. This can be attributed to a decrease in phosphate consumption due to the decrease in phytoplankton biomass, and also to the internal recycle of nutrients within the water reservoir.

Figure 2 shows numerical results for the application of the use of wetland as a sole restoration strategy throughout a 12-year horizon (three times the residence time of Paso de las Piedras reservoir), for phosphate (a) and total phytoplankton concentration (b). Figure 2(a) shows a small reduction of phosphate concentration within the water body, from 0.237 mg/L at t=0 to 0.211 mg/L at t=4380 (days). Phytoplankton concentration presents a slow reduction along the time horizon (Fig. 2(b)). These results show that reduction on nutrients discharge is not enough to improve water quality for the short and medium term.

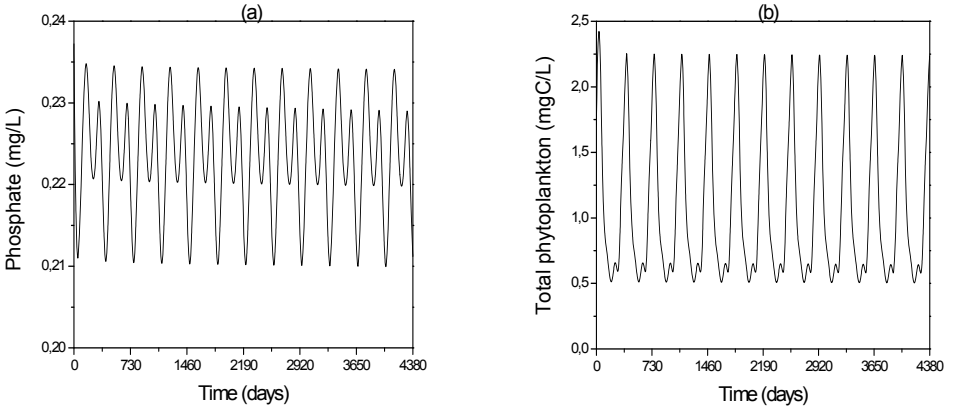

Figure 2. Temporal profiles for phosphate (a) and total phytoplankton biomass for long term restoration through an artificial wetland.

Figure 3 shows optimal profiles for total phytoplankton concentration (a) and phosphate concentration (b). Numerical results shown in Fig. 3 are obtained considering 0.21 mg/L (concentration of phosphate at t=4380 days in Fig. 2(a)) as initial concentration of phosphate within the reservoir. The comparison between Fig. 1(b) and Fig. 3(b) shows that the second peak of phytoplankton biomass can be reduced when a lower initial concentration of phosphate is considered.

Currently, the wetland model is being extended to include additional complex processes that take place within wetlands, such as nutrient (carbon, phosphorus, nitrogen) dynamics and macrophyte growth (Langergraber et al., 2009). This will allow formulating new optimal control problems to improve the wetland performance.

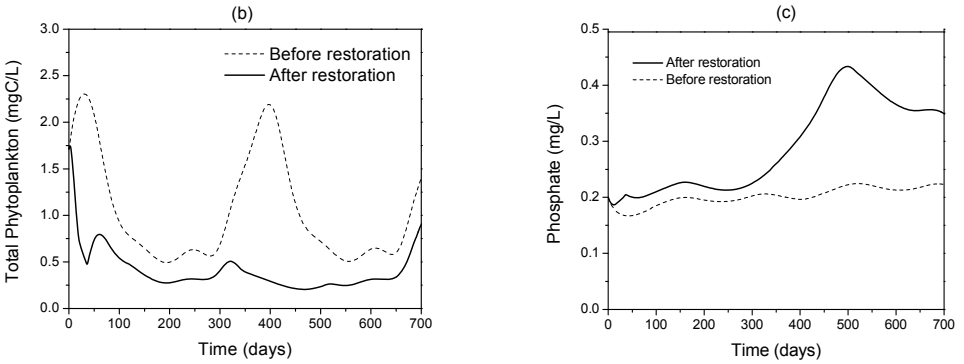

Figure 3. Optimal profile before (dashed line) and after (solid line) restoration for total phytoplankton (a) and phosphate (b), considering initial concentration of phosphate after 12 years wetland restoration

5. Conclusions

We have formulated an optimal control problem to plan short and medium time restoration in a eutrophic reservoir with a detailed ecological water model. Medium term restoration (12 years) through an artificial wetland has been explored as the sole restoration strategy. Numerical results show that both external and inlake restoration strategies must be applied simultaneously. Process systems engineering approaches have proved to be effective for the determination and planning of restoration strategies.

Abstract

Life Cycle Assessment or LCA is an effective tool for quantifying the potential environmental impacts of products, processes, or services in order to support the selection making of desired products and/or processes from different alternatives. For more sustainable process designs, technical requirements have to be evaluated together with environmental and economic aspects. The LCSoft software-tool has been developed to perform LCA as a stand-alone tool as well as integrated with other process design tools such as process simulation, economic analysis (ECON), and sustainable process design (SustainPro). An extended version of LCSoft is presented in this paper. The development work consists of four main tasks. The first task consists of the Life Cycle Inventory (LCI) calculation function. The second task deals with the extension of the Life Cycle Inventory database and improvement of the Life Cycle Impact Assessment calculation. The third task deals with analysis to investigate the contributions of processes, LCI results, and environmental impact results with respect to the production stage. Also, an uncertainty analysis is included to investigate the influence of uncertain parameters on the LCI assessment results. The fourth task has been added to validate and improve LCSoft by testing it against several case studies and compare the assessment results with other available tools.

Keywords: Life Cycle Assessment, Life Cycle Inventory, Contribution analysis, Uncertainty analysis.

1. Introduction

Environmental and sustainability awareness has lately gained much importance because of increasing depletion of natural resources, need for more efficient process-operations and product manufacturing together with sustainable waste disposal. Life Cycle Assessment is a tool for quantifying the potential environmental impact of products, processes, services and activities for the entire life cycle, of the product-process. The LCA related calculations starts from raw material extraction, raw material manufacturing, transportation, product manufacturing, product distribution, usage, and waste disposal.

According to ISO 14040 (ISO 14040 International Standard, 2006), the LCA framework are organized into four phases.

(1) Goal and scope definition: The purpose of performing LCA is clearly defined together with the system boundary.
(2) Life Cycle Inventory (LCI) analysis: LCI compiles and quantifies the amounts of all necessary input streams (natural resources, raw materials, energy types, and products) and output streams (emissions to soil, air, and water; waste; energy; products; and by-products) through relevant process within the system boundary.
(3) Life Cycle Impact Assessment (LCIA): The inventory results are classified into each impact category, such as global warming potential, natural resource depletion, human toxicity, etc., based on their effect on environment. Magnitude and potency of each substance in inventory results are characterized to impact category by using characterization factors (CFs), which represent the effect of each substance on the environment based on the reference unit.
(4) Interpretation: In order to analyze inventory results and impact assessment results, several methods are available for implementation. Sensitivity analysis, where the influence of different assumption that affects the assessment results is analyzed. Uncertainty analysis, where the influence of uncertainty in LCI data or uncertainty in calculation models on the reliability of the assessment results is analyzed. Contribution analysis that shows how processes, LCI results, environmental impacts contribute to each production stage in order to determine the significant impacts for further process improvement.

Although, several LCA software such as SimaPro (PRé Consultants, 2014), Umberto (ifu Hamburg GmbH, 2014), and Gabi (PE International, 2014) have been developed for fast and effective LCA calculations, they are not yet integrated to process synthesis-design. From a process synthesis-design point of view, there is still need for any simple software that has the ability to be integrated with other process synthesis-design tools such as process simulation, economic analysis or sustainable process design. LCSoft (Kalakul *et al.,* 2014) has been developed to fulfill this requirement under the concept of user-friendly interface such that the user can perform LCA by using LCSoft easily, effectively, and integrated with process simulation, economic analysis tool, ECON (Saengwirun, 2011); sustainable process design tool, SustainPro (Carvalho *et al.,* 2013). The objectives of this work are to develop the new version of LCSoft, which is developed with special attention to the needs of chemical and biochemical processes.

2. Development framework

The development framework of LCSoft consists of four main tasks; (1) development of LCI calculation function; (2) extension of LCI database and improvement of LCIA; (3) perform contribution analysis and uncertainty analysis; (4) validation and improvement of LCSoft.

2.1 Development of LCI calculation function

The objective of this part is to develop the LCI calculation function for compiling and quantifying input and output of given product corresponding to all relevant processes within the system boundary. The developed LCI calculation function is based on the matrix algebra approach of Heijungs and Suh (2002).

2.2 Extension of LCI database and improvement of LCIA

LCI data from US LCI (U.S. Life Cycle Inventory Database, 2014) and from other available sources are collected into LCSoft database to increase the application range of the system boundary of LCA calculations. In addition to eleven environmental impact indicators, carbon footprint calculation, and energy consumption calculation are now provided in LCSoft 2.0. Other environmental impacts added are: water resource depletion, mineral extraction, and deposited waste. Details of characterization factor for specific environmental impacts and their units are given in Table 1.

2.3 Performing contribution analysis and uncertainty analysis

Contribution analysis is divided into three parts: process contribution, LCI results contribution, and environmental impact results contribution. These results offer the user options to investigate how the results from performing LCA contribute to the production stage. Providing thereby, useful options for further process development. For investigating the influence of uncertainty in LCI data, Monte Carlo analysis is used to perform uncertainty calculations by repeating LCIA calculation with selected LCI results in various uncertainty ranges.

2.4 Validation and improvement of LCSoft

The validation of LCSoft is performed by comparing assessment results from case studies with available commercial LCA software. The results from the comparison are investigated to identify the deficiencies in LCSoft for further improvement. Within LCSoft, the calculations divided into five main steps and two optional steps: (1) check LCI data; (2) retrieve LCI data; (3) carbon footprint calculation; (4) impact assessment; (5) contribution analysis; (Optional-1) uncertainty analysis; (Optional-2) sensitivity analysis, as shown in figure 1. The details and calculation models for the five steps and two options are given in Table 2.

Table 1. Characterization factors and unit of environmental impacts

Impact Category (I^k)	Characterization factor ($CF^k{}_{t,c}$)	Unit	CF source
Acidification	$CF^{AP}{}_{t,c}$	kg H+ eq.	USEPA

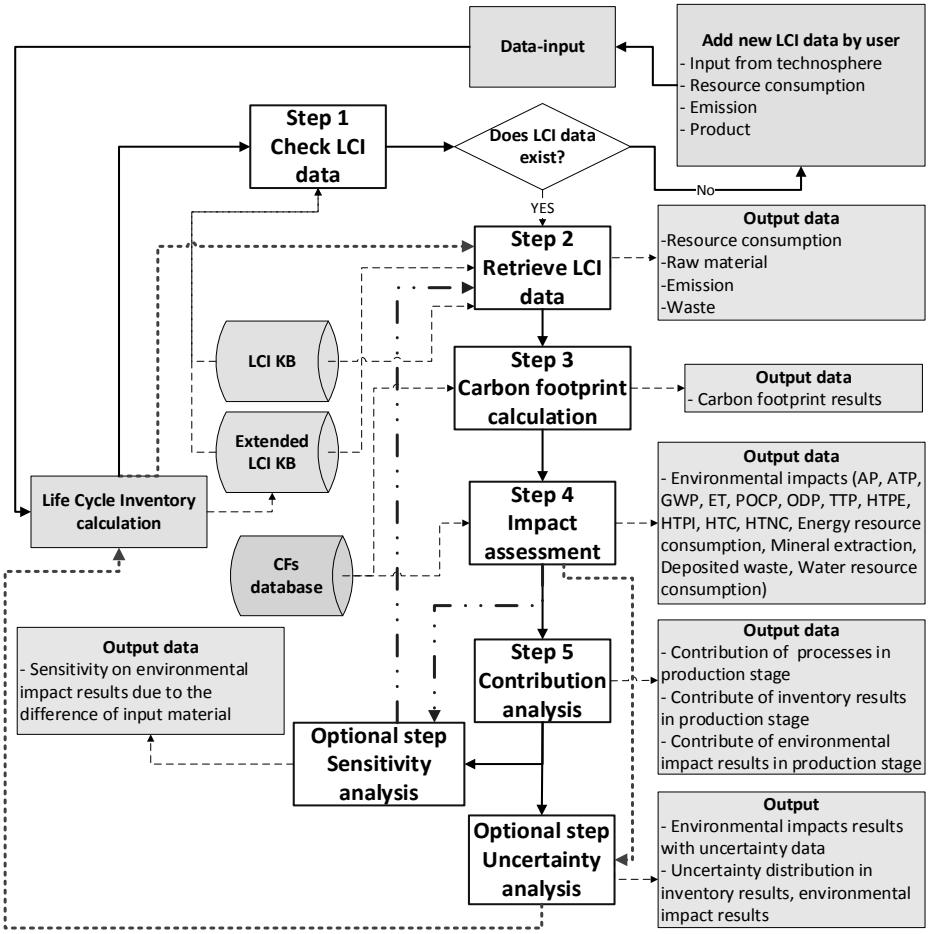

Figure 1. LCSoft framework

3. Case study

3.1 Development of LCI calculation in LCSoft

Life Cycle Inventory calculation is developed for compiling and quantifying all elementary flow through the related process based on the model given in Table 2. In Table 2, "A" represents the technology matrix that contains commodity flow of all processes. Inflow and outflow are noted by positive and negative values, respectively. "B" represents the intervention matrix that contains pollutants, natural resources, or energy emitted or consumed by processes, while, "s" is a scaling factor that is used to scale up unit processes in the technology matrix to the achieve target value defined by a functional unit. Acetic acid, 98% in H2O, at plant - RER from ecoinvent data v2.0 (Althaus *et al*., 2007) is taken to calculate LCI with LCSoft and SimaPro7.1 from cradle to gate and LCI calculation model in LCSoft is validated by comparing LCI results with SimaPro7.1. The comparison results are shown in figure 2 where the horizontal axis indicate different elementary flow (energy and substance flow) considered and the vertical axis represents the ratio of LCI results from LCSoft to SimaPro7.1. Figure 2 shows a very good match between LCSoft and SimaPro7.1.

Table 2. Calculation steps in LCSoft

Calculation step	Description	Input data/output data/calculation model
Step1: check LCI data	The LCI data of related products or processes are checked with permission to add or modify LCI data. If input from technosphere exists in added or modified data, the LCI results could be obtained by the LCI calculation function contained in software. Calculation model: Heijungs and Suh (2002).	Input data: - Mass balance (stream table) - Energy balance and duty of equipment (Equipment table) $As = f$ $g = Bs$
Step2: Retrieve LCI data	Resource consumption, raw material consumption, and emission of related products or processes are received from LCI KB for calculations in step3 and displaying of LCI results.	Output data: - Emission - Resource consumption - Energy consumption - Waste
Step3: Carbon footprint calculation	All amounts of CO2 and greenhouse gases in production process are quantified and characterized by using the Global warming potential (GWP) as an indicator. Calculation model: Guinée et al. (2002).	$CO_{2,eq} = \frac{m^{PRO}_{GHG,air} x CF^{GWP}_{GHG,air)}}{m_{product}}$ $Carbon\ footprint = \sum CO_{2,eq}$
Step4: Impact assessment	The LCI results are classified and characterized to each impact category based on their effect on environmental. Calculation model: Guinée et al. (2002).	$I^k = \sum_{t,c} EM_{t,c} x CF^k{}_{t,c}$
Step5: Contribution analysis	The process, LCI results, and impact assessment results are shown obviously in each production stage in order to investigate the contribution.	Input data: - Amount of product produced from process - LCI results - LCIA results
Optional step: Uncertainty analysis	The influence of uncertainty in LCI data to the assessment results is defined by using uncertainty analysis.	Input data: -Uncertainty range in LCI data
Optional step: Sensitivity analysis	The influence of different input material to the assessment results could be observed by using sensitivity analysis.	Input data: -Alternative input material

4. Conclusion

LCSoft, that can quantify the potential environmental impacts of products, processes, or services especially for chemical and biochemical process design in order to support the decision related to selection of a more sustainable process from different alternatives and with ability to be integrated with other process synthesis-design tools, has been

presented together with results from a case study. A new LCI calculation function has been created and to give accurate results, thus validating this new calculation option. Four impact categories have been added to software in order to increase the boundaries of the impact estimations. Future development is continuing the extension of the LCI database, creating contribution analysis functions, performing uncertainty analysis functions, validating and improving LCSoft software.

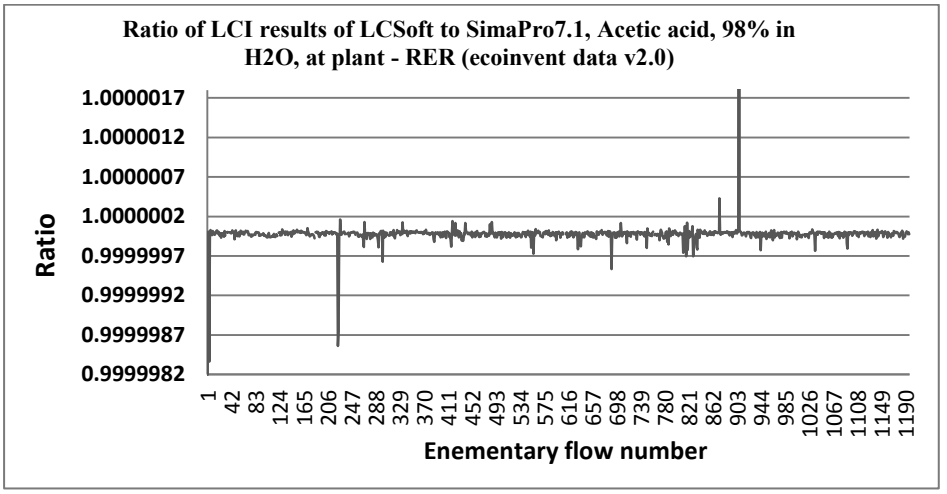

Figure 2. Ratio of LCI results of LCSoft to SimaPro7.1 (Acetic acid, 98% in H2O, at plant - RER (ecoinvent data v2.0)

Abstract

The TRENS system is a train of biological units designed for resource recovery from wastewater. It is a sequence of a modified enhanced biological phosphorus removal and recovery system (EBP2R) coupled with a photobioreactor (PBR). The bacteria-based system constructs an optimal culture media for the downstream algae cultivation. In this work, we present a control strategy to ensure an optimal nutrient balance to feed to the PBR, so the grown algal suspension is suitable for fertigation (irrigation and fertilization of agricultural crops). The system is able to recover up to 75% of the influent load, while keeping an optimal N-to-P ratio of 16 in the influent to the PBR. The system is tested under different scenarios, where the influent quality is disturbed following a step change. The control system is able to reject most of the disturbances. However, when the P-recovery is limited by the bacteria in the reactor, the control system is not able to keep the optimal phosphorus load, but only the optimal percentage recovery from the influent phosphorus. In this scenario, the system is kept under optimal conditions – in terms of nutrient balance – because the N-to-P ratio is still at 16, so the green microalgae can take up most of the incoming nutrients into the PBR. The control system is able to keep the optimal phosphorus load during dynamic conditions. However when the influent nitrogen is limiting the process, the N-to-P ratio drops under the optimal value. Further research is needed in order to assess the controllability of the PBR and the possible impact on the upstream operation conditions.

Keywords: process control; process modelling; resource recovery; wastewater treatment

1. Introduction

Conventionally, the arrangement of biological and physical unit processes in wastewater treatment systems is chosen to remove organic carbon, nitrogen and phosphorus. This treatment approach, without focus on recycling water and nutrients (N and P), is no longer regarded as sustainable (Verstraete et al., 2009). Particular scientific interest is currently focusing on the development of cost-effective ways to recover N and P from wastewater. A complete biological process for wastewater resources recovery has been developed to recover nitrogen, phosphorus and freshwater content of used water through mixed green microalgal cultivation (Valverde-Pérez et al., 2015). This innovative system, referred to as the TRENS system, is defined as a modified enhanced biological phosphorus removal and recovery (EBP2R) system coupled with a photobioreactor

(PBR). Previous work showed that the algal growth in the PBR, as well as the effluent quality, highly depends on the nutrient content of the constructed cultivation media (Wágner et al., 2015). The outcome of our work is the development and assessment of a control structure for the EBP2R to keep the optimal cultivation conditions in the downstream PBR.

2. Material and Methods

2.1. System description

The system is defined as a sequence of tanks shown in Fig. 1. The EBP2R consists of a sequence of two anaerobic and one aerobic continuous stirred tank reactors (CSTRs). The influent composition and the consequent system design (reactor volumes) are described in Valverde-Pérez et al. (2015). The system can remove most of the bioavailable COD, either by mineralizing it (most of the soluble readily biodegradable) or conveying it to an anaerobic digester (bulk of particulate slowly biodegradable organics) for biogas production. The system promotes the growth of polyphosphate accumulating organisms (PAOs), which are used to control the phosphorus load recovered from used water. Both N and P are taken up in the downstream PBR. As a side stream process, a completely autotrophic nitrogen removal (CANR) system is used to remove the fraction of influent N which cannot be recovered by the PBR.

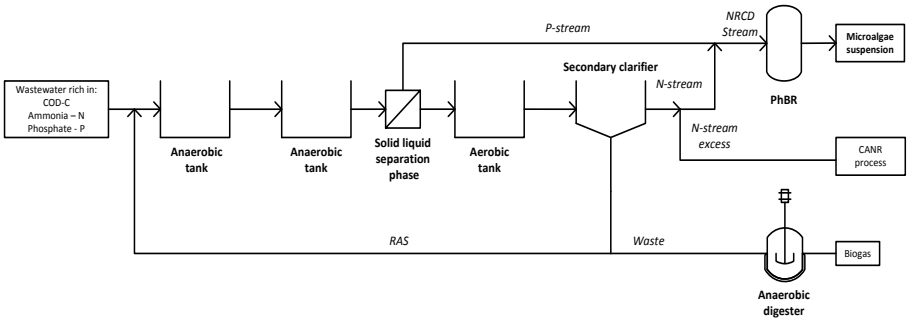

Figure 1 Flow-diagram of the TRENS system operated on discontinuous mode. CANR stands for autotrophic nitrogen removal system; NRCD stands for nutrient rich carbon depleted; RAS stands for recycling of activated sludge.

2.2. Process modeling

The EBP2R system is modelled using the activated sludge model ASM-2d from Henze et al. (1999), further adapted by Flores-Alsina et al. (2012). This model includes all the relevant bacterial groups in the EBP2R process, i.e. heterotrophs, nitrifiers and PAOs. The simulation model was implemented in Matlab-Simulink (The MathWorks, Natick, MA).

2.3. Control design procedure

The control structure was designed following a methodology adapted from plant-wide control (Larson and Skogestad, 2000). First, the goal of the system was defined. Then, the optimal operation conditions were defined through scenario simulations reported by Valverde-Pérez et al. (2015). Then, a degrees of freedom analysis was done, whereby the potential control variables as well as the available actuators in the system were

identified. The different actuators were paired with the controlled variables based on process knowledge and the resulting pairing was checked with the relative gain array (Seborg et al., 2004), thereby building the regulatory control layer. All controllers were modelled as PI controllers, unless otherwise specified, and were tuned according to Skogestad (2003). In a final step, the control structure was assessed through dynamic simulations. The dynamic influent was adapted from the benchmark simulation model 2 (BSM2, Flores-Alsina et al. 2012), including variations on the influent TCOD, TN, TP and flow rate.

3. Results and discussion

The primary objective of the control structure is to maximize the phosphorus recovered through algal cultivation, while the secondary objective is to obtain an optimal and stable nutrient balance to feed to the downstream PBR. We assume that the mixed green microalgae culture grown in the PBR is the one reported by Wágner et al. (2015), whose optimal nitrogen to phosphorus ratio in the cultivation medium is 16 mol-N/mol-P. In previous work (Valverde-Pérez et al., 2015), scenario simulations were carried out to assess the process performance in terms of both nutrient load and balance fed to the PBR (Fig. 2). According to Fig. 2a, the optimal process conditions comprise a solid retention time (SRT) of around 5 days and P-stream flow rate (Q_P) of around 30% of the influent flow, thereby recovering up to 70% of the influent phosphorus. Under other conditions, the PAOs activity may be limited by a number of factors, including SRT, availability of volatile fatty acids (VFA) and nitrate in anaerobic reactors and phosphate in the aerobic reactor, as shown in the Fig. 2a. Operating at system SRT < 3.5 days, PAOs are washed from the reactors, leading to a loss of control over the N-to-P ratio. If SRT is higher than 4.5 days, conditions support nitrifying bacteria growth, leading to nitrate production and limiting PAOs activity due to VFA starvation in the anaerobic reactors. Therefore, the maximum Q_P at high SRTs is governed by nitrate production and consequent PAOs activity limitation. When the system's SRT is lower than 4.5 days, PAOs activity is limited due to phosphorus starvation in the aerobic reactor at high Q_P. At comparably high Q_P (>45%), Fig. 2a shows a linear relation between P-load and flow rate, which implies that the system's performance is not dependent on the SRT because of the wash-out of the PAOs. Fig. 2b shows the possible effluent N-to-P ratios. At the optimal SRT (5 days), the N-to-P ratio does not accomplish with the optimal conditions, i.e. cultivation of the mixed green microalgae culture reported by Wágner et al. (2015). Therefore, it is needed to deviate 17% of the influent flow rate to the CANR system to reduce the N-to-P ratio from 19 to 16. Once the system is optimized, the oxygen set point is regulated in order to keep a stable operation. The chosen set point, based on the scenario simulations carried out in Valverde-Pérez et al. (2015), is 1.5 mg l^{-1}. The optimal operation conditions are sensitive to the influent quality, especially to the influent bio-available COD and the ammonia. In cases where there is an excess of influent COD, the inhibition by nitrate recycling is less severe than those cases that are characterized by low influent COD, thereby increasing the optimal plateau found in Fig. 2a. On the other hand, if the influent ammonia is comparably high while keeping an average influent COD, PAOs can be outcompeted in the anaerobic reactors, thereby reducing the optimal plateau in Fig. 2a.

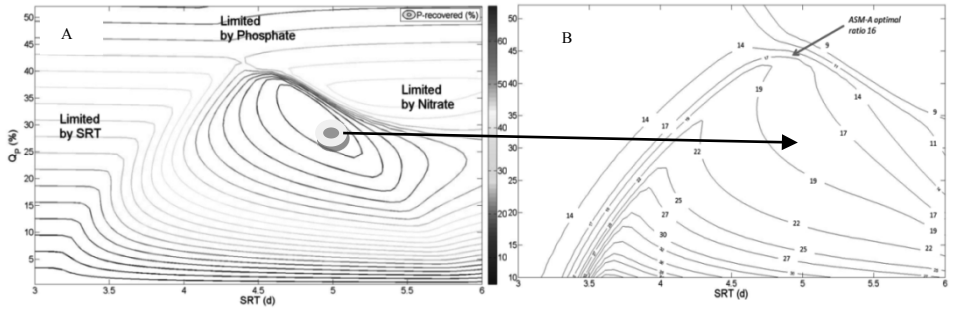

Figure 2 a) Percentage of P recovered from the influent as a function of the P-stream flow and the SRT; b) N-to-P molar ratio in the EBP2R as a function of the P-stream flow and the SRT. Adapted from Valverde-Pérez et al. (2015).

The next step is to identify the available actuators, referred to as manipulated variables (MVs), of the system: pumps, valves, mixers and air supply. The EBP2R has two different pumps. One is used to pump the Q_p while the other is placed in the recirculation line and used to waste activated sludge from the system. Both pumps are used to control the phosphorus load conveyed to the PBR and the SRT respectively. The reminder part of the influent forms the N-stream. This stream is split by a valve, so the valve controls the N-to-P ratio to the PBR by regulating the nitrogen load fed to it. The air supply is modelled as the oxygen mass-transfer coefficient (k_La). The air supply is used to keep the oxygen level at 1.5 mg l^{-1} in the aerobic tank. Since the effect of the mixing is not modelled it is not considered as a suitable actuator. The main disturbances considered in this work are the ammonia, phosphate and chemical oxygen demand (COD) influent loads. Fig. 3 shows the resulting control structure.

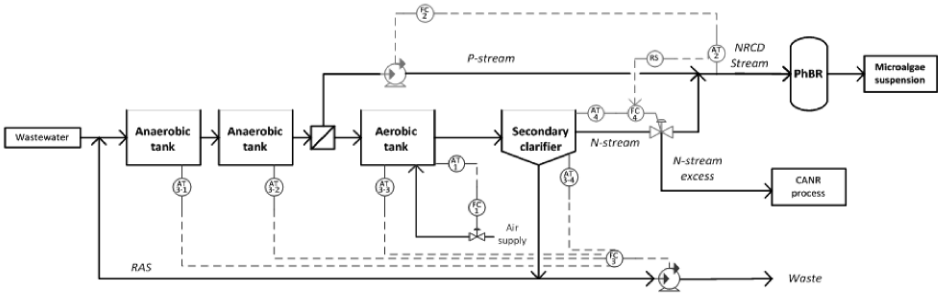

Figure 3 Layout of the control structure strategy. RAS stands for recirculation of activated sludge.

The RGA (Eq. (1)) shows that the interaction between the proposed control loops is minimal, and thus the chosen pairing is suitable for controlling the system.

$$\mathrm{RGA} = \begin{matrix} \\ \mathrm{DO} \\ \mathrm{P-load} \\ \mathrm{SRT} \\ \mathrm{N-to-P\ Ratio} \end{matrix} \begin{matrix} \begin{matrix} K_La & Q_P & Q_w & Q_n \end{matrix} \\ \begin{bmatrix} \mathbf{1.036} & 0.0027 & -0.0354 & 0.0001 \\ -0.0830 & \mathbf{0.8757} & 0.104 & 0.1032 \\ 0.0253 & 0.0058 & \mathbf{0.9189} & 0 \\ 0.0251 & 0.0658 & 0.0124 & \mathbf{0.8966} \end{bmatrix} \end{matrix} \quad (1)$$

System performance was assessed under 6 different scenarios, where the system was exposed to step disturbances on the influent TCOD (±20%), TN (±30%) and TP (± 20%). The results for the positive steps are shown in Fig. 4. Even it is not clear on the plots, due to the scale of the figure, in the moment of the step change the system barely deviates from the optimal performance. In all the three cases, the control structure is able to reject the disturbance and to keep a stable operation, thereby meeting the goals of the control system, i.e. i) stable and optimal phosphorus recovery through the P-stream; and ii) stable and balanced nutrient load conveyed to the PBR, with an N-to-P ratio of 16. Negative steps for TN and TCOD are also rejected by the control system. However, when the influent phosphorus load decreases the system is not able to keep the phosphorus load. Checking Fig. 2a again, it can be seen that by increasing Q_p the improvement on phosphorus recovery is limited by nitrifiers activity. Therefore, there is an upper boundary or maximum Q_p, beyond which PAOs are washed out from the system and the process performance cannot be recovered to the previous state. However, even the phosphorus load through the P-stream is lower than in the base case, the phosphorus recovery is still optimal in terms of percentage of influent phosphorus load, as the process operation is barely moved from the optimal conditions found through scenario simulations. In the latter scenario, emphasis should be put on controlling the N-to-P ratio, to avoid an excess of ammonia in the PBR, which would otherwise be impossible to take up by the microalgae.

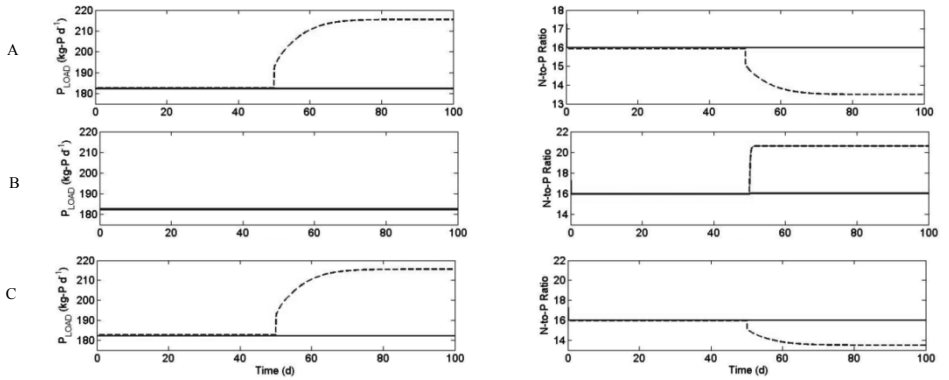

Figure 4 a) Effect of a step change of 20% on the influent phosphorus; b) effect of a step change of 30% on the influent ammonia; and c) effect of a step change on the influent TCOD of 20%. The full line represents the process response under controlled conditions, and the dashed line the process response without control.

Finally, the system is simulated under dynamic conditions. Fig. 5a shows that the control system is able to smooth the variations on the P-load, only allowing very small deviations from the set point. However, the N-to-P ratio shows some variability (Fig. 5b). When the influent nitrogen into the treatment plant is too low, the control system is not able to keep the set point and the N-to-P ratio falls under the optimal value. Nevertheless, the performance of the EBP2R is comparably better than in the case the system is not controlled. Since the algae present some flexibility due to N and P storage (Wágner et al., 2015), we expect that a comparably low deviation from the optimal N-to-P ratio does not compromise the effluent quality of the PBR.

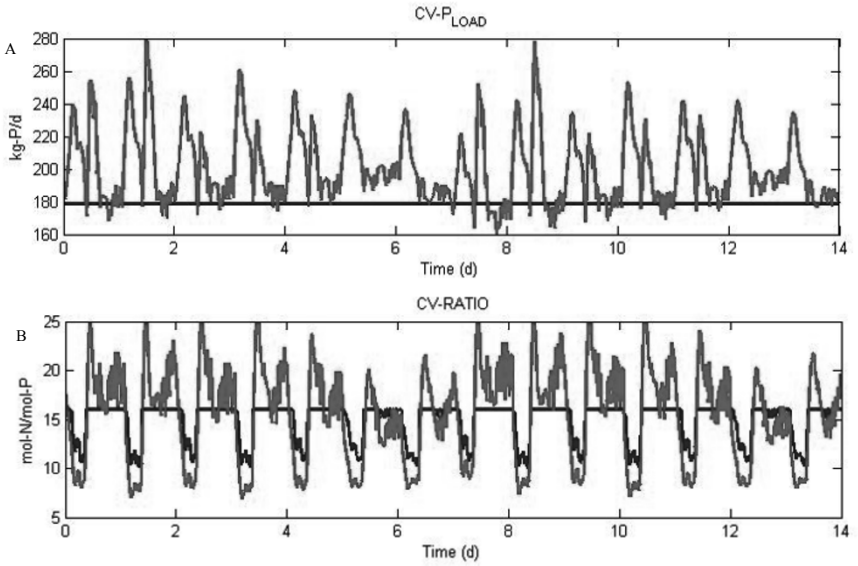

Figure 5 a) P-load fed to the PBR under dynamic conditions; b) N-to-P ratio fed to the PBR under dynamic conditions. The process response under controlled conditions (blue) and the process response without control (red) are presented.

4. Conlusion

In this work we have developed a control structure that allows a stable and optimal operation of the EBP2R. The control system is able to reject most of the disturbances. However, the process performance can be compromised when either N or P become limiting in the influent. Further research is still needed to assess the controllability of the downstream PBR and how it affects the EBP2R operation conditions.

Abstract

Phthalic anhydride is widely used worldwide for an extremely broad range of applications spanning from the plastics industry to the synthesis of resins, agricultural fungicides and amines. Its production is currently based on the vapor phase oxidation of o-xylene and naphthalene. The development of an alternative production route to the petrochemical one is highly desirable to reduce the pressure on fossil use and effects of oil depletion concerns. This work proposes the process modelling of a bio-based route to phthalic anhydride. Results show how the valorization of all the carbohydrate-rich fractions present in the biomass is crucial to obtain an economically viable process.

Keywords: phthalic anhydride, process modelling, biorefinery

1. Introduction

There has been in recent years an increasing interest in the development of chemicals manufactured from renewables (i.e. bio-based chemicals) not only due to environmental policies (at both national and international levels) but also in initiatives of private companies (like Cargill and BASF) (Golden and Handfield, 2014). The emerging bioeconomy growth is currently led by the bio-plastic sector but will soon include specialty chemicals to a specific extent (OECD, 2007). The replacement of petroleum-derived products with bio-based ones is a promising answer to energy security and climate change issues. As a matter of fact, a large number of potential applications of biomass to produce bulk and niche chemicals have already been disclosed by chemistry and biotechnology researchers (EC, 2006). However, concerns regarding the technical and practical feasibility of large-scale biorefining infrastructures still hinder the expansion of these systems. The extensive research on bioethanol has revealed that process intensification is essential to cut the production costs and ensure process viability. In the biorefining context, though, only a limited number of studies have proposed rigorous techno-economic assessments of selected bio-based chemicals. The integration of lactic acid production in the sugarcane-based biorefinery was targeted by Sikder et al. (2012). Lammens et al. (2012) have developed a techno-economic feasibility analysis of bio-based products derived from glutamic acid. Cok et al. (2014) proposed an energy and greenhouse gas emission assessment of bio-based succinic acid obtained from carbohydrates.

Phthalic anhydride (PA) has a key importance in the production of plasticizers, polyesters and resins. Its production is based on fossil feedstocks and is expected to grow up to 5 Mt per year by 2018, as such its market would be affected by petroleum

depletion concerns. A renewable route to phthalic anhydride was found by Mahmoud et al. (2014) using biomass-derived furan (F) and maleic anhydride (MA).
In this work, a conceptual design of the production process of PA from corn stover is proposed to assess its actual scalability.

2. Materials and methods

A generic, simplified PA production process (displayed in Fig. (1)) using corn stover as raw material was developed and then simulated by means of a process simulator (Aspen Plus™). The composition of the feedstock was assumed to be the same as in an NREL design study (Humbird et al., 2011). The process conceptual design was developed aiming at the full exploitation of the biomass macro-components (i.e. cellulose and hemicellulose). It was based on an extensive survey of technical chemistry solutions (i.e. experimental and industrial) to screen promising process configuration alternatives. The simulation mainly uses component physical properties internal to the software as well as property data developed at NREL (Humbird et al., 2011). Vapour-liquid equilibria were described using the NRTL model, considering O_2, N_2, CO_2, CH_4 and H_2 as components following Henry's Law. Reactors have been modelled using fixed conversion units. A rigorous modelling of kinetics was outside the scope of the work.

2.1. Process description: selected reactions

The plant was designed to treat a nominal capacity of 104,167 kg/h of milled corn stover at 20 % of bulk moisture content for the production of PA. The biomass is first pretreated to extract the xylose sugars and the hydrolysate is neutralised. The C5 sugars contained in the liquid part of the hydrolysate are dehydrated to furfural (R1) which could be converted either into F (R2) or MA (R3). The C6 sugars are extracted from the cellulose through saccharification (R4). After the separation of the lignin, the glucose is isomerised to fructose (R5) which is dehydrated to HMF (hydroxymethylfurfural) (R6) and then converted into MA (R7). F and MA react on equimolar basis to produce PA (R8). A more detailed description of each single step is presented below.
PA can be produced at lab scale in two reaction steps (Mahmoud et al., 2014): a Diels-Adler cycloaddition between F and MA at room temperature and solvent free conditions (yielding 96 % of oxabornene dicarboxylic anhydride) is followed by the dehydration of the intermediate produced in the previous step at 353 K in a mixture of sulfonic carboxylic anhydrides in methanesulfonic acid. The experimental procedure was modelled in a simplified manner involving only two reactions: one between F and MA into PA which was followed by the sublimation of the anhydride from the corresponding acid (PAc). The presence of anhydrides was not modelled in the vapour-liquid equilibrium. Pure PA could be obtained via extraction and sublimation from the mixture with its own acid (7 % by weight) (Monroe, 1919). The final PA purification step was not modelled in Aspen Plus™. A side MA-rich stream (60 % by weight) is also produced. This could be additionally purified to expand the product portfolio.
F and MA are produced as proposed below.
In order to make the hemicelluloses available, the biomass must undergo pretreatment. As such, the feedstock is mixed with steam (at 7 atm and 373.15 K) before being treated at 431.15 K with dilute sulphuric acid (2.21 % of inlet solids by weight). Under these conditions, 90 % of the xylan is assumed to convert into xylose (Humbird et al., 2011). At this stage, the hydrolysate is treated in a neutralisation and a reacidification section (350 K, 3.4 atm). Ammonia is first added to convert acids into ammonium sulphate and

acetates; the excess amount of reagent reacts with sulphuric acid into ammonium sulphate (Humbird et al., 2011). Solids (i.e. unreacted hemicellulose, cellulose and lignin) are filtered and separated from the liquid hydrolysate with unitary efficiency.
C5 sugars in the liquid hydrolysate undergo a sulphuric acid-catalysed dehydration into furfural (85 % conversion) at 7.59 atm and 441.65 K (Mandalika et al., 2012).

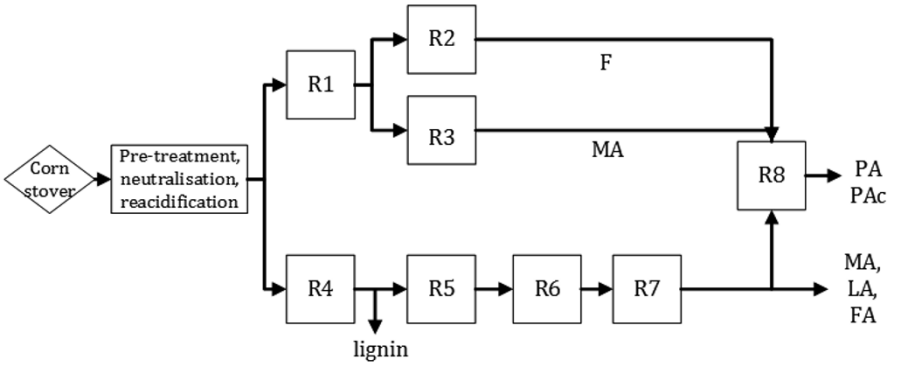

Figure 1: Phthalic anhydride proposed flowsheet. Separation steps are not shown.

Furfural in the reactor vapour outflow is immediately distilled off to avoid condensation reactions with sugars into humins. Two alternative conversions routes for furfural have been considered. In the first one, it could react with oxygen (nearly atmospheric pressure and 593 K) and be converted into maleic anhydride using VO_x/Al_2O_3 catalysts with 73 % selectivity (Alonso-Fagúndez et al., 2012). The main by-product detected after the reaction would be 2-furanone. A second avenue would be the furfural conversion into F (at 90.9 % yield) in a vapour-phase decarbonylation (atmospheric pressure and 583.15 K) in presence of a Pd-Li-alumina catalyst promoted with cesium carbonate, as described in the US patent 8710251. The main by-product reactions lead to furfuryl alcohol and THF. The optimal split ratio between the two conversion paths for furfural was found to privilege F production (60 % of the overall furfural rate).
The neutralised hydrolysate is cooled down to 321.15 K adding water, which dilutes the slurry to a 20 % solid loading before the saccharification. The enzymatic hydrolysis was modelled according to the recommendations of NREL (Humbird et al., 2011) and allowed 90 % conversion of cellulose into glucose, adding 2 % of cellulase per unit of inlet cellulose by weight. The C6 sugars (i.e. glucose) produced from the saccharification are separated from the residual solids through a centrifuge. The glucose could be dehydrated into HMF only at low yields when the reaction is carried out in an aqueous medium. Better HMF yields are achievable from fructose which could be obtained from glucose isomerisation. The isomerisation (the rate-limiting step) was modelled according to Gaily et al. (2010). The unreacted glucose was recycled to the isomerisation reactor. According to Gaily et al. (2010), a 58.9 % yield of fructose was assumed from a 10 % glucose solution at 333.15 K using immobilised isomerase enzyme (15 % by weight of the treated glucose). The obtained fructose is then dehydrated to HMF as proposed by Román-Leshkov et al. (2006), who used a biphasic system where the HMF produced in the aqueous medium (using hydrochloric acid as a catalyst) was extracted into an organic phase. Among the alternatives proposed by the authors, a good compromise between fructose conversion (91 %) and HMF selectivity (60 %) was achieved using MIBK as the extracting agent with a volumetric ratio against the liquid phase equal to 1.51. The by-products of the reaction (levulinic acid, LA, and

formic acid, FA) are recovered and sold as valuable products. The HMF is then oxidized yielding MA at 52 % over $VO(acac)_2$ catalysts according to the scheme proposed by Du et al. (2011). The system was modelled including the main reaction to MA and MA hydration to its corresponding acid. The additional by-products which lead to complete conversion of HMF (2,5 dyformylfuran, esters, humins) were modelled as side streams leaving the reactor. Acetonitrile was modelled as solvent used for the reaction.

2.2. Process description: separation system

The separation system was intended to recover the chemical intermediates at a level of purity matching as close as possible the experimental settings per each of the reactions described in section 2.1. The separation blocks are briefly explained below. Table 1 details the operating conditions for the distillation/extraction columns.

Section S1 concerns furfural purification. It is located after the xylose dehydration (R1). It is composed by a first tower (T101) which separates a bottom waste stream rich in water and salts. The distillate is then purified to extract pure furfural (T102 bottoms) via a pressure shift distillation (PSD) sequence (T102, T103).

Section S2 concerns HMF purification following R6. An extractor (E201), modelled according to the Dortmund modified UNIFAC property method, allows a preliminary separation of HMF. This is primarily concentrated in the organic phase (Román-Leshkov et al., 2006) and recovered from the solvent in T201. T202 separates an LA-rich distillate (97 % mol.) from an HMF-rich one (95 % mol.).

Section S3 concerns solvent recovery (i.e. acetonitrile). The vapour streams obtained from the oxidation reactions of furfural (R3) and HMF (R7) are cooled. The mixture is flashed and the vapour fraction treated in a water scrubber (T303). The scrubber bottoms are sent to a PSD column sequence (T300, T301, T302) to separate the water-acetonitrile azeotrope. Acetonitrile is recovered in the distillate from T302.

Section S4 concerns the purification of the intermediate of the main synthesis reaction (F, MA). The outlet stream obtained from furfural decarbonylation (R2) is cooled, flashed and the vapour sent to a water scrubber T401. The scrubber and the stabilizer bottoms (T402) are conveyed to a rectification tower T403, from which F is separated as distillate and sent to the reaction section. T402 receives the outflow of the main synthesis reactor (R8) after the solids (PA and PAc) are removed: the light compounds are separated in the overheads. T403 bottoms are sent to the MA recovery section, composed of a triple effect vacuum evaporator and a reactive distillation (T404) to remove water and promote the conversion of maleic acid to MA.

Section S5 concerns the FA recovery from E201 bottoms and evaporator condensates (S4). Residual MIBK is distilled off from T501, while T502 and T503 represent a PSD module for FA recovery (64 % mol.).

3. Results: overall material balance and costs

The overall mass balance with the estimation of the corresponding operating costs accounting for the inlet material flows is reported in Table 2. It was assumed that 99.5 % of the water was recovered via a sequence of anaerobic/aerobic digestion followed by reverse osmosis (Humbird et al., 2011). A 90 % recovery of oxygen and hydrogen from vents was considered obtainable through the use of advanced membrane technologies. The total cost for the input materials was 5757 £/h, which was distributed among the products i by applying a mass allocation factor $w_i = F_i / \sum_i F_i$, obtained from the ratio of the mass flow of product i F_i over the sum of all the product outputs. The unitary cost of each product was lower than the product market price and equal to 247 £/t.

4. Conclusions

This work presents a new process for the production of phthalic anhydride from corn stover. A full carbon recovery and valorisation of the carbohydrates into a broad portfolio of chemicals (PA, MA, LA, FA) is necessary in order to leverage the operating costs for the input materials among the products and improve the business viability.

Model Integration Using Ontology Input-Output Matching

Linsey Koo, Franjo Cecelja

PRISE, FEPS, University of Surrey, Guildford, Surrey. GU2 7XH, UK

Abstract

This paper introduces ontology controlled model integration framework using input-output matching in the domain of biorefining. The framework builds upon the existing framework and replaces the Common Object Request Broker Architecture (CORBA) object bus with more flexible semantic repository. Semantic Web Services Description Ontologies (OWL-S) are used to describe model inputs, outputs, preconditions, operating environment and its functionality. The OWL-S enables the automation of model integration through (i) discovery, (ii) selection, (iii) composition, and (iv) execution stages. This concept has been verified with a small scale model integration to demonstrate the flexibility of model integration through all four stages of the process.

Keywords: Model Integration, Ontology, Input-Output Matching

1. Introduction

Process System Engineering (PSE) and Computer Aided Process Engineering (CAPE) have traditionally been concerned with the development of systematic procedures and computer aided techniques for the design, control and operation of chemical process systems. Problems related to process optimisation, process integration, and process synthesis/design have been solved through the use of knowledge, and optimisation tools and methods, developed by the PSE/CAPE community. The traditional users of these tools and methods include the oil & gas industry, petrochemical industry, and the chemical industry (Alvarado-Morales et al., 2008).

Process modelling and simulation have become vital tools for process engineers, in order to plan, evaluate, assess, and develop different alternatives for the design of products and processes. In the process of developing a new model, the best suited modelling tools for different parts of the process are employed. However, to understand process design as a continuous work process from an integrated perspective requires the use of tools from diverse sources and disciplines simultaneously. The only existing model integration framework is the CAPE-OPEN, proposed by the European process industry which established a software based interface, Common Object Request Broker Architecture (CORBA). More precisely, CORBA provides a Common Interface Bus that allows individual models to reside in multiple computer systems and communicate with each other. Whilst the CAPE-OPEN standard is a widely recognised standard, a disadvantage has been identified in the lack of flexibility in input-output (I-O) architecture.

The exploitation and use of sustainable renewable resources have been recognised as an essential component in meeting future energy demand needs. Biofuels are alternative fuel sources to traditional petroleum based fuels that could be used to meet future demands. However, mainstream biofuel production faces a number of technical challenges due to the complexity of the characteristics of biomass feedstock, and associated processing technologies, which have very different characteristics when

compared to traditional petroleum processes. Gani and Grossmann (2007) addressed the importance of developing methods and tools that represent comprehensive biorefining technologies, through the adaptation of current systems and development of new systems. They can be further integrated by a single, flexible, reliable, and efficient system that has an ability to integrate methods and tools from different sources, to provide meaningful and useful simulation and optimisation tools.

In response to the challenges stated, this paper introduces the use of ontology in biorefining as a method of model integration, which has strong synthesis capabilities and functions to invite degrees of freedom. In particular, the ontology controlled model integration builds upon the existing CAPE-OPEN framework and replaces the CORBA object bus with a more flexible semantic repository, as shown in Figure 1. Models are described by Semantic Web Services (SWS) using Ontology Web Service Description (OWL-S) as an enabler of web services through service discovery, selection, composition, and execution stages. The Web Ontology Language (OWL) defines three upper ontologies, including *ServiceProfile*, *ServiceGrounding*, and *ServiceModel*. *ServiceProfile* ontology represents what a service does, and determines whether the service/model meets the requirement. *ServiceGrounding* ontology supports the details of how to access a service/model. Finally, *ServiceModel* ontology defines how the service/model works through the description of the work flow and the potential interoperation paths.

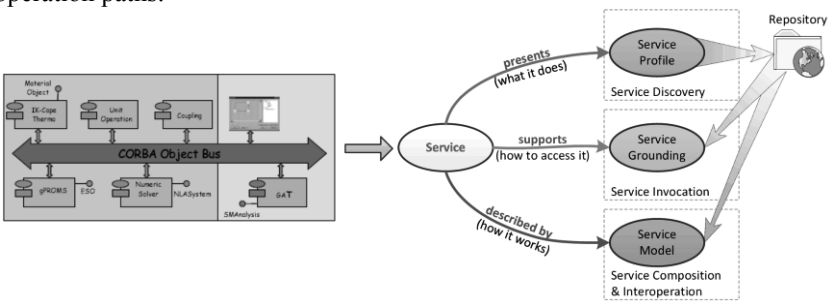

Figure 1. Introduction of repository for model integration

2. Ontological Approach to Model Integration

2.1. Basic Concept of Domain Ontology based on OWL-S Framework

Ontology is a set of interlinked common concepts and relationships between concepts, which defines the knowledge, both tacit and explicit, in a specific domain (Gruber, 1995). The synergistic relationship and interplay between tacit and explicit knowledge developed in the ontology domain, enable the generation of new knowledge. The domain ontology of biorefining, with a particular view to coordinate model integration, provides a common set of vocabulary to describe the model and data, and characterises functionality in relation to the processes of biorefining. Each model is described by the SWS to allow the models to be semantically annotated via the use of concepts from domain ontology, to form a comprehensive knowledge base which includes; model input(s), output(s), precondition(s), the environment in which it operates, as well as the functionality it performs (Raafat et. al., 2013a; Trokanas et. al., 2014). The semantically described model is then registered as an instance of the domain ontology and implemented in OWL-S framework. The respective instances are published in the purposely built public repository for I-O matching with other available models, as shown in Figure 2.

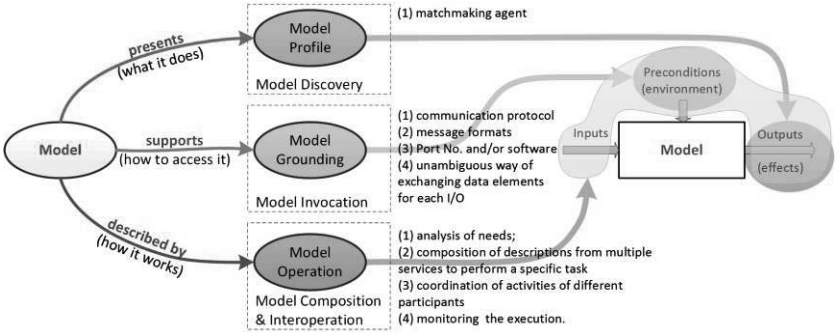

Figure 2. Semantically described model

The particular role of OWL-S ontology is to facilitate the automation of model integration through the model discovery, selection, composition, and execution stages. The discovery stage allows formation of an integrated model to organise repositories and supports the automated process of locating a model from a public repository(ies). The best option that satisfies the requestor's functionality is selected in the model selection stage. Then, the model composition stage formulates the chain of integrated models in response to the requestor's functionality. The instances of the model are created, executed and managed during the execution stage. The model selection and model composition stages are performed by semantic I-O matching (Trokanas et. al., 2014), which allows for partial matching and permits a high degree of flexibility in model integration. It is also important to mention that the proposed framework allows for integration of data residing in various forms of databases, and is concomitantly semantically described in the same way as the model with the omission of the input. The performance of the concept has been tested by large scale technology integration to satisfy requirements of industrial symbiosis, where technologies were represented by respective models (Raafat et. al., 2013b).

In a biorefining domain, a simplified model is used, which includes the conversion process itself as a black box model, desired input, targeted output streams in the form of characterisation of resources, and the environment supporting the unit operation, i.e. operating condition or software platform. To establish a common set of vocabulary and to enable the discovery of models and data that characterises functionality, a classification of biorefining is conceptualised based on two distinct concepts, which include conversion technology and resource. The term 'conversion technology' in biorefining refers to a wide array of state-of-art processes that are capable of producing value-added products, such as biofuels and biochemicals from biomass. Conversion technology has been characterised by the biorefinery platform (i.e. sugar platform, thermochemical platform), the process stage (i.e. pretreatment stage, conversion stage, separation stage), the resultant products in terms of material (i.e. biofuel, biochemical), and energy (i.e. heat, electricity). The term 'resource' in biorefining refers to both energy and material, which can be described as an input(s), output(s) and precondition(s) of the conversion process. Resources have been further characterised, by the type of material (i.e. electricity, heat, inorganic compound, organic compound) and the characteristics of property (i.e. physical property, chemical property) so that resources are processed based on the classification of the conversion process.

The relation in ontology describes the semantics of the domain between the classes and individuals. For example, the relationship *hasComposite* creates a link between type of material and characteristics of property to further describe the mereology relation. In order to encompass additional semantic information concerning the concept, the

properties that link between concepts and its data value that assist characterisation are used to define a precise characteristics, i.e. properties *hasSize* and *hasMoistureContent*. In addition, the semantic restrictions on properties provide the following: (i) the I-O matching by calculating similarity, (ii) the user navigation process through cardinality restrictions, and (iii) the inferences.

2.2. Semantic Matching

The model integration and creation of interoperability between methods and tools from different sources is referred to as the I-O matching. This allows for the automation process, and built in intelligence for automated discovery of potential and relevant models that will support model integration (Raafat et. al., 2013b).

The process of integration is performed by a purposely built matchmaker, which matches inputs and outputs of all models and data available in the public repository. There are two techniques to enable the matching, being forward and backward matching processes. The forward matching process is initialised to satisfy the requester's input parameters through an expansion, by matching inputs of the rest of the services with the outputs of the last identified service. The backward matching process is generated by identifying a suitable model, which satisfies the requested outputs. The backward matching process, compared to forward matching, avoids the processes of expansion, and can therefore be considered more efficient. After matching is completed, the respective model and data integration is reversed and perform a forward integration process. The whole process is visualised for better control and to allow intervention by the user as well as for result recording and analysis.

The semantic partial matching is considered in order to facilitate the flexibility of model integration, when the registered model is partially satisfying the input criteria. The partial matching is established through a direct matching process using semantic similarities between I-O type and property. The semantic measure for the matching by type of I-O is calculated by the distance between the respective concepts, along the class-subclass relationships in the domain ontology. The property matching is calculated from the object properties defined in respective SWS ontology. The method of measuring the similarity of the properties, which was established by industrial symbiosis case (T. Raafat et. al., 2013b), was adapted to calculate the property similarity between the property sets. Each set of property is represented as a vector:

$$p_j = \{v(d_1)\cdot w_1, v(d_2)\cdot w_2, \cdots, v(d_n)\cdot w_n\} \tag{1}$$

where p_j is set of vector properties in SWS, d_i is individual property representing concepts, $v(d_i)$ is value of the property, and w_i is weight of the property. The cosine similarity $h_k^{V,C}$ is calculated as a cosine of angle between the model vectors p_r and p_i.

$$h_k^{V,C} = \frac{p_r \cdot p_i}{\|p_r\|\|p_i\|} = \frac{\sum_{i=1}^{n} p_{r,i} \times p_{i,i}}{\sqrt{\sum_{i=1}^{n}(p_{r,i})^2} \times \sqrt{\sum_{i=1}^{n}(p_{i,i})^2}} \tag{2}$$

where n is a number of properties used for similarity calculation. To compensate in the case of the missing property value, Euclidean similarity $h_k^{V,E}$ is introduced as:

$$h_k^{V,E} = 1 - \frac{\sqrt{\sum_{i=1}^{n} w_i (p_{r,i} - p_{i,i})^2}}{max\sqrt{\sum_{i=1}^{n}(p_{r,i} - p_{i,i})^2}} \tag{3}$$

The vector similarity h_k^V is a mean average between combine cosine similarity $h_k^{V,C}$ and Euclidean similarity $h_k^{V,E}$:

$$h_k^V = \frac{h_k^{V,C} + h_k^{V,E}}{2} \tag{4}$$

The distance and property similarity, h_k^C and h_k^V respectively, are aggregate together as a fuzzy weighted average, where α and β are weighing parameters.

$$h_k = \frac{\alpha h_k^C + \beta h_k^V}{\alpha + \beta} \tag{5}$$

The above matching is comprised of three distinct stages: i) elimination, ii) semantic matching and ranking, iii) performance ranking. As a result, an optimum solution and multi-criteria analysis of model integration is established (F. Cecelja et. al., 2014).

3. Demonstration of Input-Output (I-O) Matching

A small scale model integration representing biochemical conversion technology is used to demonstrate the performance of the proposed approach. The model of co-fermentation (CF) uses the bacterium *Zymomonas Mobilis* to produce 315M litre of ethanol per year as an output from corn stover (A. Aden et. al., 2002). The operating condition of this model is temperature at 41°C with a resident time of 1.5 days and initial fermentation solids level of 20%, with an assumption that the hemicellulose sugars (arabinose, mannose, and galactose) have the same reaction and conversion as xylose, as a result, 56% of the fermentation broth is fermentable sugar.

Two models are selected as potential matches by the backward matching process. The set of respective requirements are listed in Table 1. Both of the models are pretreatment methods that break down the feedstock into fermentable sugars, dilute acid and enzymatic hydrolysis (DAEH) method and ammonia fiber expansion (AFEX) method. The DAEH process converts barley straw with composition of 38.1% glucan, 26.9% xylan, and 2.6% arabinan to monomer sugars, with yields of approximately 96% and 57% for glucose and xylose, respectively (M. Yang et. al., 2013). The AFEX process converts switchgrass with composition of 34.2% glucan, 22.1% xylan, and 3.1% arabinan to monomer sugars, with yields of approximately 93% and 70% for glucose and xylose, respectively (H. Alizadeh et. al., 2005).

Table 1. Process requirements

Process	Sugar monomer flowrate	% quantity matching	Temperature
CF (Requestor)	56 t/h	100%	41°C
DAEH	51 t/h	89%	50°C
AFEX	46 t/h	81%	37°C

In the second stage of matching, the semantic similarity by type of I-O is measured based on type of feedstock materials through class-subclass relationship. The vector similarity of the properties is then calculated related to quantity/flow rate of sugar monomers in the fermentable broth and operating temperature. As a default, the weight of the individual property and the fuzzy weight for the aggregated similarity, mentioned in Eq. 1 and Eq. 5, respectively, are equal to 1, unless user defines otherwise.

Table 2. Results from second stage matching

Resource Type	Semantic similarity	Property similarity	Aggregated results
DAEH	60%	63%	62%
AFEX	20%	50%	35%

The matching results are shown in Table 2, the DAEH and AFEX process with 62% and 35% matching similarities are found, respectively. As a result, the DAEH will be a preferable option for the requestor.
The challenges encountered while implementing the integration strategy for the models included identifying the key parameters that should be matched, and to obtain an understanding of the impact of partial matching associated with those parameters.

4. Conclusion

The wide range of models in the domain of biorefining can be described using SWS at any appropriate level of detail. A new approach was introduced to support model integration through I-O matching, which is implemented in OWL-S framework. The conversion technologies and resources in biorefining are semantically described and the relationships of SWS ontologies are established, which enables I-O matching. The backward matching process is proposed to identify a suitable model based on the input criteria. In addition, the semantic partial matching is performed to facilitate the flexibility of model integration. The proposed approach is implemented in a small scale model integration to demonstrate the flexibility, by showing model repository interaction between simulation interfaces and the data repository in the domain of biorefining.

Abstract

Biorefineries constitute representative examples of multifunctional systems which are able to produce, similarly to conventional petroleum refineries, a wide range of chemicals (pharmaceutical constituents, plastics, food additives etc.), energy carriers and power through the optimal use of diverse biomass forms (wheat straw, oils, wood chips, municipal solid waste). For this purpose, biorefineries typically comprise a complicated, integrated network of physical and chemical transformation processes, such as mechanical and physical biomass pretreatment, pyrolysis, gasification, catalytic and enzymatic reactions, and downstream purification processes. For the environmental sustainability assessment of these complicated production systems, Life Cycle Analysis (LCA, ISO-Norm 14040) is considered as a widely acceptable methodology from scientists and engineers including, however, the debated aspect of partitioning the impacts among the co-products' in the biorefinery product portfolio.

The aim of this study is to present the influence of the various allocation approaches on the LCA results of biorefinery products. The framework of this analysis systematically incorporates the steps of the LCA methodology as described in the ISO norms and estimates the impacts related with the products of interest, taking into account the contribution of the co- and by-products in the overall production path. For this reason, two wider approaches were adopted, the attributional which describes the impact of the production process itself from a retrospective point of view, and the consequential which focuses on the changes in the level of the output (as well as consumption and disposal) of a product, including market effects from increasing or decreasing demand for the study product, having therefore a more prospective point of view. Several scenarios which describe the possible options for handling those products, were developed and assessed based on different allocation methodologies, namely system expansion (substitution method) and partitioning methods according to the mass, thermal and economic values of the co-products. The estimation of the life cycle impacts of the processes was performed using the Global Warming Potential (GWP), Cumulative Energy Demand (CED) and RECIPE methodologies which provide an assessment of the burdens through the associated LCA indicators.

The outcome of this approach provides a range of LCA metrics emphasizing at the variation of the results according to the followed allocation methods and to identify

those properties of products (physical, economic, thermal) and system factors (processes to be substituted from the renewable ones, degree of utilization of co- and by- products from the markets etc.) which dominate the LCA results.

Keywords: Biorefinery products, cumulative energy demand, global warming potential, allocation, system expansion

1. Introduction

Allocation is an important issue in biorefinery systems because of the multifunctionality of the processes involved along the life-cycle stages. Some well known examples are biomass fractionation processes which aim at the exploitation of the three basic components of the lignocellulosic feedstock (i.e., cellulose, xylose and lignin) and the conversion of these intermediates into a wide range of products, or the case of biodiesel plants which co-produce biodiesel and glycerol. Many studies have performed LCA on biorefinery systems as aggregated entities. These approaches have avoided to address impacts of final products and results are reported at the biorefinery level according to functional units such as 1000 kg of biomass, ha of land use, etc. (Cherubini and Jungmeier, 2010). On the other hand, other studies have focused on the investigation of all possible allocation approaches (e.g. partitioning methods, system expansion and hybrid methods) presenting the variation of results according to the followed approach, (Cherubini and Strømman, 2011).

This study highlights the variability of life cycle impact assessment indicators for biorefinery products by applying different allocation approaches (consequential and attributional) and discusses the influence of the co-producing processes and the displaced products in the results.

2. Methodology

The methodological steps followed in this study are in accordance with the ISO 14040 norms. Two approaches, the attributional and the consequential, have been applied for the Life Cycle Impact Assessment (Brander M., et al.). According to some researchers (Weidema, 2001), attributional LCA requires market allocation while consequential applications require system expansion. In this study, four different ways of handling the co-product allocation were applied:

Mass allocation: Calculations are based on the ratio of the mass of each co-product to the entire mass of co-products with the condition that they are chemical products.
Thermal allocation: It is applied in the case of different products (e.g. electricity/chemicals), the allocation factor being the Lower Heating Value (LHV) of the product streams, or of the equivalent source of the product stream (e.g natural gas for gas turbine generating electricity).
Economic allocation: It is based on market prices (Ecoinvent 3, Brew project).
Substitution by system expansion: Allocation is avoided by expanding the biorefinery system to include the alternative/conventional ways of producing the co-products. In the substitution approach, products are distinguished into: main (determining) for which the entire production process has been designed and dependent co-products which can be fully or partly utilized from the markets.

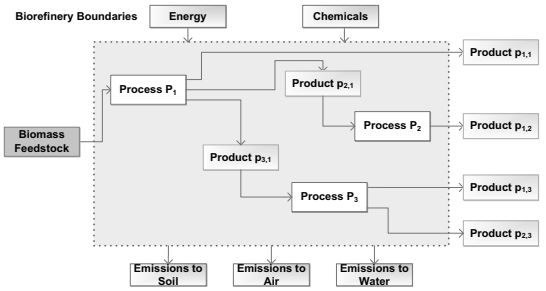

Figure 1: Example of LCA boundaries of the study system

One exemplary representation of the multiple functions of a biorefinery system is shown in Figure 1. Boundaries include a number of interacting processes, P_1, P_2...P_n, which convert biomass feedstocks into a range of products. For example, products $p_{1,1}$...$p_{m1,1}$ from process P1, (m_1 is the number of products at subdivision point 1) can be utilized either directly from the markets or they can be further converted through processes P_2...P_n into the final products $p_{1,2}$...$p_{mn,n}$,(m_n is the number of products at subdivision point n) depending on the demand for specific products each time.
The total environmental impacts EI_{total} of a specific category (e.g., acidification, global warming, water depletion etc.) can be allocated among the co-products according to the degree of the available information. In a "black box" approach no specific information is provided for the functions inside the system boundaries and allocation is applied directly among the final products. In a "detailed allocation approach" the critical subdivision points are known, followed by available information for energy and resource consumption (e.g., represented in Figure 1 by the 3 processes inside the system boundaries). The allocated environmental impact $EI_{i,j}$, for the co-product *i* produced at the subdivision point *j*, is expressed by eq.(1):

$$EI_{i,j}=\alpha_{i,j}\cdot EI_j \tag{1}$$

which finally gives the total environmental impacts

$$EI_{total}=\sum_j EI_j=\sum_j\sum_i EI_{i,j}$$

where EI_j is the environmental impact of a specific category caused at the subdivision point *j* and $\alpha_{i,j}$ is the partitioning coefficient expressed by the following equation:

$$\alpha_{i,j}=\frac{y_{i,j}\cdot c_i}{\sum_{i=1}^{mj} y_{i,j}\cdot c_i} \tag{2}$$

where $y_{i,j}$ is the flow of the co-product *i* produced by at the subdivision point *j*,(e.g., expressed in mass, energy, volume etc.), and c_i is its specific allocation factor used for partitioning related to the flow unit (e.g., MJ/unit or €/unit). It should be noted that in the "black box" approach for the system presented in Figure 1, n=1 and $m_j=m_1$=number of final products and $EI_j=EI_1=EI_{total}$.

When applying the substitution method, the first step is to define the determining (main) product based on criteria (Weidema, 2001) like mass flow, market value or other specific case rules. Then, the (dependent) co-products are investigated by defining their way of utilization (e.g treated as waste streams or by displacing other products) and the displaced equivalent products from the Ecoinvent database.

3. Impact of Allocation Scenarios

3.1. Case Study: The biodiesel platform refinery

For the selected case study, biodiesel is the main product. Glycerol is the dependent, fully utilized co-product which can be further treated through various alternative conversion processes into other co-products. Four such scenarios for the utilization of glycerol are considered in this study, namely: (S-1) biodiesel and glycerol, (S-2) biodiesel and biogas, (S-3) biodiesel and propylene glycol, (S-4) biodiesel, syngas and electricity, (Figure 2).

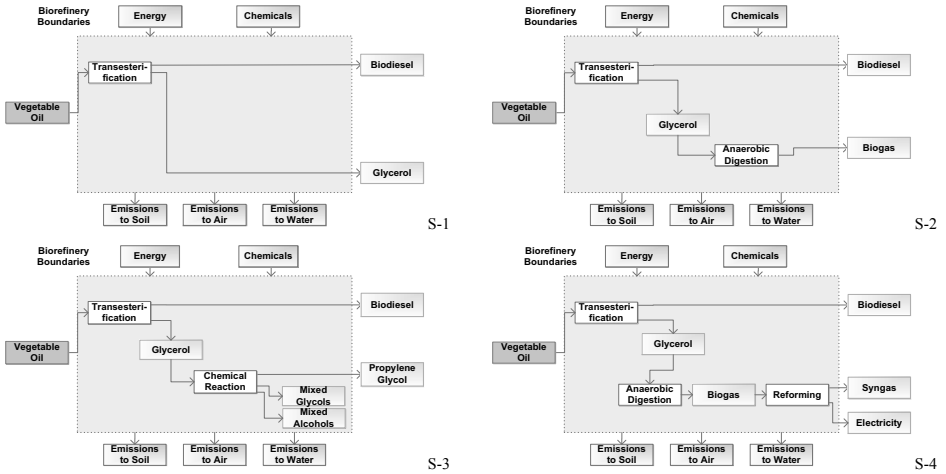

Figure 2 Configuration schemes for the scenarios included in the study

Note: S-3: mixed glycols and alcohols are assumed to be treated as waste streams due to low degree of purity, S-4: electricity is produced by heat recovery and exploitation of high pressure steam in a steam turbine)

Tables 1 and 2 show the partitioning factors and the displaced processes used in the scenarios described above for the two allocation and the substitution approaches.

Table 1 Specific values and partitioning coefficients used in the different allocation approaches

	Subdivision points (n)	Products (i)	$y_{i,n}$	c_i		Mass /Thermal Allocation	Economic Allocation
						$\alpha_{i,n}$	$\alpha_{i,n}$
S-1	n=1 transesterfication	i=1 biodiesel	$y_{1,1}$= 999.8 kg	c_1= 0.37€/kg		$\alpha_{1,1}$= 0.90	$\alpha_{1,1}$= 0.80
		i=2 glycerol	$y_{2,1}$= 113.3gk	c_2= 0.79€/kg		$\alpha_{2,1}$= 0.10	$\alpha_{2,1}$= 0.20

Note:the subdivision points with one product are not included in the table

In this assessment, natural gas (gas turbine) derived electricity is assumed in the displacement procedure in order to take into account the fossil best available technologies having a GHG emission factor of 0.24 kg $CO_{2\text{-eq.}}$/kWh, while coal derived electricity has a much higher factor, i.e. 1.08 kg $CO_{2\text{-eq.}}$/kWh (average for UCTE countries, i.e. countries included in the Union for the Co-ordination of the Transmission

of Electricity). The GHG emission savings of the biorefinery systems would therefore be greater if coal electricity is displaced.

Table 2 Specific CED and GHG emissions of the displaced processes to biorefinery products

Biorefinery product	Displaced Products	LCIA values	
	Process Name (Ecoinvent V2)	GWP	CED
Glycerine	Glycerine, from epichlorohydrin, at plant/RER	4.52	74.86
Biogas	Biogas, production mix, at storage/CH S (d=1.1kg/m3)	0.53	4.1
Electricity from steam turbine	Propylene glycol, liquid, at plant/RER	4.06	78.76
Synthetic gas	Synthetic gas, production mix, at plant/CH (d=1.15kg/m3)	0.022	8.62
Electricity from steam turbine	Electricity (Natural gas, burned in gas turbine/GLO)	0.24	4.22

Table 3 shows a sample of results for the scenarios described above for the three allocation approaches and three life cycle impact assessment methods.

Table 3 Summary of selected results

3.2. Correlations of allocation approaches

In order to investigate the variation of LCA metrics when applying different allocation approaches, correlations for LCA indicators were performed for a sample of 31 biomass based processes comprising (after combinations) 53 different configuration schemes. As shown in Figure 3, the correlations can be rather weak, which means that the selection of allocation approach has an important effect in the values of indicators. Some pairs were found to correlate better than others (GWP and CED for mass versus economic allocation, R^2 ranges from 0.5 to 0.8). Correlations including substitution method (Figures 3a, 3b) presented lower values. ($R^2 < 0.5$) this can be due to ambiguity in some cases in the determining of the displaced products

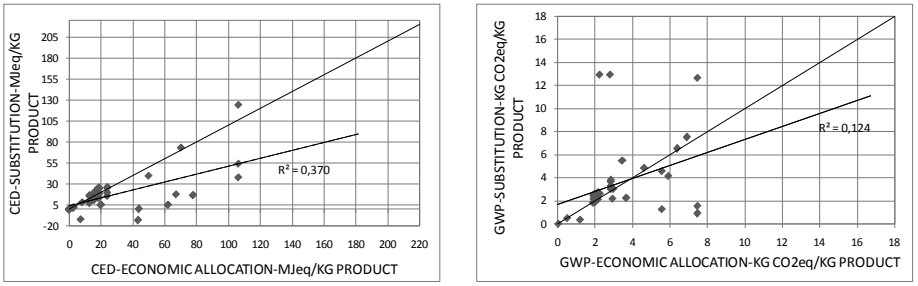

Figure 3a, 3b Cases of indicators and allocation approaches where correlation is weak

4. Conclusions and Outlook

This study investigates the effect of key parameters on the results of LCA metrics for products which are co-produced in cases of multifunctional systems. One critical parameter is the synthesis of the biorefinery configuration (i.e. the combination of the co-producing processes included in system boundaries and the type of co- and by products which attribute benefits to the main products by displacing conventional production lines). This dimension was studied in conjunction with three allocation approaches which were tested with respect to the variation of the resulting LCA metrics and the degree of subjectivity that they give to the final values.

This study is a part of an LCA database for biomass based products (chemicals, energy carriers, power) which is under development. A generic representation of the database components is shown in Figure 4.

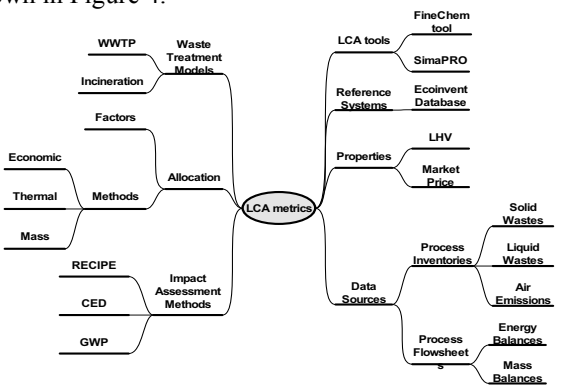

Figure 4 Components of the LCA database

LCA metrics are based on gate-to-gate inventory analysis including data from process flowsheets for mass and energy balances gathered from literature references and pilot plants. In addition, the use of existing life cycle databases (e.g., Ecoinvent database, versions 2 and 3) and tools (e.g., Simapro 8.0.2) was necessary to fill in the unavoidable data gaps. Given the variety of production paths and the number of assumptions made, LCA assessments are accompanied by the information (methodological and technical) required to provide answers on the level of individual products' scale of analysis offering the practitioners the option to select the values which fit better to the goal and scope of their study according to the adopted allocation approach.

Abstract

This study focuses on uncertainty analysis of environmental indicators used to support sustainable process design efforts. To this end, the Life Cycle Assessment methodology is extended with a comprehensive uncertainty analysis to propagate the uncertainties in input LCA data to the environmental indicators. The resulting uncertainties in the environmental indicators are then represented by empirical cumulative distribution function, which provides a probabilistic basis for the interpretation of the indicators. In order to highlight the main features of the extended LCA, the production of biodiesel from algae biomass is used as a case study. The results indicate there are considerable uncertainties in the calculated environmental indicators as revealed by CDFs. The underlying sources of these uncertainties are indeed the significant variation in the databases used for the LCA analysis. The extended LCA procedure is flexible and generic and can handle various sources of uncertainties in environmental impact analysis. This is expected to contribute to more reliable calculation of impact categories and robust sustainable process design.

Keywords: sustainable process design, LCA, uncertainty analysis, Monte Carlo, Algae biodiesel, Database.

1. Introduction

The assessment and design of sustainable chemical and biochemical processes is a complex multi-criteria and multi-objective decision-making problem, not only regarding the multi-level evaluation, but also due to the significant amount of input data required for the analysis, which may come from different sources with various degrees of uncertainties (Björklund, 2002). To support sustainability analysis, sustainability indicators (Azapagic & Perdan, 2000) have been proposed along the years as a performance measurement tool. They assist the user in two fronts, (i) analysing the performance of already built production plants, and (ii) in early stage-design, finding a solution that relatively minimizes environmental and social impact while maximizing the company's economic profit. However, the uncertainty on the input data and their impact on the decision-making procedure have not yet been entirely addressed (Björklund, 2002).

In order to characterize and quantify sources of uncertainty and their propagation to the decision-making process, a computer-aided framework for sustainable process design and assessment under economic uncertainty has been developed. It explores the economic analysis under deterministic and uncertainty conditions and proposes new design alternatives to be validated by a risk reduction strategy.

As a complementary part of the framework, the present work proposes an extended methodology for environmental life-cycle assessment (LCA) under uncertainty (Figure 1). In particular, the focus is to develop a generic and flexible methodology that systematically identifies the sources of uncertainties and quantify their impact on the environmental indicators and sustainable process analysis. Life cycle assessment (LCA) has been broadly used to (i) identify the significant environmental indicators in product systems and, (ii) to assess and compare the environmental performance of different processes (Guo & Murphy, 2012). The environmental results are often estimated based on deterministic models, where one uses a defined model (input-output mass and energy balances) and 'nominal' values for involved parameters and input data. The nominal values of parameters/data are usually taken from an LCA database. This type of analysis leads to results as point estimates conditional to the nominal set of values used in the analysis and fails to integrate the variability and uncertainty intrinsic to LCA (Lloyd & Ries, 2007). Therefore, different uncertainty categories have been identified as, (i) parameter uncertainty, (ii) scenario uncertainty and, (iii) model uncertainty (Winner, 2011). Different approaches have been proposed to quantify uncertainty in LCA (Lloyd & Ries, 2007), nonetheless, there is still a lack of a systematic approach when determining data quality, quantifying the uncertainty on the input data, and its propagation into the decision-making process (Björklund, 2002).
In this work, the life cycle principles proposed by the Environmental Protection Agency are used as a basis and extended by adding the steps for Monte Carlo based comprehensive uncertainty analysis. The extended LCA methodology aims to assist the user to identify and characterize the sources of input uncertainties and their propagation into the output environmental indicators, etc. Once the uncertainties in the output are quantified, its impact on sustainability analysis and ranking of alternatives for the decision-making is then analysed. A step-by-step explanation of the methodology is presented in the next section.

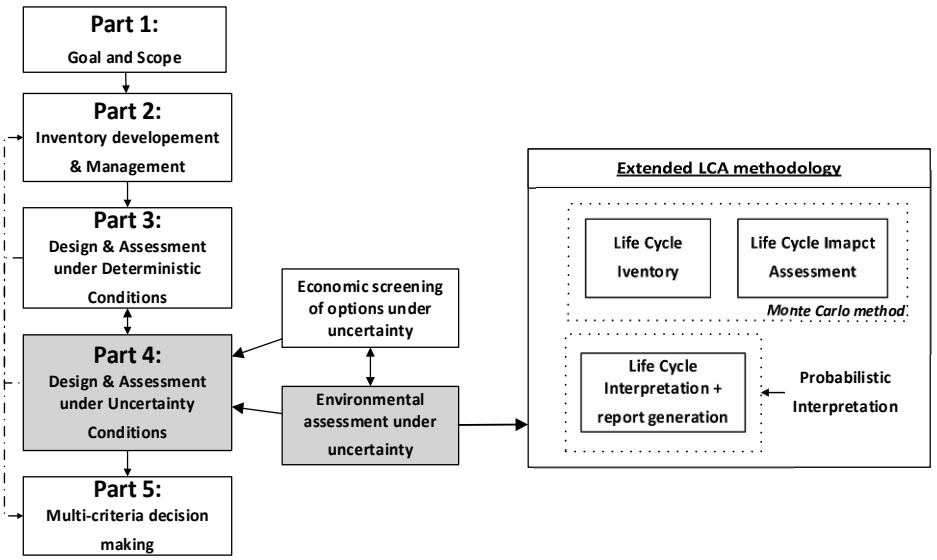

Figure 1: Framework for sustainable process design under uncertainty: focusing on the Extended LCA methodology

2. LCA extended methodology

The methodology incorporates uncertainty analysis by using the Monte Carlo technique with Latin Hypercube sampling from input uncertainty domain. A step-by-step guide through the methodology is presented as follows by applying it to two alternatives for the production of biodiesel from algae. It is noted that the alternatives being tested were identified with a first stage economic screening.

Part A: *Goal and scope*

The goal is to identify the most promising sustainable solution for the production of biodiesel from algae biomass. As mentioned, two alternatives were identified based on a first stage economic screening, they are differentiated by the transesterfication methods used, (A) H_2SO_4/Methanol and, (B) KOH/methanol (Cheali et al., 2015).

In this step, the problem statement is formulated. The following three questions were posed to of the extended LCA study: (i) which process causes the least overall environmental impact? (ii) what are the sources of uncertainty involved in the study? and, (iii) how do the uncertainties in the inputs affect the multi-criteria decision making for sustainable process design?

Part B: *Life Cycle Inventory*

This is the second stage of the extended LCA methodology and it comprised of four steps defined as follows:

Step 1: definition of the system boundaries

The boundaries were drawn around the manufacturing process including the emissions related to the utilities system.

Step 2: Database/inventory of inputs and outputs

Mass balances, energy balances and equipment duties were collected according to the system boundaries that have been defined.

Step 3: Identification and characterization of the source of uncertainty

This step is the first stage of the Monte Carlo technique and the objective is to identify the source(s) of uncertainty and characterize it through an appropriate probability distribution function. Two types of sources of uncertainty were identified: (i) process operation scenarios which refers to the different design scenarios considering the availability of fuel type for utility consumption (different energy content and composition), therefore leading to different load of gaseous emissions; and (ii) parameter uncertainty. The latter type of uncertainties is perhaps the more dominant and challenging in LCA analysis. These uncertainties refer to LCA database that compile the science-based characterization factors that are used to convert component-based inventory data into relevant categories of midpoint impact. Different databases may have different estimation/experimental values for these characterisation factors (some of them may stem from geographical/local situation, and yet some other may come from different experimental sources/measurement errors). In this study, the nominal values of the characterization factors were retrieved from an open-source database, IMPACT 2002+, which models are reported in (Humbert et al., 2002). Furthermore, due to the limited information, uniform distribution was assumed to characterize the input uncertainties. The upper and lower bound of the uniform distribution are specified by performing an analysis of data variability reported across 6 different open-source LCA databases (CML-IA-2013, *Recipe*, *IChemE*, IMPACT 2002+, IMPACT World+).

Based on the extent of variability across different databases, low (5%), medium (25%) and high (50%) level of variation around the nominal values are assigned (Sin et al., 2009).
As a motivating example, definition of the uniform distribution of the characterization factors used to estimate the photochemical oxidation potential (POP) for four of the components involved in the processes are presented in Table 1. This uncertainty definition in the input database is performed for all the relevant components in system.

Table 1: Nominal value, upper and lower bound of the uniform distribution for the characterization factors used to estimate the POP.

	Nominal/average value (IMPACT 2002+)	Lower bound	Upper bound
methanol	0.132	0.066	0.198
glycerol	0.861	0.431	1.292
ethanol	0.392	0.196	0.588
hexane	0.479	0.240	0.719
N_2O	0.700	0.350	1.050

Step 4: Latin Hypercube sampling
The output from step 3 is a definition of input uncertainty domain which is *NxN* space where N refers to total number of components (products, intermediates, raw material, etc.) in the system. In this study, *N* was 17. Latin Hypercube Sampling technique was then used to generate random samples from the input uncertainty domain. Each sample is then used to calculate the LCA model output which is the environmental impact categories. It is noted that since the correlation matrix between input sources of uncertainties is not known, instead no correlation was assumed for the sampling.
LHS technique provides a more effective coverage of uncertainty space domain with a relatively small number of sampling as compared to random sampling (the difference in the number of sampling is an order of magnitude). More information on the LHS technique and correlation control can be obtained from (Helton & Davis, 2003; Sin et al., 2009) and (Iman & Conover, 2007), respectively.
In the present case study, 200 random samples were generated by LHS for each one of the characterization factors, collected for each one of the components in the system.

Part C & Part D: *Life cycle Impact Assessment & Life Cycle Interpretation and report generation*
In the previous section the data inventory is completed, and at this stage, the user is guided towards the estimation of relevant impact categories. The potential environmental impact categories are calculated by equation (1) (EPA, 2006) as follows.

$$\text{Potential Environmental Impact}_x = \sum_i CF_i \times F_i \qquad (1)$$

where, *x* represents a certain category of impact, *i* a given component and *CF* represents the nominal value of the characterization factors that convert the component flowrates (F_i) into potential environmental impacts used to analyze the environmental performance of the processes.
For each LHS sample, eq. 1 will be calculated resulting in 200 estimates for each impact category, *x*. The distribution of impact category x, is then represented by building a cumulative distribution function (CDF). The CDF provides the basis for a probabilistic interpretation meaning that we have now a probability level for every potential environmental impact category considered relevant. To interpret the results, the impact

categories estimate that corresponds to 95% confidence level is reported and used for further analysis of process alternatives. In this way, the uncertainty analysis is complete by providing a more robust and reliable estimate of the impact category.
The cumulative distribution function of the model outputs is obtained by rewriting equation (1), where *CF* represents the sample space *N* instead of nominal values.

As illustration of the extended LCA methodology, two categories of impact (POP and GWP) were selected to evaluate and compare the environmental performance of the alternatives A and B. The y-axis in CDF reads probability of x being less than an equal to a certain value X, Pr(x < = X), while x-axis refers to the actual values of the impact categories. The range of the x-axis indicates how large the uncertainty is (the larger the range of x-axis, the larger the uncertainty). The shape of CDF function (linear, S-shape), indicates the probability of observing X. Linear CDF means that input uncertainty propagates linearly to the outputs, while S-shape CDF functions indicate input uncertainties propagate in a non-linear fashion to the output. In this CDF plot, the mean value is indicated by the probability level at 0.5 (red arrows in the figures 2 to 5 below).
As a summary of this CDF plot, we read the impact category estimates that correspond to a probability of 0.95 (black arrows in the figures 2 to 5 below). For example, for the photochemical oxidation potential (Figures 2 and 3), the upper bound (95% likelihood) is approximately 0.20 and 0.41 kg ethylene eq./ kg of biodiesel produced for alternative (A) and (B), respectively. Therefore, there is a 95% likelihood that if the plant is built the POP will potentially have values lower or equal to the upper bound identified.
Likewise, the global warming potential (Figures 4 and 5) has the upper bound equal to 4.77 and 4.93 kg CO_2 eq./ kg of biodiesel produced for alternative (A) and (B), respectively.
The decision between these two alternatives can be taken based on 0.95 probability and confidence in the estimated impact values thereby providing an improvement on the traditional LCA analysis that relies only on a single point analysis. In this case, for both impacts (POP and GWP), alternative A is a better alternative considering all the input uncertainties that went into their calculations.

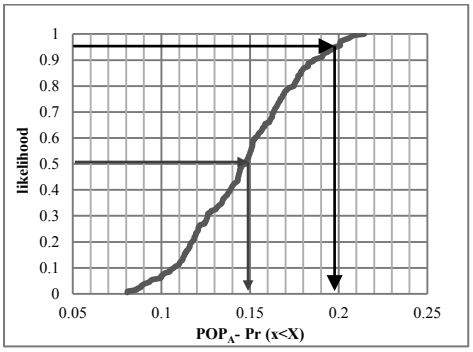

Figure 2: *Alternative A* - Cumulative distribution function for the Photochemical Oxidation Potential (POP), upper bound identification for 95% likelihood.

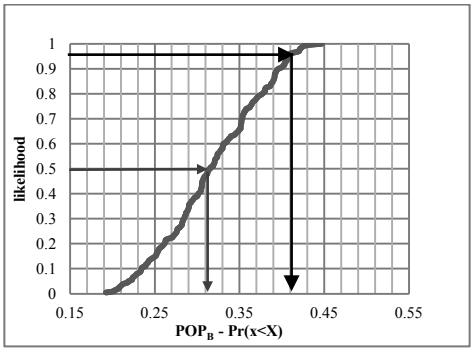

Figure 3: *Alternative B* - Cumulative distribution function for the Photochemical Oxidation Potential (POP) , upper bound identification for 95% likelihood.

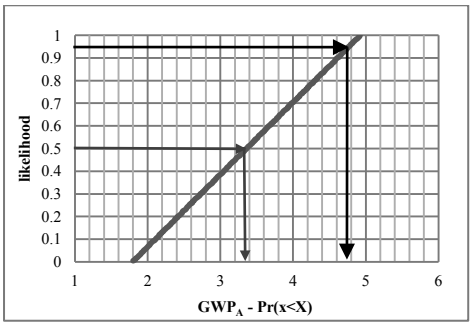

Figure 4: *Alternative A* - Cumulative distribution function for the Global Warming Potential (GWP) , upper bound identification for 95% likelihood.

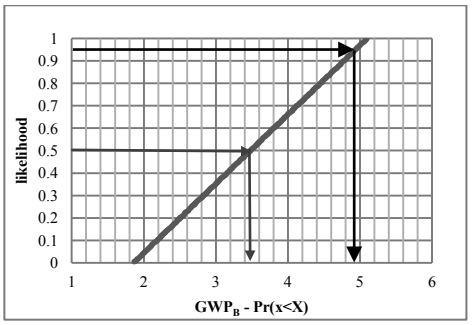

Figure 5: *Alternative B* - Cumulative distribution function for the Global Warming Potential (GWP) , upper bound identification for 95% likelihood.

3. Conclusions

In this study, the LCA methodology of EPA is extended with a comprehensive uncertainty analysis. Monte Carlo technique with Latin Hypercube sampling was used for the uncertainty analysis. To interpret the results, a probabilistic framework that uses 95% probability level of the expected value of the impact category is used.

The biodiesel production from algae biomass was used to highlight the methodology's main features. The methodology successfully quantified the uncertainties in the impact categories and is expected to contribute to performing more reliable and robust sustainability analysis of process alternatives.

Optimization of LNG Plant Operating Conditions to Anticipate Leaner Feed Gas by Steady State Process Simulation

Ferry Adhi Perdana, Johan Anindito Indriawan

Badak LNG,Plant site, Bontang 75324, Indonesia
ferry@badaklng.co.id, indriawan@badaklng.co.id

Abstract

Badak LNG has operated for producing LNG almost 30 years, with total production capability of 22.5 million metric ton LNG per annum. Badak LNG has eight (8) LNG Trains which was designed with specific range of feed gas composition. In the future, regarding with exploration of new gas wells, it is predicted that new gas wells have leaner gas composition compared to current condition. It certainly could impact to performance of LNG plant especially in refrigeration and liquefaction system. An evaluation is required to find out the potential restrictions and new operating condition when liquefying the leaner gas. By using simulation model of LNG plant, the effect of lean gas basically could be predicted. The simulation is firstly validated by using the actual performance data and used to simulate the leaner gas with optimization methods. The optimal model simulation uses specific power as objective function, the refrigerant flow rate and composition as operating variables while the existing equipment's capacity is used as parameter constraints.

The evaluation result concludes liquefying the leaner gas will need more refrigerant flow rate to keep minimum temperature approach at Main Heat Exchanger, so the compressor duty and specific power also increases while LNG product flow rate decreases. The inlet temperature of refrigerant compresor is potentially colder than minimum specification of -50 ^{o}C, it will be a constraint when processing the leaner gas. But, optimizing the operating condition such as flow rate, pressure and composition of refrigerant, can reduce the compressor duty and specific power while temperature inlet compressor can still meet the specifiation.

Keywords: Optimization, LNG, leaner gas, Process Simulation.

1. Introduction

Natural Gas is the fossil fuel which has growing consumption fast. At present, the utilization of natural gas as fuel in power generation increases around 30 % and it is predicted growing to 37 % in 2030 (Hatcher and Khalilpour, 2012). Practically, in order to make easier in transportation and storing of the natural gas, conversion of natural gas to Liquefied Natural Gas (LNG) is one of the recommended methods.

Natural gas liquefaction is a process conversion from gas to liquid phase. In order to produce LNG, the sensible and latent heat of natural gas is removed to gain the liquid phase with cryogenic temperature of -160 ^{o}C at atmospheric pressure. This process can reduce the natural gas volume to 1/600 times. LNG plants are designed to handle a certain range of feed composition. However, during operation, feed gas composition can change due to exploration of new gas wells. Based on the feed gas predictions, CH_4 content in the feed gas tends to increase in the future (see table 1). When the feed gas becomes leaner, the specific power will be greater (Zhang et al, 2012). It could affect to performance and operating condition of process unit such as liquefaction unit, propane refrigeration units and mixed component refrigeration (MR) unit.

There are several studies about process optimization of natural gas liquefaction. Aspenlund et al., (2010) reported the optimization of a natural gas liquefaction process by using aspen Hysys with Tabu Search method and Nelder Mead Downhill Simplex (NMDS) to reduce the required number

of simulations. Hatcher and Khalilpour (2012) reported about the identification of the most appropriate objective function to increase the efficiency of the natural gas liquefaction process. Gao et al. (2009) optimized the process of liquefying of Coal Bed Methane using C3MR process by varying the nitrogen content in the feed gas. Lee et al. (2002) reported the new method for design optimization of multi-component refrigeration system which combines between mathematical and thermodynamics to obtain the optimal composition of refrigerant. These studies commonly discuss the optimization of process conditions, while only a few studies discuss the optimization of operating conditions with limits on the installed equipment capacity. Jensen and Skogestad (2009) study the optimal operation for simple LNG process, namely the PRICO process with the objective function to achieve the minimum economic cost.

Table 1. Prediction of Feed Gas Composition in mole fraction

Composition	Years	
	X(current)	Y(future)
N_2	0.001	0.001
CH_4	0.914	0.955
C_2H_6	0.041	0.023
C_3H_8	0.030	0.014
i-C_4H_{10}	0.006	0.003
n-C_4H_{10}	0.007	0.003

While, this study will discuss the optimization of operating conditions of LNG plant using C3MR process and varying the feed gas composition. For the optimization process, this study uses an objective function of minimum specific power while the installed equipments capacities are utilized as constraints.

2. Simulation Details

The simulation and optimization are performed with Hysys (Aspen Technoloy, Inc.) and uses Peng-Robinson equation of state.

2.1. Liquefaction Process

Prior to entering the main heat exchanger, the impurities (CO_2, moisture and heavier hydrocarbon) are removed from the feed gas in the upstream process. Feed gas is pre-cooled with propane refrigeration to -35 ^oC before it is liquefied in the main heat exchanger.

In propane refrigeration unit, propane is compressed to 15 kg/cm^{2}a. It is then de-superheated and condensed by using sea cooling water. Afterward, propane is expanded to high pressure level of 8 kg/cm^{2}a and used to cool the mixed component refrigerant and feed gas. Furthermore, propane is expanded to medium pressure level of 4 kg/cm^{2}a for cooling mixed component refrigerant and feed gas also. Finally, propane is expanded to low pressure level of 1.5 kg/cm^{2}a for partial condensing the mixed component refrigerant and feed gas pre-cooling. The vaporized propane is then sucked by three stages propane compressor (see figure 1).

Meanwhile, in mixed component refrigeration unit, MR refrigerant is partially condensed using propane until -35 ^oC temperature. MR vapor and MR liquid, then, goes to the main heat exchanger via different tube circuit. In the warm bundle, MR liquid is subcooled until -127 ^oC and expanded by JT valve, then it is sent back to main heat exchanger as cooling medium for feed gas, MR vapor and MR liquid. Whereas, after MR vapor is condensed in warm bundle, it will be subcooled in the cooled bundle until -147 ^oC and expanded by JT valve. It is then sent back to main heat exchanger as cooling medium for feed gas and MR vapor. After providing cooling duty, the superheated MR will flow back to suction 1st MR compressor. While, after feed gas is condensed and subcooled in the main heat exchanger, it will be expanded to 1.27 kg/cm^{2}a pressure and -158 ^oC temperature (see figure 1).

2.2. Calculation and Optimization method

This study takes an assumption the impurities (CO_2, iC_5H_{12}, nC_5H_{12} and C_6H_{14}) have been removed. Therefore, the composition of the incoming feed gas into the main heat exchanger can be

predicted as shown in Table 1. This study also doesn't consider the Benzene, Toluene and Xylene (BTX) content in feed gas. The simulation model is developed by using current feed gas composition and validated with actual operating conditions during the plant performance test as a base case.

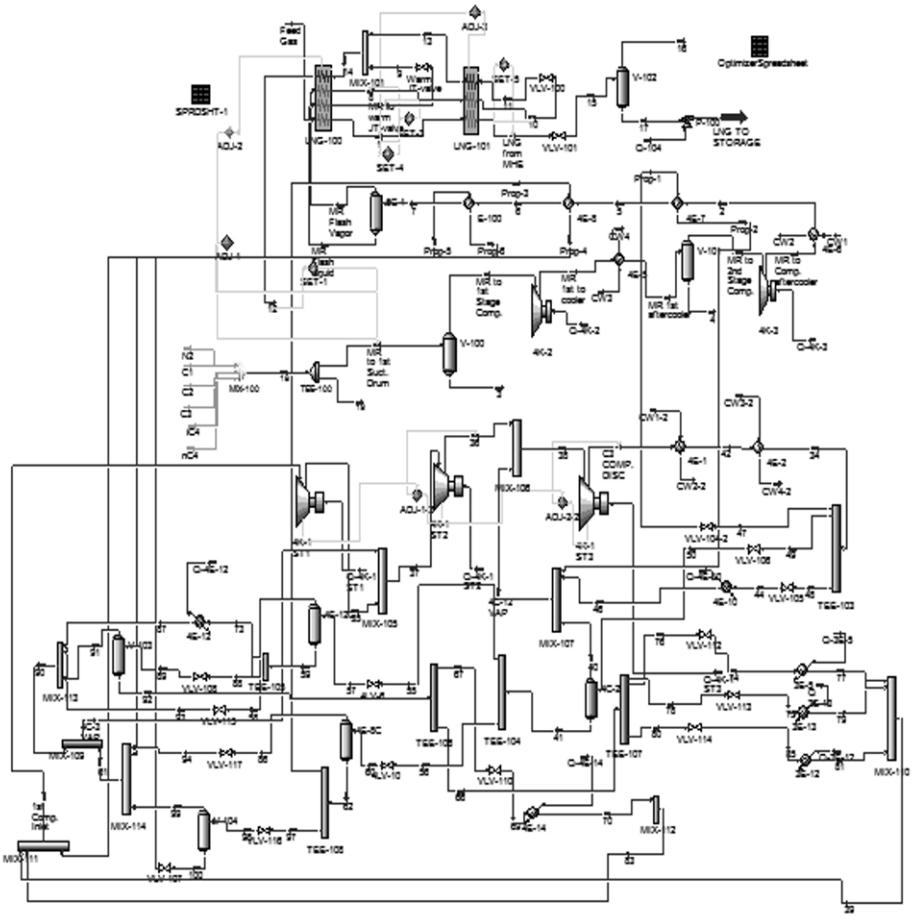

Figure 1. Simulation Model of C3MR Process

This study uses the actual capacity of existing equipment as constraint. It refers to the equipment data sheet such as compressor performance curves, sizing of sea water exchanger. Meanwhile, for the heat exchangers which are not directly related to the liquefaction are assumed have a fixed load.

2.2.1. Manipulated Inputs

There are five manipulated inputs such as MR flow rate, MR evaporating Pressure, MR composition, C3 low level Pressure, C3 medium level Pressure

2.2.2. Operational Constraints

In general, there are some constraints that must be satisfied during normal operation.

- Compressor power, capacity, surge and rotational speed: we use the actual performance curve of C3 and MR compressor
- Heat exchanger: we use overall heat transfer (UA) of sea water exchanger based on the equipment's data sheet.

- Suction temperature of MR Compressor is limited with temperature alarm low of -45 ^{o}C.
- Minimum temperature approach at main heat exchanger is 2 ^{o}C refer to the normal operation condition

It is assumed that sea water temperature steady at 30 ^{o}C, the feed gas temperature outlet of C3 pre cooler is -35 ^{o}C and feed gas has flow rate of 22,642 kmol/h,

2.2.3. Formulation of Object function

The optimization is carried through on the basis of the calculation of specific power which is one of the most important factors of liquefaction process performance. It can be calculated as Eq. (1).

$$w_s \left(\frac{HP}{mmBtu}\right) = \frac{1{,}341\ x\ w}{0.948\ x\ (HHV\ x\ q)_{LNG}} x\ 1{,}000{,}000 \quad (1)$$

Where, w is the sum of power consumption (kW) of MR compressor and C3 compressor, q is mass flow rate of LNG product (kg/h) and HHV is higher heating value (kJ/kg).

3. Result and Analysis

3.1. Effect of Feed Gas Composition to LNG Plant Performance

The simulation is an approach to know an effect of the feed gas composition to the LNG plant performance particularly propane refrigeration unit and MR unit. The simulation compares the performance of LNG plant between the two feed gas compositions as below:

- Case 1: feed gas with 90.3 % methane as base case.
- Case 2: feed gas with 95.5 % methane as the leanest feed gas.

For comparison, some parameters are kept constant for both cases such as feed gas flow rate of 22,642 kmol/h, MR composition, minimum temperature approach (MTA) in main heat exchanger. The result shows that the compressor duty at case 2 is greater than case 1, because a gap between cold composite curve and hot composite curve at case 2 is smaller than case 1 hence in order to shift the cold composite curve or keep remains MTA, it requires more MR flow rate. Since the MR flow rate is higher, the compressor duty becomes greater. In addition, suction temperature of 1st MR compressor at case 2 is also very cold, -55 ^{o}C. It is much lower than the specification of f -45 ^{o}C. Case 2 also produces LNG rate lower than case 1 because case 2 has more light component and it will flash when LNG product is expanded to 1.27 kg/cm^{2}a. Since the compressor duty increases while the LNG product rate decreases, thus the specific power of case 2 is higher than case 1.

Table 2 Comparison of Compressor Duty

Description	Duty of C3 Comp. (MW)	Duty of MR Comp. (MW)	Total duty (MW)
Case 1	42.24	77.16	119
Case 2	44.53	82.99	128

Table 3. Comparison of Specific power

Description	LNG Product rate (kg/h)	Heating value (kJ/kg)	Specific power (HP/mmBtu)
Case 1	380,729	49,289	9.00
Case 2	352,880	49,648	10.32

Based on the above evaluation, liquefying lean gas will require more refrigerant flow rate, so that the compressor duty and the specific power will also increase. The suction temperature of MR compressor is lower than specification, it will be the constraint. Therefore, the optimization of operating variable is required to achieve the minimum specific power and the suction temperature of MR compressor meet with the specification.

3.2. Optimization of Operating Variables at LNG Plant

From the evaluation, it shows that there will be any limitation for processing the leaner gas which is suction temperature of MR compressor and higher compressor's load. Therefore, in order to overcome those problems, one of the efforts is by optimizing the operating variables instead of

modifying the existing equipment. In the optimization process, there are some constraints which must be considered such as the capacity of the compressor, the heat transfer area, the minimum temperature approach of main heat exchanger and temperature low alarm of suction MR compressor.

Basically, in order to achieve the objective of optimization is to keep at distance between cold composite curve and hot composite curve to avoid a cross temperature at main heat exchanger with minimum cooling duty to obtain the lowest specific power.

Table 4. Comparison of Compressor Duty and Specific power Before and After Optimization

Description	Before	After
Suction temperature of MR Compressor (^oC)	-55.6	-42.5
MR Compressor duty (MW)	83.3	81.86
Propane Compressor duty (MW)	40.37	39.27
Total Compressor duty (MW)	124	121
LNG Production rate (kg/h)	352,880	352,880
Heating Value (kJ/kg)	49,648	49,648
Specific power (HP/mmBtu)	10.33	9.78

From the composite of curves in the warm bundle shows that after the optimization of the distance between the hot curve and cold curve become closer, it indicates that the heat transfer reaches optimum condition. By optimizing the operating variable, the compressor duty and specific power become lower and the suction temperature of MR compressor still meet the limitation. In addition, for heat exchangers area, the UA value is still lower than its design.

Table 5. Comparison UA Heat Exchanger Before and After Optimization

Description	Before	After	Design
UA MR intercooler (MW/^oC)	1.3	1.1	1.49
UA MR aftercooler (MW/^oC)	2.0	2.1	2.29
UA C_3 *desuperheater* (MW/^oC)	0.626	0.632	0.91
UA C_3 *condenser* (MW/^oC)	15.69	20.03	20.03
UA Warm Bundle (MW/^oC)	19	21	
UA Cold Bundle (MW/^oC)	2.7	2.9	

From the optimization, some of operating variables need to be re-adjusted for achieving the optimum condition when processing the leaner gas. The following is comparison of operating variable before and after optimization:

Table 6. Comparison of Operating Variable Before and After Optimization

Operating Variable	Before	After
C3 condensing Pressure (kg/cm^{2}a)	14.24	12.73
MR Flow rate (kmol/h)	33,214	33,700
Evaporating Pressure of MR (kg/cm^{2}a)	4	4
MR composition (% mol)		
Nitrogen	3.3	3.7
Methane	46	47.2
Ethane	40	39.6
Propane	10.7	9.5

The optimization indicates the existing equipment is still capable to liquefy the leaner gas with higher specific power. But, it neeed re-adjustment of the operating variables refer to the optimization result.

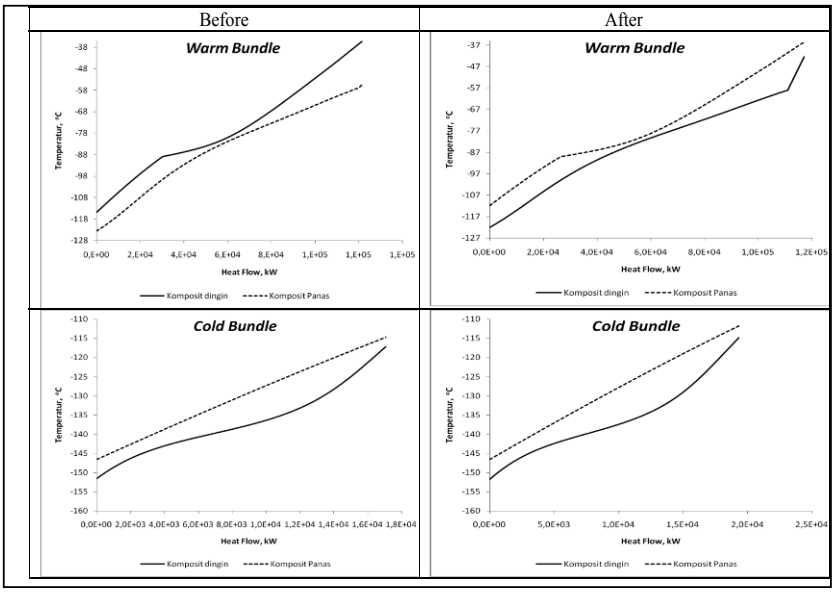

Figure 2. Comparison of Compoite Curve Before and After Optimization

4. Conclusions

The evaluation shows that leaner feed gas will results in higher compressor's load and the specific power. Meanwhile, potential obstacle will be the temperature of suction compressor. Optimizing of the operating variables can overcome the potential obstacle, and it also will reduce the compressor's load and the specific power.
